and (*ii*) coupled gastrocnemius and soleus Hill-type muscle-tendon actuators [7] implemented in Simulink (Fig. 1). We modeled inter-fascicle adhesions (i.e., MTU coupling) by simulating two shared AT lengths (10 cm and 20 cm). In models composed of independent muscle-tendons, we derived muscle excitations that maximized stance phase MTU positive work per unit activation. These excitations were prescribed for models composed of coupled muscle-tendons. We repeated all simulations using a range of tendon compliances, from 3 to 12% strain at maximum isometric force (ε_o).

RESULTS AND DISCUSSION

Simulating inter-fascicle adhesions altered muscle and tendon kinematics, with opposing changes evident in the gastrocnemius (longer fiber lengths, faster shortening velocities, less tendon stretch) and soleus (shorter fiber lengths, slower shortening velocities, more tendon stretch) compared to independent MTUs driven by the same excitations (Fig. 2). Functionally, these changes elicited up to a 16% decrease in gastrocnemius positive work

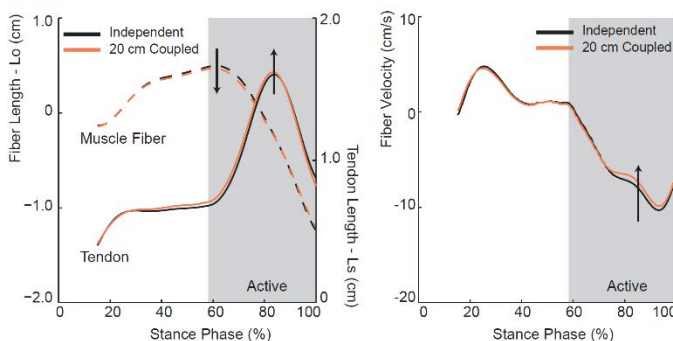
M. Gastrocnemius
Soleus


Figure 2. Group mean muscle and tendon kinematics for simulated independent and coupled gastrocnemius and soleus MTUs at 8% tendon strain (L_o: optimal length, L_s: slack length). Arrows highlight the effects of simulating tendon adhesions, which allude to changes in force generating capacity consistent with changes in the performance of positive work shown in Figure 1.

coupled with a nearly proportional increase in soleus positive work during stance ($p < 0.01$) (Fig. 1C). Thus, inter-fascicle adhesions redistributed positive work from the gastrocnemius to the soleus in a manner consistent with changes in fiber kinematics.

Like prior studies [6], we found a significant relation between tendon compliance and muscle-tendon performance (Fig. 2), wherein an optimum elasticity maximized gastrocnemius and soleus MTU positive work per unit activation ($p < 0.01$). Moreover, tendon compliance modulated the effects of inter-fascicle adhesions, with progressively larger changes in muscle-tendon behavior arising with increasing tendon compliance (interaction, $p < 0.01$) (Fig. 2). Thus, we observed the most substantial changes in muscle-tendon dynamics when co-simulating a reduced capacity for inter-fascicle sliding and an increase in tendon compliance.

CONCLUSIONS

Our *in vivo* ultrasound data suggest a link between smaller depth-dependent variations in AT tissue deformations and reduced ankle joint kinetics during walking with age [4]. Here, we found that a reduced capacity for sliding between AT fascicle bundles can couple gastrocnemius and soleus muscle-tendon behavior. Specifically, we show that this coupling would redistribute positive work from the gastrocnemius to the soleus during walking. This adaptation, exacerbated by increasing tendon compliance and consistent with changes in fiber kinematics, may help to explain the age-related reduction in forward propulsion [4], an important function of the gastrocnemius muscle.

PERFORMANCE OF A VERSATILE IN VITRO JOINT SIMULATOR WITH KINETIC CHAIN TESTING CAPABILITIES

Joshua Green, Paul Power, Jerome Hausselle, and Roger V. Gonzalez

Joint Lab, The University of Texas at El Paso, El Paso, TX, USA
email: rvgonzalez@utep.edu, web: http://jointlab.utep.edu

INTRODUCTION

Musculoskeletal diseases and disorders (*e.g.* osteoarthritis, neck and back pain), joint injuries (*e.g.* ligament failures), and natural aging of joint tissue are among the most prevalent, debilitating, and painful medical conditions. Although tremendous advances have been made in biomedical engineering, potential breakthroughs are hindered by limitations in acquiring reliable *in vivo* measurements such as internal joint contact forces. It is nearly impossible to collect *in vivo* data without using instrumented implants [1], which disrupt the biomechanics of the natural joint and cause altered loading conditions.

Attempting to circumvent this critical barrier, several *in vitro* knee simulators [1-5] have been developed to replicate the complexity of the *in vivo* joint biomechanics. However, existing simulators are limited in their predictive capabilities, lacking synchronously loaded individual muscle forces, external ground reaction forces, and joint kinematics in the three planes. In particular, muscle force control varies tremendously: nonexistent muscle loading [2], grouped flexor and extensor muscle loading [3], and individual muscle force control [4]. Since each individual muscle crossing a specific joint uniquely contributes to internal load and joint stability [5], grouping individual muscle forces or failing to represent muscle forces altogether can significantly influence the joint kinematics and thus introduce errors with respect to the *in vivo* loading conditions. Moreover, to our knowledge, all existing simulators target a single joint, *i.e.* do not simulate movements of kinetic chains consisting of several joints.

To address these limitations and provide reliable experimental data, we sought to develop a versatile *in vitro* multi-joint simulator capable of replicating highly dynamic activities such as running, jump landing, and cutting.

METHODS

Simulator design requirements were based on motion analyses of highly dynamic knee motions including jumping, braking, and cutting maneuvers. Twelve electromagnetic actuators control twelve degrees of freedom of the simulator, *i.e.* six for the upper "hip" joint, and six for the lower "ankle" joint, in analogy with current knee joint simulators. The use of electromagnetic actuators ensures accurate and precise control of positions and forces in real-time.

The control system was developed using a Real-Time LabVIEW environment (National Instruments Corporation, TX, USA) to provide controller
Figure 1: 3D schematic overview of the UTJLS with a mounted cadaver knee specimen.

centralization and flexibility during diverse applications. In order to operate with a variety of system input combinations, each control loop can be configured to react to position or force feedback with standard PID algorithms on top of a second-order system model.

The current muscle actuation system is designed to replicate eight individual muscles acting on a cadaver knee, and each actuator is located with respect to the knee joint center as computed to match a specific muscle in a generic musculoskeletal knee model [6]. The muscle actuators consist of rotational servo motors, pulleys, steel cables, ultra-light miniature load cells, and tendon connectors, which are capable of recreating highly-dynamic muscle forces (maximum force range: 750N to 1170N and maximum velocity range: 180mm/s to 490 mm/s).

RESULTS AND DISCUSSION

We have developed the Joint Load Simulator (UTJLS) (Fig. 1) to be capable of dynamically controlling twelve kinetic and kinematic conditions and eight individual muscle forces. By including control of twelve degrees of freedom instead of only the six necessary for recreating internal joint conditions, the UTJLS is capable of prescribing the entire movement of the cadaver specimen, as compared to the relative bone to bone motion replicated by other simulators.

Design of the UTJLS included the use of high quality electromagnetic actuators in order to reproduce highly dynamic motions (maximum translational velocity range: 1.4 to 4.8m/s, maximum rotational velocity range: 5.0 to 7.5rad/s). These actuators also ensure an accurate and precise control of position and force in real-time (approximate response time of 3ms). During a real-time, 9-axis squatting maneuver, all axes operated with position control and had standard deviations less than 0.49mm and 0.45deg (Fig. 2), and during a 6-axis force test, each axis had standard deviations less than 9.49N and 1.05N*m.

Although it is originally configured to test cadaveric knee specimens, this simulator has been specifically

designed to be easily modified to accommodate a wide range of joints and even entire kinetic chains.
Figure 2: Graph of hip position vs. time during a position controlled squat. Colors correspond to surrogate hip linear axes designated in Figure 1.

CONCLUSIONS

The sophistication of the UTJLS significantly expands our ability to (1) conduct non-invasive clinical and surgical procedures before *in vivo* assessment and (2) to provide an open-source database of reliable *in vitro* measurements for the validation of computational models. The specific design of this simulator allows for multi-joint testing, thus pushing the boundaries of *in vitro* testing capabilities to enhance our knowledge of multi-joint biomechanics.

MULTI-SEGMENT FOOT MODELING TO MAXIMIZE RELIABILITY AND CLINICAL RELEVANCE

[1] David J. Gutekunst, [1]Krista Coleman-Wood, and [1] Kenton R. Kaufman

[1] Mayo Clinic, Rochester, MN, USA
email: Gutekunst.David@mayo.edu web: mayo.edu/research/labs/motion-analysis

INTRODUCTION

A commonly used multi-segment foot (MSF) model uses the ankle joint center to define the hind foot segment axes [1] (Figure 1).
Figure 1: (A) superior, and **(B)** lateral views of Shriner's Hospital for Children – Greenville landmarks to define hindfoot axes.

Ideally, hindfoot axes would be defined using landmarks placed only on calcaneus, and without anatomical registration from X-ray or goniometry [2] (Figure 2). However, this model has been shown to have poor reliability, with inter-session and inter-therapist errors up to 11° [3].
Figure 2: (A) superior, and **(B)** lateral views of proposed hindfoot axes, based on the Leardini MSF model [2].

Ultrasound imaging can be used to identify anatomical landmarks. This approach could provide a safe, clinically applicable way to improve MSF reliability without X-ray or goniometry. Therefore, the purpose of this study was to assess the effects of adding ultrasound imaging (US) to standard palpation (PALP) on inter-session kinematic reliability of a MSF model. We hypothesized that the combined technique (**US+PALP**) technique would result in improved inter-session reliability compared to the standard **PALP** method.

METHODS

8 healthy volunteers with no history of foot deformity (5 female, 3 male, Age = 32.0±5.6 yrs, Height = 170.9±10.0 cm, BMI = 23.4±3.4 kg/m^2) agreed to participate and provided written informed consent. Volunteers underwent two sessions of 3D gait analysis on separate days. A single experienced physical therapist placed landmarks bilaterally on the shank, hindfoot, and forefoot. Volunteers completed 3 walking trials at self-selected walking speed per session. One limb was randomly assigned the standard palpation technique (PALP); the other limb was assigned the ultrasound technique (US+PALP). The assigned technique was maintained for both testing sessions.

Segmental motions were computed in Visual3D (C-Motion, Germantown, MD). A Cardan YX'Z" sequence was used, reflecting motion in the sagittal, frontal, and transverse planes. A total of 6 angular measures (X, Y, and Z angles for Hindfoot:Shank and Forefoot:Hindfoot) were computed for a full gait cycle within each walking trial. All angular measures were normalized to 100% of the gait cycle in 1% increments. For each angular measure, inter-trial and inter-session reliability were assessed using the method described by Schwartz *et al.* [4].

RESULTS AND DISCUSSION

Inter-trial error was similar (~1°) for both methods, for Hindfoot:Shank and Forefoot:Hindfoot angles, and in all planes of motion (Figure 3, red bars). Inter-session reliability varied by foot segment (Figure 3, blue bars):

- *Hindfoot:Shank angles :* both techniques demonstrated average inter-session of 3° across the 3 planes of motion. For dorsi/plantarflexion, US+PALP resulted in 1° lower inter-session error than PALP alone (2.5° vs. 3.5°).

- *Forefoot:Hindfoot angles:* the highest inter-session errors for both techniques were seen in dorsiflexion-plantarflexion (5.2° for US+PALP and 7.1° for PALP alone). Inter-session errors were similar between the techniques in the frontal plane (3.6° vs. 3.2°) and transverse plane (3.0° vs. 3.1°).

CONCLUSIONS

Appropriate clinical decisions and assessment of treatment outcomes depend upon reliable MSF measurements that accurately reflect skeletal motion. With the exception of Forefoot:Hindfoot dorsi/plantarflexion, both techniques showed better reliability than previously reported using anatomically-relevant segment axes **[3].**

Contrary to our hypothesis, the addition of ultrasound did not result in a substantive reduction in inter-session error. Still, the results suggest that it is possible to achieve low inter-session error using clinically-relevant MSF segmental axes *without X-ray or goniometric registration.* Additional preliminary results for multiple therapists indicate that there is a learning curve for kinematics reliability, especially using ultrasound imaging.

Further work is planned to determine (1) kinematics reliability in children and individuals with foot deformity, (2) the effects of therapist experience on reliability using palpation with or without US, (3) kinematics reliability when defining hindfoot axes using the calcaneal sulcus as a lateral hindfoot anatomical landmark, and (4) the ideal forefoot marker setup to maximize reliability and clinical relevance.

Effect of Morphology, Cross-section Type, and Apparent Density on the Elastic Properties of Open-Cell Structures

Abstract

Metallic foams are known as biocompatible materials which are good candidates for being used in orthopedic implants. This is because their open-cellular structure permits the ingrowth of the new bone tissues and the transport of the body fluids. It is especially attractive that the strength and the Young's modulus of the cellular materials can be adjusted through the adjustment of the porosity to match the strength and the Young's modulus of the nature bone which prevents stress shielding which can then lead to aseptic loosening of the implant inside body. Advent of new novel additive manufacturing techniques make it possible to create implants with arbitrary micro-geometrical features. Generally, the properties of open-cell foams depend on three main parameters: first, the material which the foam is made of; second, the morphology of the cells, and third the geometry of the struts. Not many investigations have been carried out on the explicit comparison of static properties of open-cell porous structures having different morphologies, cross-section dimensions, cross-section geometry, and apparent densities. Providing detailed comparison between the elastic properties of structures in terms of their geometrical parameters can be useful for applications in which low/high stiffness in axial/shear loadings is required. In this study, Finite Element simulations have been implemented to investigate the effect of structure morphology, cross-section type, strut length, and apparent density on the elastic modulus, shear modulus, yield stress, shear yield stress, and Poisson's ratio of open-cell tessellated cellular structures to find the appropriate configuration for applications with low-stiffness or high-stiffness requirements. Five different morphologies, namely cube, rhombic dodecahedron, Kelvin, Weaire-Phelan, and diamond were considered. For each morphology, a relationship relating the strut length, cross-section dimension, and apparent density is provided according to which 135 simulations are carried out and their results are compared in terms of different elastic properties. It was seen that the strut cross-section type does not have a considerable effect on the structure elastic modulus while its effect on the structure yield stress is significant. For all the morphologies, the triangular and the circular cross-sections lead to the highest and lowest elastic modulii, respectively. It was seen that the cube morphology has an elastic modulus and yield stress much higher than other morphologies while the diamond structure has the lowest corresponding values. It was also observed that the circular rhombic dodecahedron structure has a high yielding strength (second among all the cases) while its elastic modulus is relatively low. Therefore it is the best choice for applications with low stiffness requirements. This structure is also the strongest morphology in shear loading.

INTRODUCTION

Recent evidence suggests that the kinematics of the torso play an important role in lower extremity musculoskeletal syndromes such as patellofemoral pain[1]. In clinical gait analysis, the thoracic and lumbar spines are commonly modelled as a single trunk segment and there is no consensus on the ideal marker set to track the trunk. Importantly, Leardini *et al*. demonstrated that different marker sets for defining and tracking the trunk yielded different joint angles for the same motion[2]. Furthermore, it is unknown how tracking errors vary with specific activity. The purpose of this study was to introduce a method for determining the optimal tracking markers for the trunk. Our method quantifies the error of a trunk model by comparing accurate ground reaction force (GRF) measurements to GRF's computed from the motion of the link-segment model's whole body centre of mass (COM). We hypothesized that trunk errors would vary as a function of tracking markers as well as choice of task.
Figure 1: Trunk marker set.

METHODS

The trunk accounts for ~35% of the body's total mass; therefore, we assumed that errors in tracking the trunk will result in errors in the ground reaction force computed from the model's COM (GRF_{KM}). Our approach compares GRF_{KM} to force plate measurements, (GRF_{FP}). A full body biomechanical model was constructed from reflective markers. Different trunk models were tested by changing the trunk's tracking markers. We tested seven trunk models using combinations of the trunk markers as seen in Figure 1 and Table 1. IRB approval was obtained and informed consent was given from twelve subjects (7 male and 5 female). They performed 4 activities: single leg hop, single leg squat, double leg hop, and double leg squat. Markers were recorded with a motion capture system (Qualisys, 10-camera, 250 Hz). GRF_{FP} was acquired from a force plate (AMTI, 2000 Hz). Marker trajectories and ground reaction forces were filtered at 10 Hz. The model's COM position was computed in Visual3D (C-Motion inc.). GRF_{KM} was computed as the second derivative of COM position multiplied by

Figure 1: Visual 3D link-segment

mass (Fig 2A). Root mean square (RMS) errors were computed between vertical GRF_{KM} and GRF_{FP}. A 2-way repeated measures ANOVA determined whether errors varied as a function of model or task. We also performed a Holm-Sidak post hoc analysis to determine pairwise differences among models and tasks.

RESULTS AND DISCUSSION

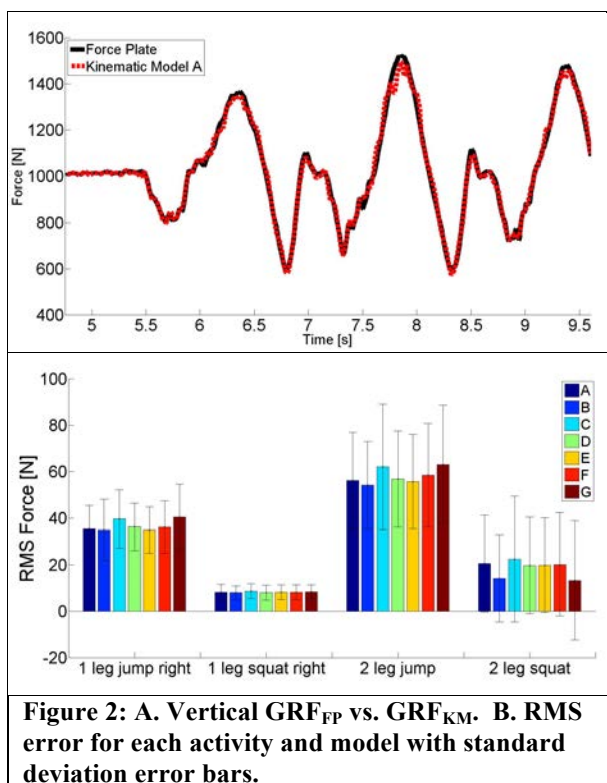
COM error varied as a function of both model (p < 0.001) and task (p < 0.0001), and there was a significant interaction between model and task (P < 0.004). Pairwise analysis revealed that error varied among all tasks (p < 0.02). Regardless of model choice, the 2 leg jump resulted in 38% larger error compared to other tasks. This task required larger GRF's and a larger trunk range of motion, which may have caused the higher errors. There was no single model that resulted in lower or higher errors across all tasks.


Figure 2: A. Vertical GRF$_{FP}$ vs. GRF$_{KM}$. B. RMS error for each activity and model with standard deviation error bars.

provide a greater understanding of compensatory strategies used by individuals with musculoskeletal diseases.

CONCLUSIONS

We have introduced a promising method for evaluating link-segment trunk models. Error varied as a function of model and task; however, task had a much larger effect on errors than model. Future work will include trunk models with 2 and 3 segments as well as an analysis of the medial-lateral and anterio-posterior components. We will also investigate model errors during running and walking. An accurate trunk model may

DESIGN AND VALIDATION OF A TDNN HUMAN WALKING MODEL

[1] Kamran Iqbal and [2] Alaa M. Abdulrahman

[1] University of Arkansas at Little Rock, Little Rock, AR, USA
[2] University of Sulaimania, Iraq
email: kxiqbal@ualr.edu

INTRODUCTION

Stroke, spinal cord injury, traumatic brain injury, and neurodegenerative diseases like Parkinson result in impairment of natural gait in humans [1]. Gait restoration and improvement constitute primary rehabilitation goals whose assessment requires estimation of muscle forces and joint moments. Inability to directly measure the biomechanical variables necessitates reliance on computational musculoskeletal models [2, 3].

Due to their universal mapping capabilities, Neural networks (NN) have been used to predict the kinematics and kinetics of human locomotion. Feed-forward NN trained with anthropometric data, kinematics, ground reaction forces (GRF), and electromyography (EMG) of seven prominent muscles was used to estimate joint moments [4]. The results lacked generality as data from specific subjects was used to train the network; moreover, same data was used for training and testing.

In this paper we present a time delay neural network (TDNN) model for computer simulation of human walking. The input to the model comprises desired generalized variable profiles (joint angles and the trajectories of a stable reference point, i.e., the position of the vestibular center). The model output includes feedforward and feedback components of generalized forces (joint moments). These are used in forward dynamic simulation of human walking. Our TDNN simulation results compare favorably to those obtained from OpenSim software (NCSRR, Stanford, CA), thus validating our model.

METHODS

To facilitate the model development, dynamics of a seven segment human body model (HBM) were considered with head-arm-and-trunk (HAT), upper legs, lower legs, and feet segments. The generalized degrees of freedom (DoF) of the model included seven joint angles, and x,y positions of head, denoting the vestibular center. For simplicity, only revolute joints were included; hence, the model only analyzed motions in the sagittal plane.

NN with tapped delay line (TDL) were used to model the forward and the inverse dynamics of the human body. Two time-delay NN (TDNN) were developed, one that captured human forward dynamics and acted as identifier ($TDNN_i$), and a second TDNN that captured the inverse dynamics during walking, and acted as controller ($TDNN_c$) for the HBM. The identifier network was validated against joint torques captured in a laboratory experiment of walking. The actuator network was validated against optimized muscle activation data obtained for walking from the OpenSim software.

We used multi-sine formula proposed by [5] to implement a persistent excitation signal generator for the human body model. The input frequencies were randomly selected in the range 1Hz-25Hz based on frequencies of rotation of human body segments while walking. The limits in the angle range of human walking were taken into account and embedded into the persistent excitation formula. A total of 5000 samples data was generated for each of the generalized variables associated with walking.

The model used for the forward dynamic identifier ($TDNN_i$) was of NARMAX type. The $TDNN_i$ had two TDLs at the input, one each for torques and feedback elements. The network was built with linear input and output layers and a nonlinear hidden layer. It was trained using Levenberg-Marquardt (LM) back-propagation algorithm. The training took 19 epochs with a performance goal of 10^{-6} for the error.

The torque controller for the model consisted of feed-forward u_{ff} and feedback u_{fb} components ($\tau = u_{ff} + u_{fb}$), both generated via TDNN (Fig. 1). Due to linearity, a single TDNN with 9 inputs (2 delays each) and 12 outputs (5 delays each) could generate both terms. The lags were chosen with the help of correlation function from the MATLAB NN toolbox. A single hidden layer with 50 neurons with sigmoid activation function was used with linear output layer. Training the NN took 14 epochs in batch processing using Levenberg-Marquardt back-propagation algorithm with recorded error of 10^{-27}.

Fig.2: A comparison of the identifier NN output with joint torques recorded in the laboratory.

Fig.1: TDNN model used to generate joint torque components

The TDNNc employed a total of 74 inputs: 42 inputs from the muscles activation data, 14 from feeding back the seven controller outputs with unit delays, and 18 inputs from feeding back the nine HBM outputs with one delay each. Its output constituted the generated torques required to derive the HBM such that it could track the reference model outputs.

Walking data for model validation were recorded in the laboratory using 10 VICON cameras, NEXUS software, and 2 AMTI force platforms. The marker data were used to construct the desired variable profiles (q_d), which were then used to develop the inertial and nonlinear torques that were input to the TDNNc that generated $\tau = NN_{ff} + NN_{fb}$ at the output.

RESULTS AND DISCUSSION

Fig. 2 shows the comparison between the output of the TDNNi and the laboratory trajectories of joint torques for one stride. The maximum root mean squared error (MSE) during one stride was 2.7×10^{-3}. The small error obtained was attributed to the ability of the TDNN to learn human body dynamics.

Fig. 3 shows the simulation output (joint angles) as the HBM was simulated driven by joint torques generated from the TDNNc. For comparison, the joint trajectories obtained from OpenSim simulation of same stride are also shown. The maximum joint torque and trajectory errors were less than 0.5%.
Fig.2: TDNN output (joint angles) superimposed on OpenSim output during simulation of two strides of walking.

In conclusion, TDNNi exhibited excellent capacity to learn human body dynamics during walking. The controller, TDNNc, correctly generated muscle activation commands and joint torques to simulate the HBM in walking mode. These results can be extended to simulation of complex movements.

EFFECT OF AGE ON BODY SEGMENT PARAMETERS IN NORMAL WEIGHT FEMALES

Molly Knewtson, Zachary Merrill, Rakie Cham, April Chambers

University of Pittsburgh, Pittsburgh, PA, USA
email: mek122@pitt.edu, web: http://www.engineeringx.pitt.edu/hmbl/

INTRODUCTION

The population of adults over 55 years old in the United States increased over 15% from 2000 to 2010 [1]. Adults in this age group are more susceptible to injuries resulting from falls, including over 10,300 fatal fall-related injuries in 2000 [2]. In order to understand the mechanisms of falls and resulting injuries in the older adult population, biomechanical research is required. Biomechanical gait analysis and injury prevention research relies on anthropometric tables to give accurate approximations of body segment parameters (BSPs) of subjects. These parameters include mass, center of mass, and radius of gyration of the common body segments: upper arm, lower arm, torso, thigh, shank, and head.

Current anthropometric tables were developed with college-aged adults and are proven to be inaccurate in predicting BSPs of other age groups [3, 4, 5]. There are many proven ways to create predictive models such as cadaver-based studies and imaging [3, 6], but each method has disadvantages such as monetary cost, time-intensiveness, and/or delivery of high doses of radiation to the participant. Dual energy X-ray absorptiometry (DXA) is a validated in-vivo method of determining BSPs [7]. It is a quick, inexpensive, low-radiation, full-body scan that can differentiate densities of bone, muscle, and fat tissue, allowing for accurate mass calculations. This study uses DXA scanning and analyzing techniques to compare BSPs of normal-weight, young females against those of normal-weight, old females, focusing on the largest segments of the body: the torso and the thigh.

METHODS

The young subgroup corresponds to ages 21 to 40, while the old subgroup corresponds to ages 55 to 70. Thirteen young and thirteen old females, with BMI 18.5-25 kg m^{-2}, were recruited for participation in this study. Height and weight of each participant was recorded to confirm BMI and eligibility. Each participant was scanned with a Hologic Discovery DXA System to gather a full body, frontal plane image.
Figure 1: *left:* Whole body DXA scan with segmental boundaries designated by red lines *right:* sub-regions of the thigh segment indicated with red boxes.

Bony landmarks were used to define boundaries between body segments in analysis of each DXA scan (Fig. 1). The segments of interest were the torso and the thigh. The torso extended from the acromion to the greater trochanter. The torso's lateral boundaries were defined with a line through the medial acromion to the axilla and a line just lateral to the anterior superior iliac spine and the ischial tuberosity of the pelvis. The thigh segment began at the greater trochanter and extended to the center of the knee joint.

Each body segment was then divided into sub-regions that spanned the width of the segment and were 2-3 pixels (2.6-3.9 cm) tall (Fig. 1). Masses were calculated for each sub-region and used to determine BSPs for the whole segment.

Sub-region and segment measurements were used to determine segment mass as a percent of body mass (SM), longitudinal distance from the proximal end to the center of mass of the segment as a percent of segment length (COM), and frontal plane radius of gyration as a percent of segment length (RG). A two-tailed t-test was run to compare BSPs between the two age groups. Statistical significance was set at 0.05.

RESULTS AND DISCUSSION

Age was found to significantly affect SM for both the torso and thigh segment and RG for the torso. Thigh and torso parameters for the young and old age groups are presented in Table 1. Thigh SM was smaller in the older age group, while torso SM was larger in the older age group. Torso RG was smaller in the older age group. These differences represent a variation in mass distribution across age groups. Young females have a higher percent of overall body mass in the thigh segment, and old females have a higher percent of overall body mass in the torso. This trend continues in old and elderly populations as well, as examined in Chambers et al. [8]. Elderly subjects were found to have a significantly higher torso SM than old subjects [8], confirming the finding that torso SM increases with age. The torso segment was found to have a more concentrated mass for the older subgroup, as indicated by a smaller RG. No significant differences in COM locations in any of the segments were found.

CONCLUSIONS

Current anthropometric tables were developed using measurements of young, normal weight adults. However, significant differences were found in the torso and thigh segments between normal-weight, young females and normal-weight, old females, indicating the commonly-used tables do not accurately model subjects in every age category. The difference in thigh SM and torso SM are of particular interest as these segments are commonly used in gait analysis and other biomechanical research. This study underlines a need for age-specific anthropometry tables.

INTRODUCTION

As people get older, their motion speeds generally tend to get slower in walking motions on flatland or stairs as well as the motions sitting and standing up. Especially, for the people over 65 years old, the frequency of injuries from fall accidents is very high enough that one-third of the aged persons experience some injuries resulting from fall accidents every year, and the number of the elderly dying or suffering from the fall injuries is gradually increased.

The R&Ds developing safety devices against fall accidents, detecting the fall events, and reducing the amount of impact based on the detected falling events by various complex sensors are actively performed. However, there are still few studies on quantitatively analyzing the influences of actual fall's impact on the human body as the basic information for the development process of safety devices. Given the fact that there is very possible to be injured at conducting a fall experience, an actual experiment targeting human subjects is extremely limited, so most experiments have utilized corpses or dummies until now.

This research aimed to make a three-dimensional musculoskeletal dynamic simulation model to overcome the limits of experiments in previous studies to analyze a fall influence on the human body injuries.

METHODS

2.1 Subject Selection

In order to make a computational model for simulation of falling situation, we selected one Korean adult man who is healthy without any orthopaedic disability or injury history in the musculoskeletal system and the nerve system (28-years old, 177cm, 76kg).

2.2 Motion Analysis Experiment

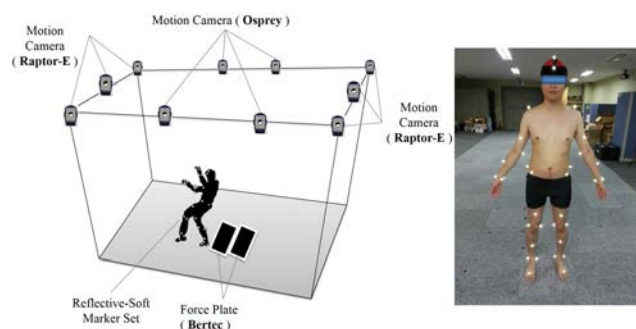
In order to obtain the human body's falling motions on space, we utilized a motion analysis system. After attaching reflective markers on the subject in an experimental space where 10 infrared cameras (6 Raptor-E cameras, 4 Osprey cameras, Motion Analysis Inc. USA) and 2 force plates (FP4060, Bertec Inc. USA) were installed, rear-side falling experiments were conducted. A program for the motion analysis (Cortex version 4.0, Motion Analysis Inc. USA) was used in collecting and analyzing the data of kinematics and kinetics (Figure 1).


Figure 1. Experimental space for analyzing falling motions and subject with reflective markers

2.3 Construction of Musculoskeletal Model and Dynamic Simulation

In order tothe subject-specific musculoskeletal model, the total 42 reflective markers (Helen Hayes Marker Set) were attached on the subject's body (upper limbs: 21 markers, lower limbs: 21 markers), and the static pose was taken by the 10 cameras. Also, full-body musculoskeletal model was scaled by utilizing the conversion programs (Motion module, Motion Analysis Inc., CA, USA). Especially, each vertebra in the neck and lumbar spines was defined separately with three degrees of freedom.

To conduct the dynamic simulations by the musculoskeletal model, several dynamic parameters including the center of mass and the moment of inertia for each skeleton were defined based on the previous references.

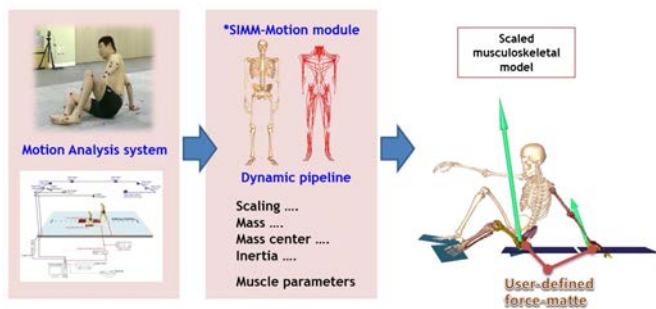
The initial values for every joint were set up based on the standing pose, and motions of all joints were not restricted to reproduce the falling situation. Besides, the data of kinematics and kinetics captured from the motion analyses were inputted as the prescribed motions. For the physical parts colliding onto the ground, the user-defined contact forcemattes were defined to calculate the contact force to the ground. The DLL (Dynamic Linking Library) was made with the SD FAST (B.2, Symbolic Dynamics Inc, USA) of the dynamic solver. After setting the DLL used as the basic library, the dynamic simulations were conducted (Figure 2).


Figure 2. Three-dimensional musculoskeletal modeling of dynamic simulation for falling events

RESULTS AND DISCUSSION

We carried out the side-rear falling simulations using a three-dimensional musculoskeletal model, and calculated the contact force on the human body by the user-defined contact forcemattes. In the falling simulations, the maximum contact force was primarily calculated (1.90 times of the subject's weight) when the hip was collided with the ground. And the maximum contact force was secondarily calculated (0.57 times of the subject's weight) when the wrist was touched to the ground.

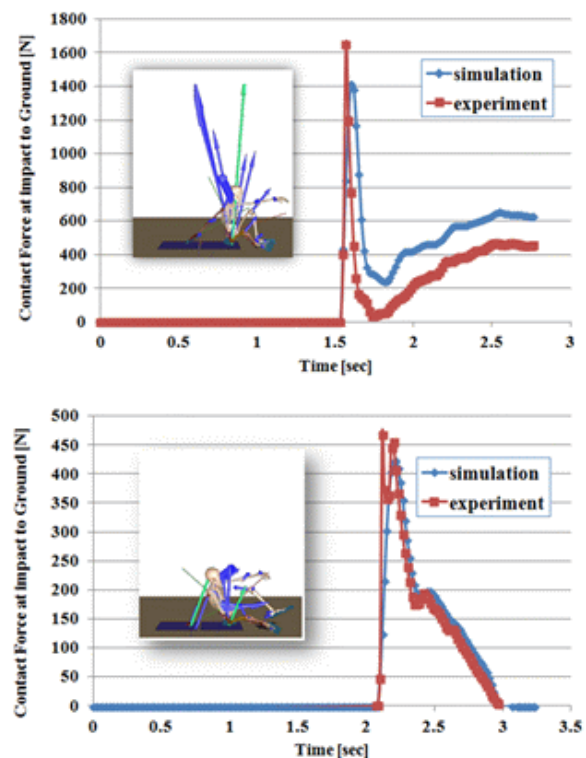
While the falling experiment generally showed similar patterns as the simulation results, the former showed a little higher values (2.21 times of the subject's weight at the hip, 0.63 times of the subject's weight at the wrist) (Figure 3). It is considered that the difference could be caused from the insufficient information on the soft tissue thickness in the hip and the wrist parts.


Figure 3. Results of falling simulation for the hip (up) and the wrist (down) joints

CONCLUSIONS

This research constructed a motion analysis-based three-dimensional musculoskeletal dynamic simulation model to estimate a falling influence on human body which can't directly be measured. It is considered that the 3D musculoskeletal dynamic simulation model will be effectively utilized to acquire basic information on the falling-injury studies using the various conditions of human body and environment in future.

INTRODUCTION

For most of the disabled people who use manual wheelchairs, they often experience shoulder pain due to steering wheelchairs with only the upper limb muscles for a long time. Some disabled people need medicine treatments, and also have a surgical treatment in serious cases. To alleviate these potential musculoskeletal disorders, several types of electric handbikes have been recently introduced, in which docking method is easy and it is possible to easily move by using the electric system after docking.

In case of a relatively high speed on various terrain after easy installation using a connector, the mechanical loads are continuously applied to the connecting parts between the manual wheelchair and the electric handbike, and the resultant force accumulated at the connecting parts is determined to affect the structural stability of the connection parts. However, related researches on this area are still rare. Therefore, this study aims to implement a three-dimensional dynamic model that can simulate the durability test through computational analysis, and to evaluate the dynamic structural stability of the parts between the manual wheelchair and electric handbike during durability experiment by verifying the model through motion analysis.

METHODS

To implement a computation analysis model for durability experiment, we constructed a three-dimensional wheelchair-handbike assembly model using a Solidworks software program (ver.2012, Dassault Systems, USA). In addition, the durability test device was modeled referred to its actual size (Korean Industrial Standards) (Figure 1).

To make a multi-flexible dynamic model for the whole system, the connection parts (snatch lock, connecting rods, etc) between the electric handbike and wheelchair that have high possibility of mechanical failure in terms of structural stability, have been implemented as the finite element model to calculate mechanical loads (von-mises stresses). Other structures have been assumed as rigid bodies.
Figure 1: Multi-flexible dynamic model including a wheelchair, a handbike with snatch lock, and a drum tester.

To perform dynamic analyses, a commercial analysis program (Recurdyn V8R2, FunctionBay, South Korea) was used. Referred to KS standards for an electric wheelchair, we set the rotation speed of the drum so as to rotate at 1m/s with a rotational joint [1], and fixed a 75kg human dummy model onto the wheelchair's seat top parts [2].

To verify a computational model, the motion analysis system was used in this study including 8 infrared cameras (Eagle 4, Motion Analysis Inc., USA), 10mm-reflective markers attached to the handle, electric wheels, connectors, rotation axis of the wheelchair, and the rotation cylinder of the drum tester, respectively. We calculated kinematical data by using three-dimensional coordinates of each reflective marker (Figure 2).
Figure 2: Motion analysis model of marker position

Through motion analysis on the durability test, the trajectories of each marker were measured in real-time. After that, we compared kinematical results between experiments and computation analyses to verify the computational model.

RESULTS AND DISCUSSION

Through comparison of kinematical data between experiments and motion analyses at the same locations, it was found that the maximum difference of the markers were about 13mm. However, it was also confirmed that they showed similar movements with similar tendency in general (Figure 3). After verifying, we performed the stress analysis for connecting parts including snatch lock, connecting rod of both sides. The results showed that maximum von-mises stress was about 216MPa (Yield stress 552MPa) for the snatch lock and 1.1MPa for the frame part (Yield stress 185MPa). By considering that the stress level of the connecting part was lower than yield stress of each structure, it was expected that the structural stability would be secured for the connecting parts during durability experiment (Figure 4).
Figure 3: Comparison of simulation (red circle) and experiment (black circle) for center wheel marker

Figure 4: Distributions of von-mises stress in snatch lock and wheelchair frame

CONCLUSIONS

In this study, we established an effective process to give the validity of computational analysis on actual durability test for wheelchair-handbike assembly system by motion analysis. Although there was a slight kinematical difference between two results, the movements of each part in the system generally showed a similar tendency.

Based on the verification for a computational model, lower stress value were calculated at the snatch lock and the frame parts of the wheelchair's major connecting parts also showed a lower stress value than yield stress.

From these results, we could estimate that this system would be dynamically stable during durability test. Afterwards, it is believed to be necessary to improve the safety for electric handbike through usability evaluation like field test in various terrain.

INTRODUCTION

Osteoporosis is defined by a decrease in bone mass and density which can cause an increased risk of fracture. Especially in the elderly population osteoporosis is treated as the significant medical problem, because the bone fracture from osteoporosis can lead to the fatal issue of patients. Therefore, the biomechanical understanding of osteoporosis has been extensively investigated [1-2].

Previous studies of osteoporosis using medical images, such as DEXA scan and Micro-CT, mainly focused on the changes of bone density. However, the bone density analysis based on 2D (dimensional) images can limit the result because each bone has inhomogeneous distributions of bone density in a 3D structure. In particular, to precisely understand bone fracture it is required to analyze mechanical behavior with bone density and bone strength in a 3D structure. Since experimental methods to understand structure and mechanical behavior of bone have technical limitations, finite element method has been effectively utilized to better understand a sophisticated bone structure.

The purpose of this study is to utilize the finite element analysis based on 3D bone structural images of Micro-CT for understanding the spatial degradation of bone strength in osteoporosis mouse femora.

METHODS

Osteoporosis Mouse Model

A surgical removal of ovaries (Ovariectomy, OVX) in mouse was used for osteoporosis animal model (Osteoporosis, OP, N=3) in this study. For the comparison, non-surgical mouse was included in a separate group (Control, Con, N = 3). At the 4 and 8 weeks after ovariectomy, mice from each group were anesthetized for Micro-CT imaging.

Micro-CT Imaging and 3D Reconstruction

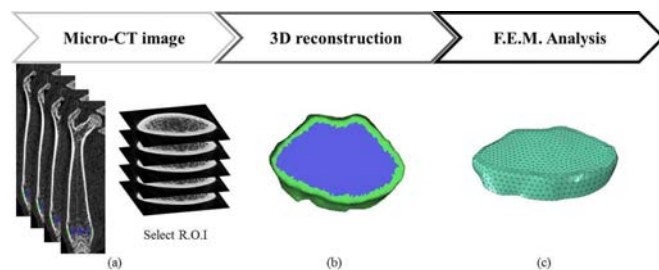
Femora from each group were scanned by Micro-CT (SKYSCAN 1076, Brucker, Germany). Image resolutions were 18×18 μm. A 3D femur reconstruction was conducted by using a 3D image process software (Mimics 16.0, Materialise) (Figure 1). For the finite element modeling, the material properties of femur were calculated based on pixel image intensities. The grey value (GV) of each pixel was linearly converted to the Hounsfield Units (HU). For the simplicity, the average Hounsfield Units was calculated for the 3D reconstructed local model for the analysis. The average Young's Modulus was finally calculated based on the conversion formula from the previous study [3].


Figure 1: 3D reconstruction of femur FE model: (a) Segmentation of femur on the MRI slides and selection of R.O.I, (b) 3D reconstruction, (c) 3D Finite Element Model.

Finite Element Analysis

Finite element analysis using a commercial solver (ABAQUS 6.10) was conducted on the local model including the region closed to the condyle where the trabecular bone showed bone density loss. Concentrated loads of 2, 4, 6, 8, and 10 N were axially applied to the plate on the top of the local model (Fig. 2).
Figure 2: Finite element model including load and boundary conditions.

RESULTS AND DISCUSSION

At 4 weeks after ovariectomy in mouse model, there is no large difference on average bone density for the entire femur. However, the bone density in the trabecular bone decreased and that in the cortical bone increased (Table 1). Under 2-10N of external force on the local model, osteoporosis group at 8 weeks had more stress and displacement compared to 0 week (Fig. 3). Under 10 N load, a maximum displacement in the axial direction decreased about 11%, and increased 67%, and stress increased about 29%, and 84% for 4 weeks and 8 weeks after OVX, respectively compared to 0 week (Fig. 3 and 4).

CONCLUSION

Based on the results, the early osteoporosis of mouse model decreased bone densities in trabecular region but increased them in cortical region.
Figure 3: Maximum displacements in the axial direction with respect to the applied forces.
Figure 4: Results of finite element analysis for axial deformations between 0, 4 and 8 weeks.

Therefore, we anticipated that osteoporosis model using mouse should consider its bone degradation behavior depending on measuring time point. Early osteoporosis in mouse model may have compensation effect on cortical bone while trabecular bone loses its bone density. Although bone density is highly inhomogeneous, an average bone density was used in this study for the simplicity of numerical calculations. Further study will aim to implement inhomogeneity of bone density to represent the intrinsic behavior of material properties and structure of bone.

EFFECT OF INCREASED BODY MASS INDEX ON BODY SEGMENT PARAMETERS IN MALES

Zachary Merrill, Molly Knewtson, Rakié Cham, April Chambers

University of Pittsburgh, Pittsburgh, PA, USA
email: zfm1@pitt.edu, web: http://www.engineering.pitt.edu/hmbl/

INTRODUCTION

Over the last 30 years, the obese population has grown to over 60 million people in the US. Along with obesity, the associated risk of injury related to biomechanical factors also increases [1,2]. In order to understand these mechanisms of obesity-related risk of injury, accurate body segment parameter (BSP) measurements are required to model joint contact forces and muscle forces applied during a given task.

Current anthropometry tables, which show the mass of each body part as a percent of total body weight (BW), and center of mass (COM) and radius of gyration (R_G) locations as percent of segment length were compiled using healthy, college-age adults, however these parameters have shown to be inaccurate in predicting BSP's in subjects with an increased body mass index (BMI), as well as in different age groups [3-6]. Several methods exist for determining BSP's including cadaver-based studies, magnetic resonance imaging, computed tomography, and measurements based on bony landmarks [7-10], however these methods have some issues as far as cost, time required, and high doses of radiation. Dual energy x-ray absorptiometry (DXA) is a validated method of determining BSP's in vivo that avoids these common problems. DXA scans are commonly used to determine bone density and body composition [11], as well as mass calculations. The scan itself is an inexpensive, low radiation scan that can differentiate between bone, muscle, and fat.

The goal of this study is to determine differences in segment masses, COM's, and R_G's in normal weight (NW), overweight (OW), and obese (OB) young males. We will focus on the differences in the torso and dominant-side thigh.

METHODS

The subjects in this study were all between the ages of 21 and 40, and the weight groups are defined by body mass index (BMI); the normal weight group covers BMI's between 18.5 and 24.9, overweight group is between 25.0 and 29.9, and obese group is between 30.0 and 39.9 kg m^{-2} (Table 1). Thirteen subjects were recruited for each weight category.

Table 1: Mass, height, and BMI for each group. Values are shown as mean ± standard deviation.

Group	Mass (kg)	Height (cm)	BMI (kg m^{-2})
Normal Weight	66.8 ± 6.2	178.4 ± 5.0	22.6 ± 1.4
Overweight	77.7 ± 7.9	175.2 ± 6.3	27.0 ± 1.1
Obese	96.4 ± 11.2	178.5 ± 6.4	32.3 ± 2.6

During the single study visit, the height and weight of each participant were recorded in order to calculate BMI to confirm eligibility and then each participant was then scanned using a Hologic Discovery DXA System (Hologic, Bedford, MA, USA) to collect a frontal plane, full body image.

Predetermined anatomical landmarks were used to define the boundaries between BSP's in each DXA scan. The head segment covered the most superior point of the head to the base of the mandible. The torso extended from the acromion to the superior border of the greater trochanter, with lateral boundaries defined by a line connecting the acromion through the axilla, and another line connecting the greater trochanter and ischial tuberosity. The thigh segment extended from the superior greater trochanter to the knee joint center, lateral to the inferior portion of the torso section. Lastly, the shank segment started at the knee joint center, and ended at the lateral malleolus.

In order to calculate segment COM's and radii of gyration, each segment was separated into small slices. Each slice covered the width of the segment, and had a height of 2-3 pixels, corresponding to 2.6-3.9 cm tall. The analysis determined the mass of each sub-region, and used the masses and known slice height to calculate the segment parameters. For each segment, COM and R_G were expressed as percent of the segment length, and mass was expressed as a percent of the total body mass. A two-tailed t-test was used to compare each BSP of interest between each of the three groups, with significance set at $\alpha = 0.05$.

RESULTS AND DISCUSSION

Significant differences were found for the thigh and torso radii of gyration (Figure 1), with the normal weight group having more distally located R_G's. While the differences appear relatively small, they are all highly statistically significant.

The normal weight group also has statistical trend toward lower torso and thigh masses as a percent of body weight compared to the overweight and obese groups, however these differences are not statistically significant (Table 2). As would be expected, no significant differences were determined for any of the segment lengths.

CONCLUSIONS

Current anthropometry tables were designed using young, normal weight adults as the measurement standard, however these parameters are not accurate in people with varying age and BMI. Significant differences were found between young normal weight, overweight, and obese males in the torso and thigh radii of gyration. These differences demonstrate that the current anthropometry sets cannot be applied across all body types, especially when analyzing gait. This study highlights the need to develop age and size specific anthropometry sets.

IMPACT OF MASS REDISTRIBUTION ON LOWER EXTREMITY BIOMECHANICS DURING SLIPPING

Zachary Merrill, April Chambers, Rakié Cham

University of Pittsburgh, Pittsburgh, PA, USA
email: zfm1@pitt.edu, web: http://www.engineering.pitt.edu/hmbl/

INTRODUCTION

Anthropometry is commonly found in tables containing measurements of body segment parameters (BSP's) such as the mass of each body part as a percent of body weight (BW) and center of mass location (COM) within each segment as a percent of segment length (SL). These tables contain values compiled from healthy, college-age adults, however they have shown to be inaccurate in predicting BSP's in subjects with increased body mass index (BMI), as well as in different age groups, therefor not properly representing real-life parameters and mass distributions [1-3]. In order to understand potential injury mechanisms in a given task, accurate BSP's are required to model joint contact forces and muscle moment contributions.

Several methods exist for determining subject specific BSP's, including magnetic resonance imaging, computed tomography, and measurements based on bony landmarks [4-7], however these methods have some issues as far as cost, time required, and high doses of radiation. Dual energy x-ray absorptiometry (DXA) is a validated method of determining BSP's in vivo that avoids these common problems. DXA scans are commonly used to determine bone density and body composition [8], as well as mass calculations. The scan is an inexpensive, low radiation scan that can differentiate between bone, muscle, and fat.

The goal of this study is to quantify the relative effects of incorrect BSP's, specifically segment masses and center of mass locations, on lower extremity biomechanics during slipping. In order to quantify the impacts of these BSP's on joint contact force and muscle moment contributions, traditional BSPs and parameters previously determined via DXA scan analysis of overweight young males were applied to a biomechanical analysis of slip during gait in an overweight young male.

METHODS

The subject used in this study was an overweight 25 year old male (stature: 182 cm, mass: 88.2 kg, BMI: 26.6 kg m^{-2}). Motion tracking data were collected by a 14-camera Vicon motion tracking system (Vicon Motion Capture, Oxford, UK), and force data with a Bertec force plate (Bertec, Columbus, OH). Data were collected during a slip event that occurred during gait [9].

Following the single study visit, data were analyzed using custom kinematic modeling software [10], with a standard anthropometry set from deLeva [1], and then again with a BMI-specific anthropometry set for young, overweight males (Figure 1). The body segments were altered for the shank, thigh, and HAT (head, arms, and torso). Because ankle moments and forces were not observed for the purpose of this study, standard foot mass and center of mass were applied for both models.

Parameters calculated include hip and knee forces in the superior-inferior (SI), medial-lateral (ML), and anterior-posterior (AP) directions, and hip and knee moments about the SI, ML, and AP axes. Forces and moments were both normalized to body weight, given as N kg^{-1} and N m kg^{-1}, respectively. The forces and moments were calculated between left heel strike (LHS) and the end of the slip, defined by the heel shear velocity decreasing to zero.
Figure 1: Mass and center of mass comparison between standard deLeva parameters and custom overweight, young male parameters derived from DXA scans. Values are given as percent of body weight or segment. p < 0.0001 for shank and thigh COM, and thigh and HAT mass.

RESULTS AND DISCUSSION

When comparing knee joint contact forces or muscle moments, the differences between the BSP sets were less than 0.05 N kg^{-1} and 0.01 N m kg^{-1}, respectively, throughout the slip and reaction, corresponding to less than 1% error relative to the deLeva parameters. There were larger relative errors (6.6-19.4%) in hip muscle moments and contact forces (Figure 2), with the largest errors occurring between 210 and 290 ms following slip initiation. While maximum hip forces in the ML direction were nearly identical, they had the largest average error over the full course of the slip. When comparing the maximum flexion, extension, adduction, abduction, and internal and external rotation moments at the hip, the values for both BSP sets were nearly identical, with less than 1% difference relative to the deLeva parameters.

The largest errors for adduction moment occurred at approximately the same time as the maximum errors in hip joint contact forces, however the largest errors in flexion and external rotation moments occurred between 250 and 350 ms following slip initiation.
Figure 2: Maximum normalized hip joint contact forces in the SI, ML, and AP directions using deLeva and overweight BSP's. Average errors relative to deLeva were 8.9%, 19.4%, and 6.6%, respectively over the course of the trial.

CONCLUSIONS

This study shows that different assumptions regarding mass distribution and body segment parameters have negative impacts on joint contact force and muscle moment calculations. Because the difference between standard and BMI-specific parameters increases with obesity and BMI, BMI-specific parameters are necessary in order to accurately determine joint kinetics. While the calculated errors appear to be relatively small, these errors due to incorrectly applied standard BSP's will increase with BMI [11] and levels of dynamic movement within the activity being observed.

MULTISCALE COMPUTATIONAL MODELING OF SHOE-FLOOR FRICTION

Seyed Reza M. Moghaddam and Kurt E. Beschorner

The University of Pittsburgh, Pittsburgh, PA, USA
Email: sem162@pitt.edu , web: http://www.engineeringx.pitt.edu/hmbl/

INTRODUCTION

Slip and fall accidents present a major health and occupational hazard. Increased shoe-floor coefficient of friction (COF) has been demonstrated to be indicative of reduced slipping risk [1].

Previous research by our group has shown that a microscopic finite element model can predict COF of shoe-floor samples by considering roughness and material properties [2]. However, that study did not consider macroscopic interactions and few other studies have attempted to model whole-shoe friction against walkway surfaces [3]. Current study builds on previous research by expanding the model to consider macroscopic (i.e., whole-shoe) interactions with the floor surface. As a first step towards a comprehensive shoe-floor-contaminant COF model, this study focuses on hysteresis friction, since it is the dominant friction mechanism on lubricated shoe-floor surfaces [2].

METHODS

The model consists of a microscopic model that simulates the interaction between shoe and floor asperities and a macroscopic model that determines contact pressure across the shoe surface. The microscopic model yields hysteresis COF as a function of contact pressure and macroscopic model uses this relationship and the predicted contact pressure to calculate the overall COF.

The microscopic model consists of a rough shoe material sliding against a rigid floor surface (Figure 1 (Left)) [2]. The asperity heights of these blocks were set to achieve a desired peak to valley roughness (R_z) and spacing between asperities was selected to achieve a desired average slope (Δ_a). Shoe material was modeled as a viscoelastic material, which causes energy loss as shoe

asperities deform and relax, while sliding over floor asperities. The hysteresis COF for micro-model was determined as the ratio of shear to normal force. Three different shoe materials were simulated against a single floor surface. Surface parameters were measured and averaged across four scans using a two dimensional stylus profilometer (Taylor-Hobson Surtronic S100 ®, Leicester, UK) (Scan length: 6.2 mm; low-pass cutoff filter: 0.8 mm). The boots had a consistent roughness (R_z = 24.5 μm, Δ_a = 29°) across the three materials. The flooring's roughness was also recorded and applied to the model (R_z = 9.5 μm, Δ_a = 24°). Shore A Hardness of the three boots was measured and used to characterize material properties of the three boots i.e. short-time shear modulus, G_0, long-time shear modulus, G_∞, and decay constant, β, using relationships introduced in [4] (Table 1). Microscopic simulation was repeated over several contact pressures to produce an exponential fit model between contact pressure and COF.

Material geometry for macro-model was determined using 3D scan of a shoe (Faro ScanArm ®) (Figure 1(Right)). Contact simulations were performed using explicit analysis (LS-Dyna, LSTC, Livermore, CA, USA). Vertical displacement of the shoe was applied until reaching a normal force level of 250 N, while the sliding velocity was 0.3 m/s and shoe-floor angle was 7°. Shoe material was modeled as linear elastic for computational efficiency since viscoelastic contributions to hysteresis friction were already accounted for in microscopic model (Table 1).
Figure 1. Micro (Left) and macro- model (Right)

Table 1. Material parameters used for boots

Shore A	G_0(MPa)	G_∞(MPa)	β (s^{-1})	E(MPa)
85	4.39	1.84	0.022	13.18
76	2.48	0.99	0.017	7.44
64	1.41	0.92	0.2	4.24

Friction force was calculated based on the contact pressure (p_i) and area (A_i) for each element from the macro-model, and the COF values as a function of contact pressures $(COF_{(p_i)})$ from the micro-model (Eq.1). COF was calculated as the ratio of average friction force to normal force (Eq. 2).

$$F_{Friction} = \Sigma \; COF(p_i) * p_i * A_i \qquad Eq.\ 1.$$

$$COF = F_{Friction} / F_{Normal} \qquad Eq.\ 2.$$

RESULTS AND DISCUSSION

An exponential fit described the relationship between predicted COF and contact pressure with an R^2 of greater than 0.93 for all three materials (Figure 2). The micro-model revealed that the hardest material experienced the greatest level of hysteresis COF and the medium and low hardness material had similar but less hysteresis COF.
Figure 2. Curve fitting for materials. Hardness: Low(Light Gray), Medium(Gray) and High(Black).

The macro-model revealed that pressures were typically along the posterior portion of the shoe. Increasing shoe hardness was found to increase average and peak pressures and reduce contact area (Figure 3.). Increased contact pressures of the hard shoe led to an overall reduction of hysteresis COF (Figure 4.). This finding was consistent with experimental measurements of shoe-floor COF (Figure 4.) and with slipping risk during unexpected human slips [5]. The model did overestimate hysteresis COF since it predicted COF values

between 0.25 and 0.3 whereas experiments found COF values between 0.15 and 0.2. This discrepancy may be due to the fact that the floor was modeled as rigid, which may have overestimated the hysteresis COF between the floor asperities and the shoe material. Overall, this study demonstrates the potential for using finite element analysis to model shoe-floor friction in a way that predicts slipping risk. The model suggests that the mechanism behind increased COF for soft shoe material is increased contact area and reduced contact pressures.

VALIDATING A COMPUTATIONAL MODEL OF REVERSE SHOULDER ARTHROPLASTY

Vijay N. Permeswaran, Carolyn M. Hettrich, Jessica E. Goetz, Donald D. Anderson

The University of Iowa, Iowa City, IA, USA
email: vijay-permeswaran@uiowa.edu, web: http://tinyurl.com/UIOBL

INTRODUCTION

Reverse shoulder arthroplasty (RSA) is indicated for treating end-stage arthritis when the rotator cuff is compromised. In RSA, the native anatomy of the ball-in-socket joint is reversed by implanting a cup onto the humerus and a sphere onto the glenoid (Figure 1). A common complication is impingement between the humeral cup and inferior scapular ridge, which causes scapular bone erosion (notching). In order to prevent notching, surgeons lateralize the center of rotation of the glenosphere. We previously presented a finite element (FE) analysis of the effect of lateralization on range of motion and stress at the impingement site [1]. This study aimed to validate that prior FE analysis by measuring the contact stress at the impingement site in a cadaveric model.
Figure 1: The image on the left shows a native shoulder, while that to the right shows a shoulder after RSA.

METHODS

A cadaveric shoulder was dissected and prepared using the bony increased offset (BIO) technique [2]. The proximal humerus was transected 5 cm distal to the deltoid insertion. The medial edge of the scapula and distal end of the humerus were both potted in PMMA. A Tornier Reversed Aequalis RSA system (Tornier, Amsterdam, Netherlands) was implanted. Metal spacers replicating BIO offsets were used to study lateralizations of 0, 2.5, 5, 7.5, and 10 mm. A custom loading frame was constructed to secure the scapula. The humerus was held in place by a cable representing the deltoid muscle. This cable was clipped onto an eyehook screwed into the distal humerus PMMA block, routed through a pulley to replicate the wrapping of the deltoid, and attached to the load frame by a turnbuckle, which facilitated adjustment of tension in the deltoid cable.

CT scans were obtained for the cadaveric specimen before and after RSA implantation. The scapula, humerus, and implant components were segmented using Seg3D software (CIBC, Salt Lake City, UT). The FE model was generated from these surfaces.

A Tekscan ankle sensor (model #5033; Tekscan, South Boston, MA) was selected to measure the impingement contact stress because of its high spatial resolution (sensel resolution of 0.834 mm x 0.834 mm). A hole was punched in the sensor in order to secure it to the post of the glenosphere. The sensor was then pinched between the glenosphere and metal spacer. A portion of the sensor around the punched hole was trimmed to eliminate major wrinkling (Figure 2). During testing, a 5 lb. load
Figure 2: Tekscan sensor aligment and positioning. The lateral end of the tekscan sensor was modified and pinched between the glenosphere and lateralization spacer.

was hung from the humeral PMMA block. The deltoid cable was tensioned to prevent subluxation. In addition, a Qualisys Oqus motion tracking system (Qualisys AB, Gothenburg, Sweden) was used to record the position of the scapula and humerus at impingement.

The FE analysis was done using Abaqus/Explicit (Dassault Systêmes, Vèlizy-Villacoublay, France). The global model included deformable glenoid and BIO bone, a rigid glenosphere, a deformable polyethylene cup, a rigid humeral component, and a rigid humerus. In addition, a series of cable and pulley elements were used to model the deltoid muscle, and spring elements were used to represent the joint capsule. The humerus was adducted until impingement and then fixed in position. Due to the highly focal nature of the contact patch, a high-resolution submodel of the impingement site was created. Boundary node displacements were applied using the submodel option. A custom Matlab (MathWorks, Natick, MA) script was used to analyze and compare the Tekscan results to the results of the FE analysis. Contact stress, area, and recovered load values were analyzed as well as location and contact patch morphology.

RESULTS AND DISCUSSION

Only results for the 7.5 mm implantation are here reported. The FE-computed maximum contact stress was 30.9 MPa, while the maximum contact stress for the Tekscan sensor was 21.2 MPa. The FE-computed contact area was 1.05 mm^2. The contact area of the two primary Tekscan sensels was 1.4 mm^2. The load transferred across the FE-computed contact patch was 39.9 N. The Tekscan sensor provided a loading of 42.3 N.

Figure 3 shows how the Tekscan sensor and FE model locations and areas correspond. The FE analysis reported a small contact patch indicative of the edge contact that occurred between the humeral cup and inferior ridge of the glenoid. The Tekscan sensor reported two sensels with contact significantly higher than all surrounding sensels (21 and 19 MPa vs. 2-5 MPa). When overlaid, the FE-computed contact patch aligned well with the two highly loaded sensels. This result provides a potential explanation for why the two sensels
Figure 3: Anterior and inferior view of glenoid region of the scapula with FE-computed and Tekscan-measured contact stresses overlaid. A close-up view of the inferior view is inset below the inferior view. Tekscan sensels reporting zero contact stress were removed for visualization.

measured a smaller contact stress than that computed in the FE analysis. In addition, the FE model would be expected to create smaller contact area than the Tekscan due to the difference in spatial resolution. Finally, the Tekscan sensor can wrinkle around load application sites, yielding artifactually low contact stress readings. The similarity in contact load calculated is an indication that difference in contact area is likely the cause for dissimilar maximum contact stress.

CONCLUSIONS

In conclusion, a finite element analysis of the mechanical consequences of lateralization in RSA was successfully validated against cadaveric measurement of contact stress. This FE model can be used to computationally assess novel implantation procedures prior to clinical application.

Simulation of Reduced Ankle Torque During the Anticipatory Postural Adjustments for Gait Initiation

[1] Matthew N. Petrucci, [2] Louis A. DiBerardino, [3] Colum D. MacKinnon and [1] Elizabeth T. Hsiao-Wecksler

INTRODUCTION

Up to half of the Parkinson's disease (PD) population eventually suffers from freezing of gait, a term used to describe episodic disruptions in walking, turning and gait initiation. Impaired gait initiation may be related to an inability to properly coordinate the anticipatory postural adjustments (APAs) that are required for stability with forward locomotion. APAs in persons with PD are usually prolonged in duration and attenuated in amplitude compared to healthy controls [1].

The appropriate sequence of an APA begins with initial bursts of the tibialis anterior (TA) muscles on both legs and a simultaneous loading of the stepping foot and unloading of the stance foot (loading-unloading phase). Then, activation of the plantarflexor muscles of the stepping leg generates the forces necessary to accelerate the center of mass forward and toward the stance foot. This phase is followed by another TA burst of the stepping leg as it comes off the ground, resulting in a step [2]. An essential component of the loading-unloading phase of an APA is the magnitude of the initial TA burst of the stepping leg, which has been shown to be correlated with gait initiation velocity [3]. In PD, the initial TA burst can be diminished or absent, resulting in a decreased excursion of the center of pressure in the sagittal plane [1,4]. However, the neuromechanical significance of this diminished or absent TA burst has yet to be fully understood.

In the current study, we utilized an inverted pendulum model to investigate the consequences of reduced dorsiflexor torque to overall body lean angle during gait initiation.

METHODS

To study the effects of reduced dorsiflexion, the upright body during gait initiation was modeled as a single-link inverted pendulum. It was assumed that both ankles pivoted around the same point; thus torque was a combined value from both ankles. The

resulting transfer function from applied ankle torque (T_A) to body lean angle (θ) was derived as

$$\frac{\theta(s)}{T_A(s)} = \frac{1}{Js^2 - mgL} \qquad (1)$$

where m was body mass, g was acceleration due to gravity, $J = \frac{1}{3}mL^2$ was the moment of inertia about the ankles, and L was body length divided by 2 (estimated position of center of mass). It was assumed that the body was a uniform rod.

In order to simulate proper gait initiation, a nominal trajectory θ_{ref} was generated from the average behavior of 10 self-initiated right leg gait initiation trials collected from one participant (age 30, ht. 180 cm, wt. 86 kg). Markers were placed on the lateral malleolus and acromion of both sides to generate the body segment.

The T_A term in equation 1 included multiple components representing different parts of the neuromuscular system. The first was a feed-forward torque (T_F), which would produce θ_{ref} in ideal conditions:

$$T_F = J\ddot{\theta}_{ref}^2 - mgL\theta_{ref}$$

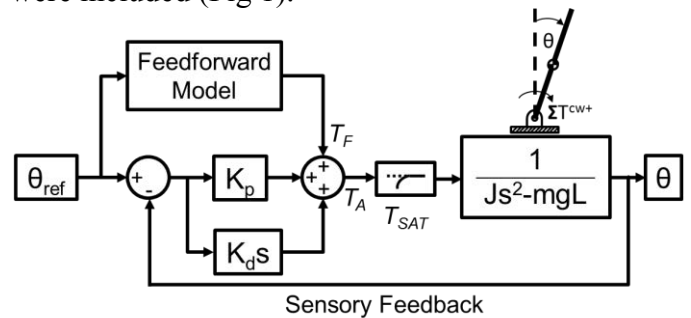
The second component of the T_A term was related to corrective torques driven by the feedback from the combined sensory systems detecting body lean angle. Both stiffness (K_p) and damping (K_d) terms were included (Fig 1).


Fig 1: Inverted pendulum model of gait initiation

Diminished TA activity and reduced dorsiflexor torque during the loading-unloading phase of an APA (time from APA onset to peak loading) through heel-off of the stepping foot were simulated by limiting the torque generated at the ankle via a saturation function (T_{SAT} in Fig 1). The saturation magnitude was decreased in increments of 2 Nm, with each condition simulated using Simulink (MathWorks Inc., Natick, MA). Prior to varying the saturation block value, the feedback gains were heuristically tuned to reduce the sum of squared error between experimental and simulated data. These gains were Kp = 6500 and Kd = 0.

RESULTS AND DISCUSSION

Application of the saturation block revealed a possible threshold for decreased body lean angle and an improper torque sequence (Fig 2). From an initial plantarflexor torque of -33 Nm, the model achieved a peak dorsiflexor torque (most positive value) at -22 Nm. Thus, saturation values of -22 Nm to -28 Nm did not result in large differences in body lean angle or torque. However, when the dorsiflexor torque was limited to -30 Nm, decreases in body lean angle became apparent and the model went into plantarflexion later than the unsaturated torque profile. When dorsiflexor torque was almost fully limited to -32 Nm, the body lean angle was more than half of a degree less than the no saturation condition, and the model never went back into plantar flexion. Even though the difference in overall body lean angle was small, these results suggest that there may be a threshold of the initial dorsiflexor torque where the neuromuscular system is unable to generate a sufficient forward lean at the ankle.

Although preliminary, these results provide insight into the mechanisms behind impaired gait initiation for persons with PD. Experimentally, it has been shown that persons with PD still plantar flex their stepping foot without first dorsiflexing, further inhibiting forward progression [4]. This aberrant activation requires further adaptations in the sequence of muscle activation, which can be difficult for persons with PD [5]. It is possible that these neuromechanical alterations may underlie the symptoms of freezing of gait or start hesitation.
Fig 2: Body lean angle and ankle torque at different dorsiflexor torque saturation values.

CONCLUSIONS

Our preliminary findings highlight the possible consequences of reduced dorsiflexor torque during the initial phase of the APA. Future studies will focus on parameter optimization to more accurately model the neuromuscular system with additions such as time delays and noise. Ultimately, this model could be used to better understand freezing of gait and inform strategies for alleviating these symptoms.

EVALUATION OF THE TRANSVERSE METATARSAL ARCH OF THE FOOT

[1] Sayed Cyrus Rezvanifar, [1] Brian L. Davis

[1] The University of Akron, Akron, OH, USA
Email: sr106@zips.uakron.edu, Web: http://bme.uakron.edu

INTRODUCTION

The existence of the transverse metatarsal arch (TMA) of the foot is controversial, with some researchers [1, 2, 3] historically describing either an arch, or a foot that rests on the floor on the heel, 1st and 5th metatarsal heads. Biomechanically, this configuration has been considered to be a shock absorber. More recently – largely due to the emergence of pressure measurement technologies – researchers have disputed the arch concept by showing that during gait the highest pressures are found at the 2nd - 3rd metatarsal heads (MTH's) and the heel in midstance [4]. According to these researchers, there cannot be a "tripod" if there are no significant pressures under the 1st and 5th MTH's.

In this study, we developed a model that could reconcile both the existence of a TMA and the fact that pressure values can be elevated under the 2nd and 3rd MTH's.

METHODS

A 2D finite element (FE) model was prepared in Abaqus 6.13 based upon a simplified cross-sectional view of the foot at the metatarsal heads (Figure 1). The considered model includes two beams having the mechanical properties of bone tied together at the apex and free to slide horizontally at the medial and lateral edges of the foot.
Figure 1. The TMA was modelled as a simplified arch, with the apex coinciding with MTH2.

The triangular free space between these two beams was filled with an elastic material representing soft tissue. Material properties used for different parts are listed in Table1.

Table1. Mechanical properties of elements used in the model

Material	Density(kg/m³)	Young's Modulus (MPa)	Poisson's ratio
Bone Beams	1750	7300	0.3
Soft Tissue	1050	2000	0.33
Ground	7800	200,000	0.3

Fillets were applied at all edges of the soft interior portion of the model in order to avoid excessive distortions. The coefficient of friction between the soft triangle and ground was set 0.5 [5]. Moreover, the angled sides of the soft tissue were tied to the beams leading to ensure no relative movement. A 10 mm vertical displacement was applied to the apex for observing the effect of applying bodyweight to the forefoot. Boundary conditions were established by setting the lower horizontal surface of the rectangular modeled ground to have no displacement or rotation in any direction. Furthermore, the beam ends in contact with the ground were constrained to translate only in the horizontal (medio-lateral) direction.

Meshing involved using beam elements for the "bone" structures and plane stress elements for soft tissue and ground since the assumed cross section with a small thickness would have negligible stresses in the perpendicular direction. Finally, the conducted analysis was modelled as Dynamic-Explicit. Of note is the fact that for quasi-static problems, Dynamic-Explicit analysis requires attention to the static status of the problem during

the iterative modelling process. Accordingly, the values of internal and kinetic energies were compared throughout the loading process. Finally, in order to verify the meshing process, a convergence study was performed to assess the influence of element sizes.

RESULTS AND DISCUSSION

The model was assessed and found to exhibit consistently lower magnitude of kinetic energy in comparison with internal energy. This implies the model was acceptable from a quasi-static point of view.

The convergence validation showed that predicted pressures at the ground-foot interface changed by only 1% when the elements were increased by a factor of four (i.e., from 2mm to 0.5mm). These results supported the decision to select elements 1mm in size.

The primary finding of this study is that the model showed that pressures can be elevated in the MTH2 and MTH 3 regions – simply by virtue of the fact that as the arch flattens, the soft tissue is compressed in a matter that leads to pressure build-up in the central forefoot region (Figure 2).

CONCLUSIONS

This study has shown that a "controversy" in whether or not there is a transverse arch can be reconciled through the use of a simple model. What the model shows is that pressures can be elevated in MTH2 and MTH3 regions even when there is a bony "tripod" made up of osseous elements within the foot. The fact that loads may be distributed through the calcaneus and 1st and 5th rays may not be at odds with elevated pressures in the central forefoot region.

GLENOHUMERAL ABDUCTION AND FLEXION MUSCLE MOMENT ARMS: A VERFICATION STUDY OF A NEW MUSCULOSKELETAL MODEL OF THE SHOULDER

[1] R. Tyler Richardson, [2] Brian A. Knarr, [1] Jill S. Higginson, and [1] James G. Richards

[1] Biomechanics and Movement Science Program, University of Delaware, Newark, DE, USA
[2] Delaware Rehabilitation Institute, University of Delaware, Newark, DE, USA
email: trich@udel.edu

INTRODUCTION

Musculoskeletal modeling possesses the capability to estimate internal muscle forces that cannot be directly measured [1]. However, the validity of the results must first be assessed to ensure that the model is sufficiently robust to recreate the mechanics that occur in vivo. Moment arms define the function of a muscle about a joint and dictate the mechanical advantage with which it operates. Accordingly, evaluation of moment arms represents a particularly important step in the model verification process as they strongly influence simulation predictions. Existing upper extremity models [2, 3] possess limitations that compromise their ability to replicate scapulothoracic kinematics and estimate the associated underlying muscle forces. In an effort to overcome these limitations, a new shoulder model (UDSM) has been developed. This study compared the UDSM glenohumeral (GH) abduction and flexion muscle moment arms with published cadaveric data [4]. It was hypothesized that the UDSM GH abduction and flexion moment arms would be similar in both function and magnitude to the established values.

METHODS

The UDSM possesses 16 degrees of freedom allowing for physiological motion of the thorax, clavicle, scapula, humerus, and forearm. Thirty-five muscle actuators have been employed to represent 18 muscles which span the shoulder and elbow joints. Continuous GH abduction and flexion moment arms for the deltoid, latissimus dorsi, pectoralis major, teres major, and rotator cuff muscle actuators were calculated for the model using OpenSim [1]. The model GH abduction and flexion muscle moment arms were assessed during in vivo shoulder abduction (10°-120°) and flexion

(2.5°-120°), respectively. Dynamic orientations of the trunk and upper extremity segments were recorded with motion capture for one healthy subject. Each motion trial permitted unprescribed scapular kinematics which were estimated by an acromion marker cluster [5]. Joint kinematics were calculated using inverse kinematics. The GH abduction and flexion moment arms estimated using these kinematics were qualitatively compared with cadaveric data from Ackland et al. [4].

RESULTS AND DISCUSSION

UDSM GH abduction moment arms accurately reflected the functional role of each muscle. The anterior and middle deltoid, infraspinatus, and supraspinatus operated as abductors throughout the motion (Fig. 1). The posterior deltoid, latissimus dorsi, sternal and costal heads of pectoralis major, subscapularis, and teres major acted primarily as adductors (Fig. 1). Teres minor and the clavicular head of pectoralis major functioned as both abductors and adductors within the motion.
Figure 1: GH abduction moment arms of the deltoid. (+) values indicate abduction.

The magnitudes of the UDSM abduction moment arms also compared favorably with cadaveric data [4]. The anterior and middle deltoid and supraspinatus had the greatest mechanical advantages for abduction while the posterior deltoid, latissimus dorsi, teres major and pectoralis major possessed the largest mechanical advantages for adduction (Fig. 1).

Glenohumeral flexion moment arms of the UDSM corresponded with the functional role of each muscle. The anterior and middle deltoid, superior subscapularis, clavicular head of the pectoralis major, and supraspinatus operated as flexors throughout the motion (Fig. 2). The posterior deltoid, middle and inferior latissimus dorsi, costal head of pectoralis major, inferior infraspinatus, teres minor, and teres major acted primarily as extensors (Fig. 2). The sternal head of pectoralis major, inferior subscapularis, superior infraspinatus, and superior latissimus dorsi functioned as both flexors and extensors at different portions of the motion. The magnitudes of the UDSM flexion moment arms were also similar to cadaveric data [4]. The anterior and middle deltoid possessed the greatest mechanical advantages for flexion while the posterior deltoid, latissimus dorsi, and teres major had the largest mechanical advantages for extension (Fig. 2).
Figure 2: GH flexion moment arms of the deltoid. (+) values indicate flexion.

While the general functional roles of all the muscle actuators of the model were in agreement with published cadaveric data, there were a few muscles displaying appreciable differences in moment arm pattern and magnitude. Conditional differences between the motions used for the model analysis and the kinematics prescribed in the cadaveric experimental setup [4] are likely responsible for these discrepancies. For both the abduction and flexion trials the model was driven with in vivo motion which involved unprescribed scapular motion with three degrees of freedom while the cadaveric experiments [4] were performed with a prescribed scapular rhythm with only one degree of freedom. Additionally, the cadaveric study [4] fixed the clavicle in a neutral position during each motion, while the kinematics used in the model's analysis permitted physiological motion of the clavicle. The observed minor variations in pattern and magnitude of GH moment arms are to be expected and can be explained considering these conditional differences in the kinematics between the cadaveric and model analyses.

CONCLUSIONS

This analysis establishes that the UDSM GH abduction and flexion moment arms are similar to cadaveric data while also allowing for unprescribed scapular motion. Continued research comparing the model's properties and predictions to published data is warranted to provide a more complete verification of the UDSM.

DEVELOPMENT OF AN OPEN-SOURCE, DISCRETE ELEMENT KNEE MODEL

Anne Schmitz

Gannon University, Erie, PA, USA; email: schmitz005@gannon.edu

INTRODUCTION
Osteoarthritis, the most common form of arthritis, occurs more in the knee than any other joint [1]. Therefore, knee models are valuable tools that can be used to study normal joint function, simulate potential strategies to prevent injury, and assess the effect of treatment programs. These models range in complexity from a hinge joint [2,3] to a complex continuum representation using finite element analysis [4]. Discrete element models offer a balance between simplified and finite element models by providing soft tissue loads at a low computational cost. Uses of these models include the estimation of immeasurable forces (i.e. muscle forces and soft tissue loads) and the performance of 'what-if' studies. For example, a discrete element model of the knee, which included cartilage loads and spring representations for ligaments, has been used to predict hamstring and quadriceps forces that could be used to restore normal joint function in a knee without an anterior cruciate ligament [5]. However, there is not an open-source, discrete element knee model available in the literature. Therefore, the goal of this work was to develop a discrete element model of the knee that is open-source.

METHODS
The right femur and tibia of a generic musculoskeletal model (i.e. gait2392 model [6]) were scaled for a 77.5 kg female in the open-source software OpenSim [7]. A six degree-of-freedom (dof) tibiofemoral joint and one dof patellofemoral joint were created that included tibiofemoral contact, ligaments, and vastii muscles (Figure 1). The patellofemoral joint was modeled as a one dof joint where the patella moved in a constrained path about the distal femur subject to vastii and patellar tendon forces. Contact was modeled between the femur and tibia using an elastic foundation model [8]. The geometry of the distal femur articular cartilage was based on an open-source finite element knee model [9]. The tibial plateaus were

modeled as two planes: the lateral plateau sloped 7 degrees posteriorly and 2 degrees laterally while the medial plateau sloped 2 degrees posteriorly and medially [5,10]. Eighteen ligament bundles were included in the model: anterior cruciate ligament (ACL, 2), posterior cruciate ligament (PCL, 2), medial collateral ligament (MCL, 5), lateral collateral ligament (LCL, 1), poplitofibular ligament (PFL, 1), posterior capsule (4), and patellar tendon (3). The origins and insertions were based on the literature and modeled as nonlinear elastic springs with properties adapted from the literature [5,11]. The properties were minimally tuned to match the model behavior to literature measures of passive motion, anterior-posterior stiffness, and axial rotational stiffness. The developed model is available from https://simtk.org/home/kneemodel and can be freely downloaded and recreated using OpenSim.

To validate the model, its passive behavior was compared to cadaveric literature. First, the model was passively flexed while the other five dof were compared with [12]. Next, an anterior and posterior force of 100N was applied to the tibia with the amount of anterior-posterior translation measured [13]. Then, an axial rotation torque of 5Nm was applied to the tibia with the resulting rotation measured [14,15].
Figure 1: Discrete element knee model created in OpenSim

RESULTS AND DISCUSSION

Passive motion and stiffness properties of the model mostly agreed with the range presented in the literature (Figure 2). This provides a comprehensive description of the passive behavior of the model and highlights its physiological relevance. However, there are some exceptions to note. When the model was flexed, the tibia did not translate as much superiorly as the literature suggests. This may be largely governed by the contact geometry. Also, anterior translation of the model under an applied anterior force was on the low side of the literature range. However, further loosening of the ligaments to increase this translation caused intercondylar lift-off during the passive flexion motion.

This model has many applications: (1) investigate the sensitivity of passive motion and stiffness to ligament properties and placements, (2) investigate the effect of scaling on passive behavior, (3) used to create a surrogate model, and/or (4) used in a cosimulation or serial (e.g. [16]) approach to predict soft tissue loading during movement.

CONCLUSIONS

In summary, a discrete element knee model has been presented. Through a comparison with the literature, the model has shown physiologically reasonable passive behavior. A novel element of the model is that it is open-source. This enables more researchers to add to the refinement of the model as well as providing modeling as an accessible tool to a wider audience.

IMPROVING PATIENT SIMULATOR UPPER ARM BIOMECHANICS

[1] K. Dyer, [1]A, Merlino, [1] N. Bouaynaya, [1] T. Merill, [1] D. Podolin, [1&2] A. Singh

INTRODUCTION

Patient simulators (SIMs) have been used effectively to teach basic science and clinical knowledge as well as clinical skills, teamwork, and communication to both undergraduate and graduate medical students [1,2]. Despite costs ranging from $30,000 to $200,000, existing high-fidelity mannequin simulators are limited in their capabilities. There is a critical need for SIMs with extremities that move realistically and respond with normal muscle tone when educating healthcare students. This functionality would allow students to learn: a) appropriate methods to move and position patients and b) neuromuscular examination techniques. Improper skill in patient positioning can result in patient injury, particularly among geriatric, obese, and immunocompromised patients. To meet this critical unmet need, this study aims to improve the biofidelity of the upper extremity by i) including normal degrees of freedom (DOF) in the elbow joint, ii) incorporating muscle tone in the upper arm, and iii) automatically controlling the upper arm to simulate different muscle tones and neuromuscular disorders

METHODS

SimMan 3G (Laerdal, NY) offers some realism as the arms rotate at the shoulder joint in a circular motion, but they do not bend at the elbow. We used mechanical design principles to incorporate required DOF at the elbow joint as shown in Figure 1.

Designing Elbow Joint: Using the anatomical details obtained from the existing SimMan 3G arm, solidwork models of the upper and lower arm was created. The final arm configuration was then fabricated after taking the degrees of freedom at the elbow joint, arm weight (<10 lbs) and biceps and triceps muscles attachment points into consideration as shown in Figure 2.
Figure 1: Sim-Man 3G Arm and the newly designed bio-fidelic arm.
Figure 2: Solidworks rendering of the biofidelic arm with human like range of motion at the elbow joint.

Designing Muscle Tone in a SimMan Arm: A real arm is a highly redundant complex system made of muscle, tendons, bones and nerve. Simulating arm with changes in any of these components has always remained a challenge for simulator manufacturers. No one mannequin offers a system that replicates a limb under the effect of an abnormal muscle, tendon or bone function. In this study, we incorporated the biceps and triceps muscles using an air-muscle model as shown in Figure 3. Muscle tone, a continuous, passive, partial contraction of the muscles is affected in patients,

such as older individuals, individuals with dementia display paratonia, patients with extrapyramidal disease, particularly Parkinson's. In the designed system, we could simulate changes in muscle tone by regulating the pneumatic pressure inside each air muscles.
Figure 3: Air Muscles simulating the Biceps and Triceps Muscles.

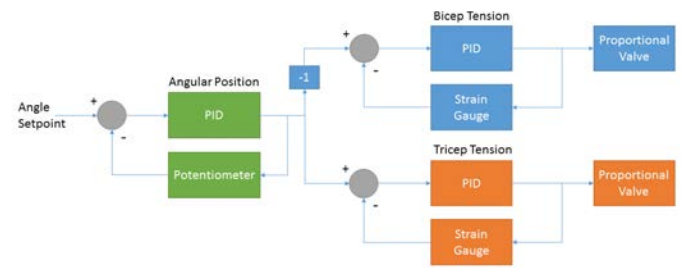
Controlling the upper arm of SimMan: The pneumatic artificial muscles are controlled through proportional valves used to control the pressure and resultant displacement. To simulate muscle tone, the angular position of the arm must be controlled. A potentiometer is used to determine angular position and provide feedback to the control system. In addition, strain gauges are placed on each muscle 'tendon' to determine the amount of force that muscle is exerting. This feedback also allows the user to be notified that they are 'hurting' the patient when too much force is applied. The block diagram of the control system can be found in Figure 4. The system uses three PID controllers for bicep tension, tricep tension, and angular position. The output of the position controller is tuned to be in the range of strain gauge feedback. If the position controller is attempting to increase angle (flexion), the output is such that the bicep controller should increase tension while the tricep controller releases tension. In order to simulate muscle tone, the position setpoint responds to the external force applied to the mannequin arm. External force is detected when the position exceeds the operating bounds of the control system. The bounds control the response of the arm and therefore the muscle tone. By responding later (bounds are larger), the control system will try to resist movement. On the contrary, when the bounds are small, the system will quickly change it's setpoint, resulting in little to no resisting.


Figure 4: Block diagram of control system using multiple integrated PID controllers

RESULTS

The newly fabricated arm offers a range of motion between 0 and 100 degrees. The two air muscles simulate the biceps and triceps muscles and precisely control the range of motion at the elbow joint. Furthermore, by regulating the pneumatic pressure within the air muscle, the muscles can be pre-strained to offer various muscle tone in the forearm. Currently, the modified biofidelic forearm is being attached to a mannequinn to carry out clinical validations and establish the efficacy of this improved arm in the medical education.

CONCLUSIONS

In the current teaching setting, the most common mannequin used to teach physiologic points lacks limb mobility and/or offer unrealistic mobility. By adding DOF in these joints, incorporating the air-muscles for muscle tone, and controlling the arm, we will offer a much more realistic teaching tools for patient positioning [3].

THE EFFECTS OF ADDED FOOT STIFFNESS ON SOLEUS MUSCLE FASCICLE BEHAVIOR DURING HUMAN WALKING

INTRODUCTION

Understanding the interplay between foot and ankle structures may help uncover the fundamental principles governing the mechanics and energetics of human locomotion. The structure of the foot, for example, defines the input and output lever arms that set the mechanical advantage of the plantar flexors during push-off in walking and running [1]. The foot and ankle can also interact in a rather unintuitive manner; while the muscles and tendons crossing the ankle do positive work during push-off, the foot may counteract the ankle by absorbing or dissipating energy [2,3]. We explored this functional interplay by adding stiffness to the foot (through footwear) and evaluated ankle plantar flexor (soleus) muscle fascicle behavior and whole-body energy cost during walking.

Prior studies involving footwear have shown that a stiffer shoe increases the gear ratio (the ratio of ground reaction force lever arm to ankle plantar flexor moment arm) and also increases the mechanical energy returned by the foot [4,5]. The effects of altered shoe stiffness on ankle plantar flexor function, however, remain unclear. In theory, increased gear ratio could enhance muscle force production through slower shortening velocity [6]. In addition, increased foot energy return may decrease the mechanical work demands elsewhere (such as from structures crossing the ankle), as net work done by the body is conserved during steady-state locomotion.

We hypothesized that adding stiffness to the foot would increase soleus fascicle force while decreasing the fascicle shortening velocity and positive work. Additionally, we hypothesized that these altered muscle mechanics would decrease the whole-body metabolic energy cost of walking.

METHODS

Kinematic and kinetic gait data were collected from 5 healthy subjects (2 females and 3 males). We fabricated carbon fiber foot insoles with four different thicknesses (0.8, 1.6, 2,4 and 3.2 mm) to vary insole stiffness. Subjects walked at a fixed speed of 1.25 m/s on an instrumented treadmill under six different foot conditions (barefoot, shod, and shod with four different insole thicknesses). The shod and shod+insole conditions corresponded to an added stiffness of 16.3, 24.3, 27.1, 30.8, and 64.1 N/mm relative to barefoot, respectively. We note that the shoe and insoles were intended to *add* stiffness to the anatomical foot, and not necessarily to modify the stiffness of the foot itself.

Soleus muscle fascicle length and pennation angle during walking were estimated using B-mode ultrasound (Telemed, Lithuania), while fascicle velocity was computed by differentiating the length with respect to time. Soleus fascicle force was estimated by dividing the total ankle joint moment (computed from inverse dynamics) by the Achilles tendon moment arm, scaled to cross sectional area of the soleus relative to all plantar flexor muscles, and then corrected for pennation angle. Work done by the soleus muscle fascicle was estimated by integrating the fascicle power (product of fascicle force and velocity) over time.

The effects of different foot conditions were analyzed using a 1-way repeated measures ANOVA for the following variables: (1) peak soleus fascicle force, (2) soleus fascicle velocity at the time of peak force, (3) soleus fascicle positive work, and (4) whole-body net metabolic power (estimated from indirect calorimetry). If a significant main effect ($p < 0.05$) was detected, we used a paired t-test to perform pairwise comparisons. Because of the

current low sample size, we opted not to adjust for multiple comparisons to control for Type I errors.

RESULTS AND DISCUSSION

With added foot stiffness, soleus fascicle peak force increased ($p < 0.01$). Furthermore, the fascicle velocity was decreased across several foot conditions ($p < 0.05$), with shod, shod+0.8mm, and shod+1.6mm having slower fascicle shortening velocity (at the time of peak force) compared with barefoot. These preliminary findings are consistent with previous findings that footwear can alter gear ratio [4], increasing plantar flexor force by reducing contraction velocity. Despite these changes in force and velocity profiles, there was no significant change in fascicle positive work ($p = 0.22$). Lastly, added stiffness was found to influence whole-body metabolic cost ($p < 0.05$). The barefoot condition had the least metabolic power (2.80 ± 0.38 W/kg) while the shod+3.2mm (stiffest condition) had the greatest metabolic power (3.08 ± 0.29 W/kg).

CONCLUSION

Our preliminary data indicate altered force-velocity behavior of the soleus muscle fascicle with varied foot stiffness conditions. We are currently collecting data from more subjects to confirm these initial observations.

There was a significant effect of added foot stiffness on peak force ($p < 0.01$, denoted by **), and velocity at the time of peak force ($p < 0.05$, with significant pair-wise comparisons denoted by *), but there was no significant effect on positive work ($p = 0.22$).

ASSESSING WIRE NAVIGATION PERFORMANCE IN TREATING HIP FRACTURES

Leah Taylor, Colleen Rink, Steven Long, Geb W Thomas, Matthew D Karam, and Donald D Anderson

The University of Iowa, Iowa City, IA, USA
email: leah-taylor@uiowa.edu, web: http://tinyurl.com/UIOBL

INTRODUCTION

One of the most common procedures performed by orthopaedic surgeons is the fixation of a hip fracture involving the proximal femur [1]. A sliding hip screw is one preferred fixation device. Its failure is most often due to cut-out of the implant from the femoral head [2]. The cannulated implant is placed after using fluoroscopy to navigate a guide wire into the femoral head. The Tip-Apex Distance (TAD) measures the accuracy of implant placement from AP and lateral radiographs or fluoroscopic images (Figure 1). A larger TAD carries with it a greater cut-out risk, especially when it exceeds 25 mm [1].

$$TAD = \left(X_{ap} \times \frac{D_{true}}{D_{ap}}\right) + \left(X_{lat} \times \frac{D_{true}}{D_{lat}}\right)$$
Figure 1: Technique for calculating the TAD. The D (diameter) values are used to adjust for radiographic magnification [3].

The TAD measure is obtained directly from two orthogonal projections, not from a 3D distance [3]. The methods for measuring TAD are ambiguous [1, 2], relying on precise radiographic landmark point definitions, the fitting of an ellipse to the femoral head, the angles at which the x-ray images are acquired, and the patient position. All of these factors contribute to calculations of TAD that are inconsistent and imprecise. The purpose of this work was to begin to develop a more reliable metric of wire navigation performance.

METHODS

Twelve first-year orthopaedic residents performed fluoroscopy-guided wire navigation on a hip bone/ soft tissue surrogate (Figure 2). Their task was to insert a K-wire from the lateral cortex centrally through the neck to the apex of the femoral head.

Figure 2: A resident is shown performing the wire navigation task.

Each resident repeated the exercise three times. The position of the fluoroscopy unit was controlled to limit variability in the projection angles. The final AP and lateral fluoroscopic images were analyzed independently. To account for intra- and inter-observer variability, each evaluator measured the TAD twice (72 fluoro images, 288 measurements) using methods previously described [3] (Figure 3).
Figure 3: TAD measurements on the lateral (left) and AP (right) fluoroscopic images.

RESULTS AND DISCUSSION

The degree to which an ellipse of best fit was able to encompass the femoral head on the fluoro images depended on the anteversion of the femur. The size, shape, and location of the ellipses were subjectively assigned by the evaluator. The lateral image was more susceptible than the AP to uncertainty of how and where the ellipse should be placed, as a slight degree of rotation would skew the image. Depending on the angle of the femoral shaft, the point where the head and neck intersection occurred was more or less difficult to identify.

The inter-observer standard deviation in TAD measurement was found to be 0.89 mm, with values ranging from 0.21 to 3.1 mm. Similarly, the average intra-observer standard deviation was found to be 0.74 mm, with values ranging from 0.0 to 3.8 mm.

Baumgaertner et al. similarly analyzed their measurements of TAD from actual surgical cases. Their results showed an average inter-observer standard deviation of 1.7 mm, with measurements ranging from 0.3 to 5.1 mm. Their intra-observer standard deviation averaged 1.2 mm, with measurements ranging from 0.0 to 5.7 mm.

With current methods, a "non-ideal" lateral image can move the apex from the outermost point of the subchondral bone inward and vertically. This reasons that this way of establishing the apex does not accurately represent the actual location from various rotations and views (Figure 4). As residency programs consider moving towards a competency-based assessment protocol, measurements such as TAD will play a role in evaluating a resident's surgical skill. As an assessment parameter the method, variability, and accuracy within a technique must be minimized.
Figure 4: Image (A) represents an ideal lateral position; images B to E represent less ideally rotated views and corresponding apex location designated by a blue dot.

CONCLUSIONS

The variation in methods of calculating TAD, as well as the variability and inaccuracy in its measurement, calls for a standardized, consistent measurement technique. It is undesirable to have research teams referencing a TAD, when one group is using an alternate method and in turn may actually be calculating a different distance. For the TAD to remain a universal standard a single, an improved technique is needed.

TRACKING THE TRUNK SEGMENT: BACKPACK VS. ELASTIC STRAP

Nienke W. Willigenburg and Timothy E. Hewett

The Ohio State University, Sports Health and Performance Institute, Columbus, OH, USA
Mayo Clinic, Departments of Orthopaedics, Physiology & Biomedical Engineering and PM & R
email: nienkewilligenburg@gmail.com, web: http://sportsmedicine.osu.edu

INTRODUCTION

Impaired trunk control may be associated with low back pain and lower extremity injuries [1, 2]. Tracking movement of the trunk segment in a motion capture setting can be challenging, as placing markers directly on the skin is not feasible in certain populations. Therefore, several studies have used a small backpack with three integrated reflective markers, which can be worn over a T-shirt or tank top, to track 3D motion of the trunk during athletic tasks. Limitations of this method are that the backpack can move with respect to the trunk, especially when the arms and shoulders move, and that the backpack is not rigid, so the markers can move with respect to each other. To overcome these issues, we developed and tested an alternative marker setup. The present study compares 3D trunk angles, as measured during athletic tasks with these two different marker configurations.

METHODS

Eight subjects (6m, 2f) performed 3 repetitions of a drop vertical jump (DVJ), a well-established symmetric task, and a cross over drop (COD), which requires frontal plane displacement and a single leg landing (Figure 1). We analyzed the landing and flight phase of the DVJ, as well as the first 0.5 second of the COD landing.
Figure 1. Cross over drop

The pelvis segment was tracked by markers on the left and right anterior superior iliac spines, iliac crests, and sacrum. The trunk segment was tracked by A) a backpack with 3 integrated markers, and B) an elastic strap surrounding the trunk just below the chest with a dorsal rigid marker cluster and a ventral marker on the xiphoid process (Figure 2).
Figure 2. Marker configurations for tracking the trunk.

3D trunk angles were calculated with respect to the pelvis segment, and time series were averaged over 3 repetitions per subject. To compare time series between the different marker configurations, we calculated the coefficient of multiple correlation (CMC) [3] for each subject and plane of motion.

RESULTS AND DISCUSSION

When averaged over subjects, the backpack tended to overestimate trunk flexion during most of the landing phase, but trunk extension during the flight phase (Figure 3). This is likely related to arm movement, which can cause the backpack to move with respect to the trunk.

Additional differences between marker configurations were observed in the transverse plane during the COD landing (Figure 4). Specifically, the backpack consistently overestimated trunk rotation in this asymmetric athletic task.
Figure 3. Sagittal plane trunk angle averaged over subjects for the backpack (solid) and elastic strap (dotted), in the DVJ landing (left) and flight phase (middle), and in COD landing (right).
Fig4. The backpack tended to overestimate trunk rotation; this pattern was consistent between subjects.

We observed substantial variation between subjects in the two trunk angle time series. Individual subjects' CMCs in the sagittal plane ranged from 0.63 to 0.98 in the landing phase of the DVJ. In the flight phase, differences between methods were larger, with CMCs ranging from 0.39 to 0.96, or yielding imaginary results. Frontal and transverse plane excursions were small in this symmetric task, but differences between methods were substantial. In the asymmetric COD landing task, individual subjects' CMCs ranged from 0.52 to 0.99 for the sagittal and frontal plane trunk angles. Time series curves were less similar in the transverse plane, with imaginary CMCs for half of the subjects, while the remaining CMCs ranged from 0.46 to 0.88.

These findings indicate that different trunk marker configurations yield different results. The overestimation of trunk flexion during DVJ landing, extension during the DVJ flight phase, and rotation during the COD landing indicate that the backpack method may be more affected by arm movement. Additional individual differences between methods may depend on spinal curvature, as the backpack is typically located higher on the thoracic spine.

CONCLUSIONS

The backpack and elastic strap trunk marker configurations yield different trunk angle measures during athletic tasks. Some differences were consistent between tasks and subjects, but others were not. The elastic strap method may be more accurate, because it seemed less affected by arm movement, and it allows for an additional xiphoid marker. However, for longitudinal studies we recommend to adhere to the original choice of marker configuration in order to obtain reproducible measures over time.

INTRODUCTION

Three-dimensional (3D) motion capture and biomechanical modeling are powerful tools to identify motor control behavior and injury risk deficits in athletes. In the past decennia, several linked-segment models have been developed and optimized for use in specific motor tasks or subject populations. Some standard models are well documented [1-3], but the specifics of tailored biomechanical models are sometimes not fully described in the literature. As biomechanical models continue to advance based on technological improvements and changes in software it is critical to detail the progression of modeling parameters. The present study describes the specifics of our model that has demonstrated reliability in recording dynamic athletic tasks for identification of injury risk and motor behavior in athletes [4].

METHODS

The lower extremity model was originally developed in Kintrak (Motion Analysis Corporation, Santa Rosa, CA, USA), and then transitioned to Visual3D (C-Motion Inc, Germantown, MD, USA). Key priorities in development and advancement of this model were 1) test-retest reliability of dynamic tasks for longitudinal cohort studies in athletes, and 2) consistency with previous model versions, to allow for comparisons with previous results.

The model employs a minimum of three retro-reflective tracking markers per segment, and its proximal and distal ends of each segment are defined by a combination of markers and/or virtual landmarks. Virtual landmarks are created relative to marker positions from a static T-pose, with the joint coordinate systems aligned with the lab coordinate system [5]. Foot placement was standardized during the static trial while the subject was instructed to stand in anatomical position.

RESULTS AND DISCUSSION

The figures below present the pelvis, thigh, shank and foot segments with the locations of the markers and virtual landmarks that (directly or indirectly) define the proximal and distal ends of the segments.
Figure 1. Pelvis markers on the 1) RASIS, 2) LASIS, 3) LIliacCrest, 4) RIliacCrest, and 5) Sacrum. Virtual landmarks are 6) PelvisJC, 7) PelvisLatProx, 8) MidHip, 9) PelvisLatDist, 10) MidHipZ, 11) MidASIS, 12) PelvisJCLabY, and 13) PelvisDistLabY.
Figure 2. Thigh markers on the 1) ASIS, 2) GrTroch, 3) ThighPost, 4) ThighMid, 5) ThighAnt, 6) ThighDist, and 7) EpicLat. Virtual landmarks are 8) ASISLabX, 9) HipJC_ML, 10) HipJCTmpZ, 11) HipJCAx, 12) HipJCTmpY, 13) HipJC, 14) HipJCLat, and 15) KneeJC. Shank markers on the 1) EpicMed, 2) EpicLat, 3) TibTub, 4) TibLat, and 5) TibDist. Virtual landmarks are 6) AnkleJC, 7) AnkleLatProx, 8) KneeJC, 9) KneeTmpY, and 10) KneeLatProx.
Figure 3. <u>Foot</u> markers on the 1) MalMed, 2) MalLat, 3) Heel, 4) PostFoot, and 5) Toe, and virtual landmarks 7) AnkleJC, 8) AnkleTmpY, 9) AnkleLatProx, 10) ToeFloor, 11) DistFootJC, 12) DistFootTmpY, and 13) FootLatProx.

To estimate the location of the hip joint center, this model uses Bell's regression equations for the medio-lateral and superior-inferior directions [6], and the marker on the greater trochanter for the anterior-posterior direction [7]. More recently we have utilized a motion trial to calculate the functional hip joint center that could replace estimations based on pelvic width. The mass and inertial properties for each segment are based on De Leva's sex-specific parameters [8]. The subject's height and body mass are included in each model.

The lack of a 'gold standard' for calculation of joint angles and moments during athletic task performance may limit adequate validation of any biomechanical model. However, both within and between-session reliability of most kinematic and

kinetic variables obtained with this model were good to excellent in athletes during the landing phase of a drop vertical jump [4]. Moreover, the present model allowed for identification of knee abduction moment as biomechanical risk factor for anterior cruciate ligament injuries in a large-scale prospective study [9].

CONCLUSIONS

The specifics of a biomechanical model used in multiple longitudinal cohort studies assessed kinematics and kinetics during athletic tasks were detailed. Sharing the details of model parameters across multiple laboratories will help to interpret differences between previously reported findings, and facilitate future large scale multi-center collaborative studies [10].

PREDICTIVE SIMULATION OF ROWING EXERCISE USING GPOPS II

Milad Zarei and Antonie J. van den Bogert

Department of Mechanical Engineering, Cleveland State University, Cleveland, OH, USA

Email: m.zarei@vikes.csuohio.edu, Web: http://hmc.csuohio.edu/

INTRODUCTION

An exercise machine presents a specific geometrical and mechanical environment to the user. The design parameters affect how the user performs the exercise and which forces are generated in musculoskeletal tissues. If we are able to predict these effects during the design process, exercise outcomes can be improved. Current approaches aim at presenting simple conditions such as constant load or constant speed, or replicate existing sports-related exercise conditions such as rowing, weightlifting and bicycling. There is, however, much more design freedom which remained unexplored.

To predict human execution and optimize machine parameters, human musculoskeletal dynamics and adaptive neuromuscular control should be taken to account. Here we will use a computational method based on musculoskeletal modeling and optimal control to predict how mechanical parameters alter human performance [1]. The specific purpose of this research is to investigate the effects of resistance parameters on movements and forces generated by the arm during periodic arm flexion exercise.

METHODS

System dynamics

We will consider a one-degree of freedom arm flexion exercise, where resistance is similar to that found in a rowing machine. The rowing machine model has two phases in which there are different dynamics. In the first phase (power phase), resistance is provided by a spring (k_1), a damper (b) and a mass, which is the total effective mass of the user (m_h) and the rowing machine (m_r) (Fig 1). In the second (recovery) phase, the resistance mechanism is disengaged, except for a weak spring (k_2) which winds up the cable (Fig 2). The user's action is represented by a force (F_{arm}) which is generated by the arm.

The rowing machine inertia was assumed to be 40 kg and the human inertia was assumed to be 10 kg. Also k_1, k_2 and b were set to 120 N/m, 10 N/m and 20 Ns/m, respectively.

A Hill-based muscle model (Fig 3) was used to model the dynamics of muscle contraction in which contractile element (CE) represents the muscle fibers, the series elastic element represents the tendon that transfers force from muscle fibers to the skeleton [2]. A small amount of parallel damping was added to the contractile element for numerical reasons. The connection between muscle and the machine was a simple lever where d is moment arm at elbow is and L is the total length of forearm and hand.

Muscle properties and other model parameters were obtained from both heads of the biceps brachii muscle in an existing arm model, and combined into one equivalent muscle [3].
Figure 1: Dynamic model for the power phase.
Figure 2: Dynamic model for the recovery phase.

Simulation

The predictive simulation was formulated as an optimal control problem, to find the force profile that produces a periodic movement with an amplitude of 0.2 m with minimal effort. Effort was defined as the integral of the squared neural control. Duration of the

entire movement fixed at 4 seconds; however the duration of each of two phases (power phase and recovery phase) was predicted.

GPOPS II [4] (MATLAB optimal control software) was used to solve the two-phase optimal control problem.

Preliminary results will be presented with a simplified static muscle model in which there was no series elastic element and no length or velocity dependence in muscle force generation. In this model, the muscle force was directly controlled by the neural control signal u.

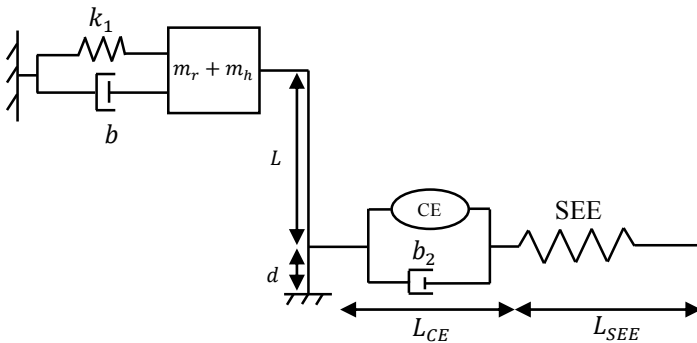
$$F_{muscle} = uF_{max} \qquad (1)$$


Figure 3: Dynamic model for the muscle model in power phase .

RESULTS AND DISCUSSION

GPOPS II required about 10 seconds of computation time to solve the problem. The optimal phase 1 occurred in 1.84 s and phase 2 had a duration of 2.16 s (Fig 3). As expected, the model starts from the initial position and moves towards the final position with positive velocity in first phase. In the second phase, the model goes back to the initial position with a negative velocity.

The optimal control profile for the phase one shows that the muscle applies about 70% of its maximal force during the power phase. During the return phase, the mass-spring dynamics rewinds the system and muscle controls the system with a small force to avoid overshooting the starting point.
Figure 4: Predicted movement, velocity and control.

CONCLUSIONS AND FUTURE WORK
GPOPS II was able to solve the optimal control problem quickly and accurately. The predicted motions and forces seem realistic. A non-linear dynamic muscle model will be added to the model to examine how it affects the results.

ISOMETIRC AND DYNAMIC ACTIVATION CHARACTERISTICS OF THE HUMAN LATISSIMUS DORSI MUSCLE

[1] Shawn M. Beaudette, [1] Rudy Unni and [1] Stephen H. M. Brown

[1] University of Guelph, Guelph ON, CAN
email: sbeaudet@uoguelph.ca

INTRODUCTION

The latissimus dorsi (LD) muscle has a unique design with an origin spanning the thoracic and lumbar spine and a common insertion point on the anterior humerus. Due to the LD muscle having a large surface area, broad spine attachment, obliquities in fiber direction and variability in neurovascular supply, previous researchers have suggested possible compartmentalization of its primary functions [1]. Furthermore, from an anatomical standpoint, functional differences between the thoracic and lumbar portion of the LD have been identified in cadaveric specimens; these differences include variation in physiological cross-sectional area and fascicle length [2]. The purpose of the current study was to identify the isometric and dynamic activation characteristics of the LD muscle. Based on previous works it was expected that the thoracic and lumbar components of the muscle would show different temporal and spatial electrical activation characteristics during both isometric and dynamic tasks.

METHODS

Eight male (mean age 23 ± 1.8 years; height 1.8 ± 0.04 m; and mass 76.9 ± 10.6 kg) and eight female (mean age 22 ± 1.2 years; height 1.7 ± 0.09 m; and mass 61.6 ± 8.6 kg), recreationally active, right hand dominant individuals participated in this study. The LD muscle was characterized about four separate compartments with reference to their spinal origin (two thoracic and two lumbar compartments, see Fig. 1). Surface EMG (sEMG) was obtained from each of these T10, T12, L1 and L4 compartments.

LD activation was obtained during both maximal isometric, as well as submaximal dynamic tasks.

Isometric activation tasks included a) humeral adduction (ADD), b) humeral adduction and internal rotation (ADD + INT), c) chest-supported row (ROW) and d) humeral extension (EXT) maximal voluntary isometric contractions (MVICs). Dynamic activation tasks included sagittal lifting/lowering movements spanning the a) floor to knee (FK), b) knee to hip (KH) or c) hip to shoulder (HS). Male and female participants lifted an absolute load of 12 kg and 8 kg, respectively.

sEMG data were linear enveloped by rectifying and low-pass filtering (2nd order Butterworth, 2.5 Hz cut-off). MVIC techniques were compared to determine which technique elicited the true participant MVIC (tMVIC). All other isometric and dynamic sEMG were normalized to tMVIC. LD compartments were compared during both isometric and dynamic activations for differences in normalized, linear-enveloped sEMG magnitude, and relative activation timing (cross-correlation; r_{xy}). Differences in sEMG magnitudes for isometric and dynamic activations were assessed using separate two, and three way ANOVAs respectively ($\alpha = 0.05$). Post hoc pairwise comparisons were made using a Tukey adjustment within each ANOVA.
Figure 1: LD muscle compartments showing T10, T12, L1 and L4 sEMG electrode sites from superior to inferior.

RESULTS AND DISCUSSION

For the MVIC tasks there was no significant difference in sEMG signal magnitude between LD compartments ($p = 0.6116$). Significant differences between MVICs ($p < 0.0001$) showed that the ROW and EXT techniques elicited larger activations than the ADD or ADD + INT techniques ($p < 0.0001$). Relative sEMG activation magnitudes for each MVIC (across all LD compartments) can be seen in Fig 2A. No temporal activation differences were observed for any LD compartment throughout any of the MVIC tasks ($r_{xy} = 0.9607$).

Peak dynamic sEMG magnitudes were observed to differ significantly with main effects of dynamic lift type (FK, KH, HS) ($p = 0.0470$) and LD compartment ($p = 0.0002$). Specifically, larger peak sEMG activation was seen in the T10 ($p = 0.0002$) and L4 ($p = 0.0076$) compartments relative to the T12 compartment. Mean dynamic sEMG magnitudes were observed to differ significantly with main effects of lifting versus lowering ($p < 0.0001$) and LD compartment ($p = 0.0002$). Larger mean sEMG activation was seen in the T10 ($p = 0.0001$) and L4 ($p = 0.0146$) compartments relative to the T12 compartment. Relative peak and mean sEMG activation magnitudes for each LD compartment (across all lifting types) can be seen in Fig 2B. No temporal activation differences were observed for any LD compartment throughout any of the dynamic tasks ($r_{xy} = 0.9114$).

CONCLUSIONS

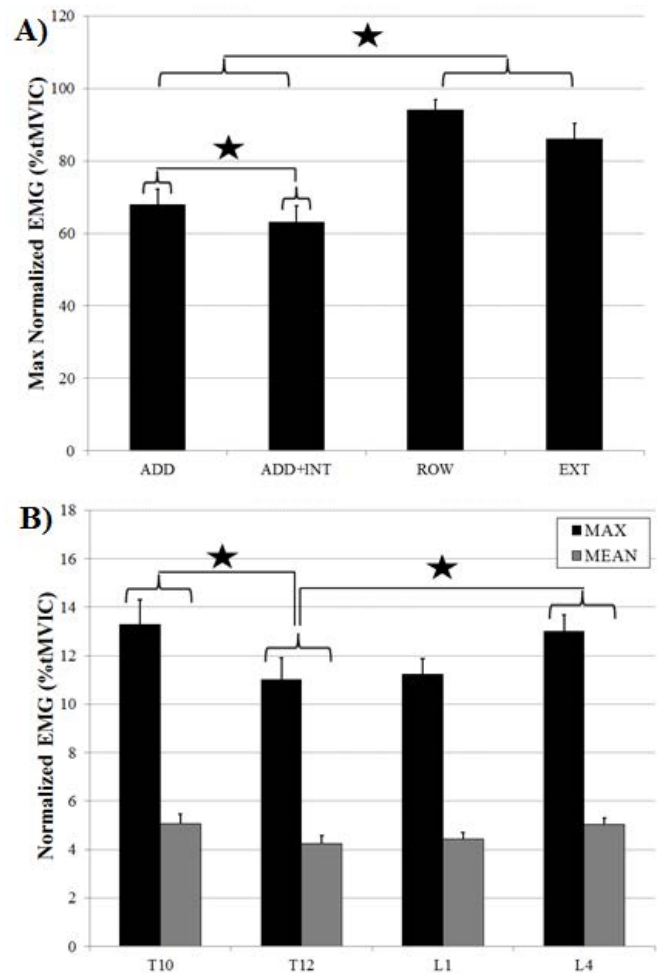
For MVIC-style activations of the LD muscle, compartmentalization of function is not apparent. For all MVIC types LD compartment activation was uniform in sEMG magnitude and timing. During dynamic activations differences in activation magnitude may suggest some compartmentalization of the LD; however activation timing was always uniform. Additionally, from this work it was determined that the optimal sEMG normalization-electrode site combination was the ROW task at T12. Similar LD EMG normalization suggestions have been made previously [3].


Figure 2: A) Normalized LD sEMG activation magnitude between MVIC types, pooled across all compartments. B) Peak and mean normalized LD sEMG activation magnitude between LD compartments, pooled across dynamic movement. Stars represent significance at $p < 0.05$.

RELATIONSHIPS BETWEEN CLINICAL AND BIOMECHANICAL MEASURES OF CORE STABILITY

[1]Courtney M. Butowicz, [2]Brian Noehren, [1]D. David Ebaugh, [1]Sheri P. Silfies

[1] Drexel University, Philadelphia, PA, USA
[2]University of Kentucky, Lexington, KY, USA
Email: cmb524@drexel.edu

INTRODUCTION

Emerging evidence suggests that poor core stability is a risk factor for low back and lower extremity injuries in athletes [1-3]. Core stability is the ability to control trunk position and motion for the purpose of optimal production, transfer, and control of forces to and from the terminal segments during functional activities [4]. Optimal neuromuscular control and muscle capacity (strength and endurance) are critical components of core stability. Frequently used clinical tests to assess core stability include the unilateral hip bridge, trunk extensor endurance, and Y-Balance tests [5,6]. Recently the trunk control test was developed to clinically assess core stability in a manner that closely resembles a biomechanical method of assessing isolated core stability [7]. Although these and other clinical tests of core stability exist, how well they assess core stability when compared to biomechanical measures of isolated core stability has not been thoroughly evalutated. Furthermore, relationships amongst clinical tests of core stability are not well understood. The purposes of this study were to determine relationships between 1) clinical measures of core stability, and 2) clinical and biomechanical measures of core stability.

METHODS

Twenty healthy active individuals (11 males; age 23.5+/-1.7 years; height 173.0+/-8.3 cm; weight 71.9+/-15.5 kg) completed the unilateral hip bridge endurance (UHBE (s)), Y-Balance test (YBT (reach as % leg length)), trunk extensor endurance tests (TEE (s)), and trunk control test (TCT (errors)). The TCT is performed with the subject sitting on a Swiss ball, one foot is lifted, eyes closed (EC), and attempting to balance for 30s (Fig 1A). The number of errors (plant foot moving, uncrossing the arms, elevated foot touches ground) are recorded. Recent work suggests the ability of the TCT to detect possible trunk control impairments in an ACL rehabilitation population [7]. Three trials/side of TCT were observed by a trained clinician and scored based on errors [7]. The biomechanical test of isolated core stability [3] was developed to reduce contribution from the lower extremities, by using an unstable chair situated on a force plate (Fig 1B). Two 60s balance trials, where subject was asked to move as little as possible with their eyes closed (EC), were used to assess core stability. Center of pressure (COP) data was quantified using the 95% confidence ellipse area (CEA) (CEA, mm^2) and average displacement of the COP per second (MVEL) (mm/s). For the biomechanical measures of core stability, higher values represent poorer core stability. UHBE and TEE tests were completed 2 times with ability to maintain control of position recorded in seconds. Y-balance was completed 3 times in each direction. Averaged trials for each test were used for analysis. Spearman's rho and Pearson's correlations were used to determine the association between measures. Correlations were interpreted according to Cohen [8].
Figure 1. A) Clinical trunk control test (TCT). B) Biomechanical measure of isolated core stability.

RESULTS AND DISCUSSION

Mean (SD) values for clinical measures: UHBE (s) = 23.01 (17.83), TEE (s) = 78.58 (24.15), TCT (errors) = 5.81 (3.94), YBT ANT (%LL) = 81.66 (6.25), YBT PM (%LL) = 96.10 (8.16), YBT PL (%LL) = 90.29 (7.73). Means for YBT and TEE were similar to those previously reported [6,9]. TCT means were slightly higher than previously reported, however that study recruited competitive athletes [7]. There was little to no correlation between TCT and biomechanical measures of core stability (rho = 0.2 – 0.22), thus it appears they are testing different aspects or regions of core stability. Biomechanical measures of isolated core stability demonstrated a moderate to large correlation to with the core endurance tests and the anterior YBT (Table 1). Our data suggest that clinical core endurance of trunk and hip muscles captures 15-33% of the variance in our biomechanical measure of isolated core stability. The TCT was moderately correlated to dynamic unilateral standing balance, but not core muscle endurance (Table 2).

CONCLUSIONS

These findings support use of the UHBE and TEE as clinical measures of core stability; however, further work is needed to develop or determine if other clinical tests can assess the neuromuscular control aspect of core stability. While the TCT was not correlated with biomechanical or core stability measures emphasizing core muscle capacity, the TCT demonstrated a significant relationship to dynamic unilateral standing balance as assessed by the YBT. Analysis of the location of the errors recorded in the TCT revealed that approximately 89% of the errors were related to lower extremity movements while 11% were related to the trunk or upper extremity. This may suggest that the TCT captures more lower extremity control than trunk control or core stability. However, further research is needed to evaluate this relationship.

INTRODUCTION

Rhythmic stimuli such as auditory metronomes have been used therapeutically to improve the walking patterns of individuals that have been affected by Parkinson's Disease [1]. The walking patterns of older adults and individuals affected by motor pathologies are known to differ from young healthy adults in terms of the variability structure of their stride-to-stride intervals [2]. In general, fractally structured movement variability has been found to be associated with healthy motor behavior [2]. Specifically, it has been shown that optimal healthy movement patterns are most closely associated with a variability structure containing pink noise structure. Pink (fractally structured) noise differs from white (random) noise in that persistent trends (i.e. long range correlations) are observed in the time series (Fig. 1).

Figure 1: Creating fractal auditory stimuli

Recent research has explored the possibility that the variability structure of human movements could be manipulated with structured auditory stimuli. This research has investigated young healthy adults listening to structured auditory stimuli while walking [3, 4]. In this research, stimuli were based upon a simple fixed period metronome with pitch changes [3] that were embedded in the tune Für Elise [4]. In the case of structured stimuli either random white noise or structured pink noise was added to the stimulus (Fig. 1). These stimuli produced white and pink variability structures in the movements studied.

Following this previous research we hypothesized that we would also be able to manipulate the movement variability of upper extremity movement patterns, such as hammering, that neurologically are controlled differently, using structured auditory stimuli. We hypothesized that coordinated hammering movements performed in time to a metronome would show a variability structure that reflects the variability structure of the auditory stimuli used.

METHODS

Eleven healthy young adults (age 21.2 ± 3.7) participated in the study. Each participant was asked to strike a force plate with a hammer in synchronization with an auditory stimulus that was delivered via headphones (Fig. 2). There were four conditions presented in a randomized fashion. The conditions included a no metronome (control) condition, a metronome with no variability (regular metronome) condition, a metronome with unstructured variability

Figure 2: Experiment setup

(white noise) condition, and a metronome with fractal variability (pink noise) condition. Each condition lasted 3 minutes during which participants performed continuous repetitions of right-hand hammering movements (with the start of the motion beginning from head height and ending with the hammer contacting a force plate. Each participant was provided with the option of having received a

1-minute break between trials. Participants' movements during the experiment were recorded with an NDI 3D Investigator system. Participants performed two tasks per condition. They were asked to either hammer anywhere on the force plate for 4 of the trials or to strike a dot in the center of the force plate for the other 4 trials. Detrended Fluctuation Analysis (DFA) was used to measure the fractal scaling (α) of the hammering movements of participants. A 4X2 (condition by task) repeated measures ANOVA was performed on the results.

RESULTS AND DISCUSSION

Overall effects of both auditory stimulus ($F(3,10) = 14.52$, $p < 0.001$) and task ($F(1,10) = 5.33$, $p < 0.05$) were observed. No interaction of the effects of task and auditory stimulus was observed ($F(3,30) = 2.25$, $p = 0.10$). Post-hoc tests with corrections for multiple comparisons were performed. For the **non-aiming task** α was higher for the no-metronome (free hammering) condition compared to the other conditions (p's < 0.05), and the pink noise condition was found to differ from the regular metronome condition (Fig. 3). For the **aiming task** α was higher for the no-metronome condition compared to the regular and white noise conditions, and the pink noise condition was found to differ from the regular metronome condition (Fig. 3). A difference in α between tasks (aiming vs. non-aiming) was observed for the no-metronome condition (Fig. 3).
Figure 3: Analysis for the inter strike time variability for each of the four stimulus conditions for both aiming and non-aiming tasks. * indicates significant difference from the non-stimulus condition within each task.

Consistent with previous work in this research area, [3] we found that the variability structure of human movement could be manipulated through the use of auditory stimuli. While the different auditory stimuli did affect the variability structure of the hammering behavior investigated, the results were not as clean as the results of similar previous studies [3]. Possible reasons for this include methodological differences between this study and previous research. For example in our research the number of hammer strikes performed by each participant was limited (i.e. 3 minutes of hammering as opposed to 15 minutes of tapping). This difference will impact the precision of the Detrended Fluctuation Analysis performed. Given this possibility we plan to run a follow up study with longer trials. Alternatively the nature of the hammering task both from a mechanical and a neuro control perspective may impact the efficacy of auditory stimuli to manipulate the variability structure of human movement.

CONCLUSIONS

This study was a variation of studies that have been recently been performed in our lab. It aimed to extend research findings from lower extremity actions like walking to upper extremity coordinated actions like hammering. It is presently unclear to what degree structured auditory stimuli can be used to manipulate the variability structure of complex motions such as that represented by hammering.

VISUALIZING THE STRUCTURE OF HIGH DIMENSIONAL FEASIBLE ACTIVATION SETS FOR STATIC FORCE PRODUCTION

[1] Brian A. Cohn, [3] Hordur F. Ingvason, [1,2]Francisco J. Valero-Cuevas

INTRODUCTION

We present a novel 'vectormap' transformation to visualize the features of feasible force and feasible activation sets. Visualizing the polyhedra and high-dimensional polytopes corresponding to these feasible sets, respectively, is challenging. Prior work [1] used their bounding boxes, which overestimate their volume, and oversimplify their shape. Understanding the structure of these feasible sets is critical to inform the central debates in motor control such as muscle redundancy, synergies and motor learning.

METHODS

The 'vectormap' is a radial projection of these polytopes onto the surface of their enclosing ball, where the resulting color-mapped sphere represents the size of the polytope in that direction (Fig. 1). As an example, we present the feasible force set of a feline hind limb, and its associated 31D feasible activation set. The parameters from the musculoskeletal model were shared with us by [2].

Extending Fig. 1 to higher dimensions, a similar idea applies. A vectormap sphere can display a muscle's activation solution across all maximal forces, as shown on the right in Fig. 2. The production of a given sub-maximal force magnitude in a particular direction can be achieved by multiple coordination patterns [4,5]. Therefore, two vectormap spheres can be created for each muscle to provide a color map of the minimal and maximal activation for endpoint forces in all possible 3D directions.
Figure 1: 2D description of vectormap for the feasible force set of feline hind limb in the sagittal plane. The polygonal feasible force set represents the maximal static force in each radial direction. That maximal force value is encoded as the color of the surface of the enclosing circle in that same direction. This same approach is extended to higher dimensions.

RESULTS AND DISCUSSION

Figure 1 shows a 2D slice of a vectormap for the feasible force set, and Figure 2 shows the activation at different levels of force magnitude for *vastus lateralis* and *medial gastrocnemius* as sample muscles. http://bbdl.usc.edu/vector_mapping/ shows the vectormaps of feasible activation for all 31 muscles. The left side of Fig. 2 shows those two vectormap spheres for different levels of force output, revealing how redundancy of activation is lost for each muscle as we march towards the maximal feasible force. These plots provide a detailed view of the structure of the 31D feasible activation set, one muscle at a time. For example, note that the lower and upper bounds naturally converge for maximal output, but they converge at different rates across muscles (vectormap progressions for all 31 muscles are not illustrated here) and directions of force output.

Interestingly, we find that the upper and lower bounds are more sensitive to than expected, with the bounds changing dramatically between vectors less than a degree apart in direction. We find that activation vectormaps can show strong discontinuities depending on the direction of output force, even at low magnitudes. Common tasks like locomotion require changes in force direction, thus muscle redundancy, synergies, and motor learning must be considered from a spatiotemporal perspective [3]. The vectormap approach allows us to pose and test musculoskeletal hypotheses for generalized force outputs, even for high-dimensional musculoskeletal systems.

LUMBAR ANGLE AND MUSCLE ACTIVATION TIME SERIES ARE STRONGLY RELATED IN INDIVIDUALS ASYMPTOMATIC FOR LOW BACK PAIN

[1] Brian C Nairn, [2] Alison Schinkel-Ivy and [1] Janessa DM Drake

[1] York University, Toronto, ON, CAN

email: jdrake@yorku.ca

INTRODUCTION

Previous studies utilizing cross-correlation (Rxy) analysis have typically involved correlating the same signal type, such as kinematics [1], and electromyography (EMG) [2]. The extent to which different signals have been correlated (e.g. EMG and centre of pressure [3]) is limited. The relationship between lumbar motion and lumbar muscle activation during typical forward flexion remains unclear. Therefore, the purpose of this study was to quantify the spatial and temporal relationship between angle and muscle activation in the lumbar region in asymptomatic individuals.

METHODS

Thirty right-hand dominant participants, asymptomatic for low back pain (LBP) were recruited from a university aged population. Data were collected as part of a larger study. Reflective clusters were placed on the spine at the level of T_{12} and L_5, and EMG electrodes were placed over the erector spinae at the L_3 level. Electromyographical data were collected using two AMT-8 amplifiers (Bortec, Calgary, Canada) and synchronized with the kinematic data using a seven camera Vicon motion capture system (Vicon Systems, Ltd., Oxford, UK). Five forward trunk flexion trials randomly distributed throughout the protocol were selected for analysis. The arms were crossed over the chest and the head was flexed forward followed by initiation of trunk flexion [1].

Both kinematic and EMG data were processed using Visual3D v.4.0 software (C-Motion, Inc., Germantown, USA). Lumbar angles were calculated as the relative angle between the clusters at T_{12} and L_1 and expressed in degrees, with positive indicating flexion. Right side EMG data were expressed as a percent of a maximum voluntary contraction (%MVC) and down sampled to 50 Hz to align with the kinematic data. The Rxy time series between lumbar angle and EMG data for each trial were calculated using MATLAB (The Mathworks Inc., Natick, USA), and the maximum Rxy and time of maximum Rxy (time lag) were identified. An Rxy value between 0.40-0.59, 0.60-0.79, and 0.80-1.00 were considered to be moderate, strong, and very strong, respectively [4]. A negative time lag indicated that the lumbar angle motion preceded the EMG activation. Both maximum Rxy and time lags were averaged across the five trials for each participant.

RESULTS AND DISCUSSION

The mean (*SD*) Rxy was 0.670 (0.046) ranging from 0.512 to 0.881 (Figure 1). The mean (*SD*) time of Rxy was -1.19 s (0.43) ranging from -3.19 s to 0.88 s. A pattern was found in individual trials when the Rxy value was in the 'very strong' category, where the EMG data in these trials did not show a reduction in EMG activity (Figure 2).

To the authors' knowledge this is the first direct quantification of the relative timing between lumbar kinematic and EMG data using cross-correlation analysis. Relationships were generally found in the 'strong' category; however, some variation was found between and within individuals.

The strong positive Rxy and negative time lag indicated this occurred when both the angle and EMG were increasing after the initiation of flexion, which corresponded to the first "burst" of EMG activity (Figure 2A). In the cases where the Rxy was in the 'very strong' category (such as Figure

2B), the EMG showed a continual increase/maintenance of activation throughout the flexion phase. This was opposed to the typical reduction of EMG activity typically found in asymptomatic individuals.

These preliminary results suggest that strong cross-correlation magnitudes may be representative of the relationship between muscle activation and motion in asymptomatic individuals. A 'very strong' Rxy magnitude tends to show a distinctly different pattern, which could have implications for clinical applications in characterizing movement differences in individuals with LBP.

DECREASED DYNAMICAL COMPLEXITY DURING QUIET SITTING IN CHILDREN WITH AUTISM SPECTRUM DISORDERS

INTRODUCTION

Movement impairments are a ubiquitous symptom in children diagnosed with Autism Spectrum Disorders (ASD) [1]. Purposeful movements necessary for functional independence, first require an ability to control one's posture. Children with ASD have been reported to exhibit impairments in their control of posture [2] and non-linear analyses of the center of pressure (COP) data during quiet stance has revealed their control to be more regular or restrictive [3]. In an effort to further explore the link between postural control and the characteristic repetitive and stereotyped behavior associated with this population, detrended fluctuation analysis (DFA) was applied to quiet, unsupported sitting posturography data in children with ASD.

METHODS

Posturographic data for sixteen children diagnosed with ASD (age: 6 ± 1years, height: 1.2 ± 0.1 m, mass: 23.8 ± 6.2 kg, Leiter-R Brief IQ: 81.5 ± 25.0) and sixteen age-matched typically developing (TD) children (age: 6± 1years, height: 1.2 ± 0.1 m, mass: 20.6 ± 2.90 kg, Leiter-R Brief IQ: 115.2 ± 13.9) were analyzed. Ground reaction forces (GRF) and moments were recorded (360 Hz) from a forceplate (Type 4060-10, Bertec Corp., Columbus, OH). During quiet sitting trials, children sat on a stool that was positioned on the forceplate. During each trial, children viewed a video that contained vibrant images and music for 120 s. Each 120 s trial was subdivided into smaller 20 s trials. Trials where the participant was moving and not attending to the video were discarded. GRF and moments were used to calculate the location of the COP in a time-series and these data were then filtered using a second order, low pass frequency Butterworth filter (cut-off frequency of 20 Hz). The filtered locations of the COP were then outputted for further analyses.

The time-dependent structure of sway variability during sitting was examined by means of DFA. This approach provides a measure of the rate of growth in the fluctuation of variance as a function of increasing time scales, and the slope of this rate of growth (α-value) provides an index of the breadth of fluctuations across the range of time scales [4]. The robustness of this technique to non-stationarity underscores the appropriateness of its use for postural sway data [5]. A larger rate of growth or steeper slope (larger α-value) indicates fluctuations occur over relatively few time scales indicating a more predictable system (decreased complexity). A smaller growth rate or gradual slope (smaller α-value) indicates fluctuations dispersed more evenly across a range of time scales and thus indicative of a more random system (increased complexity) [5]. In general, the motor patterns of mature, healthy adults are represented with an α-value of approximately 1. Alternatively, α-values for less mature systems, such as those of children, would likely be greater than 1 and would gradually decrease over their development [4].

Growth rates in the fluctuation of variance (α-value $_X$, α-value $_Y$) were calculated for the anteroposterior and mediolateral directions based on previous methodology [4]. Additionally, the movement present in the COP time series was characterized by the traditional linear measures of COP range in the anteroposterior and mediolateral directions and the elliptical sway area containing 95 % of the COP data ($COP_{RANGE-X}$, $COP_{RANGE-Y}$, and $Area_{CE95}$). Independent t-tests were used to identify differences in the dependent variables (Linear: $COP_{RANGE-X}$, $COP_{RANGE-Y}$, $Area_{CE95}$, Nonlinear: α-value $_X$, α-value

$_Y$) between children diagnosed with ASD and TD children. An a´ priori alpha level of 0.05 was set for all statistical tests and all statistical tests were performed using SPSS 16.0 for Windows (Chicago, Illinois).

RESULTS AND DISCUSSION

Children with ASD exhibited significantly larger α-values in both the anteroposterior and mediolateral directions ($p < 0.05$). The α-values were 14.5% larger in the anteroposterior direction (α-value $_X$) and 16.8% larger in the mediolateral direction (α-value $_Y$). Additionally, the three linear measures for movement present in the COP time series were significantly larger in children with ASD when compared to TD children (76.4 % larger, 135.5 % larger, and 271.9 % larger for $COP_{RANGE-X,}$ $COP_{RANGE-Y}$, and $Area_{CE95}$ respectively, $p < 0.05$ for all 3 measures) (Table 1).

Linear and nonlinear analyses of the COP time series during quiet, unsupported sitting support previous postural control findings reported in the literature. As hypothesized, children diagnosed with ASD displayed larger linear measures ($COP_{RANGE-X,}$ $COP_{RANGE-Y}$, $Area_{CE95}$) when compared to TD children [2]. Similar to previous findings for quiet stance [3], DFA analyses revealed that children with ASD had a more predictable control of posture. Growth rates in the fluctuation of variance approached values previously reported for behavior with predictive patterns or reduced complexity [4].

Unsupported sitting, when compared to quiet stance, is believed to require less control and/or coordination (fewer degrees of freedom). Previous reports suggest postural impairments may be the result of abnormalities and dysfunction in the underlying neural networks responsible for coordinated activity [3]. However, abnormalities in these same areas have also been associated with restricted, repetitive behaviors (RRBs), a cardinal feature of ASD [6]. While quiet sitting is more readily accomplished as a research task in this population, the restricted control of posture observed during the less coordinated task lends support to a global impairment associated with ASD and an underlying central rigidity that result in a lack of complexity in the control of a broad range of stereotypic behavior, including motor behavior. [3]

CONCLUSIONS

The main finding of this work is that children with ASD exhibit reduced dynamical complexity in their control of posture, over a range of behaviors that now includes unsupported sitting. Results further support the links between restricted control of posture, stereotypic behavior and the neurobiology of ASD.

MUSCLE ACTIVATION STRATEGIES OF STEPPING ONTO A COMPLIANT SURFACE IN HEALTHY ADULTS

Alexa K. Johnson, Jasmine L. Mirdamadi, Nicole C. Gervasi, and Deanna H. Gates

The University of Michigan, Ann Arbor, MI, USA
email: gatesd@umich.edu, web: http://rehab-biomech-lab.kines.umich.edu

INTRODUCTION

Walking on uneven terrain may contribute to instability, especially in those who are at higher risk of falling, such as older adults [4] or people with lower limb amputation [1]. To adjust for the potentially destabilizing surface, people increase step width [1,3]. This kinematic adaptation likely indicates altered muscular control. Gluteus medius activity has been shown to increase with step width [2]. There are peak activation differences during the transition step onto a foam surface in the biceps femoris, tibialis anterior and the medial gastrocnemius [3]. Similarly, it has been shown that there is an anticipatory effect of muscle activation in the peroneus longus, peroneus brevis, medial and lateral gastrocnemius and soleus when walking on a treadmill with a random inversion step [5]. In contrast to a single plane perturbation such as inversion, when walking over sand, there are multiple stabilization techniques the body may have require. The purpose of this study is to determine if healthy individuals utilize different muscle activation strategies when stepping into a sand pit, as opposed to a regular stride on level ground. This includes anticipatory muscle activation and peak activation strategies. We hypothesize there will be an increase in lower extremity activity when stepping into the sand as compared to a level ground stride to improve stability. The timing of muscle activation patterns on a compliant surface could be beneficial in understanding and preventing falls.

METHODS

Five healthy young adults completed this study (age 20 ± 2 years; height 1.73 ± 0.08 m; mass 66.8 ± 11.6 kgs). Subjects were instructed to walk at a self-selected speed on hard level ground as a control condition. Subjects then started on a hard level surface and stepped into a pit (12ft x 3 ft x 7 in) filled with sand and continued to walk. Full body kinematics were collected using 53 reflective markers and a 16 camera optoelectric camera system (Motion Analysis, Inc., Santa Rosa, CA). Surface electromyography (EMG) (Delsys, Natick, MA) measured muscle activity bilaterally from nine lower limb muscles. Here, we focus on five of the nine muscles; biceps femoris (BF), vastus lateralis (VL), gluteus medius (GLM), medial gastrocnemius (MG) and tibialis anterior (TA). The stride analyzed was indicative of a transition stride from the over ground into the sand pit (Fig. 1). The cycle began with heel contact on the hard level surface and with the subsequent heel strike on the same leg, in the sand pit.
Figure 1: A diagram of how the transition stride is defined, stepping from an level over ground surface to a compliant (sand) surface.

EMG data was filtered with a 6th order Butterworth filter to a band width of 20-400 Hz, full wave rectified and enveloped via a 6 Hz low-pass Butterworth filter. Finally a custom Matlab (MathWorks, Natick, MA) code was used to determine muscle activation differences between the level ground and sand conditions, of right and left BF, VL, GLM, MG, and TA.

RESULTS AND DISCUSSION

During the sand condition, there was earlier activation of the BF in pre-swing, in the left leg, when compared to a stride on level ground (Fig. 2). This 52.8% increase in BF activity during pre-swing, and earlier activation may have to do with the contralateral heel strike into the sand. As the contralateral foot sinks into the sand, the decrease in level of the step requires greater knee flexion and

BF activity. On the right leg, during the first step into the sand, there was 41.9% less activation in the BF when compared to a level ground step.
Figure 2: Mean muscle activation of BF and MG on the left leg of a stride. A transition from level ground to a compliant surface is indicated in red. Blue indicates a normal, level ground stride.

In the sand condition, during stance phase on level ground, the left GLM reached 108% greater activation than in left stance on level ground. An increase in GLM activity may have to do with individuals anticipating a greater step width for a greater base of support on a compliant surface.

The MG had decreased peak activation in both legs during the sand condition when compared to the level ground condition. In the left leg, during toe off, peak activation of the MG was 47.8% lower than toe off on a regular level ground step. This decrease may be caused by less of a push off, and greater knee flexion, as indicated by the BF activity

in pre-swing. In the right toe off in the sand, the MG activated 15.9% lower than the level ground toe off. This decrease, likely occurs as the force produced by the MG dissipates into the sand. This indicates that there need to be further compensations to accelerate the leg into swing. There was also a later peak in the MG activation during toe off, when stepping onto the sand (Fig. 2). Additionally, there was a 33.4% decrease in TA peak activation in the sand condition, compared to the level ground condition. All other muscles showed less than 10% change in peak activation.

CONCLUSION

Muscle activation strategies changed when individuals step onto a compliant surface. Changes can be seen as decreased muscle activation at toe off, and decreased activity during stance on level ground in anticipation of stepping into the sand pit. Future analysis will address timing of muscle activation patterns to understand if the central nervous system adjusts to instability through anticipatory or compensatory mechanisms. Future research about how older adults or those with pathology may interpret and maneuver the same transition stride may be beneficial to reducing their risk of falling and further injury.

MOVEMENT QUALITY DURING UNIMANUAL AND BIMANUAL FUNCTIONAL REACHING MOVEMENTS

Hari Sriram, Jeffrey C. Cowley and Deanna H. Gates

The University of Michigan, Ann Arbor, MI, USA

Email: gatesd@umich.edu   Web: http://rehab-biomech-lab.kines.umich.edu/

INTRODUCTION

In our everyday life, we often require the simultaneous use of both hands to perform tasks (e.g. buttoning up shirts, tying shoelaces). Bimanual (two-handed) tasks require a higher degree of complexity compared to unimanual tasks due to the coordination required to control both hands [1]. Unconstrained bimanual tasks, such as in activities of daily living, may enforce temporal and spatial coordination across both arms. Constrained reaching movements or simple rhythmic movements have often been used to study bimanual coordination, but these are not representative of tasks in daily life [2 3]. Improving our understanding of how people perform unconstrained bimanual tasks, may provide a basis for the assessment of pathologies associated with bimanual coordination. Therefore, the purpose of this study is to assess movement quality of healthy individuals performing unimanual and bimanual unconstrained daily life reaching tasks. We hypothesize that the bimanual tasks will be performed slower and smoother compared to unimanual tasks and that the dominant arm will perform smoother movements than the non-dominant arm.

METHODS

Seven healthy young adults (4 male, 3 female) participated. Subjects were screened for medications or conditions that could affect arm movement. All subjects were right hand dominant. Trials began with the subject standing in front of a shelf (head height) with their hands resting at their sides. Subjects were instructed to stand 100% of arm's length away from the shelf. Subjects retrieved a can from the top of the shelf and placed it on a lower shelf. The task was completed separately with each hand as well as simultaneously using both hands. Subjects completed five successful trials of each task and the reach phase of each trial was analyzed.

The motion of reflective markers placed on the radial and ulnar styloids was tracked at 120Hz using Cortex (Motion Analysis, Santa Rosa, CA). Wrist joint center was calculated by finding the midpoint of the distance between the two wrist styloids, and the wrist joint center data was analyzed. The onset and termination of the reach phase was calculated by using a velocity threshold of 2% of maximum velocity. Index of curvature (IOC) was calculated by dividing the arc length of the wrist joint path by the straight line distance between the movement start and end points. For each trial, smoothness was calculated by integrating jerk and normalizing the value to peak speed [4]. Movement time, curvature, and smoothness were analyzed using Matlab (MathWorks, Natick, MA). A two-factor within subjects ANOVA was used to test for differences between tasks (unimanual/bimanual) and limbs (dominant/non-dominant). Significance was set at $p \leq 0.05$.

RESULTS AND DISCUSSION

For movement curvature, there was a significant main effect for task (p=.04). Bimanual reaches were more curved (IOC: 1.045 ± 0.003) compared to unimanual reaches (IOC: 1.052 ± 0.003) (Figure 1). There was no significant difference between arms (p=0.603). For movement time, there was no significant main effect for task (p=0.225) or arms (p=0.661) (Figure 2).
Figure 1: Mediolateral movement (m) of dominant and non-dominant arm during reaching. Left arm (blue), Right arm (red).
Figure 2: Movement time during bimanual and unimanual tasks. Left Hand (blue), Right Hand (red). Error bars represent 95% confidence interval.

For smoothness, there was no significant main effect for task ($p = 0.321$) or arms ($p = 0.312$) (Figure 3).
Figure 3: Smoothness of bimanual and unimanual reaches. Left Hand (blue), Right hand (red). The smaller the value, the smoother the movement is. Error bars represent 95% confidence interval.

CONCLUSION

There were significant differences in the curvature of reaching between unimanual and bimanual tasks. While the differences in movement time and smoothness were not significant, this could be due to the small sample size of data collected. Additional data will be collected in the future. The results of this study show how healthy individuals perform unconstrained tasks that mimic everyday life. This can be beneficial in understanding the role bimanual coordination plays in everyday life tasks.

Motor Cortex Activation and Landing Neuromuscular Control after Anterior Cruciate Ligament Reconstruction

[1]Dustin R. Grooms, [1]Stephen J. Page, [1]Deborah Nichols-Larsen, [1]Ajit M.W. Chaudhari, [1]James A. Onate

[1] The Ohio State University, Columbus, OH, USA
email: grooms.dusty@gmail.com, web: http://medicine.osu.edu/hrs/at/research

INTRODUCTION

Anterior cruciate ligament (ACL) injury and reconstruction may induce brain motor control adaptations that influence neuromuscular function and potentially, future injury risk. Traditional neuromuscular control assessment and therapy may not adequately address this neuroplasticity. Functional magnetic resonance imaging (fMRI) provides a detailed method to assess brain changes to bridge this gap in knowledge. The purpose of this work is to determine the relationship between biomechanically measured neuromuscular control during drop landing and brain activation during a knee motor control task in those with ACL reconstruction and matched controls

METHODS

Participants were matched on height, mass, extremity dominance, education level, history and current physical activity level. Eight left anterior cruciate ligament reconstructed (ACLR) (25.5±1.37 years, 1.70±0.13 m, 75.6±19.2 kg, Tegner activity level 6.0 ± 1.5, 23±18 months post-surgery) and 8 matched healthy controls (23.6±3.14 years, 1.75±0.05 m, 73.5±12.24 kg, Tegner activity level 6.0 ± 1.5) participated. The brain fMRI was

Figure 1: Knee motor control task: Four sets of 30 seconds of rest followed by 30 seconds of 45° extension-flexion completed at 1.2 Hz.

collected during a unilateral knee motor task consisting of repeated cycles of extension and flexion while lying supine in the MRI scanner (figure 1). The brain activation pattern for knee movement was completed on a subject-specific level on the contrast between knee movement and rest with a general linear model fixed-effects analysis *a priori* threshold at $p < 0.01$ corrected (figure 2) with the Oxford Centre software package FSL. The motor cortex was selected as an *a priori* region of interest and the voxel cluster with the peak activation was extracted for analysis.
Figure 2: Typical sensorimotor brain activation for left knee movement.

A drop vertical jump task was completed to assess functional neuromuscular control. Participants were fitted with a full body point cluster marker set to track 3D kinematics via a Vicon passive optical motion capture system. Participants then completed three drop vertical jumps consisting of leaning forward from a 30.5 cm plyometric box until falling, landing and then immediately jumping up to a target for maximum height. Data were processed using Visual 3D software to assess peak knee flexion during the initial landing from the box.

A Pearson correlation was completed on the relationship between motor cortex activation during knee extension-flexion and peak knee flexion angle during landing.

RESULTS AND DISCUSSION

Motor cortex brain activation in participants with ACL reconstruction was significantly correlated with peak knee flexion during landing (r = -0.717, p= 0.034). There was no correlation for the control group (r= 0.275, p=.509) or the combined group (r= -0.211, p = 0.433). There was no difference in peak knee flexion or motor cortex activation between groups.

Table 1: Mean and standard deviations of peak motor cortex activation (percent signal change) and peak knee flexion (degrees) for each group

Group	Variable	
	Motor Cortex Activation	**Peak Knee Flexion**
ACL	1.243 ± 0.245	82.0 ± 14.0
Control	1.6 ± 0.677	76.15 ± 7.37

The ACL reconstructed cohort had a strong negative correlation between motor cortex activation and knee flexion during landing. This suggests that, as demand on the motor cortex increases to complete knee movement, the relative amount of knee flexion during landing decreased. Knee flexion was selected as it is a common metric of neuromuscular control during drop landing, with more knee flexion indicating increased ability to control the landing and decreased sagittal plane moments [1]. In contrast, a landing with decreased knee flexion is associated with increased injury risk, poorer neuromuscular control and increased sagittal plane moments [1]. The association of motor cortex activation indicates there is likely a relationship between how the brain generates knee motor control and the neuromuscular control displayed during drop landing after ACL reconstruction.

The lack of a relationship in the control group between motor cortex activation and knee flexion may indicate that the fMRI task does not offer sufficient physical demand for controls. While the relative activation level of the motor cortex between cohorts was similar, previous work has indicated greater motor planning and sensory area activation in those with ACL injury, possibility indicating the task is neurologically more challenging in this cohort [2]. It may be that, in a healthy population, a more challenging motor control task is required to be related to the more functional drop landing.

Additionally, this being a retrospective analysis, it is unknown if this relationship was present prior to the injury and may have played a role in the initial loss of neuromuscular control associated with the ACL injury mechanism or developed due to the injury. Also, the intensive unilateral rehabilitative therapy after injury may induce a greater cortical-functional relationship after ACL injury. The great deal of training to restore muscular function post injury may increase the level of cortical vs. sub-cortical or spinal cord contribution to knee neuromuscular control [3].

CONCLUSIONS

ACL reconstruction may induce specific neuroplastic adaptations in motor control within the brain that translate into neuromuscular control during landing.

Dual-Task Effects on Motor Performance in Healthy Younger Adults

Sean Wehry, Tiphanie Raffegeau, Lori J.P. Altmann, Chris J. Hass[1]

[1] The University of Florida, Gainesville, FL, USA
Email: sawehry@ufl.edu

INTRODUCTION

Daily activities often require that we perform two tasks concurrently, termed dual-task behavior. Traditional views of cognitive-motor interaction suggest that when two things are done simultaneously, performance on one or both tasks declines. However, our laboratory recently observed that performing cognitive tasks while pedaling on a stationary bicycle led to enhanced cycling speeds. This study's purpose was to determine whether this phenomenon extends to similarly rhythmic modalities with increased balance demands. Herein we compared dual-task behavior during stationary cycling and elliptical walking. We hypothesize that with an increase in cognitive complexity there will be a decrease in the facilitation of motor performance across tasks.

METHODS

Sixteen healthy young adults (9 males, 20 ±1 yrs) were tested on three separate occasions. Participants were evaluated during two separate motor tasks, cycling and elliptical exercise, and during a battery of 14 cognitive tests spanning 5 cognitive domains including verbal fluency, working memory, controlled processing, response time, and executive function [1]. Participants performed the motor and cognitive task in isolation and during dual task conditions where the cognitive challenges were done while walking/pedaling. In each modality, subjects pedaled/walked at a self-selected pace for two minutes to measure baseline performance. Then they performed the same task while concurrently performing the cognitive battery. Reflective markers placed on the foot were tracked using a six-camera motion capture system. Cycling and elliptical cadence, measured in revolutions per minute (RPM), were calculated from the marker data using custom written software.

The primary outcome variable, changes in RPM from single to dual-task exercise, is represented by Dual-Task Effects (DTE). DTE's were calculated as follows:

$$\textbf{DTE}= dual\ task\ \text{RPM} – baseline\ \text{RPM}$$

If the difference is negative, the change is interpreted as a "dual-task cost". Alternatively, if the values are positive, it is interpreted as a "dual-task benefit." Subject's DTEs were compared between cycling and elliptical modalities using paired t-tests in SPSS (version *12.2*).

RESULTS AND DISCUSSION

Cadence increased significantly during dual-tasks in both modalities ($p<0.05$). However, those dual-task benefits were significantly greater during cycling than during elliptical walking (all $p<0.05$).
Figure 1: DTE observed during cycling and elliptical. All comparisons were statistically significant.

The data above provide clear evidence that concurrent cognitive tasks facilitated performance in both modalities. This is indicated by the positive DTE values reflecting dual-task benefits during each cognitive test (Figure 1). However, the degree in which motor output improved differs significantly. Facilitation of performance by the concurrent cognitive challenge in cycling was significantly greater than that observed during elliptical walking. We suggest that walking on the elliptical is a more demanding motor task due to the increased coordination and balance demands. As the motor complexity increases, these dual-task benefits are reduced.

Previous research suggests that performing a motor and cognitive task concurrently results in depreciation in one or both factors [2]. There are multiple theories suggested to explain the decrease in dual-task performance, such as the bottleneck and capacity theory [3], but these cannot explain the observed dual-task benefits in this study. Recently, we have proposed the Arousal and Attentional Demands (AAD) model to explain the increase in motor performance due to cognitive stimuli [4]. The AAD model proposes that the cognitive task has an arousal effect, which ultimately leads to an increase in attentional resources in order to maintain motor performance [4]. If the cognitive task stimulates an optimal arousal level and the motor demands are managed, there appears to be a dual-task benefit.

The AAD model supports the DTE results during cycling and elliptical use. The cognitive arousal level was maintained across both modalities, however cycling exhibited a greater dual-task benefit than the elliptical. Cycling is rhythmic, non-weight bearing, and minimal coordination is involved, thus the attentional demands are considered low. However, elliptical use requires additional motor skills such as maintaining upright balance while pedaling and coordinating arm extension. This complexity increases arousal and attentional demands beyond the optimal levels observed in cycling, comparatively reducing the dual-task benefits.

CONCLUSIONS

This study presented unique results regarding a positive dual-task effect. The addition of concurrent cognitive tasks to cycling and elliptical exercise increased motor performance, a dual-task benefit. The increase in motor complexity from cycling to elliptical use decreased this dual-task benefit, fitting the AAD model. Further investigation should observe additional motor tasks with increasing complexity, such as treadmill walking.

SYNCHRONIZATION OF GAIT WITH FRACTAL MUSICAL STIMULI OCCURS DIFFERENTLY AT SHORT AND LONG TIME SCALES

INTRODUCTION

Lately, attention has been given to synchronization of movement with auditory stimuli containing the fractal temporal structures commonly found in nature. These stimuli are locally unpredictable, but still afford synchronization of another type, termed "strong anticipation" [1]. Strongly anticipatory systems are hypothesized to achieve synchronization through the coupling of behavior to global regularities in the environment. Research typically relies on detrended fluctuation analysis (DFA) to demonstrate the coupling of auditory input and motor output. Strong coupling is shown as a high correlation between the fractal temporal structure of variability of the auditory and motor signals. Specifically, experiments have shown this relationship between auditory stimuli and tapping [1] or gait [2]. It is clear that the presence of long-term correlations in the stimulus affect the structure of the coupled movement, however, the nature of coupling at shorter time scales is still largely unexplored [3].

Recently, Marmelat et al presented participants with metronomes exhibiting various levels of fractal structure, and assessed synchronization over short and long time scales [3]. They found significant correlation only over the long-term scaling regions, implying that the synchronizing behavior with fractal signals is dominated mainly by the long-term persistence in these stimuli.

Our previous experiments have demonstrated strong correlations between fractal auditory input and movement using a musical stimulus, rather than a metronome [2]. Synchronizing movement with music is a near-universal component of an individual's experience, and using a familiar melody (Beethoven's "Für Elise") with rhythmic structure matched to a participant's natural cadence potentially affords stronger coupling than the single tones used by others. Importantly, preliminary experiments using musical stimuli with a tapping task seem to indicate strong coupling at both short and long time scales. Thus, in the present study investigating gait, we hypothesized that the richer information in the musical signal would allow participants to be more sensitive to short-term regularities, resulting in strong correlations across a wider range of time scales.

METHODS

Ten participants walked on a treadmill at a self-selected speed for 15 minutes. We then created musical stimuli matched to each participant's cadence (at 2 beats/step, or 4 beats/stride) and amount of variability in cadence. Each stimulus consisted of an identical melody, but varying temporal structures - a constant, isochronous rhythm, and rhythms perturbed by white noise, pink noise, and brown noise. Participants repeated the walk while listening to each stimulus, having been given the instruction, "While this may be difficult, I want you to try to walk in step with the rhythm of the music. Try to imagine playing the notes with your heels." The times of each note onset and each heel strike were recorded with a Delsys footswitch system.

The resulting inter-beat interval and inter-stride interval time series were trimmed to include the middle 630 strides and the accompanying beats. These series underwent DFA to determine the fractal scaling exponent α in each of three scaling regions: overall (10 - 300 strides), short-term (10 – 50 strides), and long-term (50 – 300 strides). We

also calculated mean intervals, mean asynchrony (time of heel strike minus time of the associated beat onset) and mean accuracy (absolute value of asynchrony) for each condition.

RESULTS AND DISCUSSION

Repeated measures ANOVA revealed no significant differences due to condition in inter-beat interval, inter-stride interval, mean asynchrony, or mean accuracy (Table 1). A main effect of condition was found for overall α, and in the long-term scaling region. No differences were found in the short-term region (Figure 1).

These findings agree with Marmelat et al., in that strong coupling behavior was demonstrated in all conditions, but that this behavior was primarily occurring at the longer time scales. This remained the case despite our use of a musical signal. This differs from the behavior observed in our tapping experiment. These differences may be due to the pendulum-like swing phase in gait that places an additional physical constraint on stride-to-stride timing.

CONCLUSIONS

While our initial hypothesis was not supported, the question of whether musical stimuli lead to stronger coupling than metronomes remains to be determined. Our results suggest a direct test of this assumption is required. In addition, the differential coupling seen at different time scales suggests that synchronization with complex stimuli may not be fully characterized using DFA. Another approach to quantify coupling may be warranted.

INTRODUCTION

Reorientation of the body is an important component of many activities of daily living, i.e. turning to reach for an object on a shelf, or changing travel direction when walking along a busy sidewalk. While it may seem simple, reorienting to a new direction is actually a complex task that requires the transfer of body segments in a coordinated way. In older adults, incorrect weight transfers have, in fact, shown to be a serious cause of falls in both community dwelling and institutionalized settings [1, 2]. Past research has explored stepping and turning tasks executed during on-going gait (e.g. step and quick turn from Neurocom Balance Master; 3]. Few studies have examined the dynamic action of performing a turn and step simultaneously from a standing position though this task may, arguably, be more representative of an activity of daily living performed by older adults.

The **purpose** of our study was to investigate age related changes when performing a simultaneous turn and step task from quiet standing balance. We expected an increase in variability of the COM motion with aging, indicating a decrement in control strategies employed by older adults to complete this challenging task.

METHODS

Nine healthy young adults (5 females and 4 males; 22 ± 2.088 years) and ten healthy, community dwelling older adults (5 females and 5 males; 79.9 ± 6.315 years) were instrumented with reflective markers placed on anatomical landmarks (e.g. head, trunk) and captured using an Optitrak 3D motion analysis system. All participants were right arm and right leg dominant and older adults had never experienced a fall. Falls Efficacy Scale (FES) data was collected as a measure of balance confidence.

Both groups performed a simultaneous turn and step task (STS) from a quiet stance in two directions (towards dominant or non-dominant limb) under two self-select speed (normal and as quickly and efficiently as possible; Figure 1). Two task speeds were employed as previous work has shown many older adults report trying to rush or hurry to complete a given task just prior to experiencing a fall [4].
Figure 1. Simultaneous turn and step (STS) task performed by both healthy younger and community dwelling older adults. As illustrated, the task involves a 180 degree rotation (turn) as well as a translation (step) of the center of mass to complete.

Whole-body center of mass (COM) was estimated (modified Winter model [5]). Peak COM velocity, Coefficient of Variation (CoVa) of the COM velocity, and number of steps were recorded to characterize performance during the turning task. Cross correlation analysis of the COM velocity was also conducted to characterize the repeatability of this novel, dynamic task.

RESULTS AND DISCUSSION

A significant main effect of task speed $(F_{(1,74)}=4.969, p = 0.029)$ was observed for the CoVa of the STS task (Figure 2A) and a significant main effect of age $(F_{(1,74)} = 13.953, p <0.001)$ was observed for the CoVa of the STS task (Figure 2B).
Figure 2: Coefficient of Variation (CoVa) of the center of mass velocity for **A)** fast-paced trials (filled bars) and normal-paced trials (unfilled bars), and **B)** healthy older adults (filled bars) and healthy younger adults (unfilled bars). Mean and standard error values are illustrated (*, $p <0.05$).

A significant main effect of age was also observed for Peak COM velocity $(F_{(1,75)} = 42.142, p <0.001)$, cross correlation analysis $(t_{(73)} = -7.844, p > 0.001)$, and steps to complete the STS task $(F_{(1,75)} = 81.502, p < 0.001)$ (Table 1). No significant main effect of direction of the STS task was observed for any of the measured variables.

Previous work on the 180 degree turn in place task in older women showed increased variability due to aging, in addition to significant differences between turn directions [6]. However no differences due to age were observed for maximum pelvic rotational velocity. Our STS task demonstrates similar variability but no preferential difference in turn direction, as well as significant differences in peak COM velocity. This suggests the STS task equally discriminates between turn directions while presenting a more difficult challenge to older adults

(e.g. decreased peak COM velocity during trials under self-selected speeds). Interestingly, while cross-correlation analysis exhibited significant main effects due to age, we observed a high rate of repeatability by older adults completing the STS task, which is critical for test-retest situations.

CONCLUSIONS

In conclusion, the STS task challenged the control strategies of healthy older adult participants. Increased variability, along with decreased peak COM velocity, exemplified potential decrements in postural control in older adults even when performing the task at a slower rate. Furthermore, this decrease in performance was coupled with a high repeatability, exemplifying that subjects were still able to consistently execute the STS task. The present study provides evidence that a turn coupled with a simultaneous step may be a better discriminator of the quality of control strategies then just a simple turn in place task.

INTRODUCTION

The CNS controls motor tasks using a low-dimensional modular organization of muscle activation (muscle synergies) [1] and some synergies might be shared across different behaviors [2]. Studying slip, as a leading cause of falling accidents that occur on the same level ground is of importance. A comprehensive knowledge about the slip-related muscle synergies in healthy subjects may lead to better understandings of the motor strategy to recover from slip and could be used as a gauge in diagnosis and rehabilitation in future studies.

The objective of this study is to study the muscle synergies during slip initiation while walking and how these synergies are compared with those during normal walking. Specifically, muscle synergies and the corresponding time courses of coefficients will be extracted during both normal walking and slip. Synergies during both normal walking and slipping will then be compared to study if some of the synergies are shared. Similarly, the corresponding coefficients will be compared to learn if they are similar or not during both normal walking and slipping.

METHODS

Eleven healthy young adults (6 male and 5 female, age=22-33yrs) were asked to walk on a floor with four force plates embedded, and informed that the floor would be dry. They were fitted with surface electromyography (EMG) electrodes and donned with a harness to prevent falling due to slipping throughout the trials. Starting location was chosen in a way that subjects hit their right foot on the first and third plates.

Figure 1: The side and top view of the experiment. Red plate shows the slippery surface for slip trials.

The experiment had five normal walking trials followed by an unexpected slip trial. During the slip trial, the third force plate was contaminated by applying a thin layer of a diluted glycerol (90% glycerol and 10% water). All subjects gave informed consent prior to their participation and this research was approved by the University Institutional Review Board. The EMG signals were collected during the task at 1000 Hz from eight different muscles: medial hamstring (*MH*), tibialis anterior (*TA*), rectus femoris (*RF*), and medial gastrocnemius (*MG*) on both legs. The EMGs for the first 300ms after the heel strike on the third plate were processed off-line using MATLAB (v2014a, Mathworks, Natick, MA). The EMG data of each channel were normalized by dividing the data with the maximum recorded activity of that channel during all trials for each subject, then rectified and low-pass filtered (4th order Butterworth, 30 Hz as cut-off frequency).

To extract muscle synergies, the EMG data were averaged for each 10ms (300ms resulted in 30 time steps). Using a nonnegative optimization algorithm [3, 4], muscle synergies (W) and the activation coefficients (C) were estimated. Considering the variability curve versus number of synergies [3], four synergies were picked for both normal walking and slipping for each subject. Since the order of subject-specific synergies does not match across the subjects, rearranging of synergies for all subjects were performed as described in the following paragraph.

To rearrange the order of synergies across all subjects for each condition, the following method was used. A reference subject was chosen for each condition, (one for normal walking and one for slipping) that showed the highest similarity with all the other subjects. Specifically, correlation coefficients (*r*) for every combination of synergies of an arbitrary subject and all other subjects' synergies were calculated. Then, a subject who has the greatest number of shared synergies (i.e., $r > 0.632$ [5]) with the other subjects was defined as a reference subject. Then the order of synergies (W) and the corresponding coefficients (C) were arranged in each subject to have the best matching synergies according to the order of the reference subject. This process was repeated for the other condition as well.

Once synergies and the corresponding coefficients were reordered across all subjects for both conditions, shared synergies and coefficients between both conditions were determined in the following ways. Correlation coefficients for all possible combinations of the four reordered normal walking synergies and four reordered slip synergies (sixteen "*r*" values for each subject) was calculated. One sample *t*-test was used to check if $r \geq 0.632$ (for shared synergies) and $r \geq 0.4$ (for marginally shared synergies) (SPSS v21, IBM, Chicago, IL). The significance level was set to $\alpha = 0.05$.

The same procedure was done for activation coefficients (C) only for the first 200ms because the corrective moments on the leading foot initiates about 200ms after the heel contact onto the slippery surface [6]. Assessment of the correlation between activation was restricted to the shared synergies and only the first 200ms after heel strike.

RESULTS AND DISCUSSION

Synergies and coefficients for both normal walking and slipping were successfully extracted (Fig. 2, 3). One sample *t*-test found one share synergy (W1 in Fig.2a, r=0.82±0.13, p=0.002) and one marginally shared synergy (W2 in Fig.2a, r=0.62±0.23, p=0.024) between two conditions. The first shared synergy (W1, Fig.2a) seems to be responsible for ankle dorsiflexion, knee flexion, and hip extension on the leading foot in gait as it activates *TA_R* and *MH_R*. The second shared synergy is knee extensor and hip flexor of the leading foot, since *RF_R* is the main activated muscle. The rest of the two synergies (Fig. 2b) did not seem to be shared and could be considered as task-specific synergies.

The third and fourth normal walking synergies are responsible for the propulsive power of the support leg (as *MG_L* is activated) and dorsiflexion on the support leg (*TA_L* is activated), respectively (Fig.2b, W3 and W4 walk). The function of the third slip synergy seems to stabilize the leading foot (as it activates all muscles almost equally), while the fourth slip synergy creates a dorsiflexion on the support leg (Fig.2b, W3/W4 slip).

For the first shared synergy, the activation coefficient showed a significant correlation between normal waking and slipping for the first 200ms (C1, Fig.3a, r=0.84±0.17, p=.004). For the second shared synergy, the activation coefficient showed a marginally strong correlation (C2, Fig.3a. r=0.59±0.21, p=.026). This agreed with the expectation of having the same activation pattern in the shared synergies before reaction of the CNS (Fig.3a, before 20 time steps). However, after 200ms, the peaks of activation for slip can be considered as the primary and secondary response of the CNS to slip. The primary response (see the first peak after 200ms in C1 slip, Fig 3a) is to dorsiflex the ankle for delayed foot flat, and to flex knee to bring body COM forward into base of support [6]. The secondary response of the CNS to slip (see the second peak after 200ms in C2 slip, Fig 3a) is to extend knee and flex hip [5], which is achieved by the second shared synergy.

CONCLUSIONS AND FUTURE WORK

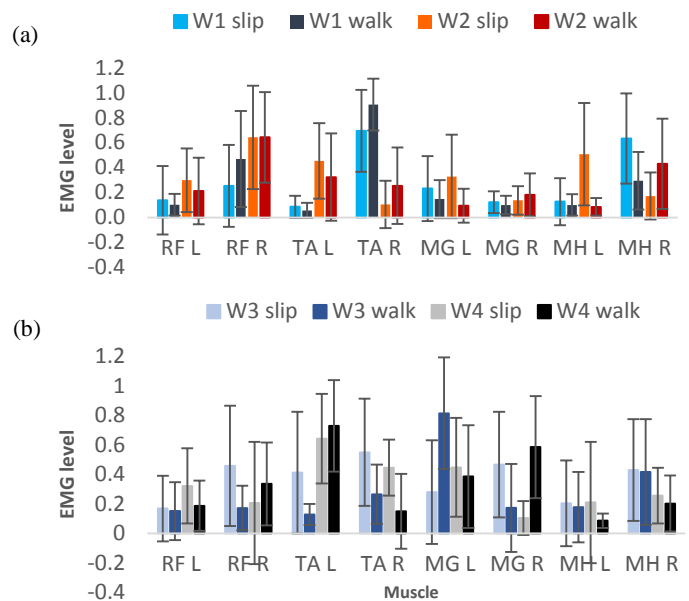
In this study, shared and task-specific synergies and their corresponding activation coefficients were examined for normal walking and slipping. Two shared synergies and two task-specific synergies were found for


Figure 2: Four synergies for both normal walking and slipping conditions. a) Two shared synergies between both conditions. b) Task-specific (non-shared) synergies between both conditions. Error bar is one standard deviation.
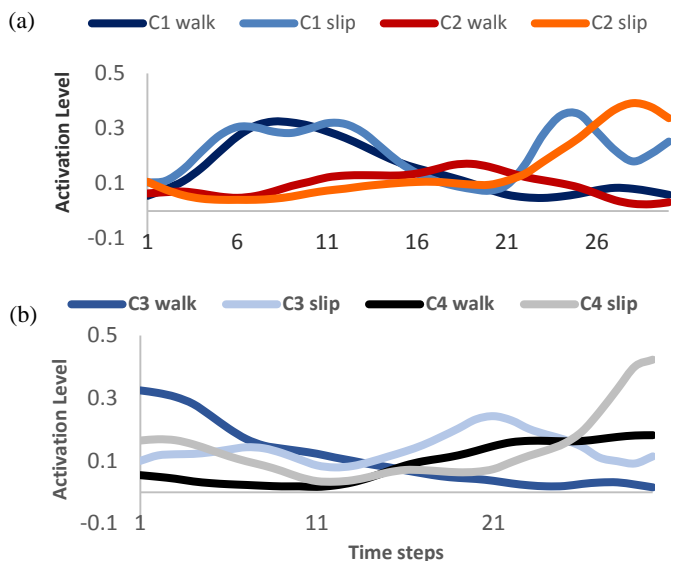

Figure 3: Activation coefficients of the corresponding 4 synergies in Fig. 2. a) Activation coefficients for the 2 shared synergies. b) Activation coefficients for the 2 task-specific synergies. One time step corresponds to 10ms.

normal walking and slipping tasks. Future work will include investigating the shared/task-specific synergies based on slip severity. Comparing synergies and coefficients of both severe and mild slip groups may help identify and intervene factors responsible for severe slips.

HIGH KNEE FLEXION AND LOWER LIMB MUSCLE ACTIVATION: DOES MOVEMENT PATTERN MATTER?

David C. Kingston, Helen C. Chong, Liana M. Tennant, Stacey M. Acker

The University of Waterloo, Waterloo, ON, Canada
E-mail: david.kingston@uwaterloo.ca

INTRODUCTION

Industrial occupations or activities of daily living require kneeling and squatting movements. Limited work has measured lower limb muscle activation during high flexion movements and no study has reported the relationship of activation and knee flexion angle. Considering the similarities in range of motion during these movements, muscle activation strategies may be alike. In addition, the use of muscle synergistic patterns can improve model optimization [1] and, should these movements be similar, these high knee flexion movements may be represented using similar synergistic patterns. Therefore, the purpose of this study was to compare muscle activation waveforms between squatting and symmetric kneeling to full flexion. We tested the hypothesis that there would be no difference in lower limb muscle activation between kneeling and squatting when normalized to knee flexion angle.

METHODS

Thirteen female participants (age 22 ± 2 yrs; height 1.64 ± 0.1 m; mass 62.0 ± 9.1 kg) were instrumented with lower limb motion tracking (Certus, NDI, Waterloo, ON) and electromyography (Wave Plus, Cometa srl, Milan, IT) equipment. Data from the right leg were assessed. EMG activity was recorded from the lateral and medial gastrocnemius, semitendinosus, biceps femoris, vastus lateralis and medialis, and rectus femoris. EMG signals were linear enveloped using a low-pass unidirectional 2nd order digital Butterworth filter with a 2 Hz cutoff to replicate an 80 ms phase shift seen in lower limb muscle neuromuscular delay [3]. These activations were normalized from 1° to 137° of knee flexion (in 1° increments) for each of the descending and ascending phases of squatting and symmetric kneeling. The upper limit of 137° was selected from the maximum range of motion of the least flexible participant. Principal component analysis (PCA) was performed for each muscle using 26 (13 participants x 2 activities) x 137 matrices for descending and ascending separately. Principal components (PCs) which discerned between squatting and kneeling movements by showing a clear delineation of z-scores on bi-plots were assessed using a student's t-test with alpha set to 0.05. The discerning PCs were categorized by operator type [2].

RESULTS AND DISCUSSION

Within muscles, PCs that discerned between squatting and kneeling are listed in Table 1. All discerning PCs were difference operators, indicated by biphasic loading vectors that peaked at the same time as mean activation profiles [2]. Only the PCs which would be retained using a 90% trace criterion were inspected.

During descent, only the biceps femoris muscle had a different normalized activation profile ($p = 0.001$) between movements. However, from 75° to 137° of flexion the squatting movement activation was, on average, only 1.2% MVC greater than the symmetric kneel. Similarly, when ascending the biceps femoris had a discerning PC ($p = 0.003$), but from 5° to 50° of flexion squatting was an average of 1.1 % MVC higher and from 70° to 105° of flexion kneeling was 1.2 % MVC higher in activation. For the purposes of this study, we have deemed these changes not biologically meaningful.

When ascending from full flexion PC2 could separate the activation profiles of the semitendinosus between movements (Table 1 and Figure 1, $p = 0.004$). From 12° to 28° of flexion the symmetric kneel activation was an average of 3.6% MVC higher. As well, from 118° to 137° of flexion, the symmetric kneel activation was 10.4% MVC higher. The only range of semitendinosus activation where

the squat movement required higher activation than the symmetric kneel was from 28º to 50º of flexion, which was 8.6 % MVC higher. For the purposes of this study, changes in ascending semitendinosus activation are considered biologically meaningful.

Considering the lack of differences in nearly all muscles for either the descending or ascending phase of these movements we have highlighted that these closed kinetic chain activities may be interchangeable. The small differences in biceps femoris activity is compounded by the variability within the data, a result inherent to EMG of dynamic high range of motion activities.

These data could be useful as input to a mathematical model as the similarities in activation profiles may allow them to be mapped to knee flexion angle. We acknowledge that an increased sample size and number of collected cycles would be required for these activities before confidence in activation mapping by flexion angle could be realized [1].

CONCLUSIONS

Using PCA we objectively identified ranges of knee flexion where activation strategies differed. These findings suggest that, when normalized to knee flexion angle, descending to high flexion postures has no meaningful differences between symmetric kneeling and squatting and only the semitendinosus requires separate activation profiles while ascending. Therefore, these movements may be generalized to a single activation profile with respect to flexion angle within each muscle. Future work may explore synergistic patterns of high flexion activities.

INTRODUCTION

Individuals with Parkinson's disease experience progressive impairment of sensorimotor control in fingers, which impacts on dexterous manipulation [1]. Basal ganglia are important neural substrates for grip force control [2]. Damage in basal ganglia might result in different behavioral strategies of grip force control. Using PD model, we may be able to study roles of basal ganglia in grip force control, investigating impairment of sensorimotor control of grip force in PD. However, measuring subtle changes of sensorimotor control in the hands for PD has been challenging because of the low sensitivity and specificity of commonly used clinical assessments, such as the Unified Parkinson's Disease Rating Scales (UPDRS). The Strength-Dexterity (S-D) test has been validated to measure sensorimotor control of dynamic fingertip force at one's maximal instability that he or she has to control [3]. The S-D test requires compressing a spring prone to buckling, and great involvement of basal ganglia was found during the spring task [4]. Therefore, the goal of study is 1) to investigate distinguishable control strategy of dynamic fingertip force in individuals with mild to moderate PD at one's maximal instability and 2) how the findings will correlate with their motor impairment level for its clinical implications.

METHODS

A total of 22 individuals with mild to moderate PD (Hoehn and Yarh stages 1-3) (68.6 ± 7.5 yrs, 11M, 11F) and 41 age-matched individuals without disability (67.0 ± 9.2 yrs, 18M, 23F) participated in the study. The S-D test was used to measure dynamic sensorimotor control of fingertip force from the thumb and index finger. The spring is prone to buckling, and designed to be impossible to compress fully. Full compression requires < 3N, or about 6-7 % of the maximal voluntary contraction of the thumb and index pinch grip (~10lbs or 44.5N). The participants compressed the spring to its solid length as much as they could, sustained the compression for 5 seconds, and release the compression. Both affected and less-affected hands were measured for the PD group (PD_{aff} and $PD_{less-aff}$), and both dominant and non-dominant hands were measured for the control group (C_{dom} and $C_{non-dom}$). Customized miniature load cells (ELB4–10, Measurement Specialties, Hampton, VA, USA) at the end caps measured fingertip force in the compression direction. Force signals were sampled at 400Hz, down-sampled to 100Hz, and low pass filtered at 25Hz. The top three-sustained compression was selected for data analysis. Outcome measures were the maximal sustained compression force level (F) and force dynamics: the 1st derivative of F (F') and its root mean square (RMS) variability from the mean sustained compression. The MDS-UPDRS motor examination was used to measure motor impairment for 14 participants from a subset of the PD group. Spearman rho coefficient was used to test association between the force outcome measures and motor impairment level.

RESULTS

Individuals with mild to moderate PD were able to compress the spring as well as the control group, revealing no significant difference in the group average maximal sustained compression level among four hands. However, how they controlled the instability at their maximal level was distinctive; force variability measured by F' and RMS of the PD_{aff} was significantly greater than those of the

C_{dom}. The greater force variability showed no correlation with the group compression force level in the PD group: F' vs. F ($\rho=0.07$, $p=0.74$) and RMS vs. F ($\rho=-0.03$, $p=0.90$) while force variability increased with the group compression force level in the control group: F' vs. F ($\rho=0.37$, $p=0.031$) and RMS vs. F ($\rho=0.37$, $p=0.031$). Interestingly, the greater F' and RMS in PD_{aff} was negatively associated with the low UPDRS motor score (the lower the score, the less the motor impairment) and the low UPDRS hand-only motor score while no correlation was found between F and the UPDRS motor scores (Table 1).

Table 1: Correlation between UPDRS motor scores and S-D test outcome measures.

	UPDRS_motor	UPDRS_hand_only
F	$\rho= -0.042$, $p =0.887$	$\rho= -0.192$, $p =0.512$
F'	$\rho= -0.526$, $p = 0.053$	$\rho=-0.479$, $p = 0.083$
RMS	$\rho= -0.561$, $p = 0.037$*	$\rho=-0.667$, $p = 0.008$**

*$p < 0.05$, **$p < 0.01$

The results of the correlation showed that the PD participants with less motor impairment exhibited higher F' and higher RMS. As an example of differences in motor strategies, two PD participants with the same UPDRS hand-only motor score as 12 showed distinctive force control strategies as shown by the phase portraits of F, the 1st derivative of F (F'), and the 2nd derivative of F (F'') plotted during a sustained hold phase (Figure 1).
Figure 1: Distinctive fingertip force control strategy in two participants with the same UPDRS hand-only motor score.

CONCLUSIONS AND DISCUSSIONS

Individuals with mild to moderate PD were capable of performing the challenging spring task at a similar level of instability as the control group. But they exhibited greater force variability in the PD_{aff} as described by F' and RMS. Damages in basal ganglia and its sensorimotor cortical closed loop in PD might result in greater force variability because the neural structures are involved in stimulus-response control including rapid automatic corrections [5]. The statistically significant correlation between higher force variability and less motor impairment as per the UPDRS motor scores suggests that force variability is compatible with healthy neurophysiological control of movement in an aging population [6]. Our methodology may be able to detect the progress of the disease as the gradual loss of this variability, which may be related to the loss of mobility in later stages of the disease seen as freezing, bradykinesia, and akinesia. Therefore, measuring changes of force variability with this unstable manipulation task might provide a higher resolution to quantify the progression of motor impairment than the UPDRS motor examination. This could be beneficial to determine a dosage of medication and parameters for deep brain stimulation; or measure motor fluctuations throughout the day.

INTRODUCTION

Humans can combine multiple sources of sensory information to estimate the state of the body and environment. Several empirical studies have shown that sensory information is integrated in a statistically optimal (i.e., minimum-variance) fashion following Bayesian rules or maximum likelihood estimation (MLE) [1]. Most of these studies have focused on the optimal integration between different sensory systems (e.g. visual and auditory, visual and tactile, or visual and proprioceptor), called inter-sensory integration [1, 2]. However, our knowledge on integration of different modalities within one sensory system (i.e. intra-sensory integration) is limited [3].

Previous studies on intra-sensory integration have primarily examined vision (e.g. color and shape). Despite the fact that auditory perception is critical in our day-to-day living, very little is known about how the central nervous system (CNS) integrates multiple features of auditory sensation (e.g. frequency and intensity) to guide motor performance (i.e. intra-auditory integration).

Therefore, our purpose was to determine if Bayesian inference can explain intra-auditory integration in a finger force-production task.. We hypothesized that intra-auditory integration would follow Bayesian inference supported by improved motor performance when both frequency and intensity modalities are used for auditory feedback as compared to a single modality condition.

METHODS

Ten right-handed adults (age 27.3 ±5.3) participated. The subjects were instructed to produce a constant target isometric force of 18 N for 20 s by pressing individual force sensors with 2nd to 5th digits.
Figure 1. Experimental setup.

Participants completed fifteen 20-s trials in each of three conditions, with 30 s rest between trials. During the task, the reference force (18N) was provided as an auditory signal, a sinusoid signal with frequency 1000 Hz and intensity 70 dB (i.e. reference tone), played to the subject's left ear. The force generated by the subject was also provided as a sinusoid signal (i.e. tracking tone) to their right ear. The tracking tone had three feedback conditions:

1) Frequency condition (F): the frequency of the tracking tone changed depending on the deviation of the subject's sum of finger forces from 18 N, with a constant intensity of 70 dB.

2) Intensity condition (I): the intensity of the tracking tone changed depending on the deviation of the subject's total finger force from 18 N, with a constant frequency of 1000 Hz.

3) Frequency & Intensity condition (FI): both frequency and intensity of the tracking tone changed depending on the sum of finger forces.

The rate of changes of frequency and intensity per Newton were set as 7Hz/N and 0.7dB/N,

respectively, according to minimum detectable differences previously reported [4, 5].

Motor performance was quantified using the average mean-squared error (*AMSE*) between the sum of finger forces and the target 18-N force:

$$AMSE = \frac{1}{N}\sum_{i=1}^{N}\left\{\frac{1}{\tau}\int [f_T - y_i(t)]^2 dt\right\}$$

where $y_i(t)$ is the sum of individual finger force at trial i, f_T is the target force, and τ is the duration of $y_i(t)$. Data were collected for 20 s, but only the data between 6 s and 17 s (11 s total) were analyzed. We also compared the experimentally obtained *AMSE* to the *AMSE* predicted by Bayesian inference (MLE) [6] as follows:

$$AMSE_{FI} = \sigma_{FI}^2 + b_{FI}^2$$

where variance is calculated as $\sigma_{FI}^2 = \frac{\sigma_F^2 \sigma_I^2}{\sigma_F^2 + \sigma_I^2}$ and

systematic error is $b_{FI}^2 = \left(\frac{\sigma_I^2 b_F}{\sigma_F^2 + \sigma_I^2} + \frac{\sigma_F^2 b_I}{\sigma_F^2 + \sigma_I^2}\right)^2$.

RESULTS AND DISCUSSION

Repeated measures ANOVA revealed that *AMSE* was lower ($p < 0.005$) with combined FI feedback than with F or I feedback alone (Fig. 2). The reduction of *AMSE* with FI feedback was mainly due to the reduction of variance ($p < 0.01$) while the systematic errors remained unchanged across the feedback conditions ($p=0.153$; Fig. 3).
Figure 2: The overall mean squared error (*AMSE*). Means and standard errors across subjects. Asterisk indicates significant differences among feedback conditions ($p < 0.05$).

No significant differences ($p > 0.05$) between experimental measurements (in FI condition?) and the MLE predictions were found for *OMSE* (Fig. 2), variance, and systematic error (Fig. 3).
Figure 3. The variance and systematic error. Means and standard errors across subjects. Asterisk indicates significant differences among feedback conditions ($p < 0.05$).

The results suggest that Bayesian inference can accurately predict observations of intra-auditory integration during isometric multi-finger force production. Notably, the target finger force was produced with reduced force variation when multiple auditory modalities were presented as auditory feedback (FI condition), as compared to single auditory modality conditions (F condition and I condition). These results are consistent with previous studies of inter- and intra-sensory integration across visual modalities [1-3]. Thus, our research supports the hypothesis that humans have the ability to optimally integrate intra-auditory modalities, enhancing motor performance.

CONCLUSIONS

Intra-auditory integration leads to the enhancement of constant finger force production, following maximum likelihood estimation. The data support the Bayesian inference in intra-auditory integration for motor performance in humans.

REPRESENTATION OF WRIST MOTION CHARACTERISTICS USING THE AXIS OF ROTATION

Mahmood Lahroodi and Ilhan Erhan Konukseven

Middle East Technical University (METU), Ankara, Turkey
email: lahroodi@gmail.com, web: http://metu.edu.tr

INTRODUCTION

Since the motion of wrist is almost pure rotation, spherical coordinate system is a compatible reference frame for analyzing the motion of wrist. Kinematically, human wrist can be modeled by 3DOF (FE, RUD, PS) manipulator with 2DOF (FE, RUD) in universal-like joint of wrist and additional DOF (PS) which comes from forearm[1]. Dynamically, it is shown that passive wrist stiffness is dominant dynamic of wrist [1] and depends nonlinearly on the position of wrist [2]. The present study shows that similar to passive stiffness, level of wrist noise depends on the position as well. For modeling the noise of wrist, we have studied the variation of Axis Of Rotation (AOR). Behavior of AOR not only depends on noise but also the biomechanical properties of wrist [3]. The results of experiment imply that fast changes of AOR is most probably because of internal noise (in actuation and sensing) and systematic patterns produced intentionally according to the dynamic of task and wrist.

METHODS

In this study, new approach has been followed for analyzing the wrist motion by adding a fixed link to the multi DOF joint. In fact, the new manipulator, let us call it wrist manipulator has a spherical-like joint in the origin of spherical coordinate system and a link which connects the origin to the surface of sphere with the radius of the length of link. The Jacobian matrix of new-defined manipulator can be easily obtained by finding the relation between rotational velocity at joint and translational velocity on the surface of sphere. The position of tip point of wrist manipulator can be written in vector form as

$$\vec{L} = L_x\ \vec{i} + L_y\ \vec{j} + L_z\ \vec{k} \qquad (1)$$

The rotational velocity of link can be written in vector form as well. The translational velocity of tip point can be obtained by cross product of rotational and position vectors.

$$\vec{V} = \vec{\omega} \times \vec{L} = \left(\omega_y L_z - \omega_z L_y \right)\hat{i} + \left(\omega_z L_x - \omega_x L_z \right)\hat{j} + \left(\omega_x L_y - \omega_y L_x \right)\hat{k} \quad (2)$$

By writing in matrix form and comparing with $V = J\dot{\Theta}$, we obtain the Jacobian matrix of this manipulator. By finding the projection of displacement vector in each axis we obtain the matrix with respect to angles.

$$\begin{cases} L_x = L\cos(\alpha) \\ L_x = L\cos(\beta) \\ L_x = L\cos(\gamma) \end{cases} \Rightarrow \quad J = \begin{bmatrix} 0 & L\cos(\gamma) & -L\cos(\beta) \\ -L\cos(\gamma) & 0 & L\cos(\alpha) \\ L\cos(\beta) & -L\cos(\alpha) & 0 \end{bmatrix} \qquad (3)$$

The Jacobian matrix of this manipulator is skew symmetric matrix and its determinant is zero. In fact, since we can show any vector in spherical coordinate system with just two angles (Azimuth and Elevation) in comparison with three angles of wrist in FE,RUD and PS directions, then it is expectable to have Jacobian matrix which is not invertible. Since we do not have an access to wrist robot [4] for measuring the angles of wrist and at the same time the Jacobian is not invertible, we had to capture the motion of tip point of wrist manipulator and utilize AOR notion for our analysis. In addition, AOR technique magnifies the deviations at wrist motion and makes it possible to capture the small and sometimes hidden dynamic of wrist. For doing so, we used following experiment with Omni Haptic device. We asked subjects to track a pre-determined circle (10 cm diameter) on space with two different positions for 4 times with just wrist motion. Figure 1 shows the connection of human wrist and pen of Omni haptic device. The link of wrist manipulator is defined from the location of wrist to the tip point of Omni pen which is shown by Orange vector.
Figure 1: Human wrist holds the pen of Omni haptic device for doing the task: first position (left), second position (right)

RESULTS AND DISCUSSION

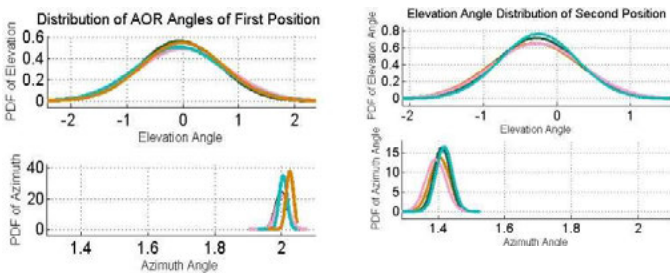
Axis of rotation of a perfect circle is a fixed line, however when human tries to produce a circle because of noisy sensory inputs and motor commands and biomechanical properties of wrist it will not be a perfect circle. Producing a perfect circle even for a skillful person may not be possible. It is important to note that producing a circle can be done in two different ways; drawing a circle (mostly engaged with internal model of this task in nervous system) and tracking a circle (mostly engaged with internal optimal control system). The distribution of axis of rotation is a good criterion for measuring a performance of operator in producing circular motions. It is obvious that producing circular motion is just a primitive example for generation versatile kinds of motions like writing a letter and doing deburring with so many curvature motions. The probabilistic model of producing circular motion reveals the performance and impairment of a subject. Figure 2 shows the distribution of elevation and azimuth angles of AOR for two different positions of wrist produced four times for one subject. It denotes that AOR is more noisy for second position in Azimuth direction.


Figure 2: Gaussian distribution of AOR for position one (left diagrams)and position two (right diagrams)

As it is shown in Figures 3 and 4 (left ones), the special region of ROM are more noisy than other
Figure 3: Behavior of AOR for first position
Figure 4: Behavior of AOR for second position

regions and this pattern is almost same for a same position and different cycles. It shows that wrist noise is position- depended signal. On the other hand, there are some sharp changes of elevation angles (right ones) which are same again for different cycles. The systematic pattern of behavior of AOR reveals that noise is not the only source of this pattern. The biomechanical properties of wrist and the dynamic of task may determine the shape of those patterns. In this study we showed that the variance of noise is changing during task; moreover; the unique behavior of elevation and azimuth angles of AOR denotes that there should be a systematic pattern for this task. However the mathematical and biomechanical reasons behind this phenomenon are not represented here. The advantage of this study is that it will help us to create a comprehensive map of wrist noise in entire range of motion.

INTRODUCTION

To investigate neural control of fingertip forces, subjects are often asked to track a target using visual feedback of their exerted force level. In the context of such tasks, measures of tracking error and force tremor can reveal a wealth of information relevant to understanding closed-loop neural control.   However, it is often difficult to disambiguate central (cognitive) vs. peripheral (reflexive or mechanical) contributions to task performance. For example, both attentional [1] and mechanical [2] aspects of a task can influence the magnitude and gain of afferent feedback from muscles, and therefore both can affect the amplitude of physiological tremor [3,4,5].

While psychosensory factors influencing tremor amplitude have received much attention, mechanical/muscular factors such as the magnitude, velocity, and dynamics of force production have not been well characterized. In this investigation, we quantified the modulation of tremor amplitude during the visually-guided production of sinusoidal forces.

METHODS

Eleven healthy participants used a 3-finger pinch grip to produce force against a transducer during visually-guided tracking tasks. Participants were asked to track sinusoidal target trajectories of either 0.1 or 0.25 Hz, each with a mean value (offset) of 7% of their maximal force and an oscillation amplitude of 1%. Each 40s target trajectory was displayed on a 19-inch computer monitor, with the vertical axis (displaying force magnitude) spanning from 5 to 9% of the maximal grip force. Subjects used a feedback cursor to trace the targets from left to right across the screen. Each subject completed 5 trials tracking each of the two target sinusoids.

Because frequencies of force tremor under 5 Hz are thought to relate to voluntary visuomotor error corrections, the force signals were high-pass filtered at 5 Hz (second-order zero-phase-shift Butterworth filter) prior to assessing involuntary physiological tremor. Wavelet analysis characterized the magnitude of force fluctuations at each frequency over time. A cross-cycle median tremor amplitude was derived for each frequency (bin size = 0.5 Hz), at each ms of the sinusoidal target cycle (Fig 1). We also assessed low frequency force fluctuations (1-5 Hz) in the same way (not shown).

RESULTS AND DISCUSSION

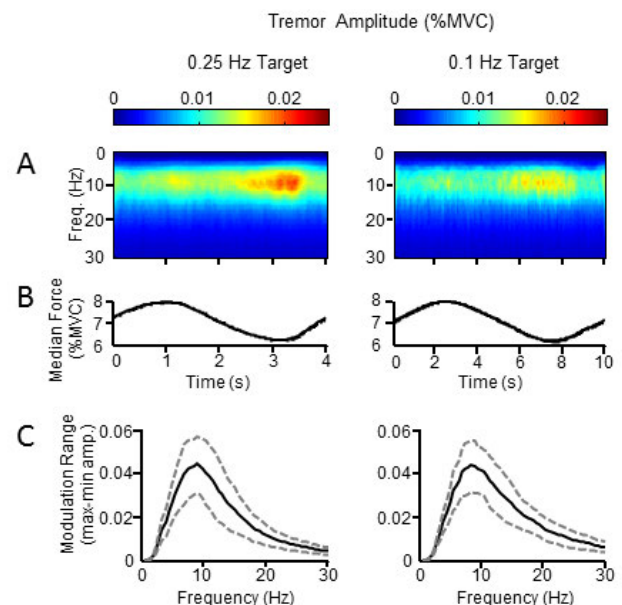
The magnitude of tremor was highly and consistently dependent upon the phase of sinusoidal force production. The most striking feature was a burst of ~10 Hz tremor when the target force was lowest, at the transition from isometric relaxation to contraction.


Figure 1: Tremor modulation during sinusoidal tracking.

Panel A (left) shows the spectrogram of force fluctuations occurring during the tracking of a 0.25 Hz target oscillation. The tremor amplitude at each time-frequency pixel represents the median amplitude over all cycles, and all subjects. To the right, the results of the same analysis are shown for the 0.1 Hz sinusoidal target. Beneath each spectrogram (Panel B) are the median forces produced at each time point shown in the above spectrograms. Panel C represents the median (black line) amplitude modulation range per frequency. This range was calculated for each cycle of the target sinusoid as the difference between the maximum and minimum tremor amplitude at a given frequency. The dashed lines represent the interquartile range (25th – 75th percentile) surrounding the median.

Tremor amplitude did not appear to be strongly determined by the overall magnitude or velocity of force at any given phase of the target cycle. Rather, a gradual buildup of ~10 Hz tremor during periods of declining force was observed prior to the large burst at the trough of the target sinusoid. The 0.1 and 0.25 Hz sinusoidal targets produced similar patterns of tremor amplitude modulation, and the degree of cross-cycle tremor modulation at ~10 Hz was nearly identical for both frequencies. Although the degree of ~10 Hz tremor amplitude modulation was similar for both target sinusoids, the faster target was generally associated with larger tremor amplitudes across all phases. An analysis of low frequency force fluctuations (not shown in Fig. 1) revealed the existence of a consistent fluctuation (~3 Hz in frequency) in force tracking which occurred simultaneously with the burst of ~10 Hz tremor. On the basis of their common timing with

respect to the phase of the target cycle, the two phenomena may share a similar neural origin.

We speculate that the tendon stretch at the transition from isometric relaxation to contraction may disrupt ongoing control of force, possibly via feedback from Golgi tendon organs and/or muscle spindles. Additional factors may include cycle-dependent alterations of reflex sensitivity [2] or changes in motor unit synchronization [4,5].

CONCLUSIONS

The amplitude of physiological force tremor depends upon the temporal dynamics of force production. The transition between isometric relaxation and contraction appears to be of particular importance, and may represent a disruption of smooth (feed-forward) force control by a sudden change in peripheral feedback.

CARPAL TUNNEL SYNDROME IMPAIRS FINGER RESPONSES TO UNPREDICTABLE PERTURBATION

[1]Kaihua Xiu, [1]Tamara L. Marquardt, [1]Chengliu Li, [2]Peter J. Evans, [2]William H. Seitz Jr., [1,2,3]Zong-Ming Li

Hand Research Laboratory, Departments of [1]Biomedical Engineering, [2]Orthopaedic Surgery, and [3]Physical Medicine and Rehabilitation, Cleveland Clinic, Cleveland, OH, USA

INTRODUCTION

Successful object manipulation requires effective integration of sensory information and motor commands. Carpal tunnel syndrome (CTS), a prevalent entrapment neuropathy, is caused by chronic compression of the median nerve in the carpal tunnel. CTS patients experience sensory deficits, such as numbness, paresthesia, and reduced sensation. However, the effects of these CTS-associated sensory deficits on finger responses are not well understood. The purpose of this study was to investigate finger muscle and force responses to unpredictable perturbations in patients with CTS. We hypothesized that CTS patients would demonstrate impaired finger responses to perturbations.

METHODS

Seven CTS patients (48±16 years) and seven asymptomatic control subjects (52±12 years) participated in this study. The experimental setup for the perturbation-induced finger response task is depicted in Fig. 1.
Figure 1: Schematic of experimental setup: (1) transducer; (2) slide; (3) baseline weight; (4) perturbation weight; (5) electromagnet.

The wrist and forearm were rested on a wedged-support with the index finger parallel to the inclination surface of the support. At the beginning of each trial, the subject pressed a plate with the index finger and maintained a 3N baseline force according to provided visual feedback. The unpredictable perturbation was implemented by releasing a 100g weight from a height of 20cm at a random instant in the 20-40s time window. The subject was instructed to stop the slide from moving as quickly as possible. The activity of the first dorsal interosseous (FDI) muscle was recorded by a surface electromyography (EMG) system and the forces from the index finger were collected by a six-component force/torque transducer. A total 15 trials were completed and 9 trials were used for analysis.

Muscle and force responses to the perturbation were quantified based on latency, duration, and intensity. For each trial, the onset of perturbation was identified as the time point when the tangential force (x-direction) exceeded 3 standard deviations (SD) of its baseline (mean of the signal 5s prior to the release of the perturbation weight). Then, the signals from individual trials were synchronized according to the onsets of perturbation and averaged for each subject. From the averaged trial, the EMG/normal force signal was used to determine the onset of muscle/force response as the time point when the EMG/normal force exceeded 3SD of its respective baseline. The muscle/force response latency was defined as the time period between the onset of perturbation and the onset of muscle/force response. The time point and magnitude of the peak EMG/normal force response were also obtained. The muscle/force response duration was the time interval between the onset of muscle/force response and the time point of peak muscle/force response. Additionally, the muscle/force response intensity was defined as the ratio of the peak EMG/normal force response magnitude to the baseline EMG/normal force. The moving duration of the

slide was also derived to determine the consequence of the finger's responses on the object. It was quantified as the time interval between the onset of perturbation and the time instant when the plate stopped sliding (i.e. when the velocity of the center of pressure measured by the transducer was zero). Independent t-tests were performed on variables between groups. A p<0.05 was considered statistically significant.

RESULTS AND DISCUSSION

For the CTS and control groups, finger responses were characterized by activation of the FDI muscle followed by increased applied normal force (Fig. 2).
Figure 2: Muscle (top) and force (bottom) responses for representative control and CTS subjects: a-onset of perturbation; b/d-onset of muscle/force response (Control); c/e-onset of muscle/force response (CTS).

Muscle and force response latencies, durations, and intensities are presented in Table 1. In comparison to the control group, the CTS group demonstrated 22.0% prolonged muscle response latency (p<0.05) and 11.7% prolonged force response latency (p<0.05). No statistical differences were found between groups for duration or intensity of the muscle or force responses. The duration of plate sliding for the CTS group (140.6 ± 3.5 ms) was significantly longer than that that of the control group (135.6 ± 3.6 ms, p<0.05).

In current study, the CTS group demonstrated prolonged response latencies to unpredictable perturbations. CTS-associated changes of the cutaneous sensory function and/or adaptations of the central nervous system may have contributed to the slower responses. In particular, decreased stimulus encoding by cutaneous mechanoreceptors or deteriorated central information processing could slow down the sensorimotor integration process, resulting in the delayed responses. Although significant differences were not found for response intensities between groups (muscle: p=0.079; force: p=0.057), the CTS group displayed trends of lower response intensities. With a larger sample size, we expect this difference will be significant. If CTS patients respond less forcefully than controls to unpredictable perturbations, then this expected result is in contrast to previous studies which have reported that CTS patients use increased grip force during static precision pinch [1]. This discrepancy may be attributable to the different strategies used to complete each task [2]. Specifically, precision pinch tasks rely predominantly on anticipatory mechanisms from previous sensorimotor memories, whereas unpredictable perturbation tasks depend more on instantaneous sensory feedback from the perturbations. Together, the delayed and decreased responses may indicate a different pattern of inefficient object manipulation by CTS patients. The deteriorated efficiency of the index finger's responses likely contributed to the prolonged duration of plate sliding, and may help to explain why CTS patients tend to drop objects.

POSTURAL STABILITY, MOTOR SKILLS, AND REPETITIVE BEHAVOIRS IN CHILDREN WITH AUTISM SPECTRUM DISORDER

[1] Melissa A. Mache and [2] Teri A. Todd

[1] California State University, Chico, CA, USA
[2] California State University, Northridge, CA, USA
email: mmache@csuchico.edu

INTRODUCTION

Postural stability is believed to be a prerequisite for the performance of mature patterns of fundamental motor skills. It has been reported that the development of postural stability is delayed among individuals with autism spectrum disorder (ASD); further, it may never reach mature levels [1]. Individuals with ASD also commonly exhibit poor motor skills when compared to typically developing peers [2]. Recent comparisons of postural stability in children and adults with ASD have indicated postural stability and motor skill difficulties may not be uniform across individuals with ASD [3]. At present it is not clear how postural stability and motor skill deficits may be related to ASD severity.

The purpose of this pilot study was to compare postural stability and motor skills among children with and without ASD. Additionally, relationships between postural stability, gross motor skills, and repetitive behaviors was examined in children with ASD.

METHODS

Twelve age-matched boys (6-12 years; 6 with ASD) provided assent to participate in the present study. Informed consent was also provided by a parent or guardian.

Postural sway and motor skills data were collected during a single testing visit. A parent or guardian completed the Repetitive Behavior Scale – Revised (RBS-R) for each child.

In order to assess postural stability participants completed three quiet standing trials. All trials were 20 seconds in duration. During the quiet standing trials participants were asked to stand quietly on the force plate, with their hands at their sides, their feet a comfortable width apart, while looking at a 'smiley face' on the wall at eye-level approximately 5 meters in front of them. Center of pressure (COP) data were sampled at 60 Hz with a Kistler force plate (Kistler, Amherst, NY, USA) or Neurcom Balance Manager Long Force plate (Neurocom, WA, USA).

In the same laboratory visit participants also completed the Test of Gross Motor Development, 3rd Edition (TGMD-3). The TGMD-3 is a criteria-based assessment consisting of 13 fundamental motor skills, including run, jump, and throw. For each skill a researcher provided a demonstration of the skill and the child then performed the skill twice. Performance of the motor skills was videoed and analyzed subsequently using the TGMD-3.

The following variables were computed for analysis: (1) Postural stability was assessed during the quite standing trials by computing postural sway area which was defined as the smallest ellipse that included 95% of the COP data points; (2) motor skills were evaluated using the TGDM-3 total score; and (3) the RBS-R total scores were computed to assess severity of ASD. Paired, one-tailed t-tests were used to assess differences between children with and without ASD. Simple linear correlation was used to explore relationships between variables (i.e., sway area, TGMD-3 score, and RBS-R score) among children with ASD. To account for the

small sample size and multiple statistical comparisons, the alpha level was set at 0.025 for all statistical analyses.

RESULTS AND DISCUSSION

There were no differences in postural sway among children with and without ASD (t = -1.54, p = 0.092) (Table 1). This contrasts some previous work, however, it supports the idea that children with ASD may not exhibit uniform deficits in postural stability [1, 3]. Children with ASD did score significantly lower on the TGMD-3 (t = 3.32, p = 0.011) than their peers without ASD (Table 1). The deficits in motor skills observed in the present population are in agreement with previous findings [2]. Furthermore, these results highlight the need for appropriate means of identifying children with ASD who may be affected by motor skill deficits and developing effective interventions to target these deficits [2].

There was no relationship between postural sway area and motor skills in children with ASD (r = -0.588, p = 0.110) (Figure 1). When considered in light of the fact that this cohort did not exhibit deficits in postural stability compared to their peers it is possible that postural stability is not the limiting factor for motor skill development in this group of children with ASD. Similarly, severity of repetitive behaviors was not related to postural stability (r =-0.571, p=0.118) or fundamental motor skills (r =0.341, p=0.23) in this group of children with ASD. Based on the present findings it does not appear that the RBS is a suitable tool for identifying children with ASD who may be affected by deficits in postural sway or motor skills.
Figure 1: TGMD-3 total score Vs. Postural sway in children with ASD.

CONCLUSIONS

Though, motor skill deficits were greater among children with ASD than among their peers without ASD this was not a predictor of postural stability. The present study is somewhat limited by the small number of participants. Differences between children with and without ASD and relationships between repetitive behaviors, motor skills, and postural stability among children with ASD may become more evident in a larger group of participants or under conditions of reduced sensory input (e.g., eyes closed or modified proprioceptive input).

PATIENTS WITH SYMPTOMATIC FEMOROACETABULAR IMPINGEMENT (FAI) DEMONSTRATE DIFFERENT LOWER EXTREMITY JOINT COORDINATION COMPARED TO HEALTHY CONTROLS DURING A DOUBLE LEG SQUAT TASK

[1] Philip Malloy, [1]Alexander Morgan, [1]Michael Kiely, [1]Christopher Geiser, [2]John T Heinrich, [1]Kristof Kipp

INTRODUCTION

Femoroacetabular impingement (FAI) is a skeletal deformity that has been linked to intra-articular hip injuries, such as acetabular labral tears and early onset osteoarthritis [1, 2]. Often times these hip injuries occur through overuse type mechanisms. FAI patients typically demonstrate losses of terminal hip flexion, internal rotation, and adduction range of motion [1]. Therefore, compensations in adjacent joints may be observed because of structural abnormality that constrains joint motion.

Alterations in joint coordination patterns have been linked to overuse type injury [3]. Kinematic changes associated with lower extremity injury can constrain movement patterns of the injured limb thereby altering the coordination of movement between all joints of the lower extremity. Principal components analysis (PCA) is a useful analytic technique for identifying kinematic pattern differences between pathologic and healthy populations [4, 5].

The purpose of this study was to investigate lower extremity joint coordination patterns in symptomatic FAI patients and healthy controls during a double leg squat task. It was hypothesized that compared to healthy controls, symptomatic FAI patients would use a more constrained joint coordination pattern in the frontal and transverse planes of motion, but not in the sagittal plane.

METHODS

Five symptomatic FAI subjects (3 male/2female) and five healthy matched controls (3 male/2 female) were included in this study. Symptomatic FAI subjects were diagnosed by a board certified orthopedic surgeon (JTH). Symptomatic FAI was confirmed by standard radiographs, MRI/A, and an intra-articular injection. Control subjects were included if they were free of hip symptoms and demonstrated a negative hip examination by a licensed physical therapists (PM).

All subjects performed five repetitions of a double leg squat task. Kinematic data were collected with a 14 camera motion capture system (Vicon Ltd, London, UK) at a sampling rate of 100 Hz. Marker position data were tracked in Vicon Nexus and processed using visual 3D software. Raw position data were filtered with a 4th order low pass Butterworth filter with a cutoff frequency of 6 Hz. Relative joint angles for all lower extremity joints were calculated in Visual 3D based on segment positions defined in a static standing trial that was collected prior to movement testing.

Principal components analysis (PCA) was used to quantify the patterns of joint coordination for the relative angle curves of the lower extremity joint. Three separate PCAs were performed for each plane of motion using the 5-trial ensemble averages of the relative joint angles for each subject. The input matrices for the PCA thus contained 3 row vectors (i.e., one for each of 3 joints) with 101 time points. Eigenvector decomposition was performed on the covariance matrices to extract the eigenvectors (i.e. principal components) and eigenvalues for plane of motion. The eigenvalues demonstrate the percent variance explained by each PC for each subject and were used as proxies to represent the degrees of freedom for the joint coordination pattern of the lower extremity for each of the respective planes of motion. To evaluate differences in the coordination

strategies between FAI and control subjects one-tailed, paired samples *t*-test were used to compare the eigenvalues for each plane of motion.

RESULTS

Although, no statistical differences in any of the mean eigenvalues were found, the results of the current study demonstrated a trend towards statistical difference between the FAI and control subjects for the eigenvalues of the first and second PC in the frontal plane (Table 1).

DISCUSSION

The results of the current study demonstrate differences in the coordination strategy of frontal plane motions between FAI and control subjects. Specifically, the differences in eigenvalues for frontal plane joint motions between the groups point toward a more constrained and simpler coordination pattern in the FAI group. This result is consistent with previous studies that suggest injured individuals tend to constrain kinematic degrees of freedom of the lower extremity [3]. Hip joint injury associated with FAI most often occurs during repetitive movements that involve end range motions as during squatting. Therefore, it seems reasonable that symptomatic FAI patients would adopt a movement strategy that constrains the degrees of freedom of the lower extremity joints so as to avoid potentially painful motions that reproduce or exacerbate symptoms.

Although previous researchers reported no differences in frontal plane hip kinematics during a double leg squat task in symptomatic FAI patients [6], it is interesting to note that these authors also reported that one third of their patients used an alternative frontal plane kinematic squat strategy characterized by greater hip adduction compared the hip abduction pattern used by the majority of the subjects [6]. These observations suggest that FAI patients may adopt alternative movement strategies to accomplish tasks that require end terminal ranges of hip motion, such as a double leg squat task.

Although the effect of FAI on movement patterns is not well understood, the current study demonstrates support for movement pattern differences in patients with symptomatic FAI. More research is needed to understand the interaction between movement patterns and FAI morphology to understand the specific mechanisms of hip joint injury associated with this pathology.

REDUCTIONS IN STRUCTURAL AND FREQUENCY COUPLING BETWEEN POSTURE AND SURFACE MOTION ARE FACILITATED BY PLANTAR TACTILE STIMULATION

INTRODUCTION
Human locomotor adaptation requires feedback and feed-forward control processes to maintain dynamic balance while exposed to external perturbations such as a moving or unstable support surface. When exposed to such conditions, the system's initial instability is reduced over time as a function of adaptation, thereby reducing the amount of movement variability, enhancing dynamic stability. Effective postural adaptation is characterized by a decoupling of the environmental perturbation and concurrent multisegmental movements of the trunk [1]. The efficacy of this type of adaptive behavior is dependent on the ability to use integrated sensory input to decompose environment and body movement dynamics and correct for deviations in postural stability [2]. The involved sensory systems provide specific contributions to the control of posture. Lower limb proprioception provides information on the orientation of the body with respect to the support surface. This is then used as a reference for the control of posture [3]. As the support surface becomes unstable, information provided through this modality becomes inaccurate. Through a process of sensory reweighting, the subsequent sensory contribution is reduced and alternate sensory signals are used as references [3]. Cues that reduce accuracy of a sensory modality can therefore facilitate sensory reweighting. For example, high frequency tactile vibration may reduce tactile sensitivity [4], thereby facilitating the down-weighting of this modality. In this study we investigated postural coupling and the effect of plantar tactile vibration on adaptation to a continuously rolling treadmill.

We hypothesize that plantar tactile vibration facilitates the down-weighting of proprioceptive information, which in turn enhances postural decoupling by allowing the system to rely more on alternative sensory inputs such as vision and vestibular perception.

METHODS
Twenty healthy young adults (9 male, 11 female) performed a walking task on a continuously rolling treadmill (Fig 1). Participants were separated into 2 groups. The control group received no tactile stimulation (NT) whereas the tactile group (TC) received vibratory stimulation (250Hz, 17.5dB), provided through tactors embedded in insoles placed in the shoes (Fig 1). The participants were asked to walk on a treadmill, which was stationary, performed a random roll motion or a sinusoidal roll motion, depending on the condition (Fig 2). In all treadmill roll conditions, the roll frequency was centered around 0.3Hz with a peak to peak amplitude of 10 degrees.
Figure 1: A) Participants wore insoles with 3 embedded tactors. B) Participants walked on a stock treadmill placed over a six degrees of freedom motion base. (C) The motion base allowed for a random or sinusoidal roll of 5 degrees to either side.

Posture control was quantified as the roll motion of the trunk in degrees, as recorded by a motion capture system. Postural coupling was quantified as

the spectral distribution (CFR) and cross recurrence quantification (RR) of treadmill and trunk roll motion. All variables were analyzed using mixed model RM ANOVA, separately for each variable.
Figure 2: Stimuli in the groups and conditions. The condition durations are provided in seconds.

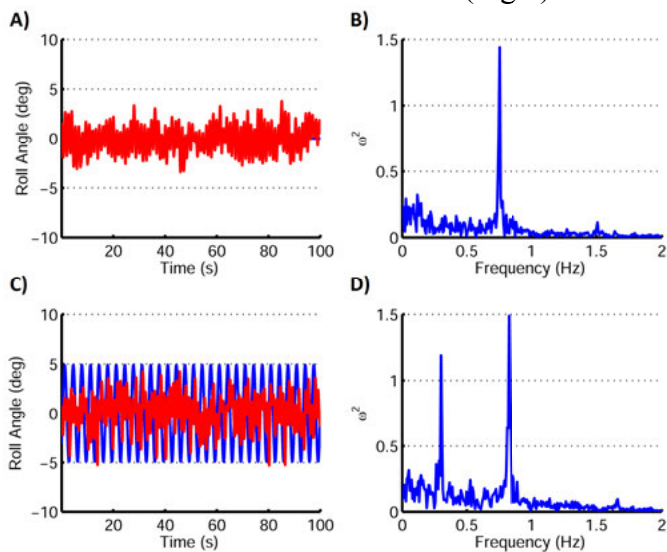
RESULTS AND DISCUSSION
The spectral distributions of trunk and treadmill motion indicated that the roll movement of the treadmill significantly affected the frequency distribution of the trunk roll motion (Fig 3).


Figure 3: A) Trunk roll (red) and treadmill roll (blue) time series in the baseline trial. B) The corresponding spectral distribution. The peak corresponds with the walking frequency at 0.8Hz. C) Trunk and treadmill roll during adaptation. D) The effect of treadmill roll can be observed in the additional peak at 0.3Hz.

The reductions in both CFR (Fig 4) and RR (Fig 5) coupling measures indicate that, as a function of adaptation to the sinusoidally rolling support surface (Sine 1, 2, 3), trunk-treadmill coupling decreases. This time-dependent reduction in coupling is significantly greater in the TC group. When exposed to a new roll environment post-training, coupling rates are significantly lower than

pre-training, however here no difference between NT and TC is noted.
Figure 4: CFR in the treadmill roll conditions. The blue lines and symbols represent NT, the red lines represent TC. Means ± SD are shown.
Figure 5: RR in the treadmill roll conditions. The blue lines represent NT, the red lines represent TC. Means ± SD are shown

CONCLUSIONS
Characteristic roles for postural and locomotor processes during adaptation to support surface roll oscillations while walking on a treadmill were demonstrated. The postural control component required integrated sensory contributions which are updated based on the accuracy of sensory inputs [2]. Improvements in balance through noisy plantar stimulation may be potentially useful for sensorimotor training in special populations by driving the system towards using a more appropriate sensory gain configuration [3].

The ability to dynamically regulate instabilities with the leg is susceptible to repetitive eccentric contractions.

INTRODUCTION

Controlling continuous instabilities with the legs (as per the Lower Extremity Strength-Dexterity (LED) paradigm [1]) is likely a product of a hierarchical organization of neural control [2]. This ability, therefore, likely requires continuous fine-tuning of motor output through intricate interactions among afferent signals, descending commands and muscle mechanics.

A pilot study suggested that LED performance deteriorates with 20-minutes of downhill walking, despite subjects reporting no evidence of fatigue. This result compelled us to investigate whether or not repetitive eccentric contractions can disrupt the fine motor control required for this task. However, studying this in walking remains ambiguous because concentric and eccentric phases coexist during downhill walking. Therefore, we investigated the effect of purely eccentric contractions of the *soleus* muscle on LED performance.

Figure 1: Schematic diagram of neurophysiological components likely responsible for the LED test performance. The original figure was obtained from Pierrot-Deseilligny and Burke (2012).

The hierarchical control of instabilities is likely mediated in part by short-latency, "low level" sub-cortical or spinal circuitry [3]. Such short-latency control is often mediated by tunable spindle

afferents (**i**, Figure 1). The H-reflex is a practical means to quantify spinal excitability to afferent signals (**ii**, Figure 1). Therefore, we hypothesized that purely eccentric contractions of the *soleus* muscle would induce changes in H-reflex.

METHODS

Nine young adult male subjects (25.4±3.8 yrs) participated in this study. They attended two separate sessions. In the first session, we quantified resting H-reflex amplitude of the *soleus*, LED performance, and electromyographic (EMG) activities of the *soleus* and *tibialis anterior* (TA) during the LED test bilaterally before and after exposure to unilateral eccentric exercise. The ankle dorsiflexion eccentric exercise consisted of 500 eccentric contractions of the *soleus* at 15% maximal voluntary contraction (MVC). The subjects were seated with the knee joint at 90˚ flexion during eccentric contractions and MVC trials in order to minimize the contribution of other plantarflexors. In the second session, those measurements were obtained unilaterally after level treadmill walking of duration required for each subject to complete 500 eccentric contractions (i.e., steps).

Note the LED test requires low forces < 25% of body weight, where the maximal compression force indicates the maximal level of instability that can be controlled. The maximal compression force was quantified as a mean of three best trials that achieved maximal mean compression force during the hold phase of the LED test.

RESULTS AND DISCUSSION

There was no measurable fatigue after eccentric contractions as per objective MVC measurements (mean percentage increase of 18.8±23.6%) and the

subjective Borg scale (mean value of 2.0±0.7 out of 10).

There was a statistically significant increase in contralateral control (p=0.029), while a decrease in the LED compression force was observed only in eccentric contraction condition (non-significant, p=0.106). In order to account for a difference in baseline LED performance among conditions, changes in LED compression force in different conditions were normalized to respective baseline LED compression forces (normalized relative change). There was a significant difference (p=0.026) in normalized relative change of the LED compression force between contralateral control and eccentric contraction condition (Figure 2).

Finally, there were no statistically significant effects of conditions on H-reflex amplitude or EMG activities of the *soleus* and the TA (average root mean square and mean or median power frequency of EMG signals) during the LED test.
Figure 2: Normalized relative change for LED compression force. There was a significant difference between contralateral control and eccentric contraction conditions. * denotes p<0.05.

Although additional subjects are needed to corroborate these trends, the results confirm that eccentric contractions likely degrade the ability to control instabilities with the leg. In this case, eccentric contractions seemed to override the positive exposure effect observed in the contralateral leg. The isolated eccentric contractions

of one muscle may also induce a smaller effect than eccentric contractions across multiple leg muscles in downhill walking.

Importantly, the hypothesis of modulation of spinal excitability due to eccentric contractions was falsified, as they did not affect resting H reflex (**ii**, Figure 1). These results, alongside retained neural drive to the involved muscles measured by EMG signals (**iii**, Figure 1), suggest the decreased LED performance did not stem from a deficit in the central neural drive to the motor units or spinally modulated gain of afferent signals. Therefore, eccentric contractions likely tend to degrade the ability to control instabilities via other mechanisms. Specifically, eccentric contractions could affect the passive and active properties of muscle, or spindle sensitivities (**i**, Figure 1) [4]. These results motivate future work to disambiguate the contributions of peripheral mechanisms involved in the short-latency corrections needed to continuously stabilize the leg at low force levels—and may have implications to injury prevention in sports activities.

CONCLUSIONS

The ability to control dynamics instabilities in the lower limb is susceptible to non-fatiguing, repetitive eccentric contractions. The neuromechanical mechanisms responsible for this effect warrant further investigation.

CAN PARAVERTEBRAL FACET INJECTION IMPROVE MOTOR PERFORMANCE IN PATIENTS WITH DEGENERATIVE FACET OSTEOARTHROPATHY?

Nima Toosizadeh, Tzu-Chuan Yen, Michael Dohm, Cindy Fastje, Bijan Najafi

College of Medicine, University of Arizona, Tucson, AZ, USA
email: bnajafi@surgery.arizona.edu

INTRODUCTION

Low back disorder (LBD) is the fifth most common reason for medical treatment and costs up to $50 billion annually in the United States alone [1]. One such LBD is degenerative facet osteoarthropathy (DFO), which has a high prevalence of 57% DFO in younger adults (20-29 years) and can increase up to ~95% in older populations (40-59 years) [2]. Corticosteroid injections are commonly requested treatments for patients with various LBDs, especially for DFO; however, no study uses motor performance assessment to evaluate the efficacy of facet spine steroid injections. Hence, the purpose of this study was to assess immediate improvements in motor performance following facet spine injection in patients with DFO.

METHODS

Thirty DFO participants were recruited from the University of Arizona Medical Center after screening based on CT and MRI images. Exclusion criteria were previous spine, hip, or lower extremity surgeries within a one month time-window of the spine injection, along with severe comorbidities (e.g., Parkinson's and Stroke). A sample of 10 healthy, age-matched adult controls were recruited from the University of Arizona Geriatric clinic. DFO Participants were treated with 1% lidocaine plain, 0.25% marcaine plain and 40 mg per cc triamcinolone for a medial branch block, intermediate branch block, pericapsular and intracapsular injection [3]. Data were collected pre- and post- surgery, with baseline measures collected within three days prior to the injection and follow-up measurements taken immediately after the procedure. The Oswestry Disability Index and the 10-point Visual Analog Scale (VAS) were used to assess patient reported disability and pain, while wearable sensor technology were utilized to assess gait, postural balance, and Timed Up & Go (TUG) (Table 1). Gait was evaluated with a minimum of 25 steps under four conditions of normal single task, normal dual task, fast single task, and fast dual task. In all dual tasks, participants were asked to count backwards by one from a number between 1 and 100. As for balance assessment, two trials were conducted for the eyes open and eyes closed conditions, where participants crossed their arms and minimized the distance between their feet. In the TUG test, the walking distance was three meters and the same chair was used every time. A total of five sensors, each with a triaxial accelerometer and gyroscope were placed on the shanks, thighs, and back to track lower extremities and hip motion (LEGSys, MA). Analysis of covariates were used to compare outcomes between DFP pre-injection and healthy controls, considering age, gender, and body mass index as covariates. Comparison between pre- and post-surgery data was performed using the paired t-test or Mann–Whitney U test for non-parametric samples (Significance: $P<0.05$).

RESULTS AND DISCUSSION

Mean age and body mass index of DFO participants were 50±14 years and 32.5±6.6 kg/m^2, respectively; corresponding values for healthy controls were 46±15 years and 25.2±4.1 kg/m^2. Before injection the Oswestry Disability Index scores ranged between 4% and 70% (mean = 44±16%), and the mean pain score was 5.6±2.6 at the moment of measurement among DFO participants. A significant improvement of 50% was determined when comparing immediate pre- and post-surgery pain ratings (post-injection pain=2.8±2.7; $P<.0001$).

Within the gait analysis, gait velocity, stride length, medial-lateral sway, and shin mid-swing velocity were 38%, 20%, 51%, and 27% larger, respectively, while gait cycle time and double support percentage were 16% and 51% smaller in healthy controls

compared to DFO participants on average among all conditions ($P<0.04$, Figure 1). After injection, significant improvements were observed in all gait parameters, except stride length ($P>0.5$, Figure 1). More noticeable changes were observed in gait cycle time and shin mid-swing velocity after injection ($P<0.03$). Double support percentage reduced 10% after injection only in the single task fast walking ($P=0.03$). Balance results demonstrated a higher amount of sway in DFO participants compared to healthy controls in both anterior-posterior (60%; $P<0.05$) and medial-lateral (43%; $P<0.05$) directions, on average among two conditions. However, no noticeable reduction in body sway was observed in DFO group after injection ($P>0.34$). Finally, for TUG, duration of sit-to-stand (82%), walking (121%), turning (80%), stand-to-sit (114%), and total TUG duration (101%) were significantly smaller ($P<0.04$) while trunk velocity within sit-to-stand (64%), turning (77%), and stand-to-sit (47%) transitions was significantly larger in healthy controls compared to DFO participants ($P<0.02$). After injection a significant reduction of 14% in the total TUG duration was observed ($P<.001$), which mainly resulted from a reduction in walking duration (21% reduction in walking speed; $P=0.03$). Although not significant, improvements in sit-to-stand, turning, and stand-to-sit performance were observed ($P>0.08$).

In agreement with previous studies [4,5], our results demonstrated a compromised motor performance caused by DFO. Furthermore, our results demonstrated that pain reduction after spine injection led to instantaneous improvement in motor performance. Improvements were more pronounced within the gait assessments, and mainly for parameters related to agility of movement. Interestingly, improvement in gait speed also caused a reduction in TUG duration. Additionally, the range

Table 1: Parameter definitions

Gait	Definition
Stride Length	Distance travelled by the same limb between two successive heel contacts
Medial-lateral Sway	Range of angular rotation of the trunk in the medial-lateral direction
Shin Mid-swing Velocity	Mean value of shin angular velocity peaks during each swing
Gait Cycle Time	Time interval starts when one foot makes contact with the ground and ends when that same foot contacts the ground again
Double Support	Time that both feet are on the ground as a percentage of the gait cycle time
Postural Balance	**Definition**
Anterior-posterior or Medial-lateral Sway	Range of center of gravity sway in the anterior-posterior or medial-lateral direction
TUG	**Definition**
Trunk velocity	Mean angular velocity of the trunk during turning, rising from a chair, or sitting on a chair

of medial-lateral sway during walking was significantly different between the two groups, which was improved after injection. The DFO group showed a smaller range of medial-lateral sway during walking, probably to alleviate pain by restricting medial-lateral motion. Turning ability was also compromised in the DFO group; DFO participants required more time to perform a turning task, which may happen due to poorer balance and lack of hip flexibility. Although not significant, improvements in turning ability was noticeable after injection in the DFO group. In summary, for the first time, we assessed the association between pain reduction and improved motor performance in DFO using innovative wearable sensor technology.

SUBJECT-SPECIFIC LANDING STRATEGIES IDENTIFY CHANGES IN MOVEMENT CONTROL

Andrew D. Nordin and Janet S. Dufek

University of Nevada, Las Vegas, Las Vegas, NV, USA
email: nordina@unlv.nevada.edu

INTRODUCTION

Single-leg landing injuries from a jump or an elevated surface are well documented in scientific literature, leading to explorations of overuse and acute injury mechanisms [1,2,3]. Within-subject movement variability across task repetitions has therefore been used in assessing musculoskeletal health and motor system flexibility [2]. In contrast, inter-subject variation confounds human movement analyses, a consequence of the large pool of motor solutions available to a performer [1]. As a result, the load accommodation strategies model has been used in classifying performer strategies following alterations in landing height and subject mass [1]. The conversion of gravitational potential to kinetic energy allows Newtonian predictions of kinetic parameters, including landing impulse [1].

The purpose of this investigation was to examine changes in movement control following alterations in mechanical task demands via external load and landing height. Single-subject analyses were used in identifying subject-specific strategies and changes in movement variability in the context of factors related to landing injuries. Two hypotheses were tested. With greater mechanical task demands: (1) within-subject movement variability would decrease; (2) subject-specific strategies would demonstrate lesser load accommodation capacity.

METHODS

Nineteen healthy volunteers (15M, 4F, age: 24.3 ± 4.9 y, mass: 78.5 ± 14.7 kg, height: 1.73 ± 0.08 m) provided informed consent prior to participation, as required by the Institutional Review Board at the affiliated intuition. Subjects completed 10 preferred limb single-leg landing trials (9 analyzed) in each of 6 experimental conditions; 3 load and 2 height conditions, computed as percentages of subject bodyweight (BW, BW+12.5%, BW+25%) and height (12.5%H & 25%H). Condition order was counterbalanced.

Twelve variables were assessed in each trial, including lower extremity sagittal joint angles and moments (hip, knee, & ankle), vertical ground reaction force (GRFz), and electrical muscle activity (gluteus maximus, biceps femoris, vastus medialis, medial gastrocnemius, & tibialis anterior muscles). Kinematic, kinetic, and EMG data were collected using a 10-camera motion capture system (Vicon Plugin-Gait; MX-T40S; 200Hz), synchronized force platform (Kister Type 9281CA; 2000Hz), and 16-channel EMG system (dual surface Ag/AgCl electrodes; Noraxon Myosystem 2000; 2000Hz).

Kinematic and kinetic data were low-pass filtered (15Hz & 50Hz cutoffs, respectively). Joint moments were calculated with matched cutoffs (15Hz). EMG data were band-pass filtered (15-300Hz), full-wave rectified, and low-pass filtered (15Hz), preserving the pattern of muscle activation in landing [3]. Data were analyzed (Matlab R2012a) in each trial from the time of ground contact (GRFz > 20N) to the time the vertical center of mass velocity reached zero. GRFz data were normalized to subject BW, sagittal joint moments were normalized to subject BW and height (BW•H), and EMG data were normalized to mean dynamic baseline activity for each subject (lowest task demands: BW, 12.5%H).

Within-subject variability was assessed using the 95% confidence interval (CI) of the integrated time-series for each subject-condition-trial-variable. Changes in within-subject variability across conditions were assessed using a 3x2 repeated measures factorial MANOVA, with follow-up 3x2 repeated measures factorial ANOVAs and pairwise comparison for each variable ($\alpha = 0.05$). Degrees of freedom were adjusted via Huynh-Feldt corrections

as necessary, with Bonferroni adjusted pairwise comparisons.

Collective within-subject movement variability was assessed using single-subject principal component analyses (PCA). Prior to PCA the time series of each variable and trial was normalized to 101 data points via cubic spline interpolation. Time series variables were converted to z-scores, subtracting the subject's baseline mean and normalizing to baseline standard deviation. Analyses were carried out on 108x101 dimension matrices (12 variables x 9 trials = 108) for each subject-condition. The number of PCs explaining 90% of the variance in each condition was used in subsequent inferential testing. Main effects were examined using Friedman tests and follow-up Wilcoxon signed-rank tests due to the ordinal nature of the extracted PCs ($\alpha = 0.05$). The interaction of load and height was explored in a 3x2 repeated measures ANOVA ($\alpha = 0.05$).

Landing strategies were identified using the load accommodation strategies model and 95% confidence intervals (CI) for the impulse ratio of each subject relative to baseline. Impulse ratios defined predicted (Newtonian) increases in landing impulse relative to baseline. Landing strategy classifications included: (1) Newtonian: CI containing the predicted impulse ratio (2) Fully-Accommodating: CI containing impulse ratio of 1.0, (3) Positive Biomechanical: CI greater than 1.0 and less than the Newtonian predicted impulse ratio, (4) Negative Biomechanical: CI less than impulse ratio of 1.0, (5) Super-Newtonian: CI exceeding the Newtonian impulse ratio [1]. Associations among conditions and observed strategy frequencies were assessed using Fisher's exact tests ($\alpha = 0.05$). Separate tests were carried out at each load and landing height.

RESULTS AND DISCUSSION

Within-subject variability and subject-specific landing strategies differed by load and landing height. Within-subject variability decreased with greater load ($F[12,26]=8.1$, $p<.001$, $\eta^2=.79$), demonstrating decreases among sagittal angle and moment variability at the hip, knee, and ankle ($p\leq.016$). Total medial gastrocnemius muscle activity variability also decreased with greater load ($p<.048$). Collective within-subject movement variability decreased with greater load ($\chi^2[2]=36.1$, $p<.001$) and landing height ($Z=-5.1$, $p<.001$), demonstrating fewer extracted PCs.

Subject-specific strategies were associated with load and landing height adjustments ($p<.001$). Landing strategies were more frequently Negative Biomechanical with greater load at 12.5%H, and more frequently Positive Biomechanical with greater load at 25%H ($p<.001$). Landing strategies were more frequently Positive Biomechanical with increased landing height at BW+12.5% and BW+25% ($p<.001$).

CONCLUSIONS

The influence of mechanical task demands on subject-specific landing strategies identified changes in movement control during single-leg landing. The observed load accommodation strategies highlight movement control adjustments as mechanical task demands outpace neuromuscular accommodation capabilities [1]. Alongside observed decreases in within-subject movement variability, the application of greater loads with fewer available motor solutions may underscore potential injury mechanisms in landing activities [2].

Combined use of the load accommodation strategies model, within-subject variability, and single-subject PCA demonstrated utility in examining subject-specific movement control adjustments across changes in mechanical task demands.

THE EFFECTS OF VIBRATORY STIMULI ON CORTICAL AND SPINAL NEURON EXCITABILITY: IMPLICATIONS FOR OSTEOARTHRITIS TREATMENT AND PREVENTION

INTRODUCTION

Vibration acutely enhances neuromuscular function [1], but the mechanism of improvement is unclear. Past research suggests that heightened motor neuron excitability within the spinal cord is responsible for improved muscle function following vibration [2]. However, reflexive activity is often depressed following vibration [3], and the response of supraspinal structures – such as the motor cortex – to vibration is unclear. Vibratory treatments could have implications for individuals with deficits in quadriceps muscle activation, such as patients with knee pathologies [4]. Whole body (WBV) and local muscle vibration (LMV) both improve quadriceps function [5], but the efficacy of treatment may vary. Furthermore, WBV is cost prohibitive, and LMV may provide an alternative treatment tool. However, there are few investigations that have compared the effects of WBV and LMV. The purpose of this study was to compare the effects of whole body and local muscle vibration on three measures of quadriceps function including: corticomotor excitability, spinal neuron excitability, and voluntary activation.

METHODS

We recruited 60 healthy subjects into a single blinded randomized control trial. Subjects were randomized into 1 of 3 different groups following pretest assessments of quadriceps function: WBV (n = 20, age = 20.2±0.9 years, height = 172.1±10.8 cm, mass = 66.4±10.4 kg, males = 9), LMV (n = 20, age = 19.5±1.4 years, height = 168.3±9.0 cm, mass = 65.5±10.7 kg, males = 8), Control (n = 20, age = 20.5±1.2 years, height = 171.1±8.8 cm, mass = 69.4±12.9 kg, males = 10).

Corticomotor excitability was assessed via active motor threshold (AMT), spinal neuron excitability was assessed using Hoffman's (H) reflex, and voluntary activation was assessed using the central activation ratio (CAR). Subjects completed 3 testing visits (Vastus medialis H-reflex, vastus medialis AMT, and quadriceps CAR) in a random order separated by 1-week washout periods, each lasting 1.5 hours. On each day, subjects completed a baseline assessment of H-reflex, AMT, or CAR and then received the WBV, LMV, or Control intervention. Following the intervention, subjects completed a follow-up assessment of H-reflex, AMT, or CAR immediately, 10 minutes, and 20 minutes following the treatment. H-reflex measurements of the vastus medialis were collected with surface electromyography (EMG) in the dominant limb. The ratio of maximal H-wave to a maximal M-wave was used for analysis. AMT was defined as the minimum transcranial magnetic stimulating intensity required to elicit a motor evoked potential greater than 10mv in at least 5 out of 10 trials. The ratio of voluntary torque to additional torque produced from a superimposed electrical stimulus during a maximal voluntary isometric contraction was used for analysis (CAR). H-reflex, AMT, and CAR were compared via separate 3x4 (group x time) analyses of variance.

RESULTS AND DISCUSSION

The group by time interaction was significant for AMT (Table 1, $F_{2,57} = 13.39$, p<0.001) and CAR (Table 2, $F_{2,57} = 2.86$, p = 0.011), but not for H-reflex (Table 3, $F_{2,57} = 1.36$, p = 0.619). Post hoc analyses revealed a significant increase in CAR immediately post-treatment in the WBV group

(+2.9%, p<0.01), and a significant reduction in AMT immediately post-treatment in the WBV (-2.6%, p<0.001) and LMV (-2.3%, p<0.001) groups. The reduction in AMT was significant 10 minutes following WBV (-2.3%, p<0.001) and LMV (-2.3%, p<0.001), and 20 minutes following WBV (-2.4%, p<0.001) and LMV (-1.6%, p<0.001).

CONCLUSIONS

These results suggest that both WBV and LMV improve voluntary quadriceps function via a reduction in AMT rather than from enhanced spinal reflex activity. Interestingly, we found no change in spinal reflex activity, indicating that the effect of vibratory stimuli on spinal neuron activity may be limited to the time while treatment is applied, rather than persisting following it. Furthermore, the effects on quadriceps function may be more pronounced following WBV compared to LMV as there was a greater reduction in AMT, and an increase in voluntary quadriceps activation (CAR) in the WBV group only. Next, the effects on muscle vibration on AMT may persist for up to 20 minutes following treatment. As such, vibratory stimuli – particularly WBV – may provide a suitable treatment for those individuals with deficits in quadriceps function. Future studies should investigate the effects of vibratory stimuli in pathologic populations, as the magnitude of effect could be larger in those with underlying neuromuscular deficits.

INFORMATION ABOUT HOW ANOTHER PERSON IS MOVING THROUGH THE ENVIROMENT IS CONVEYED IN THE MOVEMENTS OF THEIR LIMBS

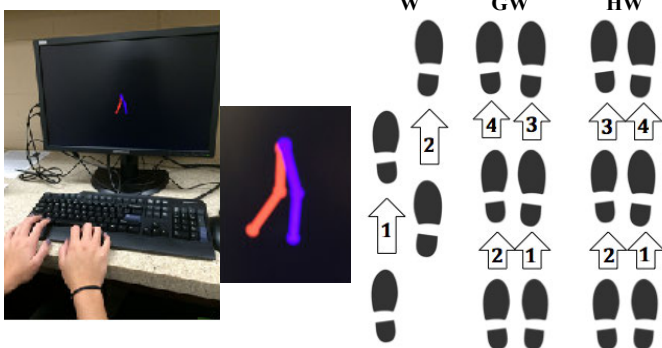
INTRODUCTION

By watching the movements of another person it is possible to know many things about them. Just by seeing how another person is moving we can perceive their age, gender, and even mood.[1] Here we investigate if it is possible to perceive how another person is moving through an environment, just based upon seeing how their lower limbs (hips, knees, ankles) are coordinated in locomotion. The way in which the limbs are coordinated in locomotion has been found to affect kinesthetic distance perception.[2,3] Kinesthetic distance perception concerns perceiving one's own movements during locomotion based upon the sensory information that is generated from coordinated body movements. Research into kinesthetic distance perception has employed simple homing tasks in which blindfolded participants travel outbound from a "home" location for a certain distance, before being told to stop and turn around, and then attempting to travel the same distance to return to "home". Depending on the gait patterns used in the outbound and return phases of simple homing tasks, systematic biases are observed.[3] For example, gallop-walking (Fig. 1) outbound followed by walking in the return phase

Figure 1: A) Experiment setup and stimulus. B) Gait patterns used in this experiment.

produces a systematic underestimation bias. Alternatively, running outbound followed by walking produced no bias.[2] This study investigates if an individual's visual perception of distances travelled by other people is affected by the way in which that person's limbs are coordinated. We hypothesized that the patterns of bias observed in our experiments would match those found in previous investigations of kinesthetic perception.

METHODS

Four experiments were conducted. Twenty participants aged between 19 and 65 took part in each experiment (n = 80). Each participant read and signed a consent form prior to taking part in this study. Motion capture recordings were used to create animations of a stick figure (Fig. 1) employing various gaits to complete a simple homing task. The animations were constrained so that the hips of the stick figure always stayed in the center of the screen. The animation was used to simulate the outbound and return phases of a homing task performed by another person. Participants attempted to perceive the distances travelled by the stick figure. Outbound distances were set as 3m, 6m, and 9m. Outbound gait performed by the stick figure was manipulated across the four experiments to be either a walk (W), gallop-walk (GW), or hesitation-walk (HW) (see Fig. 1). The return gait was always a walk. All conditions were randomized and programmed into the test prior to the participant arriving. In the outbound phase of the homing task, participants watched as the stick figure moved towards the right of the screen. The stick-figure would then stop and turn around once it had reached its predetermined distance and turn around. It would then begin moving towards the left of the screen. Participants were asked to press a button on a keyboard when


they perceived the stick figure had returned to where it started out.

RESULTS AND DISCUSSION

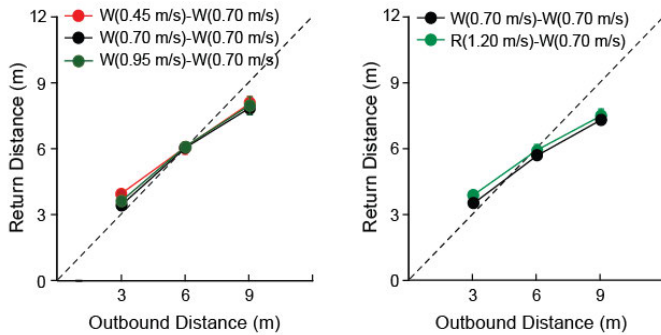
In all experiments, participants reported longer return distances as a function of increasing outbound distances (p's < 0.001). Results of all experiments are shown in figures 2 and 3.


Figure 2: Results from experiments 1 and 2.

In **experiment 1**, we manipulated the speed of the outbound gait. We found that participants were able to perceive the outbound distances independent of outbound speed (F's > 1).

In **experiment 2**, we manipulated the outbound gait being displayed; it could either be a walking or a running pattern. We observed no effect of outbound gait ($F(1,19) = 1.62$, $p = 0.22$), nor an interaction of outbound gait and outbound distance ($F < 1$). In this case the participants were able to perceive the outbound distances independent of outbound gait.

In **experiment 3**, we manipulated the outbound gait to be either a gallop-walk or a walk pattern. In this case there was a significant difference in perceived return distances as a function of the outbound gait ($F(1,19) = 11.86$, $p > 0.01$). A significant interaction of outbound gait and outbound distance was observed ($F(2,38) = 4.65$, $p < 0.05$). Paralleling previous studies of kinesthetic distance perception the results show that when employing the gallop-walk, participants came up significantly shorter than when they began with the walk.

In **experiment 4**, we manipulated the outbound gait being displayed to either a gallop-walk or a hesitation-walk pattern. The results showed that participants were able to perceive the outbound distances independent of outbound gait (F's > 1).
Figure 3: Results from experiments 3 and 4.

CONCLUSIONS

We found that people are able to accurately perceive the distance travelled by another person from information obtained by watching the movements of their legs. We also found that the ability to perceive another person's movements depended upon the way the seen person legs were coordinated in movement. The results showed that the pattern of results observed for perceiving other's movements matched those for non-visually perceiving one's own movements. We are currently investigating further into the possible visual mechanisms underlying this interesting phenomenon.

ADAPTATION STRATEGIES OF INDIVIDUALS WITH ANTERIOR CRUCIATE LIGMENT RECONSTRUCTION

INTRODUCTION

Even after ACL reconstruction (ACL-R), lengthy rehabilitation, and return to sport, asymmetry and alterations in gait and neuromuscular control persist. Interventions that may reduce the alterations and asymmetries in gait associated with ACL-R could produce improved walking patterns. Insight into whether and to what extent individuals with ACL-R can modify their movement patterns is essential for designing successful rehabilitation. Yet a lack of understanding remains regarding whether people with ACL-R are capable of adapting to gait perturbations and storing new gait patterns.[1] Therefore, the purpose of this study was to observe the ability of individuals with ACL-R to adapt and store novel gait patterns walking on a split-belt treadmill (SBT).

METHODS

Locomotor adaptation was investigated as 20 participants with ACL-R and 20 healthy matched-controls (HYA) walked on a split-belt treadmill. We assessed locomotor adaptation by 1) the magnitude of asymmetry persisting in late adaptation and 2) the magnitude of the asymmetry during de-adaptation.

After a 5 minute warm-up period of walking at self selected speed, participants walked at a slow speed (0.75 m/s) for 2 minutes (BASELINE).[2] Treadmill speeds were then adjusted such that the belt under the non-dominant leg in HYA and the belt under the reconstructed leg in the individuals with ACL-R sped up to 1.5 m/s. The belt under the contralateral leg remained at 0.75 m/s. Participants walked under these conditions for thirteen minutes (ADAPT 1). Next, the belt moving at 1.5 m/s was returned to the slow speed and participants walked for five minutes

with both belts moving at 0.75 m/s (DE-ADAPT 1). The last 30 second period of DE-ADAPT 1 was used for the second BASELINE for the following adaptation conditions. Following the DE-ADAPT condition, participants continued walking on the SBT with the belts moving in the opposite configuration of ADAPT 1. That is, the belt under the dominant leg in HYA and the belt under the uninjured leg in the individuals with ACL-R was sped up to 1.5 m/s while the belt under the contralateral leg remained at 0.75 m/s. Participants walked under these conditions for thirteen minutes (ADAPT 2). Then the belt moving at the fast speed was returned to the 0.75m/s and the participants walked for an additional five minutes, (DE-ADAPT 2). The order of ADAPT 1 and ADAPT 2 conditions were randomized between all participants.

Kinematic (120 Hz; Vicon Nexus, Oxford, UK) and kinetic data (1200 Hz; Bertec Corporation, Columbus, OH) were recorded for the first and last 30 seconds of all conditions. For clarity, all variables calculated for the leg on the belt moving at 1.5 m/s are henceforward referred to as the "fast" leg, and the leg on the belt moving at 0.75 m/s referred to as the "slow" leg. Stride length was defined as the anterior posterior distance traveled by the ankle marker from heel-strike to toe-off.[2] Stance time was defined as the percent of the gait cycle between heel-strike and subsequent toe-off of the same limb. Step length was defined as the anterior posterior distance between the ankle markers at heel-strike. Slow double-limb support refers to the time from fast leg heel-strike to slow leg toe-off and fast double-limb support refers to the time from slow leg heel-strike to fast leg toe-off. Symmetry was defined in each spatiotemporal gait parameter using the following asymmetry index:

Asymmetry = (fast leg parameter - slow leg parameter) / (fast leg parameter + slow leg parameter).[3]

RESULTS AND DISCUSSION

Healthy individuals adapted a new walking pattern and stored the new walking pattern equally in both the dominant and non-dominant limb. Conversely, individuals with ACL-R displayed impairments in locomotor adaptation and significant differences in behavior between the reconstructed and uninjured limb (Figures 1-3). Indications of significant effects of leg and walking condition are omitted for clarity.

CONCLUSIONS

This investigation supports that after surgical reconstruction and physical therapy fundamental features of motor control remain altered. Following ACL-R, participants display an altered ability to learn and store functional gait patterns. Thus, sensorimotor integration may underlie the prolonged deficits in locomotor performance and control in this population.

Hamstring Strength Deficits Three Years after Anterior Cruciate Ligament Reconstruction in Individuals with Hamstring Autografts Alter Knee Mechanics during Gait and Jogging

Matthew N. Abourezk[1], Matthew P. Ithurburn[1], Michael P. McNally[1], Louise M. Thoma[1], Matthew S. Briggs[1], Kurt P. Spindler[2], Christopher C. Kaeding[1], Timothy E. Hewett[1], Laura C. Schmitt[1]

INTRODUCTION

Anterior cruciate ligament reconstruction (ACLR) using hamstring tendon autografts may result in hamstring muscle weakness in the involved limb [1]. Altered mechanics are also observed during gait and jogging following ACLR for up to two years [2]; however, to our knowledge, the impact of hamstring strength asymmetry on involved limb gait mechanics has not been reported. The purpose of this preliminary study was to test the hypothesis that individuals with hamstring strength asymmetry would demonstrate altered involved limb knee mechanics during walking and jogging compared to those with symmetric hamstring strength two years after ACLR with hamstring tendon autograft.

METHODS

Participants (n=40; age=22.7; 21F/19M) were a subset of individuals that participated in the Multicenter Orthopaedic Outcomes Network (MOON) ACLR Two-Year Follow-up cohort. All participants had undergone a primary, unilateral ACLR with hamstring tendon autograft at least 2 years prior (mean=34.5mo.; range=27.9-42.7mo.). Hamstring strength was quantified as peak isometric knee flexion torque on an isokinetic dynamometer (Biodex) at 60° knee flexion. Limb-symmetry indices (LSI) were calculated for isometric hamstring strength using: LSI=[involved value/uninvolved value]. Hamstring strength LSI were used to divide the participants into a symmetric hamstring strength (SH) group (LSI≥0.90) and a weak involved limb hamstring (WH) group (LSI<0.85)[3], resulting in 18 participants per group. 4 individuals had LSI from .85-.90 and were not included due to small group size. Involved knee mechanics were quantified by tracking 46 retroreflective markers using a 10-camera three-dimensional motion analysis system (Vicon Nexus; 300 Hz) during walking and jogging across embedded force plates (Bertec; 1500 Hz). Visual3D software was used to calculate peak sagittal, frontal, and transverse plane knee kinematics, moments, and powers during each phase of walking and jogging. Gait phases included initial contact, weight acceptance (initial contact to peak knee flexion), mid-stance (peak knee flexion to peak knee extension), push-off (peak knee extension to toe-off), and toe-off. Jogging phases included initial contact, weight acceptance, push-off (peak knee flexion to toe-off), and toe-off. Marker trajectories and force-plate data were filtered with a low-pass Butterworth filter at 6 Hz. Joint moments and powers were normalized by body mass. Independent samples t-tests were used to compare involved knee kinematic and kinetic variables between the SH and WH groups across each phase of gait and jogging ($p<.05$; 2-tailed). Given the preliminary nature of this study in guiding future work, multiple comparisons were not controlled for.

RESULTS AND DISCUSSION

There were no differences in sagittal and frontal plane knee kinematics between the WH and SH groups during any phase of gait or jogging. During jogging, the WH group demonstrated increased tibial external rotation at initial contact (p=.02) and during weight acceptance (p=.02) compared to the SH group (Figure 1A). During gait, the WH demonstrated decreased tibial internal rotation during weight acceptance (p=.011) (Figure 1B).

In addition, the WH group demonstrated decreased internal knee flexion moment at initial contact (p=.012) and during weight acceptance (p=.011), decreased internal knee extension moment at toe-off (p=.007), and decreased peak knee power during mid-stance (p=.001), during push-off (p=.026) and at toe-off (p=.005) during gait compared to the SH group. (Table 1).
Figure 1. SH vs. WH transverse plane knee angles during jogging (A) and gait (B). (Solid = SH; Dashed = WH; Star indicates differences at initial contact)

These preliminary findings demonstrate that decreased involved hamstring strength often persists over two years after ACLR, as nearly half of our sample was in the WH group. These strength deficits may contribute to differences in involved limb knee mechanics, due to persistent morphological deficits from hamstring graft harvest during ACLR [4]. Previous work has illustrated that strength contributions must be increased from the lateral portion of the hamstring to prevent strength loss due to medial hamstring harvest for the graft [5]. This may contribute to altered transverse plane knee kinematics during gait and other functional tasks. Additionally, the findings of increased

involved tibial external rotation in the WH group were consistent with previous work comparing the involved limb to the uninvolved limb during gait post-ACLR, regardless of hamstring strength [6]. In addition, the current data demonstrated differences in sagittal plane knee moments and power between the SH and WH groups. This is similar to previous work demonstrating that individuals after ACLR with quadriceps strength deficits also demonstrate reduced sagittal plane knee moments during gait [7].

CONCLUSIONS
Two years after ACLR with hamstring tendon autograft, participants with deficits in involved hamstring strength show altered knee mechanics in the sagittal plane during gait and in the transverse plane during jogging compared with individuals with symmetric hamstring strength. Given these preliminary findings, future work will further examine the impact of persistent hamstring strength deficits on mechanics during functional and dynamic tasks after ACLR.

INTRODUCTION

Maltracking of the patella is a major cause of anterior knee pain and patellar instability. It is widely accepted that maltracking causes elevated patellofemoral contact pressures resulting in anterior knee pain and subsequent arthrosis [1,2]. Most patients with patellofemoral symptoms experience improvement with conservative treatment. However, a subset of these patients fail to respond to such interventions and ultimately require surgery. Surgeons can perform medialization and anteriorization of the tibial tubercle to correct abnormal patellar tracking. However, there is little experimental evidence regarding patellar kinematics after realignment procedures. As anteromedialization of the tubercle is surgically difficult, and associated with elevated risk of post-operative fracture, experimental insight will benefit the clinician [3]. The objective of this study was to evaluate the effects of medialization, anteriorization, and anteromedialization of the tibial tubercle on patellar tracking.

METHODS

A lower extremity finite element model was developed based on MRI and CT images of a female subject with no history of knee injury. 3D geometries of hard and soft tissues were digitized using Mimics v15.0 (Materialise, Leuven, Belgium). Geometries were converted into solid 8-node hexahedral elements for the patella, ligaments (ACL, MCL, LCL, and PCL), and menisci. The geometries of the femur, fibula, and tibia were constructed with an outer layer of wedge C3D6 elements for cortical bone and tetrahedral C3D4 elements for cancellous bone. Cartilage utilized tetrahedral C3D4 elements. Meshes were imported into ABAQUS 6.11-2 (SIMULIA, Providence, RI, USA). Capsules, muscles, tendons, and remaining ligaments were simulated using uniaxial truss elements.

Figure 1 – ABAQUS Knee Joint Model

The material properties of the ACL, PCL, and MCL were modeled with hyperelastic properties. Material properties of all other tissues were modeled as linear elastic with different moduli assigned to the corresponding tissue. The femur, fibula, and tibia were defined as non-deformable rigid bodies. All uniaxial truss elements were defined as incompressible. The resultant model was validated against cadaveric testing with respect to ligament strain in quasi static motion. Cadaveric specimens underwent loading conditions to simulate tibial rotation, anterior shear, and valgus/varus moments during knee flexion.

RESULTS

Patellar kinematics were plotted for comparison (Figs. 2-7). Anteriorization of the tibial tubercle decreased patellar flexion (herein defined as sagittal plane gliding with respect to femur) 27% and 63% for 1 and 2 cm anterior elevation, respectively (Fig. 2). Medialization resulted in medial tilting of the patella up to 34% in the 20-45 degree flexion range. At higher levels of knee flexion, anteromedialization increased medial tilting up to 52%. Medialization decreased patella rotation in the coronal plane to the medial side while anteriorization had no discernible effect on rotation. Patellar medial translation is affected by medialization of the tibial tuberosity (i.e. 6.26 mm medial translation in normal vs. 0.12 mm in lateralization). Proximal patellar motion, defined herein as superior translation of the patella with respect to the femur in the sagittal plane, decreased by 10% and 23% as a result of anteriorization and medialization, respectively.
Figure 2 – Patellar flexion for different simulated cases
Figure 3 – Patellar medial/lateral tilt for different simulated cases
Figure 4 – Patellar medial/lateral rotation for different simulated cases
Figure 5 – Patellar Medial/Lateral translation for different simulated cases
Figure 6 – Patellar anterior/posterior translation for different simulated cases
Figure 7 – Patellar Distal/Proximal translation for different simulated cases

DISCUSSION

This study directly compared the effects of contemporary patellofemoral joint realignment procedures. While both anteriorization and medialization can alter patellar kinematics, medialization decreased patellar lateral motion more than anteriorization or anteromedialization. An enhanced understanding of the resultant kinematics can influence clinical decision making with respect to surgical correction of patellar malalignment.

EFFECTS OF FOLLOWER LOAD AND RIB CAGE ON INTERVERTEBRAL DISC PRESSURES IN STATIC TESTS OF CADAVERIC THORACIC SPINES

INTRODUCTION

Cadaveric testing indicates that the rib cage adds significantly to thoracic stiffness. However, only a few studies have examined the in vitro mechanics of the full thoracic spine with the rib cage attached [e.g. 1, 2], or of the thoracic spine under a follower load [e.g. 3]. No study has previously done both simultaneously. Furthermore, it is not clear whether or how the rib cage might alter spinal loading. While the loading of a particular vertebral level cannot be measured directly, pressure within intervertebral discs is known to correlate strongly with compressive loading [4]. Thus, the purpose of this study was to determine whether the rib cage alters intervertebral disc pressure in static, upright loading conditions. We hypothesized that disc pressure would increase with increasing follower load, would decrease by artificially stiffening the rib cage, and would increase by the removal of the rib cage from the spine. We also assessed differences in disc pressure between two vertebral levels (T4/T5 vs T8/T9).

METHODS

Five full human cadaveric thoracic spines (T1-T12) with the rib cage intact were obtained (3 female and 2 male, mean age 65 years, range 61-71). Follower loads were applied by means of cables running lateral to the spine, connected to the spine by a rod inserted through each vertebral body with an eye nut at each end (Fig. 1). The specimen was positioned upright, and weights hung from the cables to apply follower loads. Five follower load levels were tested: 0 N, 200 N, 400 N, 600 N, and 800 N. Disc pressures were measured using pressure transducers side mounted on 1.3 mm diameter needles (Gaeltec, Isle of Skye, Scotland) inserted in the T4-T5 and the T8-T9 discs (Fig. 1).
Figure 1: Follower load was applied by bi-lateral cables running through eye nuts attached to rods through the vertebral bodies (left). Radiograph showing specimen with follower load hardware attached and pressure transducer needle insertions (arrows) in the T4-T5 and T8-T9 intervertebral discs (right).

Measurements were performed under three testing conditions: normal intact rib cage, "stiffened" rib cage, and removed rib cage (Fig. 2). Rib cage "stiffening" was achieved by attaching plates that bridged the costal cartilage and sternocostal joints for ribs 2-5.
Figure 2: Testing conditions included normal intact (left), stiffened rib cage (center), and rib cage removed (right).

The effects of follower load and testing condition on disc pressure were examined with a mixed effects model for each level measured (T4-T5 and T8-T9), adjusting for specimen as a random variable. The difference in pressure between levels (T4-T5 vs. T8-T9) was similarly examined for effects of load and testing condition. Significance was set at $\alpha = 0.05$, and analyses were performed in JMP (SAS Institute Inc., Cary, NC).

RESULTS AND DISCUSSION

Disc pressure at both T4-T5 and T8-T9 increased significantly with increasing follower load magnitude (p < 0.001, Fig. 3), from a mean of about 180 kPa with no follower load to 1,040 kPa with 800 N follower load. The testing conditions did not influence disc pressure at T8-T9, but T4-T5 pressures without ribs were about 100 kPa lower than in the intact condition (p = 0.010). There was no difference in pressure between vertebral levels with no follower load, but the difference between T4-T5 and T8-T9 increased with increasing follower load (p = 0.032).
Figure 3: Measured pressures in the T4-T5 and T8-T9 intervertebral disc under different testing conditions and follower loads from 0 to 600 N. Error bars show ±1 SD.

The pressures measured here and trends with follower load compare well to previous reports. For example, an average pressure of 1,270 kPa was reported for T8-T9 motion segments under a direct compressive load of 1,000 N [5]. Extrapolating the trend found here predicts a T8-T9 pressure of 1,155 kPa at a follower load of 1,000 N. Thus, the follower load approach used here successfully produces similar disc pressures to comparable directly applied compressive loads.

The effect of test condition was limited, but the significant pressure reduction at T4-T5 with rib cage removal was counter to our hypothesis. It is possible that removal of the ribcage produced kinematic differences that tend to reduce pressure, and this could be examined in future analyses. Furthermore, this analysis was limited to pressures in a static, upright position, and it is likely that the results are not representative of disc pressures in dynamic or kinematically different conditions.

CONCLUSIONS

A static follower load applied to a full cadaveric thoracic spine with the rib cage produces intervertebral disc pressures proportional to the follower load. Stiffening or removal of the rib cage minimally affects disc pressures.

DETERMINANTS OF APONEUROSES SHAPE CHANGE DURING MUSCLE CONTRACTION

[1] Christopher J. Arellano, [2] Nicholas J. Gidmark, [1] Nicolai Konow, and [1] Thomas J. Roberts

INTRODUCTION

Aponeuroses are sheet-like tendons that connect in series with muscle fibers. The mechanical behavior of aponeuroses differs from that of free tendons because free tendons are loaded uniaxially, while aponeuroses experience loads in more than one direction. During a shortening contraction, aponeuroses increase in both length and width [1, 2]. It has been proposed that forces generated from muscle bulging as fibers shorten and expand radially cause an increase in aponeurosis width [1], but this idea has not been tested directly.

We tested the hypothesis that changes in aponeurosis width are governed by two forces: 1) forces resulting from radial expansion (i.e. bulging) of shortening muscle fibers, and 2) the force acting along the muscle's line of action (longitudinal axis). Fiber bulging due to shortening should increase aponeurosis width, whereas increases in longitudinal force should decrease aponeurosis width, as expected for a biaxially loaded material. To test this hypothesis, we measured muscle force, aponeurosis length, and aponeurosis width during isotonic muscle contractions.

METHODS

Small (0.8-1.0 mm diameter) radiopaque markers were surgically implanted along muscle fibers and into the aponeurosis of the lateral gastrocnemius (LG) muscle of wild turkeys, *Meleagris gallopavo* (Fig. 1A-B; *n*=3). Following established *in-situ* methods [1], the muscle's distal tendon was rigidly attached to a lever of a servo-controlled motor that regulated force and length (Aurora Scientific, Inc).

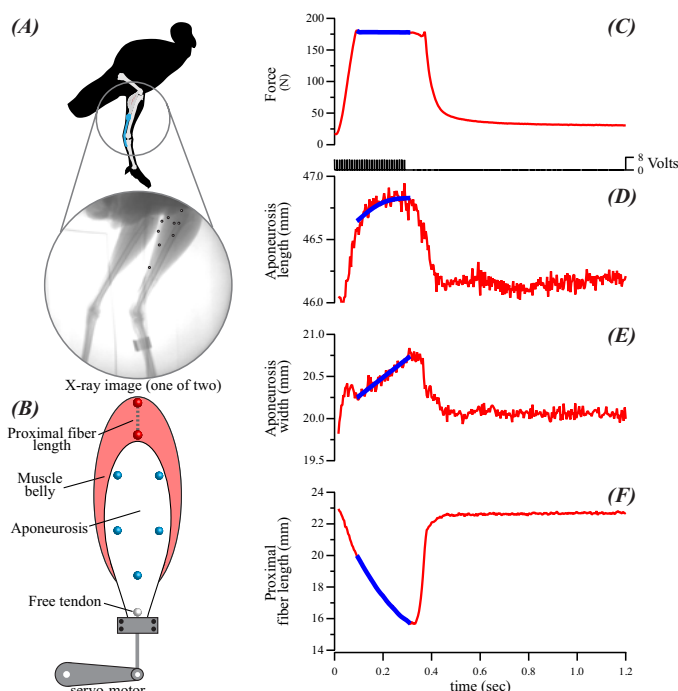
In-situ measurements of muscle force were combined with high-speed biplanar x-ray video for


Figure 1: *(A)* In combination with x-ray video, an *in-situ* preparation *(B)* allowed us to quantify the effects of muscle fiber shortening on aponeurosis width and length changes *(C-F)* during an isotonic (constant force) contraction at maximal activation. Blue lines indicate isotonic period used for analysis.

a series of isotonic contractions. For each contraction, the positions of the radiopaque markers were tracked using an established marker-based workflow (www.xromm.org). Changes in muscle fiber length, aponeurosis width, and aponeurosis longitudinal length were quantified from the 3D marker coordinates (IGOR Pro 6, Wavemetrics).

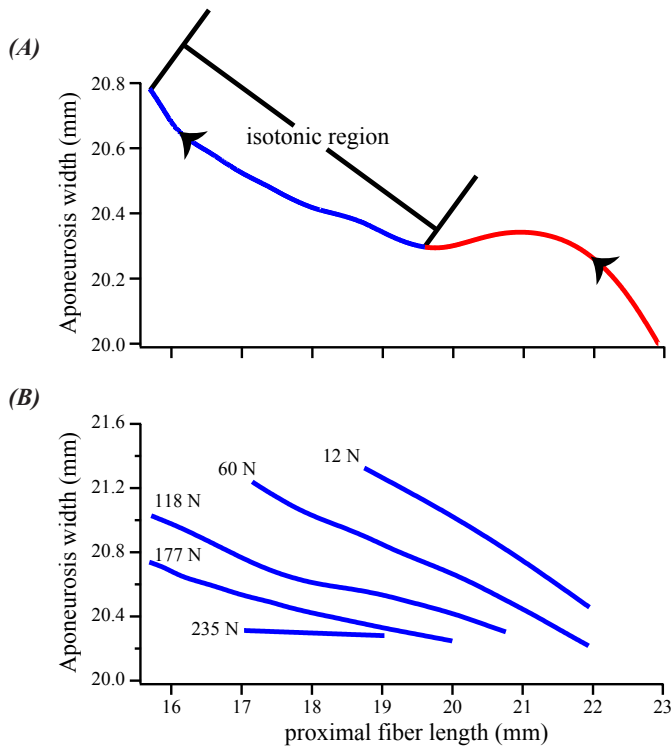
We isolated the influence of fiber shortening on aponeurosis width by plotting the two during the time when the muscle produced a constant force (Fig. 1C-F; Fig. 2). The linear slope of aponeurosis width strain versus fiber shortening strain during each contraction was calculated to give the *relative strain ratio* (Fig. 3).


Figure 2: *(A)* Data for a single contraction showing the increase in aponeurosis width as muscle fibers shorten. Arrowheads indicate direction of fiber shortening during the contraction. *(B)* For a series of contractions, increases in aponeurosis width depend on both magnitude of fiber shortening and longitudinal muscle force. Representative data from several isotonic contractions measured from a single LG muscle.

RESULTS AND DISCUSSION

Influence of muscle fiber shortening and force: During periods of constant force, aponeurosis width increased as the muscle fibers shortened (Fig. 2A). Across contractions, the amount of increase in aponeurosis width also depended on longitudinal force. At higher forces, aponeurosis width increases to a lesser extent with fiber shortening (Fig. 2B). For example, when the muscle produced 12 N of constant force, 3 mm of fiber shortening coincided with a 0.8 mm increase in aponeurosis width (Fig. 2B). At 177 N, the same amount of fiber shortening coincided with only a 0.3 mm increase in aponeurosis width.

Relative strain ratio vs. relative force: Aponeurosis width increases more for a given amount of fiber shortening at low compared to high force levels. Overall, the ratio of aponeurosis strain to fiber strain

decreased as force increased. As seen in Fig. 3, increases in aponeurosis width were negligible when the fibers shortened at the highest constant force contractions.
Figure 3: Relative strain ratio decreases as relative force increases indicating that shape change is force dependent ($n = 3$). Data are fitted with a linear least-square regression analysis (gray line). Symbols distinguish data from individual birds.

CONCLUSIONS

Our findings support our hypothesis that aponeurosis width is governed by two forces. The radial expansion of fibers associated with muscle shortening drives increases in aponeurosis width, while longitudinal forces on the aponeurosis tend to limit increases in aponeurosis width. The biaxial strain patterns in aponeuroses depends upon the relative magnitude of these two forces during a muscle contraction. These results demonstrate that muscle shape change influences the mechanical behavior of aponeuroses and highlight the mechanism for modulating aponeurosis stiffness.

REMOVABLE ANCHORING PEDICLE SCREW RESTORES PULL OUT STRENGTH IN AN OSTEOPOROTIC VERTEBRA TO NORMAL BONE VALUE - A FINITE ELEMENT ANALYSIS

M. Saeid Asadollahi, Anand K. Agarwal, Vijay K. Goel

Engineering Center for Orthopaedic Research Excellence (E-CORE)

Email: vijay.goel@utoledo.edu, web: http://www.eng.utoledo.edu/ecore/

Introduction:

Pedicle screws are the foundations in a posterior fixation system for an effective stabilization of the spinal segment(s). These have been in use for more than 25 years. However, the fixation efficacy is suboptimal in osteoporotic vertebrae. Various designs concepts have been floated to enhance their pull out strengths, but each design has some limitations [1]. Krenn et al. [1] have defined a parameter, flank overlap area – FOA, which shows the contact area between screw and bone to predict the fixation of screw in bone of poor quality. Increased FOA will lead to increase in the pullout strength. We have designed a pedicle screw whose FOA can be increased *in situ* through an anchor and which can be collapsed for ease of removal, if need arises. The biomechanics of this screw in a normal and an osteoporotic FSU are evaluated using the finite element technique.

Methods:

An experimentally validated 3-D FE model [2] of the L4-5 FSU was modified to simulate the new concept pedicle screw, a cage, and a rod posterior system. Expanding anchoring pedicle screw was drawn in solidworks with a 6mm outer diameter [3]. Wings were drawn in 30° position. An inner screw with a 2mm diameter was drawn. This screw passes through the cannula of the anchoring screw and expands the anchor *in situ*. Screw assembly was imported to Abaqus in STEP file format. Screws were put in pedicles such that expanded part was located within the cancellous bone. For anchoring screw, surfaces of the wings were tied to cancellous bone. Screw head also was tied to rod. All implants were titanium with 115GPa Young's modulus and 0.34 Poisson's ratio. Two models were prepared, one for normal cancellous bone (100MPa Young's modulus and 0.2 Poisson's ratio), and a 69.7MPa Young's modulus and 0.2 Poisson's ratio was assigned to cancellous bone for the osteoporotic bone model. Lower end plate of L5 was fully constrained and a 10 N.m moment was applied to the upper end plate of L4. For flexion and extension cases, a 400N compressive connector pre-load was applied as well. An elasto-plastic material property was considered for cancellous bone for pullout strength; 100MPa Young's modulus and 1MPa Yield stress for normal bone and 69.7MPa Young's modulus and 0.697MPa Yield stress for osteoporotic bone. For pullout strength test axial load was applied to the screw in only L4 vertebra and load-displacement curve was computed, including the yield load values in all of the model types.

Results:

Pullout strength results showed 84% improvement for anchoring screw (with wing) in osteoporotic bone compared to normal screw (without wing), and even 33% compared to normal screw in normal bone. This shows that anchoring design could successfully restore pullout strength in osteoporotic bone (Fig. 1). On an average, RoM showed 15.6% improvement in stability. RoM decreased for anchoring screw compared to normal screw in Flexion (16%), Extension (16%), LB (21%), LR (8%), Flex with pre-load (22%) and Ext with pre-load (11%) in 10N.m moment (Fig. 2). Use of anchoring screw decreased the end plate stress (73.1 MPa for anchoring screw vs 79.9MPa for normal screw), (Fig. 3).
Figure 1: Pullout strength results for anchoring screw (with wing) and normal screw (without wing) in normal and osteoporotic bone

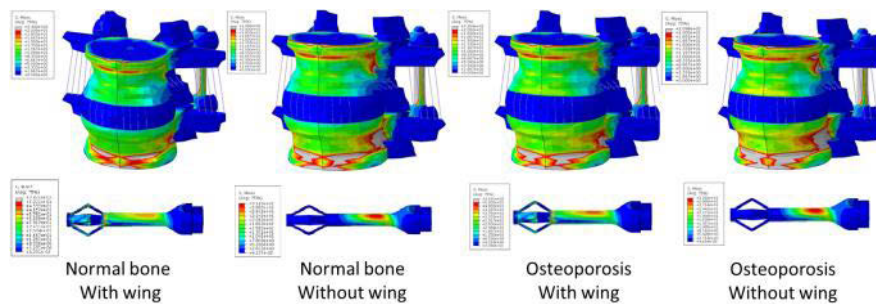
Figure 2: RoM results for L4-L5 at 10N.m for anchoring screw (with wing) and normal screw (without wing) in normal and osteoporotic bone


Figure 3: Stress distribution on whole FSU and screw in normal and osteoporotic bone

Discussion:

FE study on anchoring screw showed that increased FOA could increase the pullout strength and make it more stable in a normal and osteoporotic bone, compared to normal screw. A slight improvement in the stability of the construct was also predicted, although not significant from a cadaver test perspective.

Conclusion:

Since loosening is a challenging issue for pedicle screws, anchoring screw can improve anchorage of screw in an osteoporotic vertebra and thus may reduce loosening.

IMPROVED ROD FIXATION REDUCTION IN LOOSENING OF THE PEDICLE SCREWS DUE TO PEEK/TITANIUM SCREW CONCEPT- A FINITE ELEMENT ANALYSIS

M. Saeid Asadollahi, Manoj K. Kodigudla, Amey Kelkar, Anand K. Agarwal, Vijay K. Goel
Engineering Center for Orthopaedic Research Excellence (E-CORE)
Departments of Bioengineering and Orthopaedic Surgery, University of Toledo, Toledo, OH, USA
Email: vijay.goel@utoledo.edu, web: http://www.eng.utoledo.edu/ecore/

Introduction:

Pedicle screws are the foundations for an effective stabilization of the spinal segment(s). These have been in use for more than 25 years. However, the fixation efficacy is suboptimal in osteoporotic vertebrae. Various designs concepts have been floated to enhance their pull out strengths, but each design has some limitations [1-4]. CT-scans show a halo around the loose screw. This we feel is due to significant difference between material properties (Young's modulus) of Titanium as implant material and the bone (115GPa for Ti and 0.1GPa for cancellous bone). We propose use of Polyether ether ketone's (PEEK) pedicle screws since its Young's modulus of 3.6GPa is closer to that of bone. A pilot cyclic loading of the construct with PEEK screw showed no loosening till 100,000 cycles. However tulip at the screw head couldn't provide effective fixation between rod and screw. Thus, 5 hybrid designs of PEEK/Ti pedicle screws were compared in FE to determine an optimal design.

Methods:

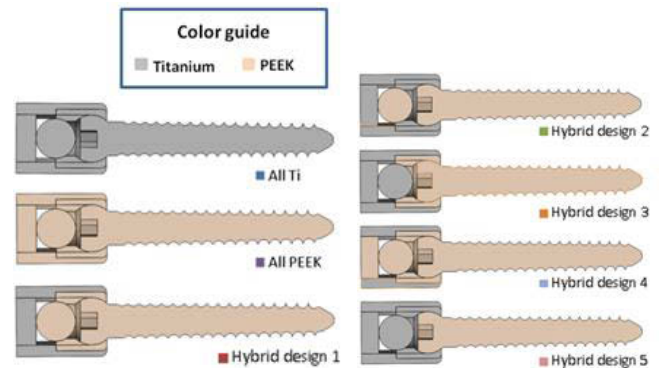
An experimentally validated 3-D FE model [5] of the L4-5 FSU was modified to simulate the new concept pedicle screw, a cage, and a rod posterior system. Five hybrid multiaxial pedicle screws consisting of PEEK and Titanium components (Fig. 1) were simulated. The results were compared to PEEK or Titanium only screw models. In the hybrid designs, tulip consisted of two parts with different materials (as shown in Fig. 1). Screws were drawn in Solidworks with a 6mm outer diameter and 40mm length.


Figure 1: Seven proposed pedicle screws with different materials for the tulip section.

Screw assembly was imported to Abaqus in STEP file format. Screws were put in pedicles and connected to each other with a 5.5 mm rod. Screw threads were tied to cancellous bone, as well as rod to tulip. Screw head also was tied to tulip and washer, as well as washer to rod. A 115GPa and 4.6GPa Young's modulus and 0.34 and 0.38 Poisson's ratio were assigned for Titanium and PEEK, respectively. For each screw, two models were prepared; one with normal cancellous bone (100MPa Young's modulus and 0.2 Poisson's ratio), and one with osteoporotic bone (69.7MPa Young's modulus and 0.2 Poisson's ratio). Lower end plate of L5 was fully constrained and a 10 N.m moment was applied to the upper end plate of L4. For flexion and extension cases, a 400N compressive connector pre-load was applied as well. Also, as a parameter for rod fixation, tulip expansion at the rod/tulip interface was computed and compared.

Results:

RoM showed comparable stability for all cases in both normal and osteoporotic bone in Flexion, Extension, Left bending and rotation,

as well as Flexion and Extension with simulated body weight (Fig. 2). All Titanium provided the most stability, though all PEEK was the least stable. Results also point out that rod's stiffness has a big effect on the stability of implanted level, while screw's stiffness doesn't affect that much. Expansion of tulip was larger than all Titanium compared to all PEEK, confirming the preliminary study showing rod loosening for all PEEK pedicle screw construct (Fig. 3). But Expansion of tulip for hybrid designs was considerably lower than all PEEK and closer to all Titanium pedicle screws.
Figure 2: RoM results for L4-L5 at 10N.m for all designs with normal bone (Left) and osteoporotic bone (Right)
Figure 3: Expansion of tulip for all Titanium, all PEEK, and hybrid design1 in Flexion with normal bone

Discussion:

Preliminary work showed that PEEK pedicle screw can successfully decrease the loosening of screw, while it is not strong in rod fixation. Combining the metal to metal interaction of rod and tulip from traditional pedicle screws, and taking the advantage of PEEK as a material with stiffness close to bone, we propose different hybrid designs that is effective in stabilizing the construct. RoM for hybrid designs showed similar stability to traditional screws (All Titanium screws) and improvement of rod fixation compared to all PEEK screws.

INTRODUCTION

In vivo investigations have identified side-to-side limb asymmetries as a biomechanical precursor to primary and secondary ACL injury.[1] Recently, novel methods of *in vitro* simulation driven by *in vivo* recorded kinematics have been developed to directly investigate knee mechanics during athletic tasks that may relate to ACL injury.[2] However, it remains unknown whether side-to-side limb asymmetries persist exhibit between contralateral specimen pairs exposed *in vitro* articulations of the knee joint driven by identical kinematics. The objective of this study was to determine if mechanical side-to-side asymmetries observed *in vivo* persist in contralateral pairs during *in vitro* simulation testing.

METHODS

In vivo kinematics were recorded for male and female drop vertical jump (DVJ) tasks using 3D motion capture. Kinematics were filtered and processed to be usable in robotic simulation.[2] 14 cadaveric lower extremities from seven unique donors were obtained from an anatomical donations program (age = 47.2 ± 8.9 years; mass = 876 ± 201 N; BMI = 29.6 ± 5.8). A six-degree-of-freedom robotic arm and custom mechanical fixtures were used to drive each specimen through male- and female-specific DVJ simulations. Throughout each task, joint forces and torques were recorded by a six-axis load cell aligned with the tibial axis and ligament strains were recorded by differential variable force transducers implanted on the ACL and MCL. For each task, data was analyzed for significance (α < 0.05) between contralateral pairs using paired t-tests.

RESULTS AND DISCUSSION

Comparison for biomechanical differences between contralateral limb pairs exhibited a lack of mechanical differences between limb sides. There were no statistically significant side-to-side differences in the peak forces or torques generated throughout each simulated task, nor were there significant differences at initial contact ($P > 0.05$). Mean forces and torques generated by each limb of a contralateral pair exhibited similar patterns of behavior throughout each simulation (Figure 1).
Figure 1: Mean anterior force (top) and abduction torque (bottom) generated at the knee by separate limbs from a contralateral pair during simulated female DVJs. These degrees of freedom represent those most associated with ACL loading and injury.

Table 1: ACL and MCL strain values as recorded throughout each simulated task.

	FEMALE DVJ		MALE DVJ	
	LEFT	**RIGHT**	**LEFT**	**RIGHT**
ACL				
IC	4.24 ± 3.28%	4.43 ± 3.22%	3.34 ± 3.28%	3.16 ± 3.53%
Peak	7.27 ± 4.14%	6.33 ± 4.70%	7.67 ± 4.48%	6.33 ± 5.34%
MCL				
IC	0.21 ± 1.69%	0.40 ± 2.96%	0.46 ± 1.77%	0.82 ± 3.15%
Peak	1.90 ± 1.71%	1.04 ± 3.25%	1.12 ± 1.62%	0.91 ± 3.15%

* indicates statistically significant difference between sides ($P < 0.05$)

Similar to the forces and torques, neither simulated task exhibited side-to-side differences in ligament strains for the ACL or MCL at peak value or initial contact (Table 1). The range of strain values observed in the MCL was statistically greater in the left limb for both the female (1.76% vs. 0.75%) and male (0.95% vs. 0.34%) DVJs. However, the clinical relevance of a 1% change in ligament strain remains unclear. This is especially true as peak ligament strain values observed during the current study were consistent with those found in previous *in vitro* simulations of drop landing tasks, which are well below reported failure magnitudes of the ACL and MCL.[3,4]

Previous literature found that removing a specimen and reinstalling it for further testing resulted in clinically significant differences.[5] That side-to-side variability between contralateral specimens expressed fewer statistical differences than repeated biomechanical testing on a single, re-potted specimen was surprising. The consistency of the present data therefore reinforced the reproducibility of our testing methodology and further validated the concept that right and left contralateral pairs can be used interchangeably in cadaveric simulations.

The present study utilized identical kinematics to simulate articulation in both limbs of a contralateral pair. *In vivo* studies would yield unique kinematics for each limb as known differences exist between dominant and non-dominant limbs, [6] but dominance information was not provided for the specimens used. However, this study was an investigation of asymmetries present in contralateral limbs for *in vitro* simulations, not asymmetries *in vivo*. Anatomical geometry was analyzed for effect on mechanical differences during simulation.

CONCLUSIONS

There was a lack of mechanical differences between limb sides in biomechanical simulations, which supported the null hypothesis that side-to-side asymmetries would not persist during *in vitro* tests. This finding suggested that contralateral knee joints are representative of each other in biomechanical tests. In future *in vitro* simulations, specification of limb side should not be a dependent variable impacting the test results. Results of this study indicated that during *in vitro* simulation, specification of left or right knee joint does not alter biomechanical outcomes during athletic movements. This finding will help to further develop protocols for robotic simulation. Contralateral limbs can be used interchangeably in cadaveric simulations. Furthermore, direct comparisons can be made between structural behaviors in one knee and between its contralateral partner for isolated conditions.

INTRODUCTION

Tibial slope has been identified as a non-modifiable risk factor for anterior cruciate ligament (ACL) injury as ACL injury patients exhibit higher tibial slopes than matched healthy controls.[1,2] Despite these findings, limited work has been done to assess how tibial slope affects ACL strain and joint loading during athletic tasks related to non-contact ACL injury. Recent advancements in robotic simulation have made it possible to create *in vitro* simulations of knee articulation using *in vivo* kinematics recorded from athletic tasks.[3] The purpose of this investigation was to quantify the influence of tibial slope on knee mechanics during an *in vitro* simulated drop vertical jump (DVJ). The primary hypothesis was that increased posterior tibial slope would be associated with increased knee loads in the frontal and sagittal planes.

METHODS

A 6-degree-of-freedom robotic manipulator articulated 18 cadaveric knees from 11 unique donors (age = 47.6 ± 7.3 years; mass = 829 ± 199 N) through simulations of kinematics recorded from *in vivo* DVJs.[3] DVJs from both male and female subjects were used to articulate separate simulations while forces and torques were recorded by a 6-axis force sensor that was aligned with the long axis of the tibia. A coordinate measuring device was used to digitize landmarks on the articulating surface of the tibial plateau at the anterior and posterior aspects of the midline in the medial tibial compartment as well as the lateral tibial compartment. These landmarks correspond with the points that were selected in previously documented methods of radiographic-based tibial slope calculation.[2] Posterior tibial slope was then calculated via these same previously published techniques using the points specified.[2] Pearson correlations were used to assess the significance of linear relationships between tibial slope and joint forces and torques. All torques are presented as internally-generated within the knee joint.

RESULTS AND DISCUSSION

During the simulated DVJs for both sexes, increased posterior tibial slope in the lateral compartment was significantly correlated with increases in peak knee adduction torque (female: r = 0.65, $P = 0.02$; male: r = 0.60, $P = 0.04$), peak knee flexion torque (female: r = 0.64, $P = 0.03$; male: r = 0.66, $P = 0.02$), and peak lateral knee force (female: r = 0.69, $P = 0.01$; male: r = 0.57, $P = 0.05$). During simulations of male DVJs, increased tibial slope in the lateral compartment corresponded with increased peak external rotation torque (r = 0.72, $P = 0.01$) and decreased peak internal rotation torque (r = -0.79, $P < 0.01$). Across sexes, increased posterior tibial plateau slope in the medial compartment was only correlated with an increase in peak knee flexion torque (male: r = 0.69, $P = 0.01$; female: r = 0.64, $P = 0.02$).

The data confirmed the *a priori* hypothesis that increased posterior tibial slope was associated with larger magnitudes of knee loading in directions that correspond with larger demand on the ACL. Previous investigations have shown that externally generated knee abduction, extension, and internal rotation torques strain the ACL or are associated with injury risk.[4-5] These degrees of freedom correspond with the internally generated torques documented in the present results. (Figure 1 & 2)
Figure 1: Significant correlations between posterior tibial slope in the lateral compartment and knee loading relative to the male DVJ.
Figure 2: Significant correlations between posterior tibial slope in the lateral compartment and knee loading relative to the female DVJ.

Published literature has traditionally shown that tibial slope in the lateral compartment is more closely related with ACL injury risk than the medial compartment.[1-2] These findings corroborate the present data, as only lateral compartment slope was correlated with the frontal and transverse plane torques most associated with altering ACL strain.

Athletes who land with greater knee extension and greater externally-generated knee extension torques increase strain on the ACL and are therefore more susceptible to injury. [6] The present data indicated that increased posterior tibial slope may drive this kind of loading in the knee as internally-generated flexion torques were moderately correlated with posterior tibial slope angle in both compartments.

It was surprising that tibial slope did not correlate with antero-posterior forces in either the male or female simulation. *In vitro* studies demonstrate that increased tibial slope generates anterior tibial translation and correspondingly anterior tibial force in the knee.[7] The present *in vitro* simulations are governed by recorded kinematics and a high-precision robotic arm.[3] Therefore, it is possible that the stiffness and precision of the manipulator only permitted minimal bone bending, despite anatomical differences, and inadvertently inhibited any antero-posterior shift that may otherwise be naturally induced with higher tibial slope.

CONCLUSIONS

Data from this investigation demonstrated that increased posterior tibial slope angle, especially in the lateral compartment, is correlated with increased knee joint loading during simulated landing in degrees of freedom that are known to place additional mechanical demand on the ACL. The mechanical data presented confirms that alterations in tibial slope angle have the potential to influence ligament loading; and thus, may be related to injury risk.

INTRODUCTION

Following anterior cruciate ligament (ACL) injury, transverse plane tibiofemoral rotation becomes underconstrained, while subsequent reconstruction leaves it overconstrained.[1,2,3] That ligament deficiency and repair cause alterations in the transverse-plane orientation of the tibiofemoral joint would suggest that the ACL is a mechanical restraint to knee motion within this plane. However, the effect of isolated internal tibial torques on knee loading has been evaluated via biomechanical testing and the current literature is conflicted..[1] The objective of this investigation was to determine the mechanical effects of transverse plane tibial rotation offsets on knee kinetics and ligament strains during *in vitro* simulations of *in vivo* kinematics recorded from athletic tasks.

METHODS

In vivo kinematics were recorded for male and female athletic tasks using 3D motion capture. *In vivo* kinematics were filtered and processed to be usable in robotic simulation.[4] 11 cadaveric lower extremities from 9 unique donors were obtained from an anatomical donations program and accepted for use in this study (age = 46.1 ± 7.7 years; mass = 861 ± 203 N). A six-degree-of-freedom robotic arm and custom mechanical fixtures were used to articulate each specimen through male- and female-specific simulations of recorded drop vertical jump (DVJ) and sidestep cutting tasks. The robotic manipulator then applied isolated ±4° rotational offsets to the tibia in the transverse plane and rearticulated the same kinematic simulations. Throughout each simulated articulation, joint forces and torques were recorded by a six-axis load cell

aligned with the long axis of the tibia and ligament strains were recorded by differential variable force transducers implanted on the ACL and MCL. Each motion condition was analyzed individually with a 3x1 ANOVA with Bonferroni post-hoc analysis was used to determine significantly different ($\alpha < 0.05$) forces, torques, and strains between each of the three simulation offset conditions.

RESULTS AND DISCUSSION

Transverse plane rotational offsets had a significant effect on peak posterior force for female motion simulations ($P < 0.01$), on peak lateral force for most simulated tasks ($P < 0.01$), and on peak anterior force, internal torque, and flexion torque for sidestep cutting tasks ($P \leq 0.01$). Rotational offsets did not influence significant differences on peak ACL strain ($P > 0.05$) or MCL strain ($P > 0.05$) for any task (Figure 1). With that consideration, during the sidestep cutting tasks, the peak magnitude of ACL strain did increase linearly as the initial orientation offset orientation shifted from and externally rotated to internally rotated position. A similar linear, but non-significant, change in peak MCL magnitude was noted. Transverse plane rotational offsets comparable to those observed in ACL deficient and reconstructed patients alter knee kinetics without significantly altering ACL strain.

Internal and external tibial rotation offsets were able to effect significant changes on the loading profile at the knee joint without effecting significant changes on ACL strains. A 4° internal offset did generally increase the peak ligament strain; however, the magnitude of this change was not great enough to be statistically significant.
Figure 1: Depiction of peak ACL and MCL strain values and standard deviations for all three rotational offset conditions for each motion task simulated. For both ligaments, there were no statistically significant differences in peak strains between offset conditions.

Kinematic changes following ACL-deficiency and ACL-reconstruction imply that the ACL has an important role in transverse plane stabilization of the knee.[2,3] However, the present results indicate that the role of the ACL in this regard is limited. Not only did magnitude changes in ACL strain lack statistical significance (1.1% mean increase for internal offset; -1.9% mean decrease for external offset), but the peak strains achieved were approximately half of previously reported failure values in the ACL.[5]

ACL reconstructions may overconstrain the joint as reconstructed patients have demonstrated 4° greater external tibial rotation during gait than healthy controls.[3] Similarly, the magnitude of mean ligament force in reconstructed ACLs can often exceed that of the native ligament tissue. [1] In the present study, ACL strain magnitudes were generally smaller in the 4° externally rotated offset condition. Therefore, it is conceivable that this external offset induced by ACL reconstructions would stress shield native ACLs from natural loading.

CONCLUSIONS

As knee degeneration is attributed to abnormal loading profiles, altered transverse plane kinematics may contribute to this. However, the data demonstrated that transverse plane perturbations on the magnitude of those applied in the present investigation likely play a limited role in ACL loading. These physiologic offsets failed to significantly influence ACL strain during tasks commonly associated with ligament loading.

SCREW PULL OUT UNDER CYCLIC FATIGUE LOADING
IN SYNTHETIC AND CADAVERIC BONE

Molly Baumann and Alan S. Litsky

Ohio State University, Columbus, OH, USA

email: Baumann.113@buckeyemail.osu.edu

INTRODUCTION

There are about 6 million bone fractures in the United States every year [1]. Fracture fixation devices are often used in these fractures to reduce recovery time and allow the injured individuals to regain their function sooner [2]. Many preliminary tests on new fracture fixation devices are done on composite bones as they are more readily available and more mechanically consistent than cadaveric bones. Zdero, et al., have studied the screw pull-out, shear stress, and energy to failure in composite bones (Sawbones®) and cadaveric bones finding that there is no statistical difference between the two bone types for these properties [3]. To our knowledge there has been no study comparing screw pull-out in cadaveric and composite bone under cyclic loading which is a clinically relevant mode of failure for these screws.

METHODS

Bicortical anterior-posterior holes were drilled 3 cm apart in both the composite and the cadaveric bones. These holes were tapped for 3.5 mm cortical bone screws which were inserted bicortically into the bone. Each test construct was loaded into a servohydraulic materials test frame [Bionix 858, MTS Corp, Eden Prairie, MN] with a custom-designed screw grip to assure axial alignment of the force and the screw. The straight pull-out force was collected under displacement control at 0.1 mm/sec. This was performed on 5 composite bones and 4 cadaveric bones.

After the straight pull-out tests were performed, the cyclic loading tests were performed. A 20 N pre-load was applied followed by a tensile cyclic load of 200 to 1000 N applied at 7 Hz for 200,000 cycles.

This approximates twelve weeks of post-fixation ambulatory activity, a clinically relevant time frame for having a fracture fixation device in place. This process was repeated on 17 cadaveric bones and 19 composite bones.

RESULTS AND DISCUSSION

The straight pull-out force results are consistent with the results of Zdero's study (Table 1); there is no statistical difference between the cadaveric and composite bones in terms of straight pull-out force ($p > 0.05$).

Table 1: Straight Pull-Out Force in Composite and Cadaveric Bone	
	Mean ± Standard Deviation
Cadaveric **n = 4**	4746 ± 553 N
Composite **n = 5**	3865 ± 571 N

The cyclic load data was collected continuously for 200,000 cycles. The displacements at initial peak load, at 100,000 cycles, and at 200,000 cycles were analyzed and used to compare failure in composite and cadaveric bone. The results are presented in Table 2 as the mean and standard deviation, in millimeters.

Table 2: Mean and Standard Deviation of Pull-Out Length in Cyclic Loading

	Entire Run	First 100,000 Cycles	Second 100,000 Cycles
Cadaveric n = 17	0.094 ± 0.030 mm	0.084 ± 0.030 mm	0.0099 ± 0.0040 mm
Sawbone n = 19	0.057 ± 0.026 mm	0.051 ± 0.027 mm	0.0065 ± 0.0043 mm

Results were compared using a two sample t-test between the cadaveric and the composite bones. The results were compared over the entire 200,000 cycles as well as the first 100,000 cycles and the last 100,000 cycles. These results are shown graphically in Figure 1. There was statistical significance for each comparison – $p = 0.001$ over the first 100,000 cycles; $p = 0.021$ for the second 100,000 cycles; $p = 0.00$ for the entire 200,000 cycles. There was also a statistical difference between the first half and the second half in terms of amount displaced. The displacement leveled off after some initial displacement.
Figure 1: Screw Pull-out in Cadaveric and Composite Bone. Screw pull-out distance is shown as mean ± standard deviation. $p < 0.05$ in all cases comparing cadaveric and composite within the same time frame.

CONCLUSIONS

This study shows that there is a statistical difference between composite and cadaveric bone screw failure under cyclic loading. This difference is not thought to be of clinical significance as the average pull-out of 0.1 mm is not enough to cause failure or clinical concern over the time frame that a device is typically implanted. This does cause some concern as to whether or not other properties of the composite bone are the same as the cadaveric bone.

Moving forward, tests can also be performed to compare the composite constructs to other bone types such as canine or equine bones. A substantial amount of veterinary research and testing is reported using the composite human bones as a model for their animal bones of interest. Studies are underway to ascertain whether these composite bones are accurate representations of the animal bones. Additional testing could also be performed with a different cyclic loading pattern (i.e. 2000 N instead of 1000 N) to determine if a different loading pattern has a different result in terms of failure.

Comparisons of Three Hip Joint Center Estimation Methods in Estimating Knee Mechanical Axis using Motion Capture

Hunter J. Bennett, Guangping Shen, Songning Zhang
Biomechanics/Sports Medicine Lab, The University of Tennessee, Knoxville, TN, USA
email: hbennet4@vols.utk.edu

INTRODUCTION

The knee mechanical axis has been utilized in assessment of frontal plane knee alignment in knee osteoarthritic and total knee replacement populations, and associated with frontal plane knee joint loading, osteoarthritic disease severity, and progression. The mechanical axis is the angle between lines drawn from the center of femoral head to the center of the tibial spines and down to the center of the talus, measured using radiographs [1]. As an alternative measure, the mechanical axis can be approximated utilizing hip joint centers and centers of the femoral epicondyles and malleoli with a three-dimensional motion capture system [2]. Although epicondylar and malleolar centers can be found more easily and accurately, determining hip joint centers is more challenging.

The three commonly used hip joint center methods are the Bell (BELL) [3], functional (FUN) [4] methods, and a method using 25% distance between the greater trochanters (TROCH) [5]. As these methods have been previously shown to differ slightly in hip joint center locations [5], it is important to determine if these differences affect knee mechanical axes estimated from motion capture data. Therefore, the purpose of this study was to validate estimations of the knee mechanical axis using the three hip joint center methods with the mechanical axis measured on a long standing lower limb radiograph.

METHODS

Seven healthy subjects (aged: 26±3 yrs, mass: 78.9±19.2 kg, height: 1.77±0.1 m) were included in this study. Each subject had a full limb anteroposterior radiograph, while standing barefoot with tibial tuberosities facing forward [1,2]. Knee mechanical axes of each limb were determined with the previously defined standardized measures using the radiograph [1, 2]. The center of the femoral head was measured through fitting a circle to the head. A nine-camera motion capture system (240Hz, Vicon) was used in determining joint centers during static and dynamic trials. Anatomical markers were placed bilaterally on the anterior superior iliac spine (ASIS), posterior superior iliac spine (PSIS), iliac crest and greater trochanter, femoral epicondyles, and malleoli. Tracking markers on rigid shells were placed on the posterior pelvis, thighs, and shanks. One static trial was captured with the subject in the same standing position used during x-ray data collection. Two functional hip trials were performed (one for each limb) using an arc motion, which included flexion/extension, ab/adduction, and circumduction of the hip [6]. All data were processed and analyzed using Visual3D (5.0, C-Motion, Inc.). The marker data were filtered using a low pass fourth-order Butterworth filter at a cutoff frequency of 8 Hz. Each anatomical marker was corrected for the diameter of the marker and its base.

Both BELL and TROCH methods were computed using the static trial. The BELL hip joint centers were determined using the CODA pelvis (determined by ASIS and PSIS) in Visual3D. The TROCH hip joint centers were determined using 25% distance between the trochanters. The FUN hip joint centers were determined based on the methods of Schwartz and Rozumalski [4] using the functional trials. All three hip joint centers were applied to the static trial and subsequently used to determine the respective knee mechanical axes.

The differences between mechanical axes measured with x-rays and the three hip joint center methods using motion capture were used for comparisons per limb. A 2×3 (limb×method) ANOVA was used to detect variations between hip joint center methods and x-ray scores.

RESULTS AND DISCUSSION

The difference scores for each hip joint center method are provided in Table 1. There was no significant limb by method interaction (p=0.54) or main effects for limb (p=0.75) or method (p=0.54). All three methods overestimated the x-ray mechanical axis by less than 2.3° on average. On an individual subject basis, mechanical axes varied as high as 4.6° and as low as 1.0° between hip joint center methods (Table 2).

Overall, the differences between x-ray and motion capture knee mechanical axes, on average, were quite small. These results assist in solidifying motion capture as a non-invasive alternative to x-ray assessments of the knee mechanical axis. The lack of significant differences between each method and the x-ray mechanical axes provides further evidence for the validity of each method in determining hip joint centers. As these methods are commonly utilized in biomechanics research, and variations in epicondylar and malleolar centers are likely to be much smaller, validation of these methods is important when considering knee frontal plane alignment using motion capture systems.

While we found no significant differences between methods for the knee mechanical axis, significant variations of the hip joint center locations have been found in the frontal plane [5]. It is possible that the hip joint center locations could still be different between methods, but they did not seem to contribute significantly to the variations of the motion capture knee mechanical axis.

A larger sample size is needed to strengthen the results. Further research is warranted to determine the validity of these methods in all three anatomical planes as well as assess their accuracy in diseased populations. Additionally, further research should focus on how each method affects lower limb biomechanics during dynamic movements.

CONCLUSIONS

Knee mechanical axes measured using motion capture were shown to differ from x-ray based mechanical axes by less than 2.3°. Comparisons of the three common hip joint center methods were shown to produce similar frontal plane knee alignment measures as the gold standard x-rays. Therefore, all three hip joint center methods seem to be valid choices when used in motion capture assessments of the frontal plane knee alignment.

EFFECT OF ROTATION ANGLE ON DISC TORSIONAL MECHANICS

Semih E. Bezci and Grace D. O'Connell

Department of Mechanical Engineering, University of California, Berkeley
email:g.oconnell@berkeley.edu

INTRODUCTION

The primary function of the intervertebral disc is to absorb and distribute large complex loads placed on the spine, including combinations of compression, tension, bending, and torsion. While extensive research has been performed on compressive mechanics of the disc, there remains a lack of information about its torsional or axial-torsional properties.

Previous studies have indicated that combinations of torsion and compression can lead to disc degeneration, back pain, and disc injuries [1, 2]. The surrounding boney architecture of the disc joint, including the facets, may absorb part of the torsional loads placed on the spine. However, these loads may also result in rim lesions, which are tears between the disc and adjacent vertebral body, and result in neovascularization and nerve ingrowth [3]. Therefore, the disc's mechanical function under torsional loading is crucial for understanding the onset and progression of disc degeneration, back pain, and injury. The objective of this study was to evaluate the torsional properties of healthy intact bovine discs under various rotation angles.

METHODS

Caudal spine sections were acquired from skeletally mature bovines from the local abattoir (~18 months). The surrounding musculature and facet joints were removed and motion segments were prepared by making a parallel cut through the vertebrae and potted in bone cement (n = 10 samples). All samples were hydrated overnight in 0.15 M saline solution and allowed to equilibrate to room temperature prior to testing. Motion segments were attached to custom-designed fixtures with screws evenly spaced 60° to ensure that samples did not slip during torsion. Samples were aligned with the center of the testing machine to ensure that the applied moment arm was similar for all samples. Then, samples were preloaded under axial compression (300 N) for 10 minutes, and 10 cycles

of axial rotation was applied at 0.05 Hz to ± 1, 2, 3, 5 or 7°. Maximum rotation angle was applied in a random order with full recovery between experiments. Axial force, axial displacement, torque, and rotation were recorded throughout the experiment.

Following mechanical testing, discs were removed from vertebral bodies using a scalpel. Disc geometry (i.e. disc height and cross sectional area) was measured using a custom-written algorithm in Matlab (Mathworks, Inc.) [4]. The disc's polar moment of inertia was calculated using Eqn. 1 [5]. Disc geometry and polar moment of inertia were used to normalize mechanical properties.

$$J = \frac{\pi(W_{AP}W_L^3 + W_{AP}^3 W_L - N_{AP}N_L^3 + N_{AP}^3 N_L)}{64} \qquad (1)$$

Torque-rotation data were analyzed using the last cycle of torsional loading. Axial displacement range (DR), torque range (TR), torsional stiffness (k_T), and energy loss (E_h) were computed. Torsional stiffness was defined as the slope of the most linear region of torque-rotation curve at rotation range of 0-1°. Energy loss was defined as the area between loading and unloading torque-rotation curve. DR was calculated by computing the difference between maximum and minimum axial displacement. Disc height (h) and the polar moment of inertia (J) were used to calculate the normalized torsional stiffness (MPa/deg), T, using Eqn. 2. Displacement range, torque range and energy dissipation were assumed to be zero under no rotation.

$$T = k_T * \frac{h}{J} \qquad (2)$$

One-way ANOVA with a Bonferroni post-hoc analysis was used to determine the effect of rotation angle on torsional mechanics. Significance was set at $p \leq 0.05$. A Pearson's correlation was performed between disc geometry and torsional mechanical

properties. Correlation results that demonstrated $|r| \geq 0.7$ and $p \leq 0.05$ were considered to be strong and significant.

RESULTS AND DISCUSSION

$$y = -0.075\ln(\theta) + 0.24$$
$$r^2 = 0.97; \ p<0.001$$
Figure 1: Normalized torsional stiffness.

There was a nonlinear decrease in the normalized torsional stiffness with rotation angle (Fig. 1). Normalized torsional stiffness appeared to plateau at approximately 0.1 MPa/^{o} for healthy discs. In contrast, there was a nonlinear increase in hysteresis, or energy loss during torsion, with rotation angle (Fig. 2). Normalizing energy loss (N-mm) by the displacement range (DR, mm) demonstrated a constant value of 28 kN for all rotations greater than 2°. The direction of rotation (i.e. + or − rotation) did not show any difference in mechanical properties, as previously reported [5].

Torsional stiffness, a solid-like property of the disc was strongly correlated with disc height, while the energy loss, a fluid-like property of the disc, was strongly correlated with disc cross-sectional area and the polar moment of inertia (Fig. 3). However, torsional stiffness was only strongly correlated with disc height at high angles of rotation. The correlation between torsional stiffness and disc height increased with rotation angle ($|r|$= 0.09, 0.39,

0.44, 0.73 and 0.71 at $\pm$ 1, 2, 3, 5 and 7°, respectively), which may suggest separate mechanisms absorbing torsional loads at very low angles versus higher angles. That is, as the disc experiences higher torsional loads, the collagen fibers become more engaged and have been shown to contribute to the highly nonlinear behavior of the disc under compression.

$$E_h = 331\theta^2 + 497\theta - 233$$
$$r^2 = 0.99; \ p<0.001$$
Figure 2: Energy loss with rotation angle.

The findings of this study demonstrate a functional difference between the elastic solid-like properties and fluid-like properties of the disc in axial rotation. The data in this study will be valuable in accurately describing the viscoelastic function of healthy discs. Further studies will examine the effect of torsional loading on healthy, degenerated, and injured human discs.

email: Bonnert2@ccf.org, web: http://mds.clevelandclinic.org/Services/BioRobotics.aspx

INTRODUCTION

In robotic testing of cadaveric knees, the reported values of measured and applied motions and loads are dependent on the defined joint coordinate system (JCS) that describes the three-dimensional translations and rotations of the tibia with respect to the femur. The International Society of Biomechanics standard for describing tibiofemoral kinematics is reported by Grood and Suntay [1], relying on the locations of anatomical landmarks to define the axes about which flexion/extension, varus/valgus and internal/external rotations occur. While calculating coordinate systems (CSs) based on anatomical landmarks allows for specimen-specific descriptions of motion, the method is not ideal for comparing kinematics of many specimens, as the representation of kinematic responses will vary with uncertainty in locating the anatomical landmarks. This variability is evident when observing the range of off-axis translations and rotations during passive flexion. Grood and Suntay recognized this issue and recommended a method for translating the tibia and femur CSs to reduce off-axis translations during passive flexion. However, off-axis rotations were not considered and no detailed methodology exists to describe how to perform the necessary transformations [1]. While the tibiofemoral joint is not truly a hinge joint, and some off-axis motion is expected, choosing a JCS that will minimize these motions might better regularize the manner in which tibiofemoral kinematics are measured, allowing for a more standardized representation that allows for tibiofemoral kinematic responses to be compared amongst specimens. Many have recognized a need for a more consistent JCS for describing tibiofemoral kinematics [1-3], but no established method has been adopted by the scientific community.

METHODS

Anatomical landmarks from six legs were digitized to define the tibiofemoral JCS reported by Grood and Suntay [1]. The JCS kinematics are reported as three translations (medial (M), posterior (P), superior (S)) and three rotations (flexion (F), valgus (V) and internal rotation (I)).

Each knee was rigidly secured to a custom testing apparatus and mounted to the Universal Musculoskeletal Simulator (UMS) [4] controlled with simVITRO^{TM} software programmed using LabVIEW software (National Instruments, Austin TX). The system is capable of manipulating in six degrees of freedom (DOF) with six-axis force-torque control applied to the tibia CS. Each knee was positioned on the UMS at a neutral position and offsets were applied so that all JCS translations and rotations were zero. Each knee underwent a passive flexion profile ramping from 0-90 degrees flexion. A constant 50N compression load was applied and all other off-axis loads were set to zero.

The representation of the JCS was optimized ($JCS_{opt}(M_{opt}, P_{opt}, S_{opt}, F_{opt}, V_{opt}, I_{opt})$) such that the tibia CS remained the same, but an offset transformation was applied to femur CS ($F_{offset}(X, Y, Z, R, P, W)$) to minimize off-axis motions during passive flexion. Eq. 1 displays the transformation chain equation.

$$T_{fem_{opt}, tib}(JCS_{opt}) = T_{fem_{opt}, fem}(F_{offset}) * T_{fem, tib}(JCS) \quad (1)$$

Tibiofemoral kinematics were considered at each 15 degree flexion increment during the passive flexion profile and optimization was performed in two parts using the LabVIEW NI_Gmath.lvlib: Constrained Nonlinear Optimization.vi. The rotational femur offsets (R, P, W) were initially set to zero and translational offsets were optimized by minimizing the cost function in Eq. 2 subject constraints ($|X, Y, Z| < 30\, mm$), where i represents each flexion angle considered.

$$f(X,Y,Z) = \sum_{i=1}^{N=7}\left(|M_{opt}(i)| + |P_{opt}(i)| + |S_{opt}(i)|\right) \qquad (2)$$

With the translational offsets calculated, the rotational offsets were optimized by minimizing the cost function in Eq. 3, subject to constraints ($|R, P, W| < 29\ degrees$).

$$f(R,P,W) = \sum_{i=1}^{N=7}\left(|(F_{opt}(i) - F(i))| + |V_{opt}(i)| + |I_{opt}(i)|\right) \ (3)$$

With the optimized femur CS, offsets were reapplied at the neutral position and the knee underwent the passive flexion profile with measured motions represented based on the optimized JCS.

RESULTS AND DISCUSSION

The optimized femur CS position differed from the original position by 5 to 34 mm and the resultant orientation differed by 1 to 18 degrees for the six specimens. Table 1 displays the femur CS offsets for all specimens.

Table 1: Femur CS Offsets

Spec. #	Femur CS Offsets					
	X (mm)	Y (mm)	Z (mm)	R (°)	P (°)	W (°)
oks_001	1.0	-21.3	8.4	-1.6	2.2	-17.2
oks_002	1.0	-6.7	5.3	0.0	7.1	4.7
oks_003	1.0	-12.0	-0.7	0.1	-2.0	-2.8
oks_004	1.0	-14.1	30.0	0.0	-0.6	1.6
oks_006	1.0	-13.2	6.8	-0.9	6.8	-2.1
oks_007	1.0	-1.3	-5.4	-0.4	8.8	3.6

Note: The X offset optimized to 1.0 mm for all specimens due to the optimization requiring a non-zero initial estimate. The default value was 1 mm and the X offset, being aligned with the medial direction, likely did not vary from the initial estimate. In the future, the initial estimate should be set to closer to zero.

Figure 1 displays an example of the off-axis translations and rotations with motions represented based on the anatomical and optimized JCSs for specimen oks-001. Off-axis motions decreased substantially with the optimized JCS. However, there are still some, which supports the notion that the tibiofemoral joint is not a true hinge.

Figure 2 displays the ranges (averages and standard deviations) of off-axis motions for the six specimens undergoing passive flexion calculated based on both JCS representations. The average motions decreased when represented with the optimized JCS for all DOF. In addition, the standard deviations decreased for all DOF, indicating that as a JCS better aligns with the mechanical axes of the tibiofemoral joint, off-axis motions will converge to values within a threshold, allowing for kinematics to be compared across specimens.
Figure 1: oks-001 Off-Axis Motions during Passive Flexion.
Figure 2: Average and Standard Deviations of the Ranges of Off-Axis Motions during passive flexion from 0-90°

A JCS optimized for minimal off-axis translations and rotations during passive flexion can facilitate a better baseline for comparing kinematics across specimens. The results in Figure 2 provides adequate evidence that our proposed methodology for optimizing the location of the femur CS decreases the off-axis motions of all knee specimens to a comparable amount during passive flexion.

INTER-SEGMENTAL SPINE JOINT REACTION FORCES DURING ACTIVITIES OF DAILY LIVING

[1,2] Scott P. Breloff and [2] Li-Shan Chou

[1]University of Oregon, Eugene, OR, USA
[2] The University of Scranton, Scranton, PA, USA
email: scott.breloff@scranton.edu

INTRODUCTION

Spine inter-segmental joint reaction forces have rarely been calculated in high resolution and it is unclear if activities of daily living will influence these inter-segmental joint reaction forces.

Direct measurements of intervertebral discs are the most accurate to fully quantify the forces associated with motions in the spine. However, these procedures are very invasive and would be difficult to apply to a large clinical population.

Therefore, the purpose of this study is to explore the feasibility of an in-vivo multi-segment spine marker set used to quantify the joint reaction forces at various spinal joints during different activities of daily living in young adults. It is hypothesized that unique ambulatory activities of daily living will effect joint reaction forces at specific joints of the spine.

METHODS

Fourteen healthy young adults (7 males/7 females; mean age: 27.9±5.9 years, mean height 176.0±27.7cm, mean mass 67.8±17.2 kg) were recruited from the university community to participate in the study.

A total of 65 markers, modified from Pruess et al. [1], were placed on the subject. Participants then preformed four different activities: level walking (W), obstacle crossing (OC), stair ascent (SA) and stair descent (SD).

A MATLAB® program was used to calculate three-dimensional peak joint reaction forces between each pair of adjoining spinal segments: Sacrum-to-Low Lumbar (SLL), Lower Lumbar-to-Upper Lumbar (LLUL), Upper Lumbar-to-Lower Thorax (UPLT), Lower Thorax-to-Lower Middle Thorax (LTLMT), Lower Middle Thorax-to-Upper Middle Thorax (LMTUMT) and Upper Middle Thorax-to-Upper Thorax (UMTUT) from heel strike (HS) to toe off (TO).

Figure 2. Definition of each task. (A) Level walking (W) – ipsilateral heel strikes, (B) Obstacle Crossing (OC) – Leading limb ipsilateral heel strikes, (C) Stair Ascent (SA) - ipsilateral heel strikes, (D) Stair Descent (SD) - ipsilateral heel strikes.
Figure 3. Free body diagram of the pelvis. Showing how lower extremity forces will be handled to continue the summation of forces into the spine.

Segmented spine joint reaction forces were calculated using the Inverse Dynamics algorithm through a rigid body linkage starting with the lower extremities. Lower extremity forces are transferred to the spine through the hip joints and pelvic segment, which includes the femur

heads, where hip joint reaction forces are well documented, and the 1st sacral vertebra [4].

$$\overrightarrow{jrf_{S1}} = m\vec{a}_{pelvisCOM} - m\vec{g}_{pelvis} - \vec{f}_{r.hip} - \vec{f}_{l.hip}$$

Equation 1. Vector form equation for reaction force at sacral joint.

$$\overrightarrow{jrf}_{proximal\ spine\ segment} = m\vec{a}_{pelvisCOM} - m\vec{g}_{pelvis} - \vec{f}_{distal\ spine\ segment}$$

Equation 2. Vector form equation for reaction force at subsequent spine segments

Peak joint reaction forces were normalized by body mass and assessed using a two-way within factor ANOVA. If the two-way interaction was non-significant, then main effects of task and spine level were examined. In all cases, adjusted p-values (Grennhouse-Geisser) were used to evaluate within subject effect ($p < 0.05$).

RESULTS AND DISCUSSION

The task * spine level interaction for the anterior-posterior segmental force peaks was non-significant ($p = 0.429$). Similarly the anterior-posterior main effects for task ($p = 0.628$) and spine level ($p = 0.952$) were also non-significant. The medial-lateral task * spine level joint reaction force interaction was non-significant ($p = 0.999$). Likewise the main effects for both task ($p = 0.536$) and spine level ($p = 0.772$) in relation to the medial-lateral force peaks were not-significant.

The two way interaction for vertical inter-segmental force peaks of task and spine level was not significant ($p = 0.842$). However, there was a significant main effect for task ($p < 0.001$). Post-hoc pairwise comparisons of the task marginal means showed the level walking ($M=8.05\pm3.19$ N/kg) task had significantly smaller peak reaction forces than the stair decent ($M=12.12\pm1.32$ N/kg) task ($p = 0.007$).
Figure 3. Vertical peak non-normalized spine joint reaction forces for spine level and multiple tasks.

Additionally, it should be noted the obstacle crossing ($M=9.43\pm0.76$ N/kg) task was trending to have larger reaction forces than level waking, ($p = 0.009$).

This study sought to compare peak spine joint reaction forces of a multi-segmented spine marker set during four distinct ambulatory activities of daily living. All of the interaction tests were non-significant, therefore only a general discussion relating how the factor (task or spine level) would influence the observed peak force is appropriate.

All tasks were completed at the subjects own comfortable pace, which generally indicates an average walking speed of approximately 1.36 m/s for young adults [2]. It has been shown a slow jog, or speeds greater than 2.0 m/s are required before changes in vertical ground reaction forces are observed [3]. Thus the self-selected speeds of the individuals in this study might not have induced changes in the ground reaction force which in turn would have induced a change in the peak spine joint reaction forces.

CONCLUSIONS

Though the hypothesis was not fully supported, the results found the main effect of peak reactions forces in the segmental spine can be influence by task. This was a new observation from previous studies and is therefore encouraging. Nevertheless, further validation is important with the inclusion of a larger and more diverse sample set and should include testing with multiple speeds. One future direction for application of this model would to investigate sports applications which involve more inter-trunk motion than walking based tasks

FRONTAL PLANE TRUNK AND KNEE ANGLES DURING UNILATERAL LANDING TASKS ONE YEAR AFTER ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION

[1]Matthew S. Briggs, [1]Joshua T. Hoffman, [1]Samuel C. Wordeman, [1]Laura C. Schmitt, [2]Mark V. Paterno, [1]Timothy E. Hewett

email: Matt.Briggs@osumc.edu

INTRODUCTION

Increased frontal plane trunk and knee motion are prospectively validated predictors of anterior cruciate ligament (ACL) injury.[1-3] In addition, risk of second injury after ACL reconstruction (ACLR), to either the involved or uninvolved knee, is dramatically higher than risk of initial injury.[4,5] However, previous investigation into trunk control and stability after ACLR during dynamic tasks is limited. The objectives of this study were to identify asymmetries and quantify relationships between frontal plane trunk and knee angles in patients following ACLR during two single-leg landing tasks.

METHODS

Sixteen patients [11 males; 5 females; mean (SD) age: 20(9)years] 12 months following ACLR [53(2)weeks] were included in this study. Fifty-five retro-reflective markers were adhered to the skin at anatomical and tracking landmarks. Three-dimensional motion capture data was collected bilaterally for 3 successful single leg drop (SLD) and cross over drop (COD) landings off a 31cm tall box. During the SLD, patients balanced on one leg, dropped from the box and landed on the same limb. For the COD, patients stood on one leg and dropped forward at a diagonal angle off the box towards their stance limb, but landed on their opposite limb. Frontal plane trunk and knee angles were analyzed for the first 100 milliseconds after initial contact for each task. Discrete variables were taken from each subject's individual data and time series averages were calculated on a time-point by time-point basis. Statistical analyses included paired t-tests and Pearson's correlation coefficients to identify asymmetries between the involved and uninvolved limbs, and the relationships between trunk and knee angles, respectively.

RESULTS AND DISCUSSION

During the COD, patients demonstrated greater peak frontal plane trunk angles away from the stance limb [8.70°(4.02), 5.09°(5.19); p=0.04] and greater total frontal plane trunk excursion [5.20°(2.28), 4.07°(1.63); p=0.03] in the involved compared to uninvolved limb (Fig. 1A). Significant differences in frontal trunk motion between limbs were not observed for the SLD. Significant differences were not observed in frontal plane knee angles between limbs for either task or frontal plane trunk motion between the tasks. However, the involved limb, during COD compared to SLD, had greater knee adduction at initial contact [1.46°(2.22), 0.13°(2.33); p=0.003], greater peak knee adduction angles [3.58°(1.96), 2.48°(2.47); p=0.02], and decreased knee abduction angles [0.12°(2.38), -1.29°(2.29); p=0.001] during landing (Fig. 1B). During the COD, total frontal plane trunk excursion negatively correlated with peak knee adduction (r=-0.58; p=0.02) and positively correlated with peak knee abduction angle (r=0.62; p=0.01) on the involved but not the uninvolved lower extremity. We did not observe any significant relationships between frontal plane trunk displacement and frontal plane knee motion during the SLD task.
Figure 1: A) Mean Frontal Plane Trunk Angles during the first 500 milliseconds of landing; B) Mean Frontal Plane Knee Angles during the first 500 milliseconds of landing. Cross Over Drop (COD); Single Leg Drop (SLD).

To the authors' knowledge, this is the first study to evaluate the relationships between frontal plane trunk and knee motion following ACLR. These findings are somewhat contradictory to other reports of frontal plane trunk motion and ACL injury risk in healthy controls. Jamison et al.[6] demonstrated that greater lateral trunk motion toward the stance limb was associated with greater knee valgus during a cutting task in healthy controls. While Frank et al. [7] did not demonstrate a relationship between frontal plane trunk displacement and frontal plane knee joint loading during a side-cutting task in healthy controls.

Differences between this study and previous investigations may be attributed to our use of ACLR patients and the difference between landing and cutting tasks. Limitations of this study include a small sample size and limited numbers of female patients, who have been shown to be at a higher risk of initial and second ACL injury.[4,5] Further, the

differences noted in the frontal plane knee angles between the COD and SLD tasks are small (1-2°) and may be attributed to measurement error associated with three dimensional motion analysis.[8] These statistical differences may not be clinically relevant.

Further evaluation of kinetics and kinematics of the lower extremity, including the hip and ankle, will provide additional insight into joint loading patterns during SLD and COD. Finally, comparison of these results to a healthy population will provide valuable insights into frontal plane trunk and knee mechanics and potentially secondary ACL injury risk.

CONCLUSIONS

One year after ACLR, patients demonstrate asymmetries in frontal plane trunk movement during a COD task. Moreover, increased knee abduction angles on the involved limb positively correlate with total frontal plane trunk excursion. Understanding the relationships between frontal plane trunk and knee movement after ACLR may assist in designing interventions focused on minimization of the risk of second injury.

KNEE ADDUCTION MOMENT IMPULSE AT BASELINE PREDICTS CHANGE IN MEDIAL TIBIAL CARTIALGE VOLUME OVER 2.5 YEARS IN KNEE OSTEOARTHRITIS

INTRODUCTION

Osteoarthritis (OA) is the most debilitating musculoskeletal condition among older adults [1]. Mechanical factors, particularly increased medial knee joint loads, play a crucial role in the structural progression of knee OA [2–4]. The external knee adduction moment (KAM) is a valid and reliable estimate of the mechanical load incurred by the medial knee compartment, relative to the lateral, during weight-bearing activities such as walking [5]. The impulse of the KAM waveform accounts for both the magnitude and the duration of medial loading during stance [6].

In cross-sectional work, the KAM impulse correlated with the severity of medial tibial cartilage defects noted on magnetic resonance imaging (MRI) scans [7] and discriminated between radiographic knee OA severities [6,8]. Longitudinal studies implicate the KAM in the progression of knee OA [2–4]. For example, higher baseline KAM impulse was associated with greater loss of medial tibial cartilage volume over 12 months in individuals with knee OA [2]. While the KAM impulse appears to be an important marker of structural disease progression [2,6–8], there is a paucity of evidence supporting a causal link between these variables [9]. Thus, longitudinal investigations with longer follow-up times are required to corroborate and clarify the existing relationships between the KAM impulse and the progression of knee OA.

The purpose of this study was to evaluate whether greater KAM impulse during walking at baseline would be associated with greater loss of medial tibial cartilage volume over 2.5 years in individuals with knee OA.

METHODS

A subset of data (n=36/53) from a cohort of older adults with knee OA was used for interim analysis. Participants were diagnosed with symptomatic and radiographic knee OA according to the criteria set by the American College of Rheumatology and the Kellgren-Lawrence classification, respectively.

At baseline and follow-up, MRI scans of the knee were acquired with a 1.0 Tesla peripheral scanner (General Electric Healthcare, USA) using a coronal fat-saturated spoiled gradient recalled acquisition in the steady state. Medial tibial cartilage volume was segmented from the scans using a highly automated, atlas-based method [10].

At baseline, barefoot walking trials at a self-selected speed were collected with a motion capture system (3 Optotrak Certus banks, Northern Digital Inc., ON, Canada) and synchronized force plate (OR6-7-1000, AMTI, MA, USA). Marker and force plate data were filtered using a 2nd order low-pass Butterworth filter (6 Hz cut-off). A validated musculoskeletal model (three-dimensional floating axis coordinate system) and inverse dynamics were used to obtain external KAM waveforms (Visual 3D, C-Motion Inc., MD, USA). For each participant, the impulse of the stance phase was calculated for 5 non-normalized KAM waveforms using trapezoidal integration, and then averaged.

Multiple linear regression assessed the relationship of baseline KAM impulse and change in medial tibial cartilage volume over 2.5 years. Regression analyses were performed unadjusted, and adjusted for the covariates sex, age and body mass index [11–13]. The independent variables were entered simultaneously in the multivariate regression equation. The level of statistical significance was set at $\alpha=0.05$.

RESULTS AND DISCUSSION

At baseline, the sample (30 women; 6 men) had a mean (SD) age of 61.1 (6.7) years, body mass index of 28.0 (5.1) kg/m^2, knee axis angle of 182.1 (3.9) degrees (>180 degrees = valgus knee alignment), Kellgren-Lawrence grade II=12; III=12; IV=12, and medial tibial cartilage volume 1657 (397) mm^3. The mean follow-up time was of 2.59 (0.53) years. Compared to baseline, the mean medial tibial cartilage volume at follow-up was reduced to 1543 (402) mm^3 (P=0.002).

Both the unadjusted results (Fig. 1) and adjusted results showed that a higher KAM impulse at baseline was independently associated with significantly greater loss of medial tibial cartilage volume over 2.5 years (Table 1). Both the univariate and multivariate regression models significantly explained part of the variance in medial tibial cartilage volume change over 2.5 years (Table 1).
Figure 1: Correlation of unadjusted baseline KAM impulse and change in medial tibial cartilage volume over 2.5 years.

CONCLUSIONS

In this interim analysis, higher KAM impulse at baseline predicted the loss of medial tibial cartilage volume over 2.5 years in individuals with knee OA. These findings corroborate previous work [2]. Analysis of the whole sample (n=53), including knee axis angle and baseline medial tibial cartilage volume as covariates, may provide more in-depth insight into the relationship between baseline KAM impulse and change in medial tibial cartilage volume over time. Since knee loading parameters are modifiable, tailored treatment strategies may potentially slow OA disease progression.

THE EFFECT OF DIFFERENT RANGES OF MOTION ON LOCAL DYNAMIC STABILITY OF THE ELBOW DURING UNLOADED REPETITIVE FLEXION-EXTENSION MOVEMENTS

Kelsey Gsell[1], Shawn Beaudette[1], Ryan Graham[2], and Stephen Brown[1]

[1]Department of Human Health and Nutritional Sciences, University of Guelph, Guelph, ON, CAN
[2] School of Physical & Health Education, Nipissing University, North Bay, ON, CAN
email: kgsell@uoguelph.ca

INTRODUCTION

Local dynamic stability (LDS) is represented by the equilibrium of a movement trajectory about an intended path [1, 2]. When confronted with small kinematic disturbances or neuromuscular control errors, a stable system will remain close or return to the original intended trajectory, whereas an unstable system will diverge away from this stable norm [1, 2]. LDS is controlled primarily by active muscles, and is known to be influenced by factors such as movement speed and inertial load [1, 3]. Other factors such as muscle length, the length of the target trajectory, and the resistance of passive tissues through ranges of motion (ROM) may also influence LDS. This study was designed to examine the effect of ROM, which impacts each of the aforementioned factors, on LDS of the elbow. It was expected that movements over a smaller ROM and at end-ROMs would be move stable due to a smaller distance over which a movement could deviate from its intended trajectory and due to increased proprioceptive input at end-ROM.

METHODS

Sixteen heathy, right-hand dominant participants took part in the study (eight male and eight female; mean age ($\pm$ SE) = 21.8 $\pm$ 0.44 years, height = 1.75 $\pm$ 0.024 m, = mass = 69.8 $\pm$ 2.21 kg). Participants performed 30 unloaded, repetitive flexion-extension movements of the elbow with varying 1) angular displacement magnitudes: 40° and 80°; 2) locations of ROM: mid-range, flexion end-range, and extension end-range; and 3) rotated position of the forearm: pronated and supinated. Movements were paced to the beat of a metronome, with the 40° at twice the speed of the 80° trials to ensure constant velocity between conditions.
Figure 1: Pictures of the custom built apparatus (A) used to control ROM magnitude and ROM location during repetitive flexion-extension of the elbow. A participant is shown using the apparatus (B) with the kinematic and sEMG electrodes placed on the right arm.

The experimental set up can be seen in Figure 1, with surface EMG (sEMG) collected at 2048 Hz from the biceps brachii (BB), the lateral head of the triceps brachii (TB), and the brachioradialis (BR) of the right arm. Optoelectronic kinematic data were collected at 64 Hz from 4 markers placed at the approximated glenoid joint centre of the shoulder, the lateral epicondyle of the elbow, and the medial and lateral wrist at the level of the carpal bones. LDS was calculated using a finite time Lyapunov analysis of angular elbow flexion-extension kinematic data [1, 3]. EMG-based muscle activation and co-contraction data were also included to examine possible mechanisms of stabilization. The statistical analyses were a three-way repeated measures ANOVA with ROM magnitude, ROM location, and forearm rotated position as independent variables and LDS, individual muscle activation, mean flexor activation (FA_{mean}), and co-contraction index (CCI) as dependant variables. Post-hoc analyses were performed using a Tukey's adjustment (α=0.05).

RESULTS AND DISCUSSION

There were no changes in LDS with any movement condition; however there were significant main effects of ROM location on muscle activation, quantified individually (Figure 2) (BB: $p<0.0001$, BR: $p<0.0001$, and TR: $p=0.0004$), and as mean elbow flexor activation ($p<0.0001$), as well as the ratio of co-contraction (CCI) between the elbow flexor and extensor muscles ($p<0.0001$) (Figure 2).

Flexion end-ROM demonstrated the highest magnitudes of flexor muscle activation while extension end-ROM demonstrated the lowest. This is explained as BB activation increased significantly from extension end-range to mid-range to flexion end-ROM, with BR activation significantly higher only at flexion end-ROM. TR activation was also significantly higher in flexion end-ROM, generating a balanced co-contraction as can be seen by a CCI close to 50. As CCI is a ratio of the activation of the extensors to the sum of the average flexors and extensors, numbers larger than 50 demonstrate greater extensor activation than flexor activation and vice versa. With both an increase in muscle activation and a balanced co-contraction, movements at flexion end-ROM experience a potential stiffening strategy. Conversely, while extension end range had the highest CCI this simply indicates that the flexors were less active than the extensors, and with a low level of muscle activation, any stiffening effect of co-contraction is limited. These differences in muscle activation patterns likely served to help maintain LDS of the elbow at consistent levels during the different ROM conditions. This has been seen previously, where LDS was maintained at consistent levels in response to decreases in the stability of the external environment while lumbar spine muscle stiffness increased [4].

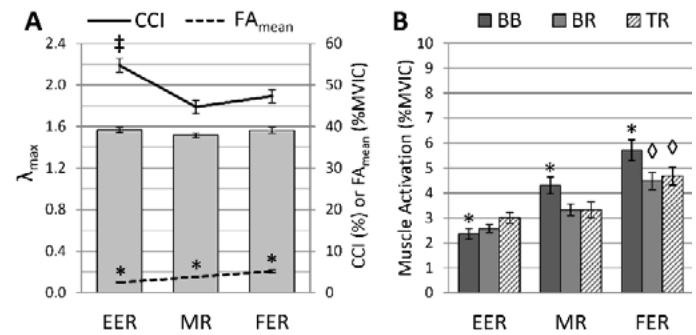
It should be noted that movements over 40° and 80° demonstrated no differences in muscle activation along with no differences in LDS. This may simply be due to a lack of difference in the overall challenge of performing this movement over these two different ranges of motion.


Figure 2: (A) Local dynamic stability (λ_{max}), average elbow flexor activation (FA_{mean}), and co-contraction indices (CCI), as well as individual muscle activation (B) during repetitive flexion-extension movements of the elbow through different ROM locations. * indicates significant differences between all levels within a condition; ‡ indicates EER is greater than each of MR and FER; ◊ indicates FER is greater than each of MR and EER. Data are shown as means ± SEM. EER = extension end-ROM; MR = mid-ROM; FER = flexion end-ROM.

CONCLUSIONS

LDS of the elbow was maintained at consistent levels through varying magnitudes of ROM, locations of ROM, as well as forearm rotated position. Flexion end-ROM demonstrated the highest magnitudes of flexor activation of any ROM location while extension end-ROM demonstrated the lowest. As flexion end-ROM also demonstrated the most balanced level of co-contraction this suggests a potential stiffening strategy was employed. These differences in muscle activation patterns, while driven by mechanical and physiological factors, likely act as a contributing mechanism to enable the maintenance of LDS. In the future it would be beneficial to assess the effect of ROM on more challenging (loaded) movements, as well as to fully consider the interplay of the active (muscle) and passive tissues on LDS.

INVESTIGATING THE RELATIONSHIP BETWEEN HIP POSITION AND LUMBAR SPINE RANGE OF MOTION

[1] Grace O. Glofcheskie, [1] Kaitlyn S. Bertram and [1] Stephen H.M. Brown

[1] University of Guelph, Guelph, ON, Canada
email: shmbrown@uoguelph.ca

INTRODUCTION

There is a clear anatomical relationship between the spine and the hip joint, as they are connected via the pelvis. However, the relationship between hip position and lumbar spine range of motion (ROM) is not yet well understood. The top of the sacrum forms the base for the L5 vertebrae, therefore changing the position of the pelvis will also affect the movement of the lower lumbar spine. Relaxed standing normally causes the pelvis to rotate slightly posteriorly, resulting in erect posture without active muscular control due to the strong iliofemoral ligaments on the anterior hip joint resisting further rotation [1]. The resting position (mechanical neutral zone [2]) of the hip is defined as the position where the capsule and ligaments surrounding the joint are in their most slack position, therefore resulting in the least resistance to movement. In the hip joint, this occurs at approximately 30° of both flexion and abduction, with slight external rotation [3]. This suggests that changing the hip position from standing neutral posture, to positions such as abduction and external rotation, has the potential to alter the relationship between the hip joint, pelvis and lumbar spine. The purpose of this study was to determine the relationship between various hip positions and the ROM exhibited in the lumbar spine. It was hypothesized that adopting an abducted and externally rotated hip position would lead to the greatest increase of ROM at the lumbar spine, while abduction alone and external rotation alone would lead to less of an increase compared to a neutral hip position.

METHODS

Healthy young adult participants (n=12, 6 male and 6 female) were recruited from the university population and exhibited no current or history of hip or back pain or associated injuries. All participants demonstrated at least 120° of active hip flexion, which has been stated in previous literature as the minimum degree of flexion for healthy ROM [4]. An active marker motion capture system (Optotrak™ Northern Digital Inc., Ontario, Canada) was used to record body segment and joint movement. Markers were placed in rigid body clusters on the lumbar spine at vertebral levels T12 and S1, on the lateral aspect of the left thigh and lateral aspect of the left shank. Rigid bodies located on the leg were placed at 50% of segment length. Electromyography (EMG) was recorded to measure muscle activity bilaterally of the thoracic (T9) and lumbar (L3) erector spinae, gluteus medius and biceps femoris (AMT-8[TM] Bortec Biomedical Ltd., Alberta, Canada). Maximum voluntary contractions were performed according to standard procedure in previous EMG literature [5,6]. Participants performed full trunk flexion and extension, trunk lateral bend and trunk axial twist ranges of motion in four different hip positions. Neutral hip position was self-selected by the participant, with the instruction to stand in a comfortable neutral width stance and feet facing forward. Hip abduction was defined as twice the distance of their self-selected neutral width stance. Hip external rotation was defined as the participant's forefoot on a 45° angle outward, while the heel remained in the same position. The fourth position was combined hip abduction and external rotation (as described above). Participants were instructed to go to their end trunk range of motion, while keeping their hips facing forward. Three trials of each movement were completed in each of the four hip positions. The dependent variables (3D lumbar spine motion, EMG amplitudes) were compared between all hip positions within each task. A significance level of $\alpha < 0.05$ was used for all statistical comparisons.

RESULTS AND DISCUSSION

Lumbar spine angles were normalized to the average maximum ROM angle each individual achieved in the neutral hip position. Therefore, a value of 1 is indicative of no change in ROM from the neutral position, as the average over three trials would be equal to the average ROM in neutral hip position. Significant increases in lumbar spine flexion were observed in the abducted and combined abducted and externally rotated hip positions when compared to neutral; however no differences were observed between abduction, external rotation, and combined abduction and external rotation (Figure 1). Significant increases in lumbar spine extension were observed when the hips were positioned in abduction, and combined abduction and external rotation when compared to neutral hip position. In lumbar spine flexion and lumbar spine extension, no significant differences were noted between abduction alone and combined abduction and external rotation, which suggests that either hip position increases lumbar spine ROM when moving in the sagittal plane.
Figure 1: Normalized lumbar spine flexion and lumbar spine extension ranges of motion in each hip position: neutral, abduction, external rotation and combined abduction and external rotation.

No significant differences were observed during lumbar spine lateral bend (Figure 2). This suggests that potentially during neutral stance, the hip joint is in the best position for the greatest amount of ROM when moving in the frontal plane. Significant increases in lumbar spine axial twist were observed

when the hips were positioned in abduction, and combined abduction and external rotation compared to neutral (Figure 2). The increases of ROM demonstrated during abduction were also significantly greater than external rotation, suggesting that abduction is the best hip position for movements in the transverse plane for the greatest increase in lumbar spine ROM.
Figure 2: Normalized lumbar spine lateral bend and lumbar spine axial twist ranges of motion in each hip position: neutral, abduction, external rotation and combined abduction and external rotation.

CONCLUSIONS

Altering hip position is one potential way to increase ROM in the lumbar spine. Increases in lumbar spine ROM were observed when the hips were positioned in abduction, and combined abduction and external rotation during lumbar spine flexion, extension, and axial twist. This suggests these hip positions increase ROM the most during sagittal plane and transverse plane movements.

A BIOMECHANICAL MECHANISM TO EXPLAIN HIGH INCIDENCE OF THORACOLUMBAR VERTEBRAL FRACTURES

[1,2]Alexander G. Bruno, [1,2,3]Mary L. Bouxsein, and [2,3]Dennis E. Anderson

INTRODUCTION

Vertebral fractures occur most frequently in the thoracolumbar region of the spine (T11-L1), but the mechanisms underlying this site-specific prevalence are not known [1]. One possibility is that this region of the spine experiences relatively high loading, increasing the risk of fracture. To investigate this possibility, we have developed an anatomically detailed and fully articulated musculoskeletal model of the full thoracolumbar spine and rib cage to estimate patterns of spine loading for a large variety of daily activities. Loading estimates from this model frequently produce a peak in compressive loading around T11-L1, supporting the idea that the high prevalence of vertebral fracture in this region may be due to high compressive loads *in vivo*. The goal of this study was to examine the mechanics of spinal loading more closely to explain why the model predicts high loads in this region.

METHODS

We used an anatomically detailed model of the fully articulated thoracolumbar spine and rib cage (implemented in OpenSim) to predict trunk muscle forces and spine loading for three activities: 1) neutral standing, 2) trunk flexion at 70°, and 3) reaching forward to open a window (40 N downward force applied to each hand). The model was previously validated against *in vivo* measures of intradiscal pressure, vertebral loading from telemetrized implants, and trunk muscle activity from EMG. The model uses a static optimization routine to predict the pattern of muscle forces required to balance moments from body weight and any externally applied loads, while at the same time minimizing the sum of cubed muscle activations (equivalent to maximizing muscle endurance).

To investigate vertebral compressive loading patterns predicted by the model, and to understand why the model generally predicts high thoracolumbar spinal compression, we calculated the flexion/extension moments applied to each vertebral body by 1) the body weight (bm) associated with that vertebra, 2) the adjacent intervertebral joint (ivj) reaction forces, and 3) the adjacent left and right costovertebral joint (cv) reaction forces and moments (only in the thoracic spine) (Fig. 1). These moments must be balanced by the pull of muscles directly attached to that vertebra.
$$\Sigma M = M_{cv} + r_{cv} \, x \, F_{cv} + r_{ivj} \, x \, F_{ivj} + r_{bm} \, x \, F_{bm} = M_{muscles}$$

Figure 1: The intervertebral joints are modeled as ball joints and the costovertebral joints are modeled as pin joints. The sum of flexion/extension moments was computed about the inferior intervertebral joint of each vertebra.

RESULTS AND DISCUSSION

For all three activities, our musculoskeletal spine model predicted a peak in thoracolumbar compressive loading (T11/T12) (Fig. 2). The erector

spinae and multifidus were the primary muscle groups activated during these activities, with the other trunk muscle groups generally producing less than 50N of tension. The multifidus activated strongly in the thoracolumbar region of the spine, contributing to the peak in thoracolumbar vertebral compressive loading (Fig. 3). Results were similar for all activities, and are only shown for neutral standing.
Figure 2: Vertebral compressive loading during neutral standing.
Figure 3: The contribution of body weight and muscle tension to vertebral compression during neutral standing.

The moments applied to each vertebra during neutral standing are shown in Figure 4. It appears that the reason for strong activation of the multifidus, and thus high thoracolumbar compressive loads, is the requirement that the muscles apply extension moments to T11, but flexion moments to T12 and L1 (dashed line in Fig. 4). The only way for this requirement to be met is for the multifidus muscle group to activate. The multifidus consists of short fascicles posterior to the spine that connect adjacent vertebrae. When contracting, the multifidus will pull down and apply an extension moment to its superior vertebra (ie: T11), and pull up and apply a flexion moment to its inferior vertebra (ie: T12). The reason for this

different requirement is that at T11 the muscles must balance flexion moments applied by the costovertebral joint reaction forces, whereas at T12 and L1 the dominant moments the muscles must balance are extension moments applied by the intervertebral joint reaction forces. The pattern of moments produced by the intervertebral joint reaction forces are likely driven by the curvature of the spine and the moment arms between adjacent intervertebral joints. Interestingly, this analysis also showed that the moments from the costovertebral and intervertebral joint reaction forces largely balanced each other in the upper thoracic spine (T1 to T6), resulting in low muscle loads and spine compression, illustrating a unique mechanism for thoracic load sharing between the ribs and spine.
Figure 4: Moments applied to each vertebra by body mass, and the costovertebral (CV) and intervertebral joint (IVJ) reaction forces, all of which must be balanced by equal and opposite moments generated by the muscles (dashed line). Negative values are flexion moments.

CONCLUSIONS

Using a unique model that accounts for the complex anatomy of the spine and rib cage, we demonstrated that the multifidus muscle group applies large compressive forces to the thoracolumbar vertebrae (T11-L1) in an effort to balance competing moments applied by the intervertebral and costovertebral joint reactions. The resulting high loading could contribute to the high prevalence of vertebral fractures in this region.

BIOMECHANICAL EVALUATION OF PATELLAR FRACTURE RISK AFTER TENDON GRAFT HARVEST FOR CRUCIATE LIGAMENT RECONSTRUCTION: A FINITE ELEMENT STUDY

[1] Robert E. Carey, [1] Liying Zheng, [1]Tom H. Gale, [2]Christopher D. Harner, [1]Xudong Zhang

INTRODUCTION

Anterior cruciate ligament reconstruction is one of the most common orthopaedic procedures performed in the United States. Two common types of grafts are quadriceps tendon and bone-patellar tendon-bone (BPTB) autografts. They both require bone block harvest of the patella, which may weaken the latter and lead to increased risk of fracture – this in fact has been reported as one of the major complications following ACL reconstruction. Previous cadaveric biomechanical studies of patellar fracture risk were limited, yielding inconsistent or incomplete guidelines for safe patellar bone harvest [1,2]. In this study, we applied a finite element (FE) modeling approach to biomechanically evaluate the effect of the shape, size and location of the patellar graft harvest on the risk of patellar fracture.

METHODS

A 3D model of a patella was developed from an MRI of the healthy right leg of a single subject. The location of the patellar tendon, patellar ligament and patellar cartilage were also determined from the MRI. Material properties were taken from the literature [3]. Non-Uniform Rational B-Splines (NURB) surface models were generated on the 3D geometric models of the patella bones with different bone block removals and automatically meshed to approximately 100,000 tetrahedral elements. The FE models were set to simulate a patella-injury-prone knee flexion posture (90-degree squat). The quadriceps tendon force (2700 N; 5 x BW) was applied at the location of quadriceps tendon insertion sites in both the proximal and distal locations of the patella. This value was within the range of bipedal squat forces in the literature (4.8-6.9 x BW) [4,5].
Figure 1: Patellar bone block cuts: a) regular cuboid cut; b) through g) alternative cuts.

Based on a cut commonly used for graft harvest – cuboid, extending to the transverse midline with a proximal depth of 10 cm (Fig. 1a) – we explored several alternatives with different shapes, lengths and locations: cuboid with rounded corners (Fig. 1b) and trapezoidal cuboid (Fig. 1c); long, above the transverse midline (Fig. 1d), and short, below the midline (Fig. 1e); medial (Fig. 1f) and lateral (Fig. 1g) shifts from the sagittal midline. The maximal stress associated with each cut was determined and its ratio to the maximal stress from the regular cuboid cut (Fig. 2a) was calculated to evaluate the risk of patellar fracture.

RESULTS AND DISCUSSION

We found that the maximal stress on the patella was near the cut. The different shapes did not show a great impact on the stress ratio on the patella: 0.96 for the rounded-corner (Fig. 2b) and 0.97 for the trapezoidal (Fig. 2c). The cut located below the midline (Fig. 2e) had a lower ratio than the long cut (Fig. 2d), with respective ratios of 0.81 and 1.22. The medially shifted cut (Fig. 2g) increased the stress (1.17), while the laterally shifted cut (Fig. 2f) had minimal effect (0.99).

CONCLUSIONS

The preliminary results of this on-going study demonstrate the ability and capacity of FE modeling to biomechanically evaluate the risk of patellar fracture. The models will be verified by experimental data and more thorough simulations will be carried out to provide the optimal graft harvesting plan. The simulation tool described here can be adapted for other surgical procedures to "digitally" and cost-effectively address clinical problems that otherwise would be difficult or impossible to study.

ACKNOWLEDGEMENTS

EVALUATION OF A SIMPLE METHOD FOR DETERMINING MUSCLE VOLUME *IN VIVO*

John H. Challis[1] and Benjamin W. Infantolino[1,2]

[1]Biomechanics Lab, Pennsylvania State University, University Park, PA, USA
[2]Division of Science, Pennsylvania State University, Berks Campus, Reading, PA, USA
email: jhc10@psu.edu

INTRODUCTION

The assessment of muscle architecture *in vivo* is an important way to augment the more detailed knowledge of muscle which can be obtained from muscle architecture in cadavers. Modern imaging methods make the measurement of various aspects of muscle architecture *in vivo* feasible but data collection and processing can both be time consuming. Albracht *et al.* [1] suggested that muscle volume can be estimated from measurements of muscle cross-sectional area and muscle belly length only, thus reducing the time for data collection and processing. This method was evaluated by Mersmann *et al.* [2] for the *Triceps Surae*, where muscle volumes were estimated with errors less than 8.5% of the criterion magnetic resonance imaging determined values.

It was the purpose of this study was to further evaluate this method for the determination of muscle volume based on a limited set of measurements. It extends the analysis of Mersmann *et al.* [2] in four ways,
1. It examines two different muscles, the *Vastus Lateralis* and *First Dorsal Interosseous.*
2. It uses direct measurement of muscle volume using cadaver dissection.
3. Uses the more generally available method of ultrasound to estimate muscle cross-sectional area and muscle length.
4. Uses a statistically optimal procedure for the estimation of the scaling parameter required in the method.

METHODS

Two sets of muscles were analyzed: the human *First Dorsal Interosseous* (FDI), and *Vastus Lateralis* (VL).

The cross-sectional area and length of the FDI was imaged using ultrasound in 22 cadaver hands (mean age at death: 64 years ± 18, mean height: 172 cm ± 8). The FDI muscles were scanned using a 7.5 MHz ultrasound probe (SSD-1000, Aloka, Japan) in B-mode. To enhance FDI image quality, by decreasing echo reverberations, a stand-off pad (2 cm thick and 9 cm in diameter) and a small amount of ultrasound gel was used. Following ultrasound scanning, the FDI muscles were dissected from the hand. Muscle volume of the FDI was determined using the water displacement technique; prior to testing it was ensured the water and muscle were at the same temperature. Test objects ranging in volume from 1 mL to 10 mL were measured in the apparatus with an accuracy of estimation of 0.01 ± 0.01 mL.

The cross-sectional area and length of the VL was imaged using ultrasound in 8 cadaver legs (mean age at death: 64 years ± 12, mean height: 171 cm ± 11). In a similar fashion to the FDI the muscles of the VL were scanned prior to dissection and determination of muscle volume via underwater weighing.

To estimate muscle volume the following equation was used [1, 2],
$$V_m = p\, ACSA\, L_m$$
Where V_m – muscle volume, p – scaling parameter, *ACSA* - muscle anatomical cross-sectional area, and L_m is the muscle belly length. Given the cadaver measurements the scaling parameter must be estimated for each of the muscles. To estimate the scaling parameter a robust linear regression was performed using a bivariate least squares method [3, 4]. This approach accounts for their being errors influencing both variables (V_m, and the product of *ACSA* and L_m) rather than assuming one variable is error free.

The sample size was small for the VL (n=8), therefore to circumvent the problem of model evaluation when there are no additional data with which to evaluate the model a cross-validation procedure was used [5]. An unbiased estimate of error was obtained by calculating the scaling parameter for sub-sets of the complete data set; the sub-set was achieved by removing one of the cadaver samples from the original data set; these removed values then served as an independent sample on which to evaluate error. By doing this sequentially for each of the muscles in turn it was possible to get multiple estimates of error from which a mean value was then computed. In addition Bland-Altman plots were also used to assess the model [6].

RESULTS AND DISCUSSION

The two sets of muscles analyzed, VL and FDI, reflect muscles of contrasting sizes (Table 1), and are representative of the larger and smaller muscles which are found in the human body [7].

Table 1: Means (± standard deviation) of length, anatomical cross-sectional area, and volume of the two sets of muscles analyzed.

	VL	FDI
Length (cm)	8.5 ± 1.5	5.7 ± 0.7
ACSA (cm^2)	33.8 ± 3.28	1.73 ± 0.40
Volume (mL)	239.4 ± 23.2	4.5 ± 1.0

For the VL the percentage root mean square error in the estimation of muscle volume was 5.0%. In the Bland-Altman plot all volume estimates were within the 95% confidence interval, with no proportional bias or relative bias in the volume estimates (p > 0.05); indicating no change in measurement accuracy with size of specimen, or the presence of a constant deviation in all estimate measures compared with the criterion. For the FDI the percentage root mean square error in the estimation of muscle volume was 18.8%. The results for the Bland-Altman plot had some predictions outside of the 95% confidence interval and the presence of proportional bias (Figure 1).
Figure 1: Bland-Altman plot of ultrasound volume estimation versus water displacement volume for the FDI.

CONCLUSIONS

The results of the current study suggest that with two measures of muscle dimensions, ACSA and length, ultrasound can be used for the estimation of muscle volume for the VL but not the FDI. Other simplified approaches should be explored for the FDI. Such analysis might be useful for tracking the changes in muscle volume of the VL with aging [8], or tracking the changes due to strength training [9]. Such applications of this method warrant further examination.

COMPARING FAILURE RATES OF AUTOGRAFTS AND ALLOGRAFTS IN ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION: A SYSTEMATIC REVIEW

[1]Albert J. Chen, [2]Julie A. Stephens, [2]Mahmoud Abdel-Rasoul, [1]Joshua T. Hoffman, and [1]Timothy E. Hewett

INTRODUCTION

With an annual healthcare expenditure of approximately $625 million, anterior cruciate ligament (ACL) rupture is one of the most costly injuries among active individuals. Injuries to the ACL are not only associated with a large financial burden, but also result in the loss of participation in athletics for at least six months. [1] Therefore, it is crucial for the patient to undergo the best treatment option so that he or she may safely return to pre-injury levels of activity.

The most effective treatment for ACL rupture is ACL reconstruction (ACLR). Ardern et al have reported that 90% of patients report normal or nearly normal knee function 41 months after ACLR. [2] ACLR involves replacing the injured ACL with an autologous or allogenic graft. Common graft choices are the hamstrings tendon autograft (HST), bone-patellar tendon-bone autograft (BPTB), or allograft. Despite numerous studies comparing reconstruction results among graft types, there is no consensus as to which graft type has the lowest likelihood of failure. In addition to patient reported functional scores, graft outcomes can be objectively determined either through laxity measurements or whether or not the graft has ruptured. These objective measures provide for a clear determination of graft integrity and function and can reveal which graft is the optimal choice.

The goal of this review is to compare failure rates across all three graft types in order to determine the ideal graft choice for ACLR. Graft failure rates based on various objective criteria will be utilized in this review. We hypothesized that all three graft types would demonstrate similar outcomes.

METHODS

A literature search was performed in the PubMed/MEDLINE, SPORTDiscus, and Scopus databases in August 2014. The search terms used were (ACL OR anterior cruciate ligament) AND (reconstruction OR surgery) AND (autograft or allograft). To be included, studies must have had sample sizes of 16 or more and at least a 2 year follow up. Furthermore, only comparative studies with level of evidence 1 or 2 were included in this review. After excluding all papers that did not meet our inclusion criteria, outcome data were extracted including Lachman and pivot shift scores, knee laxity measurements, and incidence of graft ruptures. Failure was defined as having a Lachman or pivot shift score of 1+ or more, and having a side to side laxity difference of more than 3 mm. Random effects meta-analyses were conducted for each outcome separately.

RESULTS AND DISCUSSION

Of the initial 1768 papers, 39 met the inclusion criteria and had relevant outcome data extracted. The odds of having a laxity measure greater than 3 mm was 1.624 times higher for the single bundle HST than the BPTB (95% CI: 1.158-2.278, p = 0.005) (Figure 1). In addition, the odds of having a pivot shift grade of 1+ or more was 2.934 times higher for the single bundle HST than the double bundle (95% CI: 1.030-8.358, p = 0.044), but only two studies were used for this estimate. The estimate for clinical failures comparing single bundle HST to BPTB was trending toward significant, with the odds of rupture for single bundle HST being 1.53 times higher than BPTB (95% CI: 0.96-2.42, p = 0.07). Other comparisons

of remaining outcomes were not observed to be statistically significant at the 0.05 level.

The increased incidence of greater than 3mm of laxity with the single bundle HST is not unexpected. Studies have reported a significant differences in laxity between the two graft types, especially as the time from reconstruction increases. [3] While increased laxity may be an indicator of graft failure, these studies found that there were no functional deficits reported by the HST patients.

Given that we found no other significant treatment comparisons among all the other outcomes, it may be necessary to consider other outcome measures. Some of these may include activity scores, incidence of anterior knee pain, pain when kneeling, etc. Some studies have reported a significant difference between HST and BPTB patients when reporting knee pain post-reconstruction. [4] These symptoms are generally a result of the graft harvesting process rather than the performance of the graft itself. Donor site morbidity, or lack thereof, may be a more meaningful factor to success of ACLR. In addition, pain and extensor/flexor

weakness could affect a patient's decision to return to sport. A review of subjective outcomes will be the topic of future work.

CONCLUSIONS

After a systematic review and meta-analysis of the relevant literature, it was observed that the single bundle HST had greater odds of failure, as measured by 3 mm or more on the knee laxity test, than BPTB. Because overall knee function depends on objective and subjective measures, future work is needed to explore the influence of graft type on subjective outcomes.

COMPARISONS OF COORDINATION PATTERNS BETWEEN LUMBAR SPINE VERSUS LEADING AND TRAILING HIPS IN GOLF DOWNSWING

Ahnryul Choi and Joung Hwan Mun

Sungkyunkwan University, Suwon, Republic of Korea

INTRODUCTION

Golf swing is one of complex activities that require well-coordinated movement between body joints [1]. Maximally coiled trunk in the backswing top event enables the release of the stored energy during downswing phase due to a rapid axial rotation of the trunk, leading to a transfer of the energy into the ball [2]. Specifically, the lumbar spine and hip joints have primary roles in the axial rotation in golf swing and are known to have a close relationship with each other in their movement [3]. The inner-joint coordination represents the relationship of the movements among the neighboring joints, and it provides a basic insight into how the central nervous system organizes the joints in order to perform a particular movement from a neuromuscular systematic perspective [4]. In this study, therefore, we have investigated the kinematics (angular displacements and velocities) and inner-joint coordination of rotational movement at the lumbar spine and hip joints during golf downswings.

METHODS

A total of 21 right-handed male golfers participated in this experiment. All participants were professional golfers who is affiliated with Korea Professional Golf Association. Physical characteristics of the participants were 177.5±8.7cm height and 79.2±10.0kg weight; and self-reported handicaps scores were all under 0. Each golf swing motion was captured using six infrared cameras, and recorded images were synchronized by using a VICON 460 system. Twelve optical markers (upper torso: 4, pelvis: 4 and each thigh segment: 2) were attached on each participant to extract kinematic information, and two additional markers were located on the club head and lower part of grip to determine downswing phase (Figure 1). Average of the best two shots among five trials of each participant based on the 3D reconstructed data quality was used for data analysis [5]. The anatomical coordinate system, angular displacement and velocity of the upper torso, pelvis and each thigh segment were calculated from similar methodologies of the previous studies [6, 7]. The inner-joint coordination was calculated using continuous relative phase (CRP) method [8]. All data was limited to the downswing phase, and underwent 100% normalization utilizing cubic spline technique.
Figure 1: The locations of optical markers attached on the body and golf club

RESULTS AND DISCUSSION

The average angular displacement demonstrated an increasing pattern in all three joints during downswing phase. Particularly, the lumbar spine and trailing hip joints showed a similar pattern, but the angular displacement pattern of the leading hip joint revealed a markedly different shape compared to those of other joints. In angular velocity, the lumbar spine demonstrated a steadily

increasing pattern, while the leading and trailing hip joints showed their peaks in the early and late downswing phase, respectively. These results indicated that each joint complete their rotational movement during downswing phase by coordinating each other in different patterns. It is believed that the lumbar spine works constantly throughout the downswing phase, whereas the leading hip in early phase of downswing and the trailing hip joint in late downswing phase.
Figure 2: Average rotational angular displacements and velocities of lumbar spine, leading hip, and trailing hip joints
Figure 3: Average and standard deviation of CRP curves between lumbar spine versus leading and trailing hip joints

The inter-joint coordination between lumbar spine and leading hip joints demonstrated a typical 'V' pattern, and the minimum CRP value was found at approximately 60% of the downswing phase. A faster rotational movement of the leading hip joint was observed in the early downswing phase compared to the lumbar spine, while lumbar spine joint rotated faster in the late downswing phase. On the other hand, the inter-joint coordination between lumbar spine and trailing hip joints revealed an average CRP close to 0 degree with no clear pattern. Therefore, it is considered that a clear coordination strategy exists between lumbar spine and leading hip joints rather than between lumbar spine and trailing hip joints.

CONCLUSIONS

Based on these results, we could confirm that the axial rotational movement during golf downswing is closely associated with leading and trailing hip joints as well as lumbar spine. We could also found that there were clear differences between the leading and trailing hip joints in terms of angular displacement, velocity and inter-joint coordination. Particularly, a significant inter-joint coordination strategy between lumbar spine and leading hip joints exists in professional golfers. This study will provide useful guidelines to improve swing proficiency of amateur golfers.

EVALUATION OF ROTATIONAL QUASI-STIFFNESS IN THE HIP JOINTS DURING GOLF DOWNSWING OF EXPERIENCED GOLFERS

Ahnryul Choi and Joung Hwan Mun

Sungkyunkwan University, Suwon, Republic of Korea
email: avery@skku.edu and jmun@skku.edu

INTRODUCTION

Golf is an activity that involves a predominant axial rotation with both feet fixed on the ground [1]. Golf swing in general applies biomechanical principles that deliver a drastic power to the ball by ejecting a stored energy from the coiled trunk during downswing phase [2]. Human hip joints allow rotational movement, while the excessive rotation of hip joints can cause the sports injury such as acetabular labral tears [3]. Kinematics and kinetics of the hip joints during golf downswing can provide a basic insight into the golf swing-specific injury mechanisms as well as quantitative and objective guidelines for improving swing skills [4]. Specifically, the joint quasi-stiffness, which is represented by the relationship between the given load and deformation, allows to further understand the complexities of joint dynamics [5]. In this study, therefore, we evaluated the rotational angles, moments, and quasi-stiffness of the leading and trailing hip joints in the transverse plane during golf downswing phase.

METHODS

Twenty-one tour professional golfers (height: 177.5±8.7cm, weight: 79.2±10.0kg) registered on Korea Professional Golf Association were recruited for the study. All golfers were right-handed, so left and right was determined to be leading and trailing direction, respectively. Their self-reported handicap scores were all below zero. The experimental apparatuses including six MCam2 cameras and two AMTI force platforms were prepared, and VICON 460 system was used to synchronize between devices in time domain. The modified Helen Hayes markerset protocol was employed to record the swing motion (sixteen markers on the lower extremity of each participant

[6]). Also, downswing phase was decided by an additional markers located on the clubhead and shaft region [7]. The anatomical coordinate system of pelvis and both thigh segments and the locations of joint rotation center were constructed using the markers attached on the lower body based on the previous study [8]. The anatomical angles and moments of each hip joint were calculated by the Euler angle and inverse dynamics techniques, respectively. All kinematic and kinetic data during downswing phase were normalized to 100%. Quasi-stiffness of the leading and trailing hip joints were defined as the instantaneous slope of angle-moment plot; the positive and negative slope were determined as 'resistance' and 'facilitation', respectively [9]. Additionally, the ratio of resistance and facilitation duration in a complete downswing cycle were calculated. In order to compare the difference between leading and trailing hip joints, a paired t-test was used, and the level of significance was set to $p < 0.05$.
Figure 1: Axial rotation angles and moments of leading and trailing hip joints during downswing phase for a typical participant

RESULTS AND DISCUSSION

During downswing phase, the leading hip joint rotated internally, while the trailing hip joint rotated externally. Additionally, the rotational moments were observed in the same direction with angle (Figure 1). The leading hip joint markedly rotated at the beginning of the downswing, while a change of angle of the trailing hip joint revealed in approximately 50% of the downswing. The difference of plot pattern between the angle and moment was greater in the leading hip than the trailing hip joint.
Figure 2: The angle-moment plots for the leading and trailing hip joints for a typical participant
Figure 3: Average normalized resistance duration during downswing phase of all experienced golfers

The angle-moment pattern in the trailing hip joint generally displayed a linear positive slope shape, while no typical pattern was observed in the leading hip joint (Figure 2). The average and standard deviation of the positive quasi-stiffness (resistance) duration in the leading and trailing hip joints are demonstrated in Figure 3. The resistance duration in the leading hip joint was 36% of the complete downswing cycle, and this was 18% lower than that in the trailing hip joint ($p<0.009$). This implies that the leading hip has a different biomechanical roles from the trailing hip joint of the experienced golfers during downswing. In particular, the leading hip joint of the experienced golfers has a higher rotational flexibility than the trailing hip joint.

CONCLUSIONS

In this study, we have evaluated the axial rotation angle, moment and quasi-stiffness in the leading and trailing hip joints during golf downswing phase. We concluded that the rotational movement of the leading hip joint has a more flexible strategy compared to that of the trailing hip joint in the experienced golfers, and this could speculate as the effects of repetitive training. These results will be utilized as coaching guidelines to improve swing skills, and basic knowledge to identify golf swing injuries.

INTRODUCTION

Over 90% of hip fractures in older adults are caused by falls [1]. Whether a given fall will cause hip fracture depends on bone strength, and on the impact force and stress applied to the bone during impact [2]. Improved understanding is required on how peak bone stresses during a fall depend on the mechanics of a fall, and on the state of contraction at the moment of impact of the muscles spanning the hip. Recently, Choi et al showed that, for lateral impact to the hip, peak stresses decrease with increases in hip abductor muscle force [3]. In the current study, we used an advanced hip impact simulator to examine the independent and interacting effects of both hip muscle force and pelvis impact angle on peak bone stresses during a fall.

METHODS

A second-generation "SFU hip impact simulator" was developed, consisting of a surrogate pelvis and pendulum [3]. The system allowed us to measure total force over the hip and 3D forces at the femoral neck (at 1000 Hz) under various levels of gluteus maximus and medius muscle forces, and pelvis impact angles, during simulated falls (Figure 1a). We used the system to simulate sideways falls involving an impact velocity of 2 m/s, and initial hip abductor muscle forces 300 or 700 N in each of the two abductor muscles. We also conducted trials for seven different impact configurations of the pelvis, including direct impact to the lateral aspect of the greater trochanter (zero degree), and impact to the pelvis when rotated (about the long axis of the pendulum) 5, 10 and 15° posterior or anterior to the frontal plane (Figure 1b and 1c).

Outcome variables (Figure 2) included the peak values at the femoral neck of: (a) axial force (F_z; aligned with the femoral neck axis), (b) shear force (vector sum of F_x and F_y), (c) bending moment, (d) shear stress, (e) compressive stress and (f) tensile stress (see inset to Figure 2a for equations used to calculate these parameters).

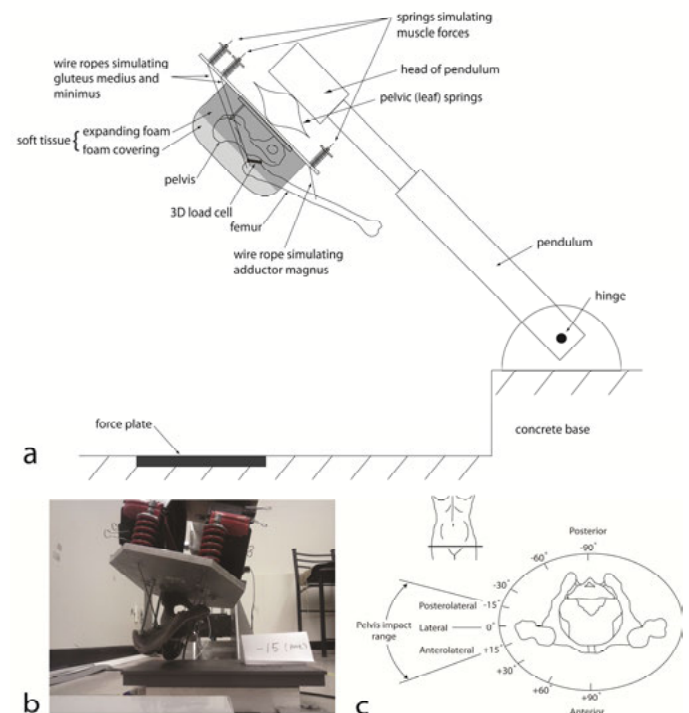
ANOVA was used to test whether each outcome variables associated with muscle force (2 levels), and pelvis impact angles (7 levels). All analyses were conducted with SPSS using a significance level of alpha = 0.05.


Figure 1. SFU Hip impact simulator, showing (a) schematic of the system, and (b) snapshot of surrogate pelvis (soft tissue covering removed) before impact with a pelvis rotation of 15° posterior along with (c) range of pelvis impact angle tested.

RESULTS AND DISCUSSION

We found that pelvis impact angle associated significantly with all of our outcome variables (p<0.0005), but had a more dramatic effect on peak tensile than peak compressive force (Table 1). On average, peak compressive and tensile stresses decreased 27% and 68%, respectively, when the pelvis impact angle changed from 15° posterior to 15° anterior. These results agree with previous findings from cadaveric studies and finite element modeling that posterolateral hip impact carries highest risk of hip fracture during a fall [4,5].

We also found that the hip abductor muscle force associated significantly with all of our outcome variables (p<0.018). Furthermore, there was a significant interaction between muscle force and pelvis impact angle for all outcome variables (p<0.02). Overall, peak tensile and compressive stresses were 25% lower and 5% greater, respectively, with 700 N than 300 N hip abductor muscle force. When the pelvis impact angle was zero, peak tensile and compressive stresses averaged 73% and 8% lower in the 700 N than 300 N muscle force condition. These results are similar to our previous findings for lateral impacts under a variety of knee boundary conditions [3].

In general, increases in muscle force were protective (caused a reduction in bending moment, and peak compressive and tensile stress) at zero degree and anterior impact angles, and dangerous (caused an increase in bending moment and peak stresses) for posterior impact angles. This likely relates to the muscle force having a greater protective "tension band" effect when the impact force and muscle force are aligned to create moments about a similar axis.

INFLUENCE OF PELVIS IMPACT ANGLE DURING A FALL ON THE PROTECTIVE BENEFIT OF HIP PROTECTORS

[2] Department of Biomedical Physiology & Kinesiology, Simon Fraser University, Burnaby, BC, CANADA
Email: wchoi@chapman.edu

INTRODUCTION

Over 90% of hip fractures are due to falls [1]. Laboratory measures have shown that wearable hip protectors reduce impact forces to the proximal femur during a simulated sideways fall on the hip [2, 3]. However, clinical evidence suggests that hip fractures still occur when hip protectors are worn [4]. Furthermore, while falls in real life result in a variety of impact configurations, biomechanical tests to date have focused only on lateral impact to the pelvis. In the current study, we examined how the force reduction provided by wearable hip protectors is affected by pelvis impact configuration during simulated sideways falls.

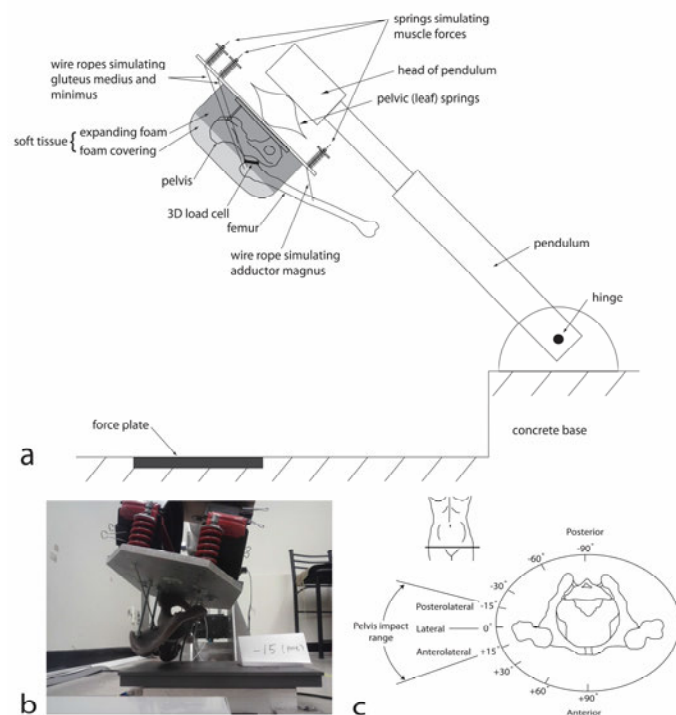
METHODS


Figure 1. SFU Hip impact simulator, showing (a) schematic of the system, and (b) snapshot of surrogate pelvis (soft tissue covering removed)

before impact with a pelvis rotation of 15° posterior along with (c) range of pelvis impact angle tested.

We conducted experiments with a second-generation "SFU hip impact simulator" consisting of a surrogate pelvis and pendulum [5]. The system (Figure 1a) allowed us to simulate falls involving different magnitudes of gluteus maximus and medius muscle forces, and pelvis impact angles, and systematically examine how these factors affect total force over the hip and 3D forces at the femoral neck (measured at 1000 Hz).

We used the system to simulate sideways falls involving an impact velocity of 2 m/s, and initial hip abductor muscle force of 700 N in each of the two abductor muscles. Trials were acquired for seven different impact configurations of the pelvis: (a) direct impact to the lateral aspect of the greater trochanter, and (b) impact to the pelvis when rotated (about the long axis of the pendulum) 5, 10 and 15° posterior or anterior to the frontal plane (Figure 1b and 1c). Trials were also acquired with no pad applied (unpadded) and with two commercially available hip protectors (HipSaver and SafeHip).

Our main outcome variable was the percent attenuation in peak compressive stress at the femoral neck provided by the padding devices, when compared to the unpadded condition:

$$\%attenuation = 100 \times (1 - \frac{\sigma_{padded}}{\sigma_{unpadded}})$$

Secondary outcome variables (Figure 2) included the peak values at the femoral neck of: (a) axial force (Fz; aligned with the femoral neck axis), (b) shear force (vector sum of Fx and Fy), (c) bending moment, (d) shear stress, (e) compressive stress and (f) tensile stress (see inset to Figure 2a for equations used to calculate these parameters).

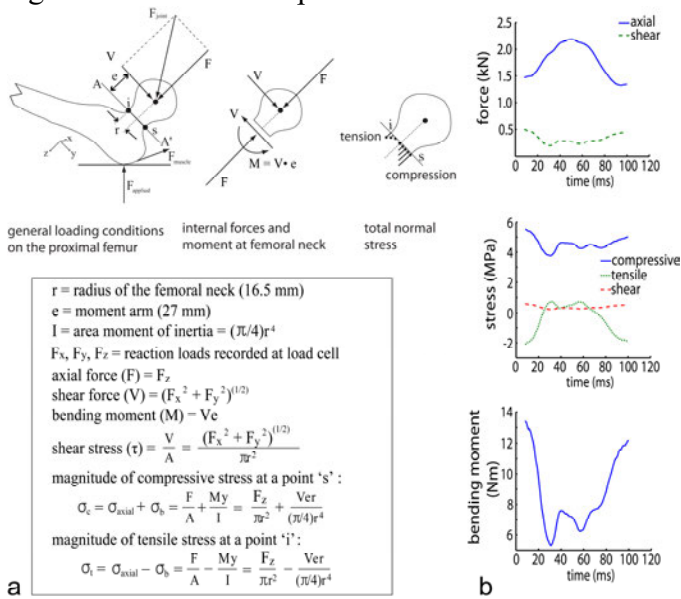
We used ANOVA to test whether the outcome variables associated with the padding devices (3 levels), and pelvis impact angle (7 levels). All analyses were conducted with SPSS using a significance level of alpha = 0.05.


Figure 2. Experimental measures and calculated outcome variables. (a) Free body diagram and stress analysis at the proximal femur at impact from a fall. (b) Sample force and stress traces for SafeHip with +15° of pelvis rotation (anteriolateral impact).

RESULTS AND DISCUSSION

Our main outcome variable (percent compressive stress attenuation at the femoral neck) associated with padding device (p<0.0005) and pelvis impact angle (p<0.0005). On average, the percent stress attenuation was greatest while falling with HipSaver (30.7%) than SafeHip (20.9%) (Figure 3). Furthermore, the percent attenuation was greatest while impacting slightly anteriorly (+5 or +10°; 35%) and least while impacting anteriolaterally or posteriolaterally (+15 or -15°; 17~18%) (Figure 3). There was a significant interaction between padding device and pelvis impact angle (p<0.0005).

All of other outcome variables associated with padding device (p<0.0005) and pelvis impact angle (p<0.0005). Furthermore, there were significant interactions between padding device and pelvis impact angle for all outcome variables (p<0.0005).
Figure 3. Effect of pelvis impact angle on percent compressive stress attenuation.

Our results confirm that padding devices help to reduce risk of fall-related hip fracture during a fall by attenuating peak compressive stress at the femoral neck up to 42%. However, our results also suggest that the protective effect may be compromised by pelvis impact configuration during fall impact, especially at the extremes of anteriorly and posteriorly directed impacts, where the point of contact was outside or at the edge of the padding device. These results agree with Choi et al (2010) who reported that performance of padding devices declines with poor positioning, for laterally-directed impacts [6]. These results should help to inform the design of improved padding devices that provide protection over a greater range of fall impact configurations [4].

EFFECT OF MUSCLE CONTRACTION ON IMPACT VELOCITIES OF THE HEAD DURING BACKWARD FALLS IN YOUNG ADULTS

[1] Woochol Joseph Choi, [2]Stephen N. Robinovitch, [1]Daniel Cipriani and [1]Jimmy Phan

[1] Department of Physical Therapy, Chapman University, Irvine, CA, USA
[2] Department of Biomedical Physiology & Kinesiology, Simon Fraser University, Burnaby, BC, CANADA
Email: wchoi@chapman.edu

INTRODUCTION

Falls are a direct cause of head injuries in older adults, and 60% of traumatic brain injuries are due to a fall, accounting for 32% of hospital admission and 50% of death from falls [1,2]. Most head impacts in older adults in long term care occur from backward falls [3], and a recent kinematic analysis of video-captured real-life falls in older adults suggested that contracting the core and neck muscles during decent and impact may help to prevent, or lessen the severity of head impact during backward falls [4]. In this study, we have conducted falling experiments with young adults to determine how muscle contraction during a fall influences the impact velocity of the head during backward falls.

METHODS

Healthy young adults (n=8) aged between 19 and 35 participated in falling experiments. Participants were taught and trained to mimic older adults backward falls on the buttock, back and head, captured by surveillance cameras installed in long-term care facilities [5] (Figure 1). The experiment was approved by the IRB of Chapman University, and all participants provided written informed consent.

For all falls, participants were instructed, "fall naturally while imagining you are falling on a hard surface", and were not allowed to use their arms to arrest fall. Participants were also instructed to fall in three different ways: a. "fall backward and prevent your head from impacting the ground", b. "fall backward and allow your head to impact the ground, but with minimal impact severity", and c. "fall backward and allow your head to impact the ground, while inhibiting your efforts to reduce head impact severity". All participants wore wrist guards and helmets, and fell onto a padded mattress. Reflective markers were placed on bony landmarks of the body to monitor participants' fall kinematics through 10 Raptor motion analysis cameras (Motion Analysis Corp, Santa Rosa, CA) at a sampling rate of 250 Hz. Muscle activation of the core and neck muscle was monitored through electromyography (EMG) electrodes placed bilaterally on the skin over the rectus abdominis and sternocleidomastoid muscles, at a sampling rate of 2,000 Hz (Noraxon EMG DTS system, Scottsdale, AZ).

Figure 1. Self-initiated backward fall on a 12" thick gymnastics mat. Participants mimicked older adults' backward falls and head impacts, based on video-captured backward falls in long term care.

Outcome variables included the vertical and horizontal velocities of the head at impact, and the integrated EMG (IEMG; a measure of the intensity of muscle activity) over the time period a. between fall initiation and head impact for falls resulted in head impact, or b. between fall initiation and a moment when the head marker was at its lowest point in z axis for falls involved no head impact. The time of fall initiation was defined as 10 frames (40 ms) after the instant when the greater trochanter started to move downward. The time of head impact was defined as the moment that the head marker

passed a threshold height 240 mm above the mat surface [6]. EMG data were full-wave rectified and low-pass filtered with a cut-off frequency of 20 Hz (4th order Butterworth algorithm). IEMG data from right and left sides were averaged for each muscle.

ANOVA was used to test whether our outcome variables associated landing type during backward falls (3 levels). We also conducted a regression analysis to test whether impact velocity associated muscle activity. All analyses were conducted with SPSS using a significance level of alpha = 0.05.
Figure 2. Association between vertical head impact velocity and neck muscle activity during backward falls.

RESULTS AND DISCUSSION

The experimental instruction associated with neck muscle activity (p=0.009), but not with core muscle activity (p=0.14). On average, neck muscle IEMG was 197% greater in falls where participants attempted to avoid head impact when compared to falls where they allowed head impact, while inhibiting efforts to reduce impact severity (13.4 versus 4.5 mV*S) (Table 1). The falling instruction also associated with vertical head impact velocity (p<0.0005) and horizontal impact velocity (p<0.0005). Overall, vertical head impact velocity was 82% greater in falls where participants inhibited efforts to reduce impact severity versus impacted softly (3.24 versus 1.78 m/s). Furthermore, our regression analysis indicated that vertical head impact velocity associated neck muscle activity (p=0.01, R^2=0.28) (Figure 2). Our average value of vertical head impact velocity in falls where participants inhibited protective responses (3.24 m/s) is similar to the mean value (2.91 m/s) we recently observed from analysis of real-life falls in older adults captured on video in long term care [4].

Our results provide novel measures of head impact velocities during backward falls in humans, to inform the design and testing of protective gear (helmets, crash mats). Our results also indicate the essential role, in reducing the frequency and severity of head impacts in backward falls, of neck and core muscle activation during the descent and impact phases of falling. Further research is required to understand age-related changes and the role of neck and core strengthening exercises to prevent fall-related head injuries in older adults.

INTRODUCTION

The comparison of the force production and muscle activation of seated and prone positioning when testing a commonly measured muscle, the rectus femoris (RF) is currently unknown. The RF is a biarticular muscle crossing both the knee and hip joint and its force output can be altered by different positions of the hip for a given knee angle [1]. The amount of force a muscle can generate is dependent on its length and velocity [2]. In the seated position, the RF is shorter than in its prone counterpart which allows for a mechanical advantage in the seated position. We hypothesize there will be a significant difference in both force production and muscle recruitment of the RF when testing in the seated position and prone position.

METHODS

Thirteen subjects (8 male, 5 female; age 24 ± 5.1 yr; height 175.05 ± 7.46 cm; mass 72.67 ± 8.77 kg) participated in the study which involved a unilateral test of their dominant leg. All subjects were free from musculoskeletal injury at the time of testing and volunteered their participation. Informed consent was given through a process approved by The Ohio State University's Institutional Review Board. Electromyography (EMG) was used to compare muscle activation of the RF. The skin was prepared by abrading and cleansing it with alcohol pads prior to placing the electrodes as per Surface Electromyography for the Non-Invasive Assessment of Muscles (SENIAM) recommendations. For load cell (BTE Technologies, Inc., Hanover, MD) testing, subjects laid on a table in a prone position and Velcro straps were used to secure the subject above the knee and across the lumbar region. The load cell was

Figure 1A: Seated Position

Figure 1B: Prone Position

rigidly attached to a wall at ankle height and an ankle cuff was attached to the subject after their knee was placed in 90º flexion and hips at 0º flexion (Figure 1B). A Biodex System III isokinetic dynamometer (Biodex Medical Systems, Shirley, NY) was used to assess isometric strength while seated. Subjects were placed in a seated position with the hips and knees in 90º flexion with straps around the dominant ankle and thigh to isolate knee motion, and around the waist and trunk to limit whole body involvement (Figure 1A). Three trials of the leg extension task were completed on the self-selected dominant leg. Activity from the RF was captured via EMG (1500 Hz). Prior to testing, maximum voluntary isometric contraction (MVIC) of the RF was recorded to normalize task EMG. RF MVIC testing involves placing the participant in a seated position and instructing them to provide a maximal effort isometric hip flexion contraction. Both MVIC and task isometric contractions were held for five seconds. Raw EMG data underwent full wave rectification, band-pass filter of 50-500Hz, and moving RMS smoothing window of 150ms. Recruitment output was normalized to % MVIC.

Peak force from each trial was normalized to % body weight of each subject. A students *t*-test with *a priori* α=0.05 was utilized to examine differences between force production in seated Biodex and prone load cell positions. A second students *t*-test was utilized to test the differences in muscle activation in the same positions.

RESULTS AND DISCUSSION

There were significant differences between force production ($p<0.01$) and RF activation ($p<0.01$) in the seated and prone position.   The average force output of the RF was 78.2 ± 12.7 lbs. in seated testing and 49.6 ± 11.6 lbs.in prone testing as seen in Figure 2A. The average activation of the RF was $182.3 \pm 128.9\%$ of MVIC was seen in seated testing and $88.4\% \pm 45.2\%$ of MVIC in prone testing as seen in Figure 2B.

CONCLUSIONS

Testing the RF in a seated position and in a prone position does not produce comparable results in muscle activation or force output. Therefore, the tests are not interchangeable and can't be used in place of one another. The length-tension relationship plays an essential role when it comes to muscle function [2]. In the prone position, the RF is at a greater length than at its seated counterpart which causes a mechanical disadvantage producing less force output and activation [1]. The seated testing position is commonly used and has standardized normative values for strength testing. Different testing positions yield different force outputs and muscle activation patterns having both advantages and disadvantages.

AGE AND SEX EFFECTS ON FORCE ASYMMETRY DURING JUMP AND PUSH-UP TASKS IN YOUTH SOCCER PLAYERS

Mara J. Cosgrove, Mitchell L. Stephenson, Taylour J. Hinshaw, Kathryn L. Overton, Austin L. Roberts, Elizabeth A. Meyer, and Boyi Dai

email: mcosgrov@uwyo.edu, web: http://www.uwyo.edu/kandh/

INTRODUCTION

Playing soccer is associated with improved health but also risks for injuries. Previous studies have suggested that increased asymmetry in lower extremity bilateral strength is associated with increased risks for lower extremity injuries and decreased sports performance [1]. Several factors including injury history, asymmetry in lean mass, and muscle activation have been identified as contributors to asymmetry in bilateral strength. Understanding how strength asymmetry changes as a function of age and sex may inform injury prevention and performance training in soccer [1].

One validated tool to quantify asymmetry in lower extremity bilateral strength is a countermovement jump for a maximum height [2]. Similarly, a maximum push-up task may be used to assess asymmetry in upper extremity bilateral strength. A previous study has quantified the performance asymmetry between the preferred and non-preferred legs in soccer players aged 6 to 10 years old [3]. A recent study has examined the force asymmetry between the dominant and non-dominant legs during squat in soccer players aged 13 to 17 years old [4]. The strength asymmetry during jump and push-up tasks in youth soccer players, however, has not been investigated.

The purpose of this study was to investigate the effects of age and sex on force asymmetry during jump and push-up tasks in youth soccer players aged 7 to 14 years old. It was hypothesized that force asymmetry would be present and different between males and females and increase as age increases in youth soccer players.

METHODS

Thirty male and 29 female youth soccer players (age: 10.6 ± 2.0 years; mass: 36.9 ± 11.0 kg; height: 141.7 ± 20.7 cm) participated in the current study. The dominant leg was defined as the preferred leg to kick a ball and the dominant arm was defined as the preferred arm to throw a ball. Participants performed three trials of a countermovement jump and a maximum push-up with each limb on a Bertec force plate. The vertical ground reaction force was sampled at a frequency of 1000 frames/second. The maximum force produced by the dominant and non-dominant legs and arms during jump and push-up tasks were extracted for analysis and normalized to body weight (BW). The bilateral force asymmetry index between the dominant and non-dominant limbs was calculated and expressed as a percentage of the stronger limb. Paired t-tests were used to compare the maximum force between the dominant limb and non-dominant limbs during jump and push-up tasks. Regression analysis with age as a continuous variable and sex as a dummy variable was used to predict the force asymmetry index as a function of age and sex. A type I error rate was set at 0.05 for statistical significance.

RESULTS AND DISCUSSION

With regard to force asymmetry in lower extremity strength during the jump, t-tests indicated that the dominant leg (1.26 ± 0.19 BW) tended to demonstrate increased maximum force compared with the non-dominant leg (1.24 ± 0.18 BW, $p=0.08$). The bilateral force asymmetry index (Figure 1), however, was not significantly correlated with age ($p=0.77$), nor different between the sexes ($p=0.36$) (Fig. 1).

With regard to force asymmetry in upper extremity strength during the push-up, t-tests indicated that the dominant arm (0.48 ± 0.06 BW) demonstrated increased maximum force compared with the non-dominant arm (0.46 ± 0.04 BW, p=0.01). The bilateral force asymmetry index (Figure 2), however, was not significantly correlated with age (p=0.441), nor different between the sexes (p=0.431) (Fig. 2).
Figure 1: Bilateral force asymmetry during the jump as a function of age and sex
Figure 2: Bilateral force asymmetry during the push-up as a function of age and sex

Our first hypothesis was supported that force asymmetry would be present in youth soccer players. For both jump and push-up tasks, participants tended to demonstrate greater force on the dominant limb compared with the non-dominant limb. The findings were consistent with the findings

by Teixeira and Teixeira [3], who observed greater velocities when youth soccer players kicked with their preferred leg. On the other hand, Atkins et al. [4] observed bilateral force asymmetry during a squat task in youth soccer players, but the non-dominant leg demonstrated greater force compared with the dominant leg. The discrepancy between the findings of the current study and the study by Atkins et al. [4] may be due to the high physical demand of the jump task versus the relatively low physical demand of the squat task.

Our second hypothesis, however, was not supported. It was expected that older individuals were more likely affected by limb dominance and history of injury and therefore may demonstrate increased force asymmetry. The findings of the current study did not support the notion of a general increase in force asymmetry as age increases in youth soccer players. The findings were generally consistent with the findings by Atkins et al. [4], who did not observe increased force asymmetry as age increased.

CONCLUSIONS
Preliminary results from this study indicate potential asymmetry in lower and upper strength between the dominant and non-dominant limbs in youth soccer players aged 7 to 14 years old. The asymmetry, however, did not tend to change as age increased. Males and females also demonstrated similar asymmetry. The findings suggest that screening for asymmetry in lower extremity strength should be initiated in childhood and adolescence in soccer players. An individual-based strategy may be needed for screening and injury prevention instead of simply using age and gender to classify the injury risk.

AUTOMATED CALCULATION OF LONG BONE BENDING STIFFNESS FROM CT SCANS AND ONE-DIMENSIONAL FINITE ELEMENT ANALYSIS

[1]Eric Arnold and [1,2]John Cotton

[1]Mechanical Engineering, [2]Biomedical Engineering, Ohio University, Athens, OH, USA
email: cotton@ohio.edu

INTRODUCTION

Traditional CT-based finite element (FE) modeling of long bones uses 3D models that require a skilled user, specialized software for model creation and solution, and moderate to large resources for solution and data storage. The goal of this project was to create an alternative, lean and fast method that reads serial transverse CT images and automates creation of a 1D FE model that can be solved with minimal resources and user experience. We then test the accuracy of this method against experimental data and 3D FE results for 18 cadaveric ulnae.

METHODS

CT images of cadaveric ulnae and results from quasistatic mechanical tests (QMT) in three-point bending were provided by Bowman [1]. Transverse slices spaced 2.5 mm apart were rotated with the mid shaft interosseous crest pointed downward (Figure 1) to match QMT orientation.

We wrote MATLAB code (Mathworks, Natick, MA) that read each transverse CT slice, and for every pixel assigned a value for Young's modulus, E, in MPa according to

$$E = (k \cdot im)^B$$

where im is the pixel brightness in Hounsfield units and k and B are tunable parameters. With E mapped for each pixel in the slice, the centroid of each section was found. Then the section modulus EI was calculated about the horizontal axis through the centroid according to

$$EI = \sum_i \sum_j E_{ij} \left(y_j - \bar{y} \right)^2 \Delta x \Delta y$$

where i and j represent the pixel indices, $\bar{y}$ is the centroid location, and Δx and Δy are the pixel dimensions.
Figure 1: CT scan of a representative ulna, with lateral view (A) and six transverse slices (B), shows geometric and bone density changes in the ulnar shaft. Actual simulations examined approximately 100 slices per model.

These section moduli were used to create a 1D FE model with Hermitian beam elements and one element per slice. End conditions of a simply supported beam were assigned and deflection calculated under a 1 N mid-span load modifying and extending code from [2]. We then calculated the bending stiffness k_b as the mid-span load divided by the mid-span deflection.

Results of our 1D FE models were compared to stiffness values generated from QMT [1] and 3D FE models [3]. The parameters k and B were optimized using a Nelder-Mead algorithm to minimize the sum of the square of the residuals compared to QMT. This was done on a subset of ulnae randomly selected from three equal subsets of high, medium, and low QMT stiffness values. These results are referred to as *tuned* values. To separate geometric from tuning effects of material properties, simulations were also run where all pixels above a threshold value were assigned the same cortical bone stiffness used by the 3D models. These results are referred to as *standard E*.

RESULTS AND DISCUSSION

The results of the optimization found parameters of $k = 1.064$ and $B = 1.27$. Figure 2 shows results of a single ulna's calculated EI variations and the simulated displacement. All FE simulation results are compared to QMT measurements in Figure 3.
Figure 2: Results for a representative ulna.
Figure 3: Comparison of experimental stiffness against three FE modeling methods. Dark line represents identity line, $y = x$.

A linear regression of all three FE methods compared to QMT experiments showed that the intercept was not significantly different from 0. Slopes were not significantly different from one at the 95% confidence level model for the 3D Standard E and 1D standard E methods. Table 1 shows results of the regression analysis.

Table 1. Data from regression analysis of the three FE methods compared to experimental QMT data.

Method	Slope [95% C.I]	R^2	SEE (N/mm)
1D Tuned E	1.06 [1.01-1.11]	0.93	8.1
1D Standard E	0.99 [0.92-1.05]	0.92	11.1
3D Standard E	1.03 [0.97-1.09]	0.93	10.0

CONCLUSIONS

We have implemented a fast technique to create 1D FE models to estimate the stiffness of long bones. This method produces comparable results to a more complex process of 3D FEA, but takes less than 1 second to read the scans, mesh, and solve the problem. While experiences vary, 3D FE modeling and analysis from a set of CT scans in our lab would take a trained user two to four hours.

Our results indicate that optimizing material property relations add little accuracy. Somewhat surprising was the deviation from the *1D standard E* and the *3D standard E* models as these had similar geometric information and the same material properties. Differences in these cases may indicate the importance of precise 3D boundary conditions, and torsional or shear deformation neglected in the formulation of the 1D case.

THE EFFECTS OF MEDIAL AND LATERAL WEDGES ON ILIOTIBIAL BAND STRAIN DURING OVERGROUND RUNNING

[1] Evan M. Day and [1] Jason C. Gillette

[1] Iowa State University, Ames, IA, USA
email: eday@iastate.edu

INTRODUCTION

Iliotibial band syndrome (ITBS) is an overuse injury that is the second most prevalent running injury behind patellofemoral pain syndrome [1]. Excessive hip adduction and internal knee rotation have been linked to individuals with ITBS [2,3], but not without confounding results [4,5]. Iliotibial band (ITB) strain and strain rate have been observed to be higher in individuals with ITBS, suggesting that a high strain rate could be the underlying factor for development of ITBS [6]. Orthotics are commonly used in clinical settings to alter gait mechanics to prevent injury. The goal of this study was to manipulate ITB strain and strain rate by using medial and lateral wedges to influence foot motion and change other kinematic parameters that affect the length of the ITB. Our hypotheses were that lateral wedges would increase strain and strain rate of the ITB, where as medial wedges would reduce strain and strain rate.

METHODS

Fifteen males (21 ± 2 years, 71 ± 3 in., 158 ± 11 lbs.) and fifteen females (21 ± 2 years, 65 ± 3 in., 124 ± 11 lbs.) were recruited for this study. Participants were healthy runners. Subjects completed five running conditions using a lateral 7° wedge, lateral 3° wedge, no wedge, medial 3° wedge, and medial 7° wedge. Wedges were made of EVA and extended from the back of the shoe to the base of the metatarsals. Subjects wore their own running shoes. Subjects completed 5 trials per condition at their preferred running speed ± 5%. Order of conditions was randomized between subjects. Subjects ran on a treadmill for 1 minute between conditions. Stance phase kinematics of the knee and hip in the sagittal, frontal, and transverse plane were input to a custom MATLAB program that calculated strain and strain rate of the ITB. The ITB model was created using dimensions from OpenSim. Data were analyzed using MANOVA tests in JMP.

RESULTS AND DISCUSSION

There were no significant differences in strain (p > .05) or strain rate (p > .05) in males. There were no significant differences in strain (p > .05) or strain rate (p > .05) in females. Strain and strain rate were observed to be higher in females than males.
Figure 1: Average maximum ITB strain in males and females
Figure 2. Average maximum ankle eversion in males and females

The wedges produced systematic results in influencing ankle eversion. Other kinematic variables associated with lengthening the ITB were analyzed. Control condition results differed between genders. Knee internal rotation was greater in males (11.3° vs. 2.5°), knee flexion was greater in males (48.8° vs. 45.1°), knee valgus was greater in females (3.6° vs. -0.3°), and hip adduction was greater in females (15.3° vs. 13.8°). No significant differences in kinetics were observed between conditions in either males or females.

Our hypotheses were that strain and strain rate would be greater when using the lateral wedges than the medial wedges. Contrary to our hypotheses, strain rate was greater in females using the medial wedges, although not statistically significant.

Failure to produce significant differences in strain and strain rate could be due to using a wedge insert that extends to the base of the metatarsals, and not a rigid or full foot orthotic. The wedges did produce systematic results for peak ankle eversion, but failed to influence differences at the knee and hip. A rigid or full foot orthotic has potential to have a greater influence on skeletal motion.

Subjects using their own footwear could have dampened the effects of the wedges. Shoes with a softer midsole will absorb the effects of the wedge more than shoes with a firm midsole. Controlling footwear would increase internal validity and potentially influence greater differences between conditions.

A limitation of this study is that the subjects were healthy individuals that do not wear orthotics. By inserting wedges into the running shoes we essentially created a problem for the subject. This could result in the subjects fighting the effects of the wedges. However, no significant differences were observed in plantarflexion or ankle inversion moments for males or females ($p > .05$).

It has been previously reported that individuals with ITBS exhibit greater ITB strain and strain rate than healthy individuals [6,7]. By redoing this study with groups of healthy runners and runners with ITBS, we could gain further insight into how wedges affect ITB strain and strain rate in injured individuals as they are the target demographic of this study.

Conclusions

The wedge inserts used did not have a significant effect on ITB strain and strain rate in healthy individuals. The goal of this study was to manipulate strain and strain rate of the ITB as a high strain rate is theorized to be the underlying factor for development of ITBS [6]. Using a semi rigid or full foot orthotic and a subject pool including individuals with ITBS could result in different results.

TIBIAL STRESS DURING LANDINGS FROM TWO HEIGHTS

[1]Steve Dado, [1]Elizabeth R. Boyer, [1]Timothy R. Derrick
[1]Iowa State University, Ames, IA, USA
email: tderrick@iastate.edu ; web: http:// www.kin.hs.iastate.edu/

INTRODUCTION

It has been suggested that subjects can maintain levels of strain in the tibia while landing from varying drop heights [1]. The suggested mechanism is an increase in the range of motion at the joints when the height is increased. Data providing evidence for this come from strain gages that are mounted to staples that are embedded within the bone of human subjects. Questions persist as to the normalcy of the landing under these conditions and the limitation of measuring the strain at a single point on the tibia. The purpose of this study was to estimate the peak stresses in landing from two heights using non-invasive techniques. It was hypothesized that there would be no difference in peak compressive, tensile and shear stresses between the two heights.

METHODS

Nine young adults (5 males, age: 25.6±5.0 yr, body mass: 68.3±8.1 kg, height: 1.81±0.07 m and 4 females, age: 20.8±1.7 yr, body mass: 57.0±12.0 kg, height: 1.64±0.06 m) with no lower limb injuries volunteered to participate. All subjects landed 5 times by stepping off a box with both feet hitting the ground at the same time. This was repeated for two heights (28 cm and 48 cm). Kinematic data were collected at 200 Hz (Vicon MX, Vicon, Centennial, CO, USA) and force data at 1000 Hz (AMTI, Watertown, MA).

A succession of 3 models were used to estimate tibial stresses during the landing. First, a rigid body model was used to estimate 3D joint moments and reaction forces at the ankle, knee and hip joints during the first 500 ms after contact with the force platform. Second, a musculoskeletal model was used to estimate length and velocity adjusted maximal muscle forces and moment arms of 44 lower extremity muscles. Muscle parameters for this model were derived from Arnold et. al, [2]. Static optimization was used to estimate the dynamic muscle forces using an optimizing criteria that minimized the sum of the muscle stress squared. The muscle forces were constrained to equal the sagittal plane ankle, knee and hip moments and the frontal plane ankle and hip moments that were estimated using the rigid body model. They were also bound by zero and the maximal muscle forces estimated by the musculoskeletal model. Third, a bone model was used with beam theory and finite element methods [3] to derive stresses in a cross section of the tibia located approximately 67% of tibial length from the knee joint. Bone parameters were derived from CT scans (Toshiba Prime 40, 120 kV, .4 mm resolution) and used to create a 600 element (60 circumferential and 10 radial nodes) mesh for each subject.

Peak compressive, tensile and shear stresses were located in the tibial cross section and recorded during each landing. Paired t-tests were done on each variable and p-values were compared to an alpha criterion of 0.016 (0.05/3 variables) to determine statistical significance.

RESULTS AND DISCUSSION

Peak compressive stress was located on the posterior medial aspect of the cross section while the peak tension was located on the anterior lateral region (Figure 1). Peak shear was inconsistently located from subject to subject. Peak compression, peak tension and peak shear all occurred about 100 ms after contact with the ground. Most of the normal stress (82% at peak compression) was caused by muscular contraction – predominantly triceps surae. This caused the tibia to bend concave posterior. The reaction force was responsible for the remainder of the stress and it caused a concave anterior bending during the first 50 ms followed by a concave posterior bending during the second 50 ms. Bending of the tibia resulted in much more stress on the bone than did the axial forces (89.1% at peak compression). Peak compressive stress increased from the low landing height to the high landing height (low: -146.7±27.0 MPa, high: -174.9±33.5 MPa, p<.001). Peak tensile stress also increased (low: 152.5±40.4

MPa, high: 179.9±47.8 MPa, p<.001). However there was not a significant difference in the peak shear stress (low: 8.6±2.4 MPa, high: 9.4±3.3 MPa, p<0.424).
Figure 1. Stresses during peak compression of a drop landing. PT indicates the location of peak tensile stress and PC indicates the location of peak compressive stress averaged across subjects.

CONCLUSIONS

The evidence provided by these data did not fully support the hypothesis that landing height would not affect stresses. Tensile and compressive stresses increased with landing height, however, shear stresses did not change significantly.

One difference between these data and previous research is that Milgrom et al. [1] mounted strain gages to the anterior medial aspect of the tibia. This would result in strain measurements close to the neutral axis (Figure 1) and thus may have underestimated the loading in the tibia.

Compressive stresses at the distal 1/3 of the tibia were generally not as high during these landings as they would be during running. This is likely due to both feet making contact with the ground at the same time. The tensile stresses were relatively higher during the high drop height compared to running. This may indicate that athletes performing a lot of jumping may be more susceptible to anterior tensile stress fractures while runners might be more susceptible to posterior compressive fractures.

INTRODUCTION

Femoroacetabular impingement (FAI) is an increasingly recognized source of hip pain and disability in active individuals [1]. In an attempt to maintain their level of sport participation, 71% of athletes report modifying their technique [2]. Only one published study to date has characterized the biomechanical adaptations of a small group of individuals with FAI during a sports-related jump-landing task [3]. Importantly, the association of biomechanical adaptations to self-reported hip function has not previously been evaluated, but could provide valuable insight into why some athletes are able to maintain a high level of sports participation in spite of a painful hip joint. The purpose of this study was to evaluate the relationship between sagittal plane joint moment asymmetries during a drop vertical jump and self-reported hip function. The hypothesis tested was that higher self-reported function in athletes with symptomatic FAI would be associated with smaller involved hip moments and larger moments of the uninvolved knee and ankle.

METHODS

Thirty-six highly active individuals with symptomatic FAI scheduled to undergo hip arthroscopy (19 females; age: 25 years ± 10; mass: 72.9kg ± 16.9; height: 1.70m ± 0.10) were recruited from The Ohio State University Hip Preservation practice. The Institutional Review Board approved this study and all subjects provided written, informed consent prior to participation. All subjects underwent standard three-dimensional motion analysis testing (Motion Analysis, Santa Rosa, CA). Kinematic data during three drop vertical jump (DVJ) trials were sampled at 240Hz and ground reaction force data (1200Hz) were simultaneously collected from embedded force platforms. Marker trajectories and ground reaction force data were low pass filtered at 15Hz with a bidirectional Butterworth filter. Inverse dynamics were used to calculate external joint moments with custom Visual 3D (C-motion Inc., Germantown MD) and Matlab (Mathworks Inc. Natick, MA) coding. Ensemble averages were generated for both the involved and uninvolved limbs. Peak joint moments were identified during the landing phase of the DVJ (initial contact to lowest center of mass point), normalized to body mass and height (Nm/kg*m) and then used to calculate an asymmetry value (involved - uninvolved limb). Positive asymmetry values denoted larger joint moments in the involved limb.

Subjects were also asked to complete the Hip Outcome Survey Sports subscale (HOS-S), which is a reliable and valid questionnaire of hip function in patients with non-arthritic hip pain. Higher HOS-S scores reflect better hip function. Spearman rank correlation was used to test the association between HOS-S and sagittal plane joint moment asymmetries during the landing phase of the DVJ. A priori significance level was set at 0.05.

RESULTS AND DISCUSSION

The HOS-S scores ranged from 12.5% to 83.3% (52.4% ± 20.4). Hip and knee joint moment asymmetries were not significantly associated with HOS-S scores (Hip: r = -0.151, p = 0.380; Knee: r = -0.244, p = 0.151; **Figures 1 and 2)**. Only ankle joint moment asymmetry was associated with HOS-S scores (r = 0.410, p = 0.013; **Figure 3)**. Specifically, higher ankle moments on the involved

limb (positive asymmetry values) were associated with higher HOS-S scores.
Figure 1: Scatter plot of HOS-S scores and external hip joint moment asymmetry during the landing phase of the DVJ.
Figure 2: Scatter plot of HOS-S scores and external knee joint moment asymmetry during the landing phase of the DVJ.
Figure 3: Scatter plot of HOS-S scores and external ankle joint moment asymmetry during the landing phase of the DVJ.

The wide range of HOS-S scores reflects the established variability in self-reported function previously reported in this population. In partial support of our *a priori* hypotheses, higher ankle joint moments on the involved limb were identified in individuals with higher self-reported hip function. This 'ankle strategy' may reflect a neuromuscular compensation that allowed individuals to maintain a high level of sports participation. Ultimately however, this strategy was not an adequate, sustainable compensation; at the time of testing, all subjects were scheduled to undergo hip arthroscopy after failed attempts at conservative treatment.

CONCLUSIONS

Active individuals with FAI demonstrated kinetic asymmetries at the hip, knee, and ankle during a DVJ task. However, only ankle joint moment asymmetry was associated with self-reported hip function, and may be indicative of a compensatory strategy of athletes who maintain the highest levels of sport-related function despite painful hip symptoms.

This study was limited to sagittal plane kinetics during a bilateral landing task. We did not examine multiplanar compensatory strategies, which are known to occur during activities of daily living in this population. Future work is also required to determine whether hip arthroscopy allows athletes to achieve more symmetrical joint loading strategies, or if these adaptations require special attention during post-surgical rehabilitation efforts.

INTRODUCTION

Intra-articular fractures of the proximal tibia (plateau) have lower rates of post-traumatic osteoarthritis (PTOA) compared to those of the distal tibia (pilon). PTOA following joint injuries has been strongly correlated with mechanical factors, such as initial damage at the time of injury and repetitive damage from changes in joint congruity, alignment, and/or stability.

Differences in PTOA incidence between these fracture types may result from different impact energies absorbed by the joint surface. Differences in articular fracture edge lengths (AFELs), edges along which chondrocyte death is elevated [1], may also play a role. In this study, novel objective CT-based measures of fracture energy and of AFELs were used to describe differences between tibial plateau and tibial pilon fractures.

METHODS

Thirty-seven patients with intra-articular tibial plateau fractures and 32 with pilon fractures were enrolled from three different medical centers. A validated CT-based assessment was used to objectively measure fracture energy [2]. When bone is fractured, new surface area is liberated. This fracture-liberated (interfragmentary bone) surface area, scaled by its CT-derived bone density, provides an estimate of fracture energy [3,4]. Newly developed methods for measuring AFEL were used to analyze all of the fractures of the tibial pilon and 17 of the plateaus.

Custom software was utilized to identify fracture edges on CT-segmented bone fragments and to classify interfragmentary surface area for each fragment (Figure 1). AFELs were then measured directly at the intersections between subchondral and interfragmentary bone surfaces. Fracture
Figure 1: Views of tibial plateau and pilon fractures in the custom software. The left panel demonstrates the classification of a tibial plateau fracture into intact and interfragmentary bone. The right demonstrates two intra-articular fragments of a tibial pilon fracture, with the measured articular fracture edge lengths (AFELs) highlighted in yellow (bottom right images).

energies and AFELs measured from tibial plateau and pilon fractures were then compared.

RESULTS AND DISCUSSION

Fracture energies for tibial pilon fractures ranged from 6.43 to 37.95 J and for tibial plateau fractures from 3.55 to 39.63 J (Figure 2). The range of AFELs for tibial pilon fractures was from 56 to 289 mm and for tibial plateau fractures from 68 to 385 mm (Figure 3).

The fracture energy for tibial pilon fractures was 15.88 ± 8.71 J (mean $\pm$ standard deviation) and for tibial plateau fractures was 15.33 ± 9.16 J. There was no statistically significant difference between these groups.

The AFEL for tibial pilon fractures was 130 ± 55 mm and for tibial plateau fractures was 204 ± 82 mm. There was a statistically significant difference between these findings at a P-value of 0.003.

There were minimal differences in fracture energy between the two fracture types. There was a difference in articular fracture edge length, however. The injury mechanisms that produce these fractures are similar, but prior clinical studies have shown that PTOA develops in substantially fewer plateau cases. Anecdotally, orthopaedic surgeons believe there to be more crush in the tibial plateau fractures, potentially explaining the increased AFEL found in these cases.

CONCLUSIONS

PTOA is a complex disease. The underlying mechanical factors are poorly understood and likely joint specific. The data reported here suggest that fractures of the tibial plateau involve equivalent fracture energy as do fractures of the tibial pilon, but they generate larger AFELs. The reported discrepancy in PTOA incidence may be better explained through differences in joint anatomy such as cartilage thickness and the presence of a meniscus, mechanics of load distribution, or a combination of additional factors.

DYNAMIC SIMULATION OF PATELLAR TRACKING FOR KNEES WITH INSTABILITY

INTRODUCTION

Patellar dislocation is the most common acute knee disorder in children and adolescents. Numerous surgical options are available for treatment of recurrent lateral patellar instability, with limited consensus on how to optimize treatment based on the pathology of an individual patient. In vitro and computational evaluations of surgical options have consistently been based on normal knees. The current study focuses on development of a technique for dynamic computational simulation of patellar tracking for knees with instability that can be used to evaluate surgical options.

METHODS

Computational models were developed to represent knees of four patients with recurrent patellar instability who participated in an IRB-approved study to quantify the influence of tibial tuberosity realignment on patellar tracking [1]. Both pre-operatively and post-operatively, each patient performed a 10 second knee extension exercise against gravity within the bore of a dynamic CT scanner (Aquilion ONE, Toshiba Medical Systems). Bone models were reconstructed from the CT images to represent the femur, patella and tibia at 5 or more time points. Shape matching techniques were used to represent each position of knee extension with a single model of each of the three bones. Patellofemoral and tibiofemoral kinematics were characterized based on anatomical coordinate axes using the floating axis convention. Cartilage surfaces and bone models were also reconstructed from MRI scans of the knees, and shape matching techniques were used to align the cartilage surfaces to the bone models developed from CT.

Each knee model was individually imported into a multibody dynamics simulation platform (RecurDyn, Function Bay Inc). The ACL, PCL, MCL, LCL, posterior capsule, patellar tendon, and lateral retinaculum were represented with multiple springs and dampers, with anatomical attachment points [2]. Medial retinacular structures were not modeled as they are damaged by recurrent dislocation. Nonlinear force-strain relationships were assigned to the ligaments [2]. Pre-operative and post-operative (following tibial tuberosity realignment) patellar tendon attachment positions on the tibia were established based on the respective CT scans. Quadriceps forces representing the vastus medialis obliquus, vastus lateralis, and the vastus intermedius were applied through springs representing the quadriceps tendon, with a total force of 600 N (Fig. 1). Hamstrings forces were applied with a total force of 100 N. The mass of the lower leg was represented with structures extended from the proximal tibia. With the femur fixed and no other degrees of freedom constrained, dynamic extension from flexion was induced with application of the muscle forces. Cartilage contact was governed by a compliant model based on simplified Hertzian
Figure 1: Dynamic knee motion for one knee: computational simulation (top) and in vivo motion (bottom). The computational model includes cartilage embedded within the bone surfaces.

contact [2], allowing for simulation of knee extension in less than 15 minutes. Knee kinematics were quantified using the same coordinate systems used for the computational reconstruction of in vivo motion. Linear regressions were performed to relate simulated patellar tracking to the in vivo data at the knee flexion angles recorded for in vivo motion.

RESULTS AND DISCUSSION

Simulation produced kinematics trends similar to those measured in vivo (Fig. 1). For both the multibody dynamics models and the in vivo data, pre-operative patellar lateral shift and tilt tended to increase dramatically near full extension, and tibial tuberosity realignment tended to reduce both parameters near full extension (Figs. 2, 3). The in vivo data and the data from the simulations were significantly correlated ($p < 0.001$) with r^2 values of 0.71 and 0.61 for lateral tilt and shift, respectively. With the regression line passing through the origin, the slope of the regression was 0.98 for lateral tilt and 0.57 for lateral shift, indicating that lateral shift tended to be underpredicted, with more accurate predictions for patellar tilt.

The strengths of the modeling technique include an ability to represent unstable motion patterns, incorporate abnormal anatomy associated with instability, and rapidly characterize dynamic motion. Additional development is needed to improve the accuracy of representation of lateral shift and to represent functional activities more likely to induce patellar instability.

CONCLUSIONS

The multibody dynamics simulation models can be used to simulate in vivo patellar tracking patterns representative of knees with patellar instability. Tracking changes induced by surgical stabilization procedures can also be simulated. The modeling technique will be used to evaluate treatment options for patients with patellar instability while accounting for initial maltracking and abnormal anatomy.

ACKNOWELEDGEMENTS

THE BIOMECHANICAL ADVANTAGE OF LOCKED VERSUS NON-LOCKED SYMPHYSEAL PLATING OF UNSTABLE PELVIC RING INJURIES

[1]Ryan Godinsky, [1]Gregory Vrabec, [1]Loredana M. Guseila, [1]Danielle E. Filipkowski, and [1]John J. Elias

[1]Akron General Medical Center, Akron, OH, USA
email: john.elias@akrongeneral.org

INTRODUCTION

Symphyseal plate systems for treating pubic symphysis diastasis in unstable pelvic ring injuries are available with locked and non-locked capabilities. Locked plating systems were developed to improve post-operative stability and reduce the risk of failure, although a biomechanical advantage for locked symphyseal plating has yet to be experimentally demonstrated. The current study was performed to characterize the stiffness provided by locked and unlocked screws used for anterior pelvic ring internal fixation.

METHODS

In vitro testing was performed with pelvis models (Sawbones model 1301 full pelvis, foam with cortical shell). Each model was disarticulated at one sacroiliac joint and stabilized with S1 sacroiliac screws (Synthes 7.3 mm, cannulated, partially threaded) inserted via standard technique under direct visualization and real-time fluoroscopy. Anterior fixation consisted of symphyseal plating (Synthes 3.5 mm, 6-hole, locked symphyseal plate) used in either a locked (7 models) or non-locked (7 models) fashion.

The setup and loading protocols were adapted from previous in vitro studies simulating the single limb stance phase of gait [1-3]. The affected hemi-pelvis was supported by an articulating femoral head oriented at an angle of 15° adduction and steel cables secured to the iliac wing and the testing frame to recreate the effects of the abductor musculature (Fig. 1). A contralateral load of 80 N was applied through pulleys to represent the weight of the contralateral limb. Each model was cyclically loaded through the sacrum from 150 N to 350 N at 1 Hz for a total of 1000 cycles.
Figure 1: Experimental testing setup.

Opening at the symphysis was measured with a three dimensional video tracking system (MaxTRAQ 3D). Three pairs of markers were placed across the pubic symphysis, with several other markers distributed along the pelvis. Following calibration of the three cameras with a standardized frame, the position of each marker could be tracked as a function of time with an error of 0.1 mm (Fig. 2). The marker data was read in custom written software (Matlab). The software created a local coordinate system at the symphysis
Figure 2: Markers identified on a specimen.

that moved with the markers on the hemi-pelvis supported by the hip stem. The software applied a Gaussian filter to the cyclic motion of the markers and averaged data for 3 successive cycles at every 100 cycles of loading. Relative motion was measured between opposing markers across the symphysis in regards to medial-lateral gap formation, shear along the symphysis, and along an axis perpendicular to the other two (distal translation of the unsupported hemi-pelvis at the symphysis). For each cycle number evaluated, data was compared between the locked and non-locked conditions with t-tests.

RESULTS AND DISCUSSION

At the symphysis, distal translation during cyclic loading was larger for the non-locked models than the locked models. For the non-locked models, the translation tended to increase from cycle 1 to 100, and hold steady until 1000 cycles, while the motion did not tend to increase after the first cycle for the locked plates. For the markers closest to the plate (top markers) the translation was approximately 0.4 mm larger for the non-locked than locked models, compared to approximately 0.7 mm at the bottom markers (Fig. 3). At the onset of loading, average ($\pm$ standard deviation) distal translations at the bottom markers for the non-locked and locked models were 1.6 ± 0.5 mm and 1.2 ± 0.5 mm, respectively ($p = 0.182$). At 1000 cycles, the distal translations for the non-locked and locked models were 2.3 ± 0.6 mm and 1.4 ± 0.6 mm, respectively ($p = 0.015$). No significant differences were identified for gap formation or shear motion ($p > 0.3$).

CONCLUSIONS

The data indicates that symphyseal plating performed with locked screws provides more rigid stability than plating with non-locked screws. The primary mode of increased motion was the unsupported hemi-pelvis moving in a direction perpendicular to the symphysis, close to the direction of loading, with respect to the supported side. Reduced motion with locked screws could potentially allow earlier mobilization after injury
Figure 3: Distal translation for the top markers (closest to the plate) and bottom markers at the symphysis. Significant ($p < 0.05$) differences occurred at the cycles with nonsolid symbols.

with reduced risk of destabilization due to repetitive motion.

AGREEMENT BETWEEN 3D RECONSTRUCTIONS FROM FLUOROSCOPIC CONE BEAM AND CONVENTIONAL HIGH RESOLUTION CT FOR TRACKING NATIVE KNEE KINEMATICS

Arin M. Ellingson, Ryan Breighner, Joseph D. Mozingo, Dixon J. Magnuson,
Mark W. Pagnano, and Kristin D. Zhao
Mayo Clinic, Rochester, MN, USA
email: zhao.kristin@mayo.edu

INTRODUCTION

Kinematic assessment is a critical aspect of understanding normal and pathological joint function. Traditional analysis methods using surface based markers are inherently prone to error due to skin motion, which is exacerbated by high velocity motion.

Fluoroscopy offers a solution by directly capturing dynamic radiographic images of the bones and when combined with a 3D model of the bony anatomy, can properly quantify motion *in vivo*. The method uses a 2D/3D shape-matching approach, where the projection of a bony model is aligned with fluoroscopic image frames obtained dynamically during movement (Fig. 1). These models are generally created from a high resolution CT, which are costly, irradiative, and time consuming – as the patient or subject must be imaged by another scanner in a different location than the fluoroscope.
Figure 1: Shape-Matching Software. A- Screenshot of femur being tracked in Autoscoper. **B-** World view of 3D geometric model of femur. **C-** World view of 3D geometric model of tibia.

Fluoroscopic cone-beam CT (CBCT) – a volumetric acquisition capability on many fluoroscopes – overcomes these limitations since the bony geometry can be collected during the same session on the same device used for dynamics fluoroscopy acquisition. This ability portends a potential economical, radiation dose, and a clinical translation improvement over conventional CT.

Therefore, this research effort aimed to assess the comparative accuracy of surface models (femur and tibia) generated from a conventional multi-detector CT to a flat-panel cone beam acquisition via a fluoroscope. Additionally, these models were applied to a 2D/3D shape-matching protocol of a lower extremity during a flexion-extension activity and the limits of agreement between the kinematics outcomes were assessed.

METHODS

A fresh-frozen cadaveric lower extremity was obtained from Mayo Clinic Bequest Program and imaged using conventional multi-detector CT (0.57 x 0.57 x 0.7mm) and fluoroscopic cone-beam (1 x 1 x 1mm) 3D models of the femur and tibia were generated from each modality using simple thresholding techniques (Analyze 12.0 Mayo Clinic Biomedical Imaging Resource). Anatomical landmarks were digitized to define local coordinate systems for each bone [1]. Additionally, comparison of surface geometries was performed by first co-registering the mesh surfaces using a surface matching algorithm and then computing the Euclidean distances between the vertices on the CT reconstructed surface and the CBCT surface [2].

The femur and tibia of the intact lower extremity were secured in a custom apparatus that allowed for unconstrained knee flexion at a manually guided rate. The knee was centered in the imaging field of view of the 48 cm flat-panel Multi-Diagnost Eleva C-arm single-plane x-ray system (Philips Medical Systems, Best, Netherlands). X-ray (63 kV, 160 mA) images were acquired at 30 Hz with a Pulse Width of 1ms while performing a flexion-extension activity. A custom cube with evenly spaced tantalum beads was imaged to calibrate the image volume.

An open-source software, Autoscoper (Brown University www.xromm.org) was utilized to perform the 2D/3D shape-matching and relative tibia to femur kinematics defined using Euler angles (Z-X-Y sequence; flexion, abduction, external rotation) was measured for the flexion-extension activity from sets of bones generated from each image acquisition technique [3]. The limits of agreement for the relative 3D position and orientation between each technique were defined using a Bland-Altman approach.

RESULTS AND DISCUSSION
Effective dose between conventional CT and CBCT was 0.128 mSv and 0.022 mSv, respectively. A strong agreement between the surfaces of both femur and tibia was observed when comparing CT to CBCT reconstructed surfaces. As shown in Figure 2, the articular surfaces of the femur and tibia show surface reconstruction differences smaller than the mesh resolution (~1.685mm). On the femoral surface, 91.8% of CBCT vertices were within sub-resolution proximity of their respective neighbors on CT surface. This figure is 88.5% for the tibia, owing largely to the simplicity of the segmentation approach. The RMS of the distances for the femoral surfaces (an aggregate of registration and surface reconstruction errors) was 1.595mm, and 1.464mm for the tibial surfaces.

The average mean kinematic differences were 0.8°, 0.7°, and 0.4° (flexion, abduction, external rotation) and 0.3mm, 0.4mm and 1.4mm (anterior, superior, and lateral). Figure 3 displays a Bland-Altman plot quantifying the limits of agreement between the two models. As anticipated, the largest mean differences

were in medial-lateral translation. The error is associated with in-plane subjectivity with a single fluoroscope and the software's inability to view both the femur and tibia simultaneously during the analysis.

Figure 2: Surface Comparison between CT and CBCT. A strong agreement was observed between the surfaces from each modality. The RMS of the distances for the femoral surfaces (an aggregate of registration and surface reconstruction errors) was 1.595mm, and 1.464mm for the tibial surfaces. The distances are normalized to the mesh resolution and the errors are generally smaller than the finer of the two mesh resolutions – a mark of good agreement.

CONCLUSIONS
In conclusion, segmented 3D models generated from fluoroscopic cone beam and high resolution CT resulted in comparable surface geometries and sufficient kinematic agreement – similar to other reports [4,5].

EFFECT OF LONG-TERM USE OF HIGH-HEELED SHOES AND KNEE POSITION ON CALF MUSCLE ISOKINETIC STRENGTH

[1] Walaa H. Elsayed and [2] Ahmed T. Farrag

[1] University of Dammam, Dammam, Saudi Arabia
[2] Cairo University, Cairo, Egypt
email: ahmedfarrag@cu.edu.eg, whelsayed@uod.edu.sa

INTRODUCTION

Wearing high-heeled shoes (HHS) was reported to negatively impact different body structures [1]. Few studies examined the effect of long-term use of HHS on the muscular performance of the calf muscle [2, 3]. Furthermore, none of them tested how knee position would influence the calf muscle performance in high heels users. The importance of this study comes from the fact that the knee joint position was reported to significantly affect torque productivity of the calf muscle in non high heels users [4]. We thought that it is essential to explore that effect in high heel users as well. Therefore, the aim of this study was to test the combined effect of habitual wear of HHS and knee position on the calf muscle isokinetic torque productivity and the ankle joint active range of motion (ROM).

METHODS

A sample of 24 healthy young females was recruited (age: 23.4±2.9 y, weight: 58.5±0.8 Kg, height: 1.6±0.1 m). Participants had to have never suffered from major musculoskeletal or neurological disorders of the lower limbs. Participants were assigned to either the high-heel (HH) group or the control (CTRL) group. The HH group consisted of 12 participants who must have worn HHS of at least 5 cm high for a minimum of 40 h/week and for at least a year before joining the study. Participants who have worn HHS for less than 10 h/week were assigned to the control group.

A Biodex 4 pro dynamometer (Biodex Medical Systems Inc., Shirley, NY, USA) was used to measure the peak torque of the calf muscle. System calibration was performed each session prior to data collection. The movement velocity was set at 60º/s and the ROM was set between 15º of dorsiflexion and 30º of plantar flexion. After signing a consent form, subjects were seated and secured in the Biodex chair with the back support inclined to 80º. According to the test condition performed, the knee joint was positioned in either full extension or 90º flexion. The knee was supported and secured in place using a knee pad and velcro straps. Participants were secured by trunk and pelvic straps in addition to a thigh strap to limit body and lower limb rotations. Positional adjustments ensured the alignment of the ankle joint axis with that of the dynamometer. After that, the ankle joint ROM was measured using a BASELINE digital inclinometer. The inclinometer was placed along the fifth metatarsal bone. Participants were instructed to avoid non-sagittal plane movement of the foot and to move the foot from full dorsiflexion to full plantar flexion. Measurements were recorded in both testing positions. The foot was then secured to the foot plate. Following familiarization trials, participants were instructed to move the foot throughout the pre-set range as fast and as strong as possible. This was followed by a 2 minutes rest, during which the lower limb position was changed to fit the other knee position. Then, the participants performed the task under the new arrangement. This was followed by a 5 minutes rest. Then, the entire procedures were repeated for the contralateral side. Order of the test conditions was randomized.

Three repetitions were performed for each condition. Data were averaged for statistical analysis. An unpaired t-test was used to test the effect of high heels long-term use (HH×CTRL). A paired t-test was used to test the knee position effect (Flex.×Ext.). The alpha level was set at $p \leq 0.05$.

RESULTS AND DISCUSSION

Knee joint position significantly impacted torque measurements in both groups (p<0.001). The extended knee position resulted in a 37% and 27.8%

greater peak torque for the HH and CTRL groups, respectively, compared with the flexed knee position (Figure 1).

The calf muscle is primarily composed of the biarticular gastrocnemius and the uniarticular soleus muscles. Therefore, manipulating the knee position could be mechanically disadvantageous for the gastrocnemius muscle. According to the length-tension relationship, flexing the knee joint can limit force productivity of the gastrocnemius muscle. Interestingly, flexing the knee decreased torque measurements in the HH group (37%) more than it did in the CTRL group (27.8%). Furthermore, Torque measurements in the flexed knee position were significantly different between the two test groups (p=0.04). The CTRL group exerted a 22.5% greater torque compared to the HH group. This would imply the likelihood of structural changes that might have occurred in the soleus muscle of the HH group.
Figure 1: Peak torque measurements as a function of group and knee position. * indicates significant paired t-test. § indicates significant unpaired t-test.

Shortening of the gastrocnemius fascicle length in long-term users of HHS was previously reported. It was concluded that it could have been compensated by the observed increase in the achilles tendon size and stiffness [2]. This resulted in an insignificant difference in torque measurements between high heels users and non-users. However, this conclusion was based on measurements performed in an extended knee position only. In our study, it seems that such structural changes of the achilles tendon could not produce a similar compensatory effect when the knee joint was flexed. This could be attributed to the increased slack of the musculo-tendinous unit and the limited contractility of the gastrocnemius muscle in the flexed knee position.

The CTRL group performed a significantly greater ankle joint ROM (p<0.001) in the flexed knee position compared with the extended position (Figure 2). Furthermore, ROM of the CTRL group was significantly greater (15.8% difference) than that of the HH group, only in the flexed knee position (p<0.001). This would reflect a decreased flexibility of the muscular and connective tissue structures of the calf muscle, which is further evidenced by the insignificant difference observed between the two test positions for the HH group.
Figure 2: ROM measurements as a function of group and knee position. * indicates significant paired t-test. § indicates significant unpaired t-test.

CONCLUSIONS

The results suggest that knee flexion has a more profound effect on plantar flexion torque in habitual high heel users compared to non-users. This may indicate that the contractile properties of the soleus muscle could be significantly affected, even more than the gastrocnemius muscle, by the long-term use of high-heeled shoes. Therefore, it is recommended that upon evaluating the effects of prolonged use of HHS, evaluators should consider the test position of the knee in order to properly assess the functional capacity of the calf muscle.

A NOVEL PLANNING PARADIGM FOR AUGMENTATION OF OSTEOPOROTIC FEMUR

[1] Amirhossein Farvardin, [1] Ehsan Basafa and [1,2] Mehran Armand

email: farvardin.amirhossein@gmail.com, web: http://bigss.lcsr.jhu.edu/

INTRODUCTION

The one-year mortality rate after osteoporotic hip fracture in elderly is 23% [1]. Current preventive measures commonly do not have a short-term (less than one year) effect. Moreover, the risk of a second hip fracture increases 6-10 times in elderly with osteoporosis [2]. Osteoporotic hip augmentation (femoroplasty) is a possible preventive approach for patients at the highest risk of fracture and who cannot tolerate other treatment modalities. Recent computational work and cadaveric studies have shown that osteoporotic hip augmentation with Polymethylmethacrylate (PMMA) can significantly improve yield load and fracture energy [3]. However, higher volumes of PMMA injection may introduce the risk of thermal necrosis. In this study, we introduce a modified planning approach to lower the injection volume as compared to the previous work [3]. This will likely reduce the risk of thermal necrosis caused by exothermic polymerization of PMMA. The method was preliminarily tested in a pilot experiment where we also monitored the surface temperature of bone tissue during the procedure.

METHODS

A pair of frozen osteoporotic femora (neck T-score of -2.0 left and -3.8 right sides) was acquired from Maryland Board of Anatomy. The PMMA injection was computationally planned on the weaker specimen using the method discussed in the following. Invasive bone fracture experiments were then performed and the results were compared to the plan.

The modified planning paradigm involves three steps: 1) finite element (FE) optimization of the PMMA distribution, 2) geometric optimization for approximating the FE-optimized model geometry with spheroids, and 3) hydrodynamic simulation to predict the resulting PMMA distribution in the bone. FE models of the femora were created using CT scans obtained from the specimens following the procedure described earlier [4]. The boundary conditions simulated a fall to the side. For the first step of planning, three injection patterns were optimized utilizing the Bi-directional Evolutionary Optimization (BESO) method [5].

In the second step, the FE-optimized injection pattern was approximated by a number of spheroids (realistic injection volumes) along a single injection path. During this step the size and location of the spheroids along the injection path was optimized to find the best match between FE model and the spheroid alignments (Fig. 1). Finally, we used a particle based simulation to predict the resulting pattern of cement diffusion inside the bone.
Fig. 1: Schematic of the optimized injection pattern by BESO (blue), practical injection volume (green) and line of injection (red)

To accurately inject PMMA in selected regions of the bone, we used a previously developed navigation system along with a custom-made injection device [3]. Surface temperature of the

bone was recorded utilizing 3 k-type thermocouples placed at neck, greater trochanter, and trochanteric crest of the femur.

Finally, mechanical testing was performed to fracture the bones in a configuration that mimics a fall to the side on the greater trochanter [3]. The mechanical strength of the femora was determined from these invasive tests.

RESULTS AND DISCUSSION

From planning, it was determined that only 7.7 cm^3 of bone cement is sufficient to increase the yield load of the specimen by 67% (from 1350 N to 2256 N). Adding to the volume of cement did not significantly increase the predicted yield load. The calculated amount of bone cement was 23% less than the 9.5 cm^3 average volume used in the previous method of augmentation planning [3].

Mechanical testing showed that the yield load for augmented specimen was 59% higher than that of control (Fig. 2). Also yield energy was 161% higher for the augmented pair (2897 vs. 7549 N.mm). These results show significant improvements in bone strength with a reduced amount of PMMA.
Fig. 2: Force-Displacement curves obtained from mechanical testing

The measured profiles (Fig. 3) show that maximum temperature-rise of 10 ℃ occurs at 12 minutes after the injection. The 10 degrees temperature-rise was maintained for less than 30 seconds which is well

below the level causing osteonecrosis [6]. Of note, for this preliminary study the exact distance of the thermocouple from the bone-cement interface was not determined.
Fig. 3: Recorded temperature rise of bone surface at different locations.

CONCLUSIONS

Both simulation and experimental results suggest that the modified planning for bone cement injection remains effective while reducing the cement volume and the number of required injection paths. Reduced volume of bone cement can lead to a lower risk of thermal necrosis a potential challenge associated with bone augmentation. Future work will include additional experiments to fully validate the findings of this study.

EXPLORING THE REGIONAL RESPONSE OF THE INTERVERTEBRAL DISC UNDER POSTURAL VARYING LOADS

INTRODUCTION

This investigation examined differences between the anterior and posterior radial displacement (*i.e.* bulging) of the annulus of the intervertebral disc. Generally, there have been very few studies that have quantified the magnitude of IVD disc bulging on the posterior aspect of the disc. This is attributable to bony structures and passive tissues that occlude a direct line-of-sight to the posterior-lateral region of intact functional spinal units (FSUs). Recent work [1], has characterized the effect of posture on IVD bulging on human lumbar FSUs. With the posterior elements removed, results from this investigation revealed that the median IVD bulge in the anterior and posterior-lateral regions was altered, when a 7.5 Nm flexion moment was applied. However, to the best of the author's knowledge the combined effects of increasing magnitude of compressive load and posture on IVD bulging have yet to be investigated. Therefore, to better understand how the structural responses of the anterior portion of the IVD may be related to the posterior portion, this study quantified the magnitude of anterior and posterior-lateral radial displacement in the IVD across different postural conditions and magnitudes of compressive load. In-line with this objective it was hypothesized that a negative correlation between anterior and posterior bulging would emerge. Results from this study may elucidate a link between radial displacement on the anterior side of the IVD that would facilitate inferences on the structural changes on the posterior side on intact specimens with the posterior element intact.

METHODS

Six cervical porcine FSUs were tested. A modified servo-hydraulic materials testing system was used to apply flexion/extension motion and compressive loading to intact specimens. A 3D non-contact laser displacement sensor (LJ-V7080, Keyence Corporation, Osaka, Japan) was used to measure annulus fibrosus (AF) radial displacement across four levels of compressive load (10 N, 300 N, 600 N and 1200 N) and two posture conditions (neutral and flexion). The anterior aspect of the six FSUs were scanned during all conditions with the posterior elements intact (i.e. anterior-intact condition). Then the posterior elements from these specimens were removed, leaving a reduced FSU. Both the anterior and posterior sides of the IVD were scanned during all remaining conditions (anterior-reduced and posterior). A total of 24 scans (load x4, posture x2, location x3) were collected from each specimen. The primary dependent measure analyzed was peak AF radial displacement across conditions, which was computed from the 3D IVD surface profiles measured using a using a computer-aided bulge analysis software platform produced by the Vision and Image Processing research group, designed to track and quantify AF radial displacement (Version 8.5, Matlab, Mathworks Inc., Natick, MA, USA) (Figure 1).

To facilitate a comparison of peak AF bulging measurements between specimens and to improve anatomical interpretation of the measure, the maximum bulge perpendicular to a vector defined by the endpoints of the superior and inferior endplates has been reported [2]. To determine whether the removal of posterior elements had any effect on the bulge size, a paired t-test was employed to compare the anterior and anterior-reduced AF bulge measurements. A Pearson's *r* correlation analysis was also conducted on the anterior and posterior AF bulge measurements. Initially, a paired t-test was used to determine if there was a significant difference in the slopes of the posterior-anterior bulge comparisons across magnitudes of compressive load. There was no significant difference that emerged therefore all

loading conditions were collapsed into one correlation analysis.
Figure 1: Anterior (left) and Posterior (right) 3D surface profiles of radial displacement measured from the surface of an IVD.

RESULTS AND DISCUSSION

No significant difference was observed between anterior-intact and anterior-reduced peak AF bulge ($p = 0.312$). Therefore, anterior-reduced surface scans were utilized to make comparisons to peak posterior AF bulge. A significant negative correlation between anterior-reduced and posterior bulge measurements was observed in a flexed posture (Pearson's $r = -0.432$; p = 0.018). As posterior AF bulging increases anterior AF bulging decreases. (Figure 2).
Figure 2: Scatter plot illustrating a negative correlation between anterior-reduced and posterior AF bulging in a flexed posture.

Results also demonstrated that in a flexed posture, as the magnitude of compressive loading increased,

there was a trend that emerged of an increased posterior AF radial displacement and a decrease in anterior AF bulge (Figure 3). No significant correlation was observed between anterior-reduced and posterior radial displacement measurements in a neutral posture ($p = 0.312$).
Figure 3: Average anterior-reduced and posterior peak AF radial displacement in a flexed posture across loading conditions. Standard error bars are displayed.

CONCLUSIONS:

The preliminary results from this investigation elucidate a link between measured AF bulge on the anterior and posterior side of the IVD. Understanding how the AF responds under various loads in flexion and extension postures has clinical relevance, as IVD herniation has been observed with repeated flexion-extension under modest amounts of compressive load. The magnitude of posterior AF bulge increased in flexion as the magnitude of the applied compressive load increased. As such, the magnitude of strain and risk of tissue damage in the AF is expected to follow a similar trend.

PRELIMINARY FINITE ELEMENT ANALYSIS OF SUBCHONDRAL BONE CYSTS IN THE STIFLE OF THE HORSE

[1] Lance L. Frazer, [1] Kenneth J. Fischer, and [2] Elizabeth M. Santschi

[1] The University of Kansas, Lawrence, KS, USA
[2] Kansas State University, Manhattan, KS, USA
email: fischer@ku.edu

INTRODUCTION

Medial femoral condylar (MFC) bone cysts (SBC) develop in the trabecular subchondral bone of the MFC of young horses (Fig. 1), and can cause lameness and limit performance.[1] Experimental MFC defects demonstrate progressive changes (void enlargement and MFC collapse) very similar to equine natural disease, and mechanical alterations that negatively affect the bone repair process due to the voids have been hypothesized, but not proven.[2] Recent clinical evidence in the horse indicates that lag screw placement across the MFC promotes bone healing and lameness resolution[3], but little is known about the biomechanics of an intact or damaged MFC, or how mechanics can optimize healing. The objective of this preliminary study was to develop a finite element model of the equine stifle joint and to describe stress in the medial femoro-tibial joint with an intact MFC, with two sized of MFC voids, and with sclerotic trabecular bone, which is present before cyst development.

METHODS

Using Simpleware™ software, a finite element model was generated using a CT scan of a cadaveric normal yearling equine stifle joint (Fig. 2). Bone was semi-automatically segmented by thresholding with manual adjustment, and the soft tissues were manually segmented. Segmented structures included: femur, tibia, and associated articular cartilage, medial and lateral meniscus, and menisco-tibial and menisco-femoral ligaments. The final mesh contained 336,000 linear, tetrahedral elements with the highest concentration of elements in the MFC. Bone material properties were assigned using the grayscale properties from the CT. The range of apparent density was 0.007 to 1.82 g/cm^3, and the equation $E = 6000\rho^{2.5}$ was used to relate density to

Young's Modulus (YM), resulting in YM up to 20 GPa for cortical equine bone, and a Poisson's ratio of 0.3 was also assigned. The mesh and bone material properties were then imported into ABAQUS finite element analysis software. Approximate relaxation soft-tissue material properties were assigned also based on prior published studies.[4,5,6] Thus, a YM of 4 MPa was assigned for cartilage, 20 MPa for meniscus, and 345 MPa for ligaments, each with a Poisson's ratio of 0.2. The model was analyzed under four MFC conditions; 1) intact, 2) with 1000 mm^3 of stiffened subchondral trabecular bone (sclerosis) (YM raised to 20 GPa), 3) a subchondral void of 80 mm^3 and, 4) a 1000 mm^3 void in the central weight bearing surface of the MFC.

The models were tested in extension (approximately 155°), and all tissues were modeled as isotropic and linear elastic. Contact surfaces were established for all exterior surfaces to fully allow normal meniscal sliding. The friction coefficient between these surfaces was set to 0.02. Displacements were fully constrained for the distal tibia. In the cystic models, the void was assigned a YM of 0.001 MPa. All 4 models underwent the same testing procedure with a normal pressure loading at the proximal femur (1000N resultant load).

RESULTS AND DISCUSSION

Max principal stress values for each model are summarized in Table 1. Figure 3 illustrates that the intact model yields negligible Von Mises stresses. The sclerotic model shows increased stress distribution in the superior and inferior aspects of the sclerotic region; SBCs originate at the inferior aspect of sclerotic subchondral bone. The 80 mm^3 MFC causes large stress concentrations caudal and cranial to the lesion as well as tensile stress above

the lesion, not present in the intact model (Table 1). The 1000 mm³ void results in severe stress alterations around the void with high tensile stress in the bone just below the cyst region (Table 1).

CONCLUSIONS

This preliminary study provides insight into the biomechanics of the yearling stifle joint under 4 MFC conditions: intact, with sclerotic subchondral bone, and with 2 sizes of subchondral voids. Under load, the MFC with sclerotic bone and 80 mm³ or 1000 mm³ voids demonstrates stress increases around the void, suggesting a biomechanism for formation of subchondral lucencies, an explanation for their frequent failure to heal, and a justification for the use of a transcondylar MFC screw. The increase in tension under any condition may suggest a formation mechanism as trabecular bone is weakest under tensile force. Understanding the biomechanics of the intact MFC and the MFC with a void and will help direct the development of future therapies for treatment of SBCs in the horse. Future models will examine bone stress and strain with variations in load, flexion angle, and cyst size. The model itself will also be improved by implementing viscoelastic properties for the various soft tissues, using quadratic elements, and gaining a better understanding of tissue property changes before and during cyst development.

INTRODUCTION

Finite element (FE) modeling provides an established, useful tool for assessing biomechanics without invasive testing. One important and emerging application is the use of FE models to assess the risk of long bone fractures, which are prevalent in populations with bone fragility due to aging, osteoporosis, and various genetic and metabolic disorders. For example, FE modeling can be used to assess bone strength and fracture risk in individuals with osteogenesis imperfect (OI), a heritable bone fragility disorder [1, 2]. Children with OI have an especially high prevalence of long bone fractures. As the major load-bearing bones during ambulation, current models of OI have focused on lower extremity bones [1, 2]. However, the upper extremity bones, including the humerus, experience weight-bearing loads during assisted ambulation with crutches and walkers. Analysis of children walking with instrumented Loftstrand crutches showed they experienced shoulder forces up to nearly 35% of their body weight [3]. It has also been shown that assisted ambulation can cause a 24Nm bending moment at the shoulder joint [4]. However, to date, no study has examined how loads sustained during assisted mobility may put patients with OI at risk for upper extremity fractures.

This project focused on the development and validation of a humeral FE model subjected to physiologic bending loads such as those seen during assisted ambulation [3, 4]. This model is appropriate for application to various populations at increased risk for humeral fractures who use assistive devices for ambulation.

METHODS

Fourth-generation composite humeri (named H-VHP model; Sawbones Worldwide, Pacific Research Lab, Inc., Vashon, Washington, USA) were manufactured for this project based on the humerus geometry of the National Institutes of Health (NIH) Visible Human Project (VHP).

A composite humerus was instrumented with two stacked rectangular strain gage rosettes (Vishay Micro-Measurements, Raleigh, North Carolina, USA) and subjected to bending loads. The center gage of each rosette was aligned with the anatomic axis on the anterior and posterior side of the humerus. A four-point bending setup was used, in which the support rollers were on the anterior side, 92 mm distally and proximally from the gage rosettes. Loading was applied on the posterior side; each roller positioned 28 mm on either side of the gage rosette (Fig. 1a). The humerus was loaded with 200 N through a servo-hydraulic materials testing machine (MTS 809, Eden Prairie, Minnesota, USA). This load was selected in order to simulate a 24 Nm bending moment about the shoulder joint axis that an individual would experience during assisted ambulation with Loftstrand crutches [4]. Strains were recorded from each gage and the principal strains were calculated for each rosette.

The testing conditions were then replicated in a three-dimensional (3D) FE model of the humerus (Fig. 1b) and processed in Abaqus 6.10 (Dassault Systèmes Americas Corp.; Waltham, MA). The 3D model geometry was defined from a CT scan of the composite humerus and then imported into IA-

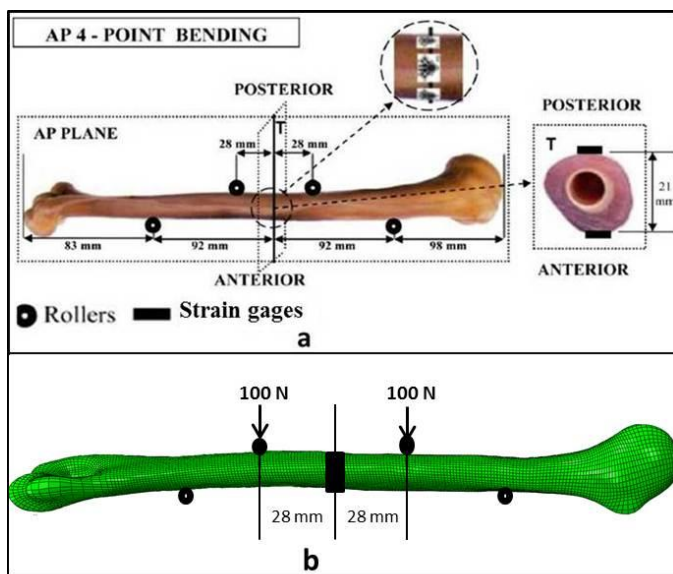
FEMesh software [5]. The humerus was meshed with 59,852 eight-noded linear hexahedral elements (C3D8) with an average element size of 1.25 mm. Meshing of both the cortex and cancellous layers of the humerus was performed using the multi-block approach in IA-FEMesh [5]. Cortical bone was defined with a Young's modulus (E) of 10.6 GPa (based on experimental data of tensile testing) and a Poisson's ratio (ν) of 0.3 (from composite bone manufacturer). Cancellous bone regions were assigned material properties provided by the composite manufacturers: E = 0.160 GPa and ν = 0.26. A set of elements corresponding to the locations of each strain gage rosette was defined. These elements were used for the FE model analysis in order to correspond with the testing data since the rosette locations may not coincide with overall maximum and minimum principle strain locations.


Figure 1: Four-point bending of humerus models during a) experimental bending test of the composite humerus in the anterior-posterior (AP) plane and b) finite element (FE) model analysis. The FE model also shows the location of the strain gages (SG) from experimental testing.

RESULTS AND DISCUSSION

The FE analysis showed excellent agreement with the experimental data during AP bending in maximum principal strain with a difference of 1.4% (Table 1). The difference in minimum principal strains between the experimental and FE results showed good agreement with a difference of 10.8% (Table 1). Limitations in this study include some variability between the three experimental trials and the inherent assumptions in FE modeling and analysis. Despite these limitations, there was good agreement between the FE model results and experimental data.

CONCLUSIONS

The high level of agreement between the two results validates the use of the FE model of the humerus to examine biomechanical responses to loading. This model has potential applications in populations such as the elderly or those with OI. These populations may use assistive devices for ambulation and would, therefore, be loading their upper extremity long bones, such as the humerus, with a percentage of their body weight.

INTRODUCTION

Osteogenesis imperfecta (OI) is a heritable disorder characterized by skeletal deformity and bone fragility. While the mechanisms are not fully understood, the fragility is believed to stem from a combination of bone mass deficiency and compromised bone material properties [1, 2]. Poor bone quality poses unique orthopaedic and rehabilitation challenges for treating persons with OI. Risk of fracture becomes a major consideration not only for prescribing physical therapy but also for activity restrictions and modifying activities of daily living (ADLs). Unassisted ambulation may result in a high enough load to cause a fracture in persons with moderate to severe OI. Due to these challenges, fracture risk quantification can be an invaluable tool in OI management and fracture rehabilitation. Finite element (FE) models have recently been applied to quantitatively assess *in vivo* loads experienced by long bones in persons with OI [3, 4]. Material properties reflective of the mechanical response of OI bones to loading are imperative to accurate fracture risk assessment [5]. A recent study confirmed that cortical bone material strength of OI bone is substantially lower than normal pediatric bone, indicating that reduced mechanical tissue quality is a contributing factor to fracture risk in this population [6].

The present study examined the response of an FE model of pediatric femurs with normal, mild-moderate OI and severe OI material properties under ambulatory loads (i.e., joint forces and moments and intrinsic muscle activation forces).

METHODS

Three-point bending tests were performed on bone specimens obtained from the femoral diaphysis of three donors: 1) an 11-year-old male (cadaveric) with no known bone disorder, 2) a 10-year-old male with OI type I (mild-moderate), and 3) an 11-year-old male with OI type III (severe). The OI specimens were acquired and tested under informed consent/assent and following a protocol approved by our Institutional Review Board (IRB). Longitudinal and transverse Young's modulus (E) and yield strength (σ_y) were determined for each specimen.

A previously developed hexahedral FE model of a pediatric femur was used for this study (Fig. 1) [7].
Figure 1: Finite element (FE) model of the femur with boundary conditions (condyles) and representative loadingv during mid-stance.

Three models were created, corresponding to the material properties of each cortical bone specimen (Table 1). Young's modulus for cancellous bone was conservatively modeled as being 60% of cortical bone [8]. Shear modulus was estimated assuming transversely isotropic material behavior. Each model was loaded based on forces experienced during the mid-stance phase of gait. Gait data was previously collected under IRB approval from a 12-year-old with OI type I [3]. All three femurs were modeled with normal geometry (no bowing). The geometry and loading were kept constant among the three models in order to solely focus on the effects of the bone material properties (Fig. 1). Maximum longitudinal stresses and strains were analyzed. Results were compared between models as well as against yield strength from the mechanical analyses.

RESULTS AND DISCUSSION

The model's material properties and the resulting maximum stresses and strains are presented in Table 1. While the analysis did not show major differences in the maximum longitudinal stress values between bone types, these values are much closer to a level of stress causing yield for the OI bones than for a normal pediatric femur. This can be clearly seen by looking at the maximum longitudinal stress as a percentage of σ_y, which provides a metric for proximity to fracture level. Maximum transverse stresses only reached a maximum of 13.5 % of transverse yield strength for OI type III bone, with lower values in the other two models. However, the severe OI (type III) reaches about 80% of its longitudinal yield strength. It must also be kept in mind that persons with OI often have deformed long bones. Increases in lateral bowing of the femur have been shown to cause a linear increase in maximum stress results [5, 7].

CONCLUSIONS

This study demonstrates the need to not only understand the difference in mechanical properties, such as Young's modulus, seen in OI bone, but also their failure loads and mechanisms. Finite element modeling and analysis has the capabilities to estimate safe loading levels from activities such as walking, running and jumping in which children with OI may want to participate. The current work, combined with previous analyses, shows the multifactorial requirements for subject-specific FE analysis of material properties, loading and geometry to provide the most accurate assessment of femoral loading during ADLs [5, 7, 8].

PTH SINGALING MEDIATES PERILACUNAR REMODELING DURING EXERCISE

[1]Joseph D. Gardinier, [1]Salam Al-Omaishi, [1]Michael D. Morris, [1]David H. Kohn

email: josephdg@umich.edu

INTRODUCTION

The structural integrity of bone is constantly adapting in response to dynamic loading and calcitropic hormones, specifically parathyroid hormone (PTH) [1]. The transient increase in PTH levels during short-term treadmill exercise contributes to the increase in structural and tissue-level properties of bone despite no significant changes in mineral content or overall geometry [2]. Un-like osteoblasts, osteocytes are ideally located throughout cortical bone to augment its intrinsic properties by modifying the perilacunar tissue through osteocytic osteolysis [3]. Given that the osteocytes' ability to modify the perilacunar tissue is also mediated by PTH signaling [3], we hypothesize that PTH signaling during exercise contributes to changes in the perilacunar tissue composition. Therefore, the purpose of this study is to (1) establish that changes in perilacunar composition occur following short-term exercise and (2) demonstrate the influence PTH signaling has on perilacunar adaptation during exercise.

METHODS

16 week old male C57Bl/6J mice were used along with an exercise regimen involving 30 minutes of running on a treadmill at 12 m/min and 5° incline for 21 consecutive days. Mice were divided into four weight-matched groups: sedentary + vehicle, sedentary + PTH(7-34), exercise + vehicle, and exercise + PTH(7-34). Each mouse received a subcutaneous injection of either 60µg/kg of PTH(7-34) to inhibit PTH signaling or vehicle control each day over the course of 21 consecutive days. On day 22, each mouse was sacrificed and tibiae were removed. One tibia was used for ex-vivo micro-CT scans and then mechanical testing, which applied four-point bending with the medial side in tension. The second tibia was embedded in PMMA, sectioned at the mid-diaphysis, polished to a thickness of 200 µm, and then imaged using a locally constructed Raman microprobe with a line focused 785-nm diode laser (Invictus, Kaiser Optical Systems) and 40X/0.75DIC objective (Plan Fluor, Nikon Instruments). Raman spectroscopic signatures were taken across the perilacunar (< 5 µm from an osteocyte) and non-perilacunar regions (>15 µm from an osteocyte) regions of 3 to 4 osteocytes within the medial cortex of each tibia. The carbonate-to-phosphate ratio (CPR) was calculated based on the carbonate (1071 cm-1) and phosphate (959 cm-1) band intensities. The mineral-to-matrix ratio (MMR) was calculated based on the phosphate and hydroxyproline (855 cm-1) intensities. Peak fitting was implemented using GRAMS software and the MMR and CPR for each group was the average of 4 samples, where each sample was the average of 3 to 4 representative perilacunar or non-perilacunar regions. Two-way ANOVA with a post-hoc Tukey-Kramer test was used to establish interactions between groups.

RESULTS AND DISCUSSION

Across the vehicle treated groups, exercise caused a significant increase in the mechanical properties at the structural and tissue levels: stiffness (105.1 ± 13.7 N/m vs. 84.3 ± 4.6 N/m), post-yield displacement (171.8 ± 34.4 mm vs. 96.9 ± 6.4 mm), modulus (12.6 ± 0.6 GPa vs. 9.8 ± 0.6 GPa), ultimate stress (206 ± 6 GPa vs. 180 ± 6 GPa), and post-yield toughness (2.6 ± 0.4 MPa vs. 1.3 ± 0.1 MPa) compared to sedentary controls, along with a decrease in pre-yield work (1.8 ± 0.1 mJ vs. 2.5 ± 0.2 mJ). Despite these changes in mechanical properties, there were no significant differences in cortical area, moment of inertia, or bone mineral density. However, there were significant changes in tissue composition, which included an overall increase in the CPR (0.14 ± 0.01 vs. 0.12 ± 0.01, p-value < 0.001) compared to sedentary controls (Fig 1). The largest increase in CPR was found in the perilacunar region (0.12 ± 0.01 vs. 0.15 ± 0.01, p-value = 0.08) compared to the perilacunar region of sedentary controls. Exercise also caused a

significant decrease in the perilacunar MMR compared to sedentary mice, and as a result exhibited the same MMR as the non-perilacunar tissue (Fig 2). In contrast, sedentary mice exhibit a significantly higher MMR in the perilacuanr tissue compared to the non-perilacunar.
Figure 1: Exercise had a main effect on the CPR. Significant differences in perilacunar CPR between exercise + vehicle and exercise + PTH(7-34) indicates that PTH signaling mediates perilacunar remodeling during exercise. (mean ± SEM, n = 4).
Figure 2: In response to exercise, adaptation to the MMR only occurred in the perilacunar region. PTH signaling during exercise mediated changes in perilacunar MMR given the significant differences between exercise + vehicle and exercise + PTH(7-34). (mean ± SEM, n = 4).

Comparisons between sedentary and exercise groups treated with PTH(7-34) revealed no significant changes in the mechanical properties of the tibia (stiffness, post-yield displacement, modulus, ultimate stress, pre-yield work, and post-yield toughness). In addition, the perilacunar tissue did not exhibit significant changes in the CPR or MMR during exercise and PTH(7-34) treatment compared to sedentary controls treated with PTH(7-34) (Fig 1 & 2). However, significant differences in the perilacunar MMR and CPR were found between exercise + vehicle and exercise + PTH(7-34).

CONCLUSIONS
Exercise induced significant changes in the mechanical properties of bone in coordination with significant changes in tissue composition without altering its geometry, size or bone mineral density. As a result, the increase in stiffness and ultimate stress due to exercise were attributed to the increase CPR, given that an increase in carbonate substitution increases tissue stiffness [4]. Similarly, the increase in post-yield displacement and toughness were considered a function of a decrease in MMR [5], due to a potential increase in collagen synthesis during exercise [6]. Adaptations in MMR and CPR during exercise were localized predominately within the perilacunar regions, and dependent upon PTH signaling at the cellular-level. In response to lactation, the osteocytes ability to remodel the lacunae structure is mediated by the PTH/PTH-related protein receptor [3]. In this study, the use of PTH(7-34) revealed that PTH signaling during exercise mediates changes in the perilacunar tissue composition, which also corresponded with changes in the mechanical properties at the whole bone level.

LUMBAR SPINE KINEMATICS FOR END-RANGE TRUNK POSITIONS
IN HEALTHY INDIVIDUALS USING UPRIGHT MRI

INTRODUCTION

Low back pain (LBP) is a problem that affects up to 80% of people at some point in their lives [1]. Poor posture and movement abnormalities have been identified as contributing factors to the problem. Researchers have measured spine kinematics using imaging technologies such as x-ray, dual fluoroscopy, and magnetic resonance imaging (MRI) [2-4]. Prior MRI studies have examined kinematics during unloaded positions, including rotation [2]. Studies using x-ray and dual fluoroscopy have been limited in their ability to measure a wide variety positions and axial plane mobility. A recent study by Rodriguez-Soto et al has used upright MRI to measure lumbar spine kinematics in military personnel during different loading conditions [5], however, only sagittal plane motion was measured. The purposes of the current study are: 1) to quantify end range lumbar spine kinematics in healthy individuals using MRI, and 2) to determine which intervertebral segments contribute most in each plane of movement. Examining kinematics across a variety of positions with MRI will help researchers and clinicians better understand normal mobility in the lumbar spine with physiologic movements and provide a basis for comparing these to measurements in people with spine disorders.

METHODS

Sagittal T2-weighted images were acquired using a 0.6T upright MRI scanner (Fonar Corporation, Melville, NY). Eight healthy individuals (3 male and 5 female), with an age range of 18-33 years, height 67.0 ± 3.9 in, and weight 144.0 ± 3.9 lb were imaged in eight different static positions (standing, sitting flexion, prone on elbows, prone extension, sitting right and left rotation, standing right and left lateral bending) in blocked random order based on position (Figure 1). Global and local measurements

were used to quantify the alignment of the lumbar spine using a validated endplate-based joint coordinate system [6].
Figure 1: Sample T2-Weighted MRI of Standing (A), Sitting Flexion (B), Prone Extension (C), and Left Lateral Bending (D).

Briefly, the endplates and posterior elements of each vertebra (L1-S1) were marked on each slice using the region of interest (ROI) tool in OsiriX. ROI's were imported into a custom-written Matlab program to calculate three-dimensional rotations and translations of the whole lumbar spine and each intervertebral segment. Global measures of lumbar spine alignment were: angle with respect to the horizontal and sagittal and coronal Cobb angles. Local measures were lumbar intervertebral angles.

To determine differences in global measures of lumbar spine alignment in each plane, repeated measures ANOVA tests were conducted to determine the effect of position on sagittal and coronal Cobb angles. To determine which vertebral segments contributed most to kinematics in each

plane, separate repeated measures ANOVA tests were conducted to examine the effect of level (L1-S1) and position on intervertebral kinematics.

RESULTS AND DISCUSSION

There was a significant effect of position on angle with respect to the horizontal and sagittal Cobb angle (P<.01) for **sagittal plane** positions, with larger Cobb Angles associated with more extended positions (61.9-74.0º). For sagittal intervertebral angles, there were significant main effects of position and level, and a position x level interaction effect (Figure 2, P<.01). The greatest degree of change between positions occurred at L5-S1.
Figure 2: Sagittal Intervertebral Kinematics

For **coronal plane** positions, there was a significant effect of position on coronal Cobb Angle (P<.01). For coronal intervertebral angles, there was a significant effect of position (P<.01), no effect of level (P=.9), but a significant position x level interaction effect (Figure 3, P<.01).
Figure 3: Coronal Intervertebral Kinematics

Greater movement occurred in the upper lumbar spine segments and to the right with lateral bending. For **axial plane** positions, there was a significant effect of position on coronal Cobb Angle (P<.01), indicating that participants displayed coronal plane movement with sitting rotation positions. For axial

intervertebral angles, there was a significant main effect of position (P<.05), but no level (P=.25) or level x position (P=.89) interaction effects (Figure 4).
Figure 4: Axial Intervertebral Kinematics

CONCLUSIONS

The greatest degree of movement in the lumbar spine occurred in the sagittal plane, followed by the coronal plane, with the least mobility in the transverse plane. The greatest degree of sagittal plane movement occurred in the lower lumbar segments, while more coronal plane movement occurred in the upper lumbar segments. Minimal rotation movement was observed with positions of loaded, sitting rotation. These data provide information on lumbar spine kinematics during end-range, loaded positions using upright MRI and can provide a basis for comparing people with low back pain.

INTRODUCTION

The North American working population is aging. American workers over 55 comprised 19% of the labour force in 2010 [1] and the proportion of Canadian workers over 55 increased by 21.7% between 1997 and 2010 [2]. Occupational injuries sustained by American workers 65 and older resulting in a lost-time claim increased by 6.4% between 2007 and 2008 [3]. The low back was the body location ranked highest in number of injuries sustained among Ontario workers in 2013, accounting for 17% percent of all lost time claims, with the leading demographic group 50-54 year old males [4]. A mechanistic understanding of the age-related responses to loading in spinal tissues is essential to the prevention of low back injury throughout the aging process. Known age-related changes to the intervertebral discs (IVDs) of the spine include; the denaturation of collagen fibres [5], reduction/altered distribution of proteoglycans [6] and an increased propensity to form microstructural clefts in response to tensile loading when compared to more juvenile samples [7]. The formation of clefts is a known mechanism of initiation and propagation of an IVD herniation [8]. The aim of this investigation was to quantify the effect of age on the mechanical properties of annulus fibrosis tissue following exposure to cyclic loading.

METHODS

A total of 8 (4 mature, 4 young) cervical functional spinal units (FSUs) were obtained fresh-frozen from mature (aged ~3 years) and immature (aged ~6 months) porcine spines. The FSUs included two adjacent vertebral bodies with the intervening disc and were tested in a modified servohydraulic testing system (Model 8872, Instron Canada, Burlington, ON, CAN). To counteract post-mortem swelling, specimens were loaded with 300 N of compression for 15 min while the zero moment posture about the flexion/extension axis was determined. Following the preconditioning phase, specimens were loaded with 1400 N of compression and cyclically loaded at 1 Hz to a range of motion 8.5 degrees in flexion and extension around the midpoint of each specimen's neutral zone for 3000 cycles.

Following the cyclic loading protocol, specimens underwent further biaxial mechanical testing to determine how age impacts the mechanical properties of the annulus following loading exposure. A total of 12 (6 mature, 6 young) anterio-lateral annular specimens were excised from the intermediate layers of the IVD with an average (SD) thickness of 0.9 (0.2) mm and comprised of 3-5 annular layers. The specimens were tested in a humidity and temperature-controlled environment of 30 (1.4) degrees Celsius and 94.3 (1.5) % humidity to prevent dehydration. Specimens were dissected to dimensions of approximately 5 mm x 5 mm and mounted into a biaxial tensile (BioTester 5000, CellScale, Waterloo Instruments Inc., Waterloo, ON, CAN) testing system by puncturing the edges with sharpened tungsten wires. Following the mounting procedure, specimens were preloaded in the axial and circumferential directions with 10-15 mN, followed by preconditioning of 5 cycles of 10% actuator stretch at a rate of 1%/s and subsequently loaded to 20% actuator stretch for 100 cycles at a rate of 2%/s.

Dependent measures of interest included neutral zone range (degrees) and neutral zone stiffness (Nm/degree) both pre and post loading protocol for intact FSUs. Additionally, peak stress (MPa) in the circumferential and axial directions for excised annular samples during cycles 1, 50 and 100 were examined.

RESULTS AND DISCUSSION

Of the 8 FSU specimens tested; sagittal plane radiographs indicated that 2 of the specimens (1 young, 1 mature) sustained a herniation due to the loading protocol. There was a significant effect of age on neutral zone range (p=0.0448) where mature specimens had a smaller range before and after the loading protocol compared to the younger specimens (Figure 1). There was a main effect of age on neutral zone stiffness (p=0.0446) where mature FSUs had greater stiffness compared to younger specimens (Figure 2). There was no main effect of the loading protocol on neutral zone range or neutral zone stiffness.
Figure 1: Neutral zone range by age across time point
Figure 2: Neutral zone stiffness by age across time

Decreased specimen flexibility among the mature FSUs is consistent with previous work [9]. There was no main effect of age or cycle on the peak stress. While not statistically significant, Figure 3 depicts a trend consistent in both loading directions of higher peak stress in the mature specimens compared to the young specimens with an overall reduction in peak stress with a more cycles.
Figure 3: Peak stress in the circumferential direction by age and cycle

Ongoing work continues on samples excised from the posterio-lateral location of the annulus and on mature and young annular samples in the absence of cyclic loading in order to isolate any innate differences due to aging alone. The results from this work will provide insight into differences in the responses to loading due to age. The biological changes and the cumulative exposures that occur throughout the aging process are important to understanding the mechanisms of injury given an aging workforce.

THE EFFECTS OF A FIVE-WEEK EXERCISE INTERVENTION USING EMG BIOFEEDBACK ON SCAPULAR KINEMATICS AND SCAPULAR STABILIZER MUSCLE ACTIVATION

[1] Samantha R. Gunderson, [1] Jun G. San Juan, [1] Wren L. Cunningham, and [1] David N. Suprak

[1] Western Washington University, Bellingham, WA, USA
email: Samantha.Gunderson13@gmail.com

INTRODUCTION

Research on utilizing electromyography (EMG) biofeedback training as a preventative tool is limited. It is well documented that EMG biofeedback has become a useful tool with rehabilitation of subacromial impingement syndrome. Biofeedback gives patients a better sense of the activation of different muscles that are involved in the movement of the shoulder girdle [1]. With the muscle activation patterns shown on a projected screen, patients are able to get a visual representation of the proper firing of the muscles [2]. However, research on utilizing EMG biofeedback as a preventative tool in the reduction of the risk of onset subacromial impingement is limited. The purpose of this study is to investigate changes in scapular kinematics as a result of changes in muscle activation patterns in a healthy population.

METHODS

Twenty-one healthy subjects (12 females, 9 males) participated in this study. The mean age was 22.3 ± 1.92 years old, mean height was 1.71 ± 0.11 m, and a mean weight of 67 ± 10.28 Kg. Those who had shoulder pain within a year, were diagnosed with impingement, who had shoulder surgery, or previously participated in EMG biofeedback were excluded. The subjects were randomly assigned to two different groups that consisted of an exercise only group, and an exercise with biofeedback group. Both groups participated in exercises that targeted activation of the lower trapezius. The scapular stabilizer exercises (I, W, T, Y) were performed three times a week at 1 set of 10 repetitions. The exercise with biofeedback group participated in an EMG biofeedback session once a week. To measure muscle activation, a Noraxon Desktop DTS (Gain 500, CMRR > 100dB, input impedance > 100Mohm) was

utilized and sampled at 1500 Hz. The EMG data were normalized using maximum voluntary isometric contraction for all the muscles tested. Bi-polar Ag/AgCl surface electrodes were placed parallel to the muscle fibers of the upper and lower trapezius, serratus anterior, and lumbar paraspinals of the dominant arm with an inter-electrode distance of 1.7 cm (Figure 1 A).

A Polhemus Fastrak magnetic tracking device was used to measure 3-dimensional scapular kinematics. The receivers were attached to the spine of the scapula using a customized scapular tracker, thorax, and distal humerus (Figure 1 B). A Polhemus sensor pen was utilized to digitize the spinous process of C7, T1, T7, and T8, the sternal notch, the sternoclavicular joint, and lateral and medial epicondyles of the humerus to set-up the coordinate system following the standard set by the International Society of Biomechanics.
Figure 1: (A) Set up of the EMG electrodes on UT, LT, SA and LPS and (B) set up of the Polhemus Fastrak 3D kinematics system.

The EMG data were displayed on a stationary overhead projector connected to a PC-type of computer using MR3.4 MyoMuscle software (Figure 2). Subjects were told to actively try and reduce the

muscle activation shown on the screen for the upper trapezius during the exercises.
Figure 2: EMG muscle activation patterns projected on a screen during a biofeedback session.

A three-way mixed ANOVA was utilized to compare scapular kinematics, and mean EMG amplitude at baseline, week 6, and week 8. The independent variables were humeral elevation (30°, 60°, 90° & 110°), group, and time (baseline, week 6, and week 8). The dependent variables were scapular kinematics (upward rotation, external rotation, and posterior tilt), and EMG amplitude. Alpha level was set to 0.05.

RESULTS AND DISCUSSION

One subject dropped out due to injury that was unrelated to this study. There was a statistically significant interaction between time and elevation during scapular posterior tilt ($p < 0.001$), for the exercise only group (Figure 3). After the exercises, the scapula was in a less posteriorly tilted orientation. There were no significant differences found for scapular upward rotation, nor for scapular external rotation at all humeral elevation angles between times, and group. There was no significant difference found between the groups for mean EMG amplitude, at baseline, week 6, or week 8. The decrease in posterior tilt that was observed with the exercise only group could lead to a decrease in subacromial space. A decreased subacromial space brings the subacromial bursa, biceps brachii long head tendon, and supraspinatus tendon closer to the coracoacromial arch [3].
Figure 3: Scapular posterior tilt for the exercise only group at baseline, week 6, and week 8. An asterisk denotes statistical significance.

Electromyography biofeedback intervention training does not seem to have an impact on altering scapular kinematics or scapular stabilizer muscle activation patterns in healthy individuals. However, the exercises that were performed by both the exercise only group, and exercise with biofeedback group may alter scapular kinematics. Moving toward a more functional type of exercise may be more beneficial in altering the scapular kinematics and muscle activation patterns. Utilizing EMG biofeedback with a more functional type of task could improve the muscle activation patterns and scapular kinematics.

CONCLUSIONS

Exercises focusing on activation of the lower trapezius, and serratus anterior may alter scapular kinematics in healthy individuals. A less posteriorly tilted scapular might result in a decrease in subacromial space, which can help in the development of shoulder pathologies such as subacromial impingement. The exercises performed in this study did not elicit the desired alterations in muscle activation patterns and scapular kinematics.

USING DIGITAL IMAGE CORRELATION TO INVESTIGATE THE EFFECT OF IMPACT VELOCITY ON THE RESPONSE OF A VERTEBRA

[1] Hannah Gustafson, Kohle Merry and Peter Cripton

[1] Department of Mechanical Engineering and ICORD, The University of British Columbia, Vancouver, BC, Canada
email: gustafson.30@gmail.com, web: www.sites.mech.ubc.ca/~injury/

INTRODUCTION

Vertebrae exhibit rate dependent behavior with a stiffer response observed at higher displacement rates [1-3]. Therefore, it would be expected that the strain would be lower at higher loading rates. However, the full-field strain response at different loading rates has not been quantified.

We propose investigating strain on cadaveric vertebrae at varying impact rates using digital image correlation (DIC), an optical method which provides full-field non contact strain measurements on the bone surface. We hypothesize that with increasing impact rates, the deformation and strain magnitude at a given force will be lower; furthermore, we predict the strain magnitudes at one impact rate will be predictive of the strain magnitudes at other impact rates.

METHODS

A custom built impactor rig with a mass of 1.6 kg was attached to a drop rail. One fresh frozen cadaveric L1 vertebra was used for initial testing. All soft tissue and the posterior elements were removed from the bone. The bone was potted in polymethylmethacrylate (PMMA) to create parallel surfaces for loading. For the DIC, the bones were painted white and speckled with black paint using an airbrush. Images of the anterior surface during loading were captured with two high speed cameras (Phantom V12s, Vision Research, USA) at 11,000 fps (Figure 1). The forces and moments were collected with a six-axis load cell placed below the specimen. The bone was impacted 30 times at heights of 2 cm, 5 cm, and 10 cm. These heights correspond to nominal velocities of 0.62, 0.99 and 1.40 m/s. During testing, no visible damage was

observed. Furthermore, the 2 cm drops at the start and end of testing had similar force-deformation responses and peak forces indicating that the overall response of the bone was similar with time and no significant structural damage occurred which may have contributed to changes in the bone's mechanical response.

The DIC was processed using commercial software (Strainmaster, LaVision Inc., Germany). The displacement was measured on the anterior surface in the superior-inferior direction and the strain was analyzed over a region in the center of the anterior surface (Figure 1).
Figure 1: High-speed camera image of the anterior surface of the bone potted in PMMA. The line indicates the location where the displacement was measured. The box indicates the location over which the DIC pattern was compared

RESULTS AND DISCUSSION

The force-displacement curves of 14 (of the 30) tests are presented along with the average curves for the three drop heights (Figure 2).
Figure 2: Average force-displacement response. Displacement was measured on the anterior surface of the bone (Fig 1); force was measured in the axial direction.

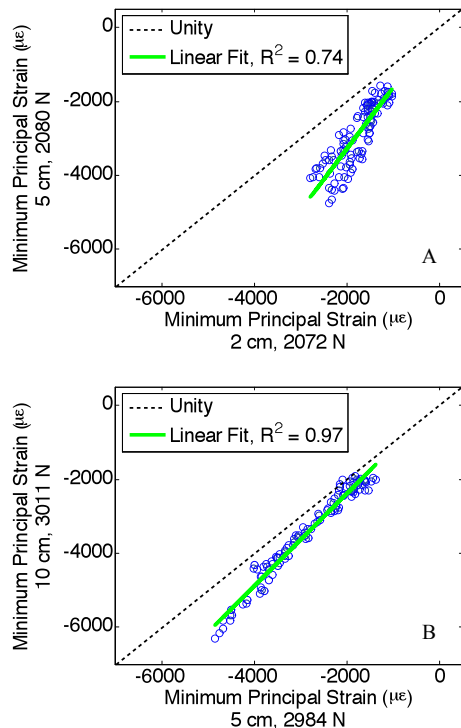
The patterns of DIC strain were compared using regressions in which the minimum principal strain magnitude on the anterior surface of the bone was plotted against the strains measured at the same locations on the bone surface at another drop height and at similar applied force values (Figure 3).


Figure 3: Strain regressions comparing the DIC-measured strain from (A) 5 cm drop height to 2 cm drop height at ~ 2080 N and (B) 10 cm drop height to 5 cm drop height at ~3000 N. Each dot represents the strains at a particular location.

As impact velocity increased, a greater displacement was measured at a given force. This result does not support the hypothesis that the bone would deform less at higher impact velocities. Furthermore, in the strain patterns we similarly observed more strain at the higher impact velocity for a particular force value. The strain patterns at lower impact velocities predicted the strain patterns at higher impact velocities (R^2 = 0.74 and 0.97). Since strain is related to failure, this result suggests that vertebral failure locations on the anterior surface of the bone are similar at different impact velocities.

In contrast to previous research and our expectations, the tested vertebra did not behave viscoelastically. This may be a result of the quality of the bone or a result of inertia-driven impact loading instead of loading with a driven actuator such as in a materials testing machine.

CONCLUSIONS

The tested vertebra did not behave viscoelastically, based on the force-displacement curves and strain results. Although the strain at lower velocities was strongly correlated with the strain at higher velocities, the magnitudes were larger for the higher velocity impacts. Understanding of the strain on the bone surface at varying impact rates helps us better understand bone fracture initiation and failure mechanics and can be used to validate computational models.

Finite Element-Based Adjacent Level Intersegmental Rotation and Intradiscal Pressure Analysis after Lumbar Fusion for Scoliosis

[1]Ram Haddas, [2]Ming Xu, [3]Isador H. Lieberman, [2]Brandon J. Snailer, and [2]James Yang

[1]Texas Back Institute Research Foundation, Plano, TX, USA

INTRODUCTION

Degenerative adult scoliosis results from age related changes leading to segmental instability, deformity and stenosis.[1] Spinal fusion is a standard method of surgical treatment for deformity.[2] Loss of native lumbar lordosis, abnormal loading and increased mobility in adjacent segments, may alone or in combination explain the development of adjacent level deterioration.[3] Finite element (FE) model studies have made important contributions to the understanding of functional biomechanics of the lumbar spine.[4] In comparison to in vitro or in vivo approaches, computational methods eliminate the issues with cadaver use, animal use and clinical human studies, in addition to being cost efficient, time efficient, and an accurate surrogate.[5] The purpose of this study was to develop a finite element model of a lumbar scoliotic spine, and investigate the effect of adjacent load transfer before and after fusion surgery.

METHODS

Two three-dimensional nonlinear finite element models of the lumbosacral spine were created from a 73-year old male subject's pre and post scoliosis surgery CT scans (Fig. 1). Pedicle screws and rods were implanted during surgery at the L_2 to S_1 levels. The FE spine models were developed encompassing the T_{12} to S_1 levels, along with the screws and rods for the post surgery model (Fig.2). 3D Slicer software was used to generate the outer shell virtual model of each individual vertebrate and disc. This was followed by a smoothing process to smooth these outer surfaces and fill in holes using Geomagic Studio software. These modified virtual models from T_{12} to S_1 were imported into Truegrid

and Hyperworks software to form 3D solids and these solids were meshed. Finally these meshed models were input into LS-DYNA for FE analysis under different loading conditions.

Figure 1. Pre and post scoliosis fusion surgery scans.
Figure 2. Pre and post fusion surgery finite element models of scoliosis spine from T_{12}-S_1 level with pedicle screws and rods at L_2-S_1.

For the analysis the S_1 level of the model was fixed. Seven ligaments and local muscle forces were added to this model.[6] A 500N compressive follower load and six different moments were applied to this model: (1) flexion bending moment; (2) extension bending moment; (3) right lateral bending moment; (4) left lateral bending moment; (5) right axial rotation moment; and (6) left axial rotation moment. The compressive follower load was applied to represent the subject's upper body weight. The six types of bending moment represent the six movements of the spine. The following values for pre- and post-surgery were compared for each load condition: intradiscal pressure and intersegmental rotation (flexion, extension, lateral bending, and axial rotation) at the L_{1-2} level.
Figure 3. Pre and post fusion surgery intersegmental rotation of scoliosis spine at the L_{1-2} level.

RESULTS AND DISCUSSION

The extent of intersegmental rotation in degrees and the extent of the intradiscal pressure at the L_{1-2} level post surgery increased or stayed the same under the six loading conditions compared to the pre surgery condition (Fig. 3, Table. 1). The post surgery pressure contours on the L_{1-2} intervertebral disc varied with the different applied moments for the pre-and post-surgery (Table 1).

CONCLUSIONS

With this study we were able to develop a finite element model of a lumbar scoliotic spine, and investigate the effect adjacent load transfer before and after fusion surgery. The results of this study will help define the variables contributing to adjacent level deterioration in the clinical environment. With this information a surgeon can plan the most appropriate surgical strategy pre surgery to prevent mid and long term adverse outcomes associated with adjacent level deterioration.

INTRODUCTION

Lifting is a ubiquitous activity, where individuals are required to manually handle materials and loads while engaged with occupational tasks and activities of daily living.[1] Asymmetric lifting, including flexion and rotation, is the most frequently reported culprits associated with low back disorder.[2] Degenerative adult scoliosis resulting from age related changes leads to segmental instability, deformity and stenosis.[3] Spinal fusion is a standard method of surgical treatment for deformity.[4] Loss of native lumbar lordosis, abnormal loading and increased mobility in adjacent segments, may alone or in combination explain the development of adjacent level deterioration.[5] Finite element (FE) model studies have made important contributions to the understanding of functional biomechanics of the lumbar spine.[6] In comparison to in vitro or in vivo approaches, computational methods eliminate the issues associated with cadaver use, animal use and clinical human studies, in addition to being cost efficient, time efficient, and an accurate surrogate.[7] The purpose of this study was to develop a finite element model of a lumbar scoliotic spine and then investigate the effect of asymmetric loadingas is common with lifting, on the adjacent segment after lumber fusion surgery.

METHODS

A post operative CT scan of a 73-year old male scoliosis subject was used. Pedicle screws and rods were implanted at L_2-S_1 levels. A FE spine model was developed encompassing the T_{12}-S_1 level along with the screws and rods (Fig.1). 3D Slicer software used to generate the outer shell virtual model of each individual vertebrate and disc. This was followed by a smoothing process to smooth these outer surfaces and fill in holes using Geomagic Studio software. These modified virtual models from T_{12}-S_1 were imported into Truegrid and Hyperworks software to form 3D solids and these solids were meshed. Finally these meshed models were input into LS-DYNA for FE analysis under different loading conditions. All screws that were used to fuse the spine from L_2-S_1 were built into the FE model as well.
Figure 1. Post fusion surgery finite element model of scoliosis spine from T_{12}-S_1 level with pedicle screws and rods at L_2-S_1.

For this subject the S_1 vertebral level of the model was fixed. Seven ligaments and local muscle forces were incorporated into this model.[8] Two types of

combined loads were applied to this model: (1) 7.5 Nm flexion and right axial rotation moments and (2) 7.5 Nm flexion and left axial rotation moments with compressive follower loads of: 500N, 750N, 1000N, 1250N, and 1500N, respectively. The compressive follower load was applied to represent the subject's upper body weight. The FE analysis was conducted and compared for post-surgery for each load condition: intersegmental rotation and intradiscal pressure at the L_{1-2} level, the L_{2-3} level pedicle screws and rod forces.
Figure 2. Post fusion surgery finite intersegmental rotation at L_{1-2} for right and left rotation along with flexion moment and five different load conditions.

RESULTS AND DISCUSSION

The intersegmental rotation angle and the intradiscal pressure at level L_{1-2} were recorded for each of the five loading conditions (Table. 1, Figure 2). The maximum resultant forces in the pedicle screws and rods at the L_{2-3} level were recorded under each loading condition as well (Table 1.) Increasing the amount of compression load increased the intersegmental rotation and the intradiscal pressure nonlinearly. As the compression

force increased, the pedicle screws and the rod were subject to higher stresses.

CONCLUSIONS

With this study we have developed a FE model of a lumbar scoliotic spine in an effort to determine the adjacent level stress and strain as well as the stress and strain on the pedicle screws and rods. The results of this study will help define the variables contributing to adjacent level deterioration in the clinical environment. With this information a surgeon can plan the most appropriate surgical strategy pre surgery to prevent mid and long term adverse outcomes associated with adjacent level deterioration.

Peak Knee Joint Contact Force Increases with Body Borne Load During Run-to-Stop Task

[1]Clifford L. Hancock, [1,2]John W. Ramsay, and [1]Tyler N. Brown

INTRODUCTION

Musculoskeletal injury, particularly of the lower extremity, is a serious military issue that increasingly leads to long-term disability and discharge of the soldier [1]. These injuries often result from repetitive forces that impact the lower limbs during military-relevant tasks, such as the run-to-stop (RTS). Performing the RTS requires rapid deceleration which potentially places large compressive forces on the knee. These compressive forces may further increase with the addition of body borne loads commonly worn during military training, e.g., 20 kg or greater, and potentially lead to musculoskeletal injury. However, to date, the effect of body borne load on knee joint contact force during the RTS is unknown. Unexpected stops, i.e., performing an unplanned, reactive RTS, may further elevate these compressive forces and the subsequent risk of musculoskeletal injury. Therefore, the purpose of this study was to determine if peak knee joint contact force (PKJCF) increases with the addition of body borne load during anticipated and unanticipated RTS tasks.

METHODS

Seven males (21.7 ± 4.2 years; 1.8 ± 0.1 m; 71.7 ± 9.1 kg) had lower limb biomechanical data recorded during a series of RTS maneuvers. Each participant performed the RTS with three military-relevant body borne loads: no load (NL; 6.2 kg), fighting load (FL; 20.0 kg) and approach load (AL; 40.0 kg). While wearing each load, participants performed three anticipated (AN) and unanticipated (UN) RTS maneuvers with their dominant limb. Each RTS required the participant to run at 3.5 m/s $\pm$ 5% on a walkway, plant their dominant limb on a force platform (AMTI) embedded in the floor, and immediately stop in a low-ready position. For the AN maneuver, each participant responded to a visual stimulus delivered ~5 s prior to initiation of the movement. During the UN task, each participant responded to a visual stimulus triggered ~600 ms prior to force platform contact.

For each RTS maneuver, sagittal plane limb biomechanics were quantified from the 3D coordinates of 36 reflective skin markers recorded using twelve high-speed (240 Hz) optical cameras (Qualysis AB). The marker trajectories were low-pass filtered with a fourth-order Butterworth filter (12 Hz) by Visual 3D (C-Motion). Biomechanical data (kinematics, kinetics and GRF) were imported into OpenSim [2] to estimate lower limb joint moments, segment positions and muscle forces. The force estimation process entailed generation of an anthropometrically scaled subject-specific model, residual reduction analysis and static optimization. The FL configuration was modeled with a 20 kg point mass applied at the torso center of mass, while the AL included the FL mass and an additional 20 kg attached to the posterior torso. PKJCF was estimated using the Joint Reaction tool and was defined as the force acting on the tibial plateau parallel to the longitudinal tibial axis [3]. Limb stiffness (k) was defined as the ratio of peak vertical ground reaction force (vGRF) to change in leg length (ΔL) [4].

For analysis, PKJCF, peak vGRF, knee flexion moment at PKJCF, ΔL, and k were assessed during the stopping phase (from initial contact of the dominant limb to contact of the non-dominant limb) of each RTS maneuver. Subject-based means for both the AN and UN maneuvers were calculated. The subject based mean for each dependent variable was submitted to a repeated measures ANOVA to test the main effects of and possible interactions between body borne load (NL, FL and AL) and movement type (AN and UN). Where statistically significant ($p<0.05$) differences were observed, Bonferroni pairwise comparisons were used.

RESULTS AND DISCUSSION

The biomechanical results of the RTS tasks are presented in Table 1. During the RTS, adding body borne load increased the PKJCF ($p<0.001$) and the potential for musculoskeletal injury. Specifically, participants exhibited a significant 1.15 N/kg increase in PKJCF with the AL compared to the NL configuration ($p=0.006$), but a similar increase was not evident compared to the FL (0.54 N/kg; $p=0.107$), or between the NL and FL configurations (0.61 N/kg; $p=0.063$).

The increased PKJCF evident with body borne load may stem from a simultaneous increase in vGRF ($p=0.002$) and knee flexion moment ($p=0.025$). During the RTS, peak vGRF was significantly greater (0.5 N/kg; $p=0.014$) during the AL compared to NL configuration. Yet, similar increases of peak vGRF were not evident between the AL and FL (0.3 N/kg; $p=0.114$), or between the FL and NL conditions (0.2 N/kg; $p=0.156$). To prevent musculoskeletal injury, the vGRF needs to be attenuated through lower limb (e.g. knee) joint moments. The fact that participants exhibited significantly larger knee flexion moment with the AL compared to NL ($p=0.010$), but not compared to the FL ($p=1.000$), or between the NL and FL configurations ($p=0.147$), supports this contention. The larger external knee flexion moment, which must be counterbalanced by eccentric quadriceps activation to prevent lower limb collapse, potentially increases compressive force and subsequent injury risk of the knee joint, particularly with the heavy (i.e. 40 kg) body borne load.

To prevent collapse of the lower limb and successfully perform the RTS, participants exhibited a significant increase in k ($p=0.015$) with the addition of body borne load. However, after controlling for Type I error, k was not significantly different ($p>0.05$) between any of the load configurations, which may be attributed to the fact that ΔL did not change ($p=0.899$) when adding body borne load [3]. As such, future research is warranted to determine if varying ΔL (i.e. greater lower limb flexion) while performing military-relevant tasks helps soldiers attenuate the larger compressive forces exhibited on the knee joint with the addition of body borne load.

Performing an unplanned RTS did not further elevate the potential for musculoskeletal injury. Specifically, PKJCF did not significantly differ ($p=0.693$) between the UN (3.05 N/kg) and AN (2.96 N/kg) maneuvers. The insignificant increase in PKJCF during the UN task may be attributed to the fact that participants failed to exhibit a significant increase of peak vGRF ($p=0.280$), knee flexion moment ($p=0.864$), k ($p=0.463$), or ΔL ($p=0.398$) as compared to the AN maneuvers.

CONCLUSIONS

The addition of body borne load during military-relevant tasks likely increases the risk of musculoskeletal injury. This elevated risk results from greater compressive force on the knee joint that may be attributed to the increased peak vGRF and knee flexion moment evident with the heavy (40 kg) body borne load. Yet, performing an unplanned task did not result in greater knee joint force and risk of musculoskeletal injury. Future research should determine the lower limb mechanical patterns necessary to decrease the compressive force on the knee joint, particularly with heavy body borne loads.

MEASURING CAPULOHUMERAL RHYTHM WITH SUPRASPINATUS IMPAREMENT: A PRE- AND POST-OPERATIVE COMPARISON

[1] Ashley N. Hannon and [1,2]Thomas R. Jenkyn

[1]Western University, London, ON, CANADA, Dept. of Kinesiology
[2] Western University, London, ON, CANADA, Dept. Mechanical Engineering
email: ahannon@uwo.ca

INTRODUCTION

A common clinical measurement of glenohumeral kinematics is the evaluation of scapulohumeral rhythm. Inman[1] measured this motion in-vivo through bone pins and x-rays. Observations of scapulohumeral motion after the initial stabilization period, which is variable, lead to a 2:1 ratio of glenohumeral motion to scapulothoracic motion.

Improvements in technology allows for non-invasive in-vivo measurements to be observed. Giphart[2] used biplanar fluoroscopic radiosteriometric analysis (RSA) in healthy normal subjects and noted results similar to Inman[1] for abduction, but slightly lower in forward flexion.

Quantifying the motion during abduction (ABD), flexion (FF), and compound motion (arm across chest (AAC) using a biplanar fluoroscopic RSA technique in subjects with healthy, normal shoulders as well as pre- and   post- surgical repair supraspinatus muscle uses a very accurate technique to describe motion in 3D and gains further insight for clinicians.

METHODS

Five healthy normal subjects were recruited. The subjects performed one trial of right arm ABD to 90˚, FF to 90˚ and the compound motion of moving the right hand to the left shoulder (AAC). These were completed at a self-selected pace. One subject with medium sized supraspinatus tear determined by MRI by operating clinician also completed the movement trials, 7 days prior to surgical intervention, and 6 weeks post-surgical intervention.

Biplanar fluoroscopy was collected at 30 Hz on all subjects and was matched with a Sawbone® generic shoulder model CT scan according to Hannon[3] RSA technique was employed in Rhinoceros® 3D modeling software. Once each frame of motion was matched in both planes, ISB recommended[4] landmarks of the scapula and humerus were exported, as seen in Figure 1, below.
Figure 1: Virtual 3D biplanar fluoroscopic laboratory set up in Rhinoceros® with Sawbone® imported.

The measurements of the humerus in relation to the scapula for the motions were calculated. Data was filtered with a 4th lowpass Butterworth filter with a cutoff frequenzy of 3Hz. Data was normalized to 100% of motion. Standard error was calculated to determine excursion from the mean. Descriptive statistics were determined for all three rotations of the humerus in relation to scapula.

In order to obtain scapulohumeral rhythm measurements, glenohumeral motion was subtracted from total scapulohumeral motion, calculating the scapular motion component of ABD, FF and ACC motions.

RESULTS AND DISCUSSION

Results for this study illustrate that there is a large variability within all scapulohumeral motion. Figure 2 illustrates the glenohumeral motion during abduction. It is evident that the healthy population has a large variability as the humerus reaches 90° in relation to the midline. The trial of the subject prior to surgical intervention shows that there is a larger component of humeral motion. Finally, post-surgical intervention, the subject has a slightly lower component of glenohumeral abduction during this motion.
Figure 2: Glenohumeral abduction during ABD in healthy (with SEM), pre and post intervention

The increased glenohumeral motion could be due to increased activation of associated humeral abductor muscles including deltoids as a compensatory mechanism for the weakness in the injured supraspinatus.

Table 1 illustrates that there is slightly less motion during the overall movement in the injured population, prior to surgical intervention, while the healthy population maintained the approximate 2:1 ratio of humerus to scapula found prior [1, 2]. The post-operative group could have increased humeral motion in relation to the scapula due to the other muscles of the rotator cuff compensating for the injured supraspinatus for a period prior to intervention, and with the repair, all abductors are activated, increasing the humeral component of abduction. Additional changes in variability could be due to the calculation accounting for the entire range of motion as opposed to only the portion above 30° in ABD or 60° FF, in addition to attempting to quantify motion of the AAC compound motion[1].

CONCLUSIONS

It is evident that scapulohumeral motion is variable. Further work is needed to quantify motion for individuals with rotator cuff imparements, to create a body of knowledge for clinicians to determine success of invasive interventions for repair of supraspinatus tear and investigate causes for increased humeral motion.

INTRODUCTION

Duchenne muscular dystrophy (DMD) is a genetic disorder that primarily affects males. The hallmark of disease is proximal weakness with a gradual loss of ambulation in the second decade of life. While basic kinematic deviations have been documented, the purpose of this study is to determine how the ability of individual muscles to perform eccentric and concentric work changes with disease progression, and compare this with fatty infiltration as reported in the literature [1, 2]. We hypothesized that work production would decrease in the proximal thigh muscles and increase in the distal shank muscles with disease progression in DMD.

METHODS

Overground gait data were collected at self-selected walking speeds from a participant with DMD over three visits at 1 year intervals beginning at 9 years of age and compared to normative data (n=8). Experimental data were collected with Cortex (Motion Analysis Corp., Santa Rosa, California, USA) and analyzed with a scaled 92 muscle model in OpenSim [3]. Individual muscle velocity, force, power and work were normalized and calculated as described by Hu and Blemker [1]. This study focused on the stance phase of gait.

RESULTS AND DISCUSSION

Eccentric and concentric work generated by individual muscles is shown in Figure 1. The same 22 muscles used in the previous paper [1] have been separated by location and ordered by fat fraction rank as reported by Wokke et al [2].

Eccentric work was below the normal average in the one boy with DMD at all time points for most proximal and all distal muscles. Exceptions to this came from the rectus femoris, which was within the normal range at the baseline visit only, and the adductor longus and adductor magnus, which were both above the normal average at all time points.

Concentric work was below average at all time points for most proximal muscles. Exceptions to this came from the semitendinosus, which was above normal at baseline, and the semimembranosus (SM), which was above average at all time points, but trended toward the normal average with disease progression. For the distal muscles, the dorsiflexors were within the normal range initially, but progressively decreased with disease progression. However, the plantar flexors progressively increased concentric work with disease progression. While the medial and lateral gastrocnemii were below the normal average at baseline, concentric work increased markedly with increasing disease progression.

Our data agree with Hu and Blemker [1] in that muscles that normally generated more eccentric work had higher fat fractions in DMD [2]. However, the eccentric work of the biarticulate hamstring muscles were much lower in the present study, which can be attributed to the exclusion of the swing phase. In DMD, muscles with a higher fat fraction are less able to generate force, resulting in reduced mechanical work as evident in the reduced eccentric work in the quadriceps and triceps surae and the reduced concentric work in the adductor magnus, long head of the biceps femoris (LHBF), and the tibialis anterior.

Results for the SM and triceps surae suggest possible compensatory mechanisms. The SM had a lower reported fat fraction and initially provided excessive concentric work (in contrast to the LHBF, which had a higher fat fraction and showed decreased concentric work). Interestingly, Hu and Blemker [1] reported that in normative gait, the SM had a larger eccentric demand than the LHBF, which they hypothesized would result in more fatty infiltration. The results of our study suggest that the SM is less affected by stresses associated with eccentric work as shown by the increased concentric work production. Physiological differences between the SM and LHBF may explain why the former has a lesser fat fraction in response to similar eccentric demands and should be studied further to better understand this potential compensatory mechanism. The triceps surae showed progressively increasing concentric work with disease progression despite having nearly the highest fat fraction of the distal muscles. Kinetic changes associated with toe walking, which occurred after baseline, explain the shift from eccentric to concentric work. Toe walking eliminates the eccentric requirement of the triceps surae to control the forward progression of the tibia over the foot. The ankle plantar flexes into single limb support, during which the associated plantar flexor moment would be supplied concentrically. This action adds energy and work to the stance limb to support and propel the center of mass and would compensate for the decreased work production of the proximal muscles. Fatty infiltration data as reported previously [2] were not available for the gluteal muscles; however, we did find a marked reduction in both eccentric and concentric work production for these muscles.

CONCLUSIONS

With disease progression in DMD, the demands placed on individual muscles changes as compensatory gait patterns arise in response to muscle weakness. Based on the muscle work simulation, proximal extensor muscles provide less concentric work and distal extensor muscles provide more concentric work. In general, muscles that have greater fat fraction are those that have a greater eccentric demand, especially for the proximal group. Compensatory mechanisms reflect changes in muscle use, as distal muscles transition from eccentric to concentric work production, which may alter muscle stresses and fatty infiltration in mid to late disease states.

INTRODUCTION

Muscle strength is a significant predictor of mortality [1]. Additionally, decreased muscle mass and strength, or sarcopenia, is also associated with decreased independence for older adults. This occurs because as they become weaker, activities of daily living become more difficult to perform without assistance. Decreased muscle size and strength are also associated with increased instance of falls and fractures [2], and strongly correlated with quality of life in older adults [3].

It is reasonable to recommend resistance training as a potential means of combating age-related muscle mass loss. However, there have been many studies that have found that older adults have a diminished response to exercise when compared to their younger counterparts [4, 5]. The observed decreased response to exercise seen in the aged population indicates that the hypertrophic response is impaired. There are many levels of the hypertrophic response at which the impairment may occur, but evidence suggests that the impairment occurs at or near the level that the mechanical signal is sensed [6]. A possible explanation is the mechanotransduction is impaired as a result of extracellular matrix stiffening. The overarching hypothesis for this study is that the attenuated response to exercise seen in older adults is caused by an impaired ability to sense mechanical stimuli as a result of increased muscle stiffness.

In order to conduct an experimental study of our hypothesis, a means to manipulate muscle stiffness in vivo was needed. Stretching has been shown to be an effective intervention to increase range of motion. We examined changes in muscle material properties, rather than simply changes in range of motion, as a result of a stretching intervention.

METHODS

The participants were three generally healthy women aged 70+ years with BMIs of less than 30 kg/m^2. All participants were free of neurological illness, cardiovascular disease, lower extremity musculoskeletal dysfunction, peripheral artery disease, cancer, type II diabetes, and high blood pressure. Men were not recruited for this study because the prevalence of sarcopenia is greater in women. It is also currently unknown if there are gender differences in muscle stiffness values.

Ultrasound elastography (Supersonic Imagine, Aix-en-Provence, France) was used to measure muscle stiffness of both heads of the gastrocnemius. A 10 second clip was collected to allow for stabilization. At the 5 second mark of the clip, a 2mm region of interest was placed in the center of the muscle and shear modulus was calculated as the average across this region.

The participants were taken through a series of contract-relax Proprioceptive Neuromuscular Facilitation (PNF) stretches for the lower body. Each stretch began with the subject passively taken to the end of their range of motion or the point at which they begin to feel a stretch, but no pain. They were held in this position for 20 seconds then told to push against resistance for 7 seconds, activating the agonist muscles. They were then instructed to relax and the stretch was taken to a new end point and held for an additional 20 seconds. Each stretch was performed three times bilaterally, alternating between sides. Subjects will participate in this stretching routine 3 days a week for 8 weeks. The data presented in this abstract are from the first 4 weeks of the intervention.

RESULTS AND DISCUSSION

Due to the small sample size, at this point, data for each participant is presented individually rather than mean values for the group. This provides a more clear illustration of the observed changes.
Figure 1: Changes in medial gastroc stiffness from baseline to the beginning of week 5
Figure 2: Changes in lateral gastroc stiffness from baseline to the beginning of week 5

Based on the data, it appears that each of the participants to this point has a slightly different response compared to the other two participants. The participant listed as S 01 has shown a large decrease in stiffness in both the medial and lateral gastrocnemius muscles. S 02 has not exhibited much change in either muscle with one increasing slightly and one decreasing slightly. S 03 also increased in one portion of the muscle and decreased in the other, but these changes were larger than the changes exhibited by S 02.

CONCLUSIONS

It is still early in the intervention and the sample size is too small to draw many conclusions based on the current data, but it does appear that at least in some subjects stretching has the capacity to change muscle stiffness.

Interestingly the oldest participant is the one who has exhibited the greatest change in muscle stiffness at this time. Additionally she was also the subject who was stiffest in the pre-test. Further research may show changes in stiffness may be dependent on the initial stiffness. As this study continues, the relationship between age and response to the intervention will also be investigated further.

Matrix stiffness affects human mesenchymal stem cell differentiation uniquely in 2D and 3D culture

[1] Nathaniel Hogrebe and [1] Keith J. Gooch

[1] The Ohio State University, Columbus, OH, USA
email: nathaniel.hogrebe@gmail.com

INTRODUCTION

Matrix stiffness has been shown to be an important regulator of cell behavior. For example, given the same biochemical environment, soft matrices induce human mesenchymal stem cells (hMSCs) to become adipocytes, while stiff matrices with a modulus similar to bone sends them down an osteogenic lineage [1]. It is still unclear, however, how these effects translate to more physiologic 3D culture. In this study, we investigated how matrix stiffness affected hMSC differentiation differently in 2D and 3D culture using a biomimetic self-assembling peptide (SAP) hydrogel system that allowed for independent control of stiffness and RGD binding site concentration.

METHODS

To study the effects of stiffness and culture dimensionality on hMSC differentiation, we used a SAP hydrogel system with a fibrous microstructure similar to collagen. This system allowed for non-spherical morphologies similar to those observed within collagen matrices in 3D culture without the drawbacks of heterogeneous natural matrices, such as the lack of controllable biochemical functionality. We altered matrix stiffness (G' = 0.25, 1.25, 5, and 10kPa) while maintaining a constant RGD binding site concentration, and hMSCs were either grown on top of (2D environment) or encapsulated within (3D environment) these gels. Either growth medium or a 1:1 mixed adipogenic/osteogenic induction medium was used to investigate the possibility that stiffness and culture dimensionality alone are able to induce differentiation, or alternatively if these physical parameters work synergistically with biochemical factors to direct differentiation. For experiments involving ROCK inhibition, 10μM of Y-27632 was added to the culture medium every 24 hours.

After 26 days of culture, cell morphology was assessed with differential interference contrast (DIC) microscopy. Differentiated cells were stained with either Oil Red O for lipids, Alizarin Red for calcium deposition, or with BCIP/NBT substrate for alkaline phosphatase, and all were imaged with a brightfield microscope. Quantitative RT-PCR was performed to test for markers of differentiation, including PPARγ-2 for adipogenesis and alkaline phosphatase for osteogenesis.

RESULTS AND DISCUSSION

As illustrated by Figure 1, both matrix stiffness and dimensionality heavily influenced cell morphology, which is of note since cell shape has been strongly correlated with its function [2].
Figure 1: HMSC morphology is strongly influenced by both stiffness as well as whether the cells are grown on top of or encapsulated within the gels. Cells in the bottom half of figure were stained for F-actin.
Scale bars = 25 μm.

After 24 hours, hMSCs cultured on top of the gels progressively spread with increasing stiffness and

had an increasingly more organized actin structure. Cells within the gels spread greatest at intermediate stiffness, adopting stellate morphologies. As time progressed while using growth medium, the cells within the 1.25, 5, and 10kPa gels took on an elongated, spindle morphology as they do within collagen gels. Cells cultured on top of the gels continued to spread and increase in area.

Using growth medium, no visual signs of differentiation appeared after 26 days in culture, and this lack of differentiation was confirmed with qRT-PCR (Fig 2A-B). With a 1:1 adipogenic/osteogenic induction medium, however, overt differentiation was observed as indicated by adipogenic lipid vacuoles that stained with Oil Red O as well as osteogenic mineralization that stained with Alizarin Red (Fig 2C). QRT-PCR after 26 days in induction medium confirmed this differentiation. In addition, correlating PPARγ-2 gene expression with the percentage of cells possessing lipid vacuoles showed good agreement between gene expression and visual indications of differentiation.

While stiffness and culture dimensionality alone were unable to induce differentiation, they both acted synergistically with induction factors to direct differentiation. Specifically, low stiffness promoted higher adipogenic gene expression as well as lipid formation, while increasing stiffness drove cells toward a more osteogenic phenotype as indicated by higher alkaline phosphatase activity and mineral

deposition (Fig 2A-D). Interestingly, there were notable differences between 2D and 3D culture at a given stiffness. For example, PPARγ-2 expression was higher in 3D than in 2D at a particular stiffness. In contrast, alkaline phosphatase was much higher in 2D than 3D at a given stiffness. Thus it seems that 3D culture is more conducive to adipogenesis, while 2D facilitates osteogenesis more efficiently at a given matrix stiffness.

Rho-kinase (ROCK) is vital to a cell's ability to respond to matrix stiffness. Inhibiting ROCK increased adipogenesis and decreased osteogenesis, consistent with the work of others [2]. Much of the differences between stiffness seemed to be abrogated by ROCK inhibition, but notably differences between 2D and 3D at a given stiffness persisted (Fig 3). Thus there seems to be another mechanism independent of the ROCK pathway that is contributing to the variations in differentiation observed between 2D and 3D culture.
Figure 3: ROCK inhibition eliminates much of the variation in hMSC differentiation between stiffness, but differences between 2D and 3D remain.

CONCLUSIONS

Matrix stiffness is now widely recognized as an important determinant of cell behavior, but how these effects translate to a 3D environment is not fully understood. In this study, we observed that while the general trends seen with changes in matrix stiffness appear to be the same in 3D culture, the magnitude of this effect differs. Specifically, 2D culture appears to be more conducive to osteoblast formation while 3D culture is better at facilitating adipogenesis at a given stiffness.

A PROBABILISTIC MODEL OF THE SUBACROMIAL SPACE: IMPLICATIONS FOR SUBACROMIAL IMPINGEMENT SYNDROME

[1]Jaclyn N. Chopp-Hurley, [2]Joseph E. Langenderfer, [1]Clark R. Dickerson

[1]Department of Kinesiology, University of Waterloo, Waterloo, ON
[2]School of Engineering and Technology, Central Michigan University, Mount Pleasant, MI

INTRODUCTION

Glenohumeral (GH) and scapulothoracic (ST) kinematic relationships, as well as morphological characteristics of the scapula and humerus affect the dimensions of the subacromial space [1-2]. Each measure varies considerably across the population, which can lead to misestimation of mechanical impingement of the subacromial space (SAIS). Further, the relative influence of each parameter on the size of the subacromial space is unclear.

There were three primary objectives:
1. To predict the distribution of the minimum subacromial space width (SAS) among a young, healthy male population due to variability in morphological and fatigue-related kinematic parameters across humeral elevation and fatigue state conditions.
2. Determine the relative importance of each parameter for modifying the size of the SAS.
3. Calculate the probability that measured subacromial tissue thicknesses would exceed this predicted SAS for each condition.

METHODS

A deterministic subacromial geometry model was developed that enabled calculation of the SAS based on modifying acromial, glenoid, and humeral morphology, and GH and ST kinematic parameters.

Morphological Model Parameters:
- Glenoid inclination (GI)
- Lateral acromial angle (LAA)
- Acromial anterior slope (AS)
- Acromial tilt (AT)
- Acromion index (AI)

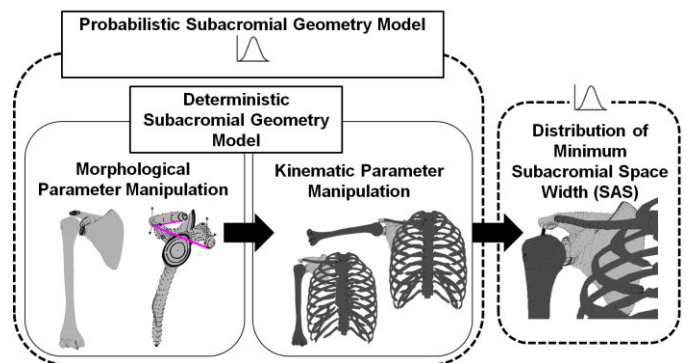
GH/ST kinematic model parameters:
- Superior-inferior humeral head translation (HHT)
- Upward-downward scapular rotation (SR)
- Posterior-anterior scapular tilt (ST)
- Scapular protraction-retraction (SPR)


Figure 1: Overview of subacromial geometry model: morphological and kinematic model parameters were modified using empirically measured input distributions, from which the distribution of SAS could be obtained.

A probabilistic subacromial geometry model was then developed (NESSUS, SwRI, San Antonio, TX) which, using input distributions obtained from empirical data for each of the described model parameters, predicted the distribution of SAS for ten conditions (Figure 1).
- Humeral elevation angle (0, 30, 60, 90, 120°)
- Fatigue state (pre-fatigue, post-fatigue)

Using the AMV probabilistic method, importance factors (α) were calculated to evaluate the relative contribution of each parameter to predicted outputs.

A second probabilistic subacromial impingement risk model was then constructed. This model calculated the probability that experimentally measured subacromial tissue thicknesses (supraspinatus tendon, subacromial bursa) would

exceed the SAS predicted from the subacromial geometry model, thereby generating an estimate of the SAIS risk.

RESULTS AND DISCUSSION

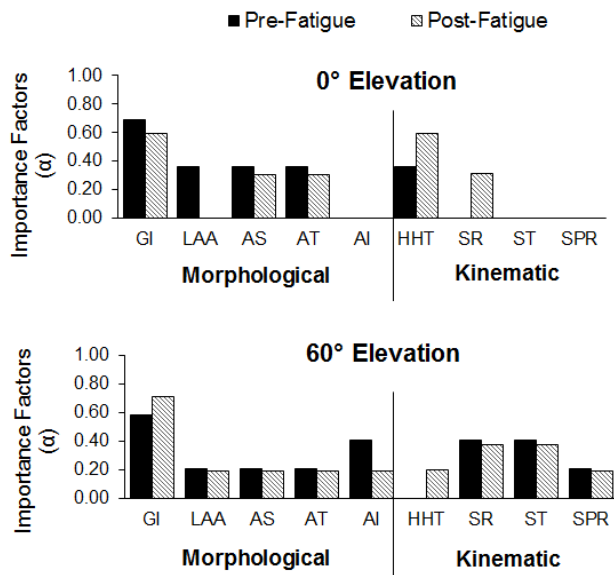
Across all conditions, the SAS was highly variable, as evidenced by wide 1-99% confidence intervals (spanning a mean of 8mm) (Table 1). The SAS was not influenced by fatigue, but reduced considerably with arm elevation (4.5-5mm) within each fatigue state. Morphological parameters, notably glenoid inclination (α = 0.57 [range, 0.33 – 0.71]), had consistently high relative importance in modulating the size of the SAS across all conditions, while the influence of kinematic parameters was modulated by elevation angle and fatigue state (Figure 2). While targeted interventions for morphological characteristics which predispose an individual to SAIS are challenging, glenoid inclination has been associated with superior humeral head translation [3-4]; this in turn promotes rehabilitation strategies that target GH stability maintenance.


Figure 2: Importance Factors (α-levels): pre- and post-fatigue states at 0° and 60° humeral elevation angles.

The probability that subacromial tissue thicknesses would exceed the SAS (causing mechanical tissue impingement) was <5% at low elevation angles. At mid-range elevation, the probability was between 46.1% and 68.6%, while at 120° of elevation, the probability was as high as 73.6%. However, previous research has concluded that at elevation angles >90° (and possibly even >72°) the SAS vector passes lateral to the supraspinatus tendon [5-6]. This indicates that mid-range elevation likely poses the highest risk for mechanical SAIS.

CONCLUSIONS

The highly variable SAS suggests that solely considering the population average may strongly underestimate SAIS risk. The high probability of tissue compression at critical elevation angles (60-90°) implicates repetitive elevation that includes overhead arm postures as a likely contributor to rotator cuff degeneration and pathology. Additionally, the high relative importance of glenoid inclination across all conditions indirectly suggests high importance for superior humeral head translation. This finding supports glenohumeral stability maintenance and rotator cuff strengthening to alleviate the risk of SAIS and additional shoulder pathologies.

INTRODUCTION

Cartilage contact force, congruency, and contact area affect cartilage contact stress and high stresses in the patellofemoral joint are associated with cartilage degeneration. Cadaveric studies have been conducted to evaluate patellofemoral contact mechanics. However, physiological loading of a healthy patellofemoral joint may not be evaluated accurately using cadaveric methods [1]. A musculoskeletal computational model capable of accurately predicting cartilage contact pressures may serve as a valuable tool to orthopaedic surgeons. In this study, patellofemoral contact mechanics were studied in four different cases:

1. Normal model
2. Increased tibial tuberosity – trochlear groove distance (TT-TG) of 20mm
3. Patella alta – patella abnormally high
4. Patella baja – patella abnormally low

METHODS

With institutional approval and informed consent, magnetic resonance imaging (MRI) and gait lab measurements (motion capture and ground reaction forces) were obtained for one healthy subject (female, 20 years, 159.5 cm, 59.0 kg). MRI measurements were used to determine the TT-TG distance (12mm) and the Caton-Deschamps index (1.09) of the subject's right knee. The MRI and gait data were previously used to develop a subject specific computational musculoskeletal model (Fig. 1) as described in [2]. For the model, bone, cartilage and meniscus geometries were created from the MRI. Patellofemoral and tibiofemoral joints were defined as deformable contacts. Ligaments were defined using anatomical insertion and origin points on the bone geometry and the force was calculated using a non-linear force-length relationship [3]. Zero-load lengths for the ligaments were derived from experimental laxity tests. The menisci were modeled as wedge shaped rigid bodies connected by 6 x 6 stiffness matrices as previously described [4]. The muscle forces were calculated using a feedback control loop to duplicate the experimental motion measurement in the gait lab. The foot segment was divided into five segments to calculate the ground reaction force [3].

The current project looks at the contact pressure distribution of the patellofemoral joint by discretizing the patella cartilage into 3mm x 3mm elements and defining contact between each element and the femoral cartilage. Four different models were developed. One normal condition (the original model based on the MRI measurements) to be compared against three pathological conditions:

1. TT-TG value of 20mm: TT-TG is increased by moving the Patellar tendon insertion points (tibial Tuberosity) 8 mm laterally.
2. Patella Alta: Caton-Deschamps index value is increased to 1.2 by increasing patellar tendon length.
3. Patella Baja: Caton-Deschamps index value is decreased to 0.8 by decreasing patellar tendon length.
Figure 1: Muscle force driven model during gait (a.) and the anatomical right knee model (b.).

RESULTS AND DISCUSSION

Maximum vasti activation occurs at loading phase of the gait cycle. The pressure distribution and location of maximum pressure were measured for each model during the loading phase (21% of gait cycle). Predicted contact parameters are presented in Table 1. The contact pressure and area are comparable to that of experimental studies under similar loading conditions [5]. The increase in contact area with patellar tendon shortening (Patella Baja) matches the experimental results for knee flexion at 15° [6]. Predicted contact area for the normal model agrees with measured female contact area in an MRI based study [1].

The region of high contact pressure area moved distally in the Patella Alta case as the patella rode higher on the femoral trochlear groove due to longer patellar tendons. The Patella Baja model predicted the opposite outcome with the contact area occurring more proximally on the patella. It should be noted that the Patella Baja model predicted a lower maximum contact pressure at the loading phase mainly due to higher contact area. Moving the Tibial tuberosity distally leads to a more lateral contact distribution and also higher contact areas on the lateral side. The maximum contact pressure was also increased.

Table 1: Patellofemoral contact parameters at loading phase

	Maximum Contact Pressure (MPa)	Contact Area(mm^2)	Average Contact Pressure (MPa)
Patella Alta	3	162	0.61
Patella Baja	1.7	324	0.29
Normal	2.2	225	0.49
TT-TG 20	2.7	189	0.70

CONCLUSIONS

Patellofemoral contact pressure was predicted during the loading phase of a gait cycle using a computational model of a healthy female subject. The model predicted changes in the contact mechanics of the patellofemoral joint in response to modification of tibial tuberosity location and patellar tendon length.

Future work will include models in other anatomical variations such as trochlea dysplasia as well as more movement simulation activities such as a dual limb squat.

INTRODUCTION

Spinal fusion for individuals with adolescent idiopathic scoliosis (SF-AIS) is aimed at correcting the three dimensional deformity of the spine. Consequently, pelvic alignment would be expected to improve, thereby leading to more typical lower limb mechanics. However, whether spinal fusion influences pelvic dynamics thereby influencing lower limb and inter-limb mechanics during physical activities is not known. Therefore, the objective of the study was to compare the lower extremity kinetics displayed during the stance phase of stop-jump (Figure 1) between SF-AIS and healthy matched controls (CON) and inter-limb mechanics within the groups.

METHODS

The stop-jump task was performed by 10 SF-AIS (physically active; posterior-approach spinal fusion: 11 ± 2 fused segments; post-op time: 2.0 ± .6 yrs), and 10 CON individuals, pair matched for gender, age (17.4 ± 1.3yr, 20.6 ± 1.5yr, respectively), mass (63.5 ± 12.2kg, 66.4 ± 10.9kg), height (1.7 ± 0.1m, 1.7 ± 0.1m) and level of physical activity participation (International Physical Activity Questionnaire [1]).

The locations of the 18 reflective markers placed on the pelvis and lower extremities were recorded via 7-camera VICON motion capture system when the participants performed 5 acceptable trials of the stop-jump. Vertical ground reaction forces (vGRF) were measured (Bertec 4060-NC®; Sampling Frequency: 1200Hz) and joint moments were calculated for the stance phase using inverse dynamics and Euler's equations of motion using joint centers, segmental mass, ground reaction forces and kinematics of the joint. 2 (*Group*: SF-AIS or CON) x 2 (*Limb*: dominant leg or non-dominant leg) mixed-model ANOVA ($p < .05$) and Tukey's HSD posthoc test were used to compare peak vGRF and peak joint moments normalized to body mass of both lower extremities in the three planes of motion displayed in the stance phase. Jump heights between the two groups were compared using a one-way ANOVA ($p < .05$).
Figure 1: Stop-jump task and phases.

RESULTS AND DISCUSSION

Several main effects and no interactions were detected (Tables 1a and 1b). At the hip joint, for peak internal rotation moment, SF-AIS generated significantly greater moment (mean difference $_{main-effect}$: 0.06 Nm/kg; $p = .015$) than CON, and the dominant limb displayed a tendency of greater moment than the non-dominant limb (range: 0.02 – 0.06 Nm/kg; $p = .096$).

At the knee joint, a lower peak extensor (0.39 Nm/kg; $p = .011$) and greater abduction moment (.40 Nm/kg; $p = .032$) were displayed by SF-AIS than CON.

At the ankle joint, SF-AIS produced a greater peak internal rotation moment (0.03 Nm/kg; $p = .033$) and tendency for greater peak plantarflexion moment (.18 Nm/kg; $p = .065$). Jump height was not significantly different between the two groups ($p = .872$).

No significant interactions or main effects were observed for vGRF. Jump height was not different between groups.

Greater hip internal rotation moments coupled with greater knee abduction moments could predispose SF-AIS to knee injuries. This along with lower knee extensor moments coupled with greater knee abductor moments for SF-AIS compared to CON during the stance phase of the jump could potentially increase strains on the anterior cruciate ligament [2].

The lack of inter-limb differences for the sagittal plane and frontal plane joint moments suggests that SF-AIS may have acceptable inter-limb symmetry for joint moments, contrary to asymmetries reported for gait [3]. Another explanation may be within-group variability influenced by the participants' experience with jumping movements.

CONCLUSIONS

SF-AIS display mostly comparable lower limb kinetics to that of CON to prepare and propel their body vertically to a similar jump height. Clinically, these results suggest that spinal fusion does positively influence lower extremity mechanics, and physically-active AIS individuals who have had spinal fusion surgery, can successfully produce typical lower limb kinetics similar to healthy controls during high-effort tasks such as the stop-jump.

COMPARISON OF MEDIAL-LATERAL CONTACT FORCE BALANCE IN KNEE JOINT BEFORE AND AFTER HIGH TIBIAL OSTEOTOMY FOR OSTEOARTHRITIS

Tserenchimed Purevsuren, Won Man Park, Kyungsoo Kim and Yoon Hyuk Kim

Kyung Hee University, Yongin, Korea
Email: yoonhkim@khu.ac.kr

INTRODUCTION

The opening wedge high tibial osteotomy (HTO) has been usually recommended for a young and active population for treatment of medial knee osteoarthritis (OA). Its main principle is to shift the weight-bearing line from medial compartment to lateral compartment of the knee and decompress the degenerated cartilage [1]. Relatively good outcome of HTO has been reported in clinical short-term, mid-term, and long-term studies [2, 3]

The joint forces on human knee during normal walking are dominant on medial compartment due to external knee adduction moment [1]. Therefore, the conventional gait analysis based on three-dimensional (3D) limb motion has been usually performed to evaluate surgical outcome of HTO. Previous studies demonstrated that the HTO successfully reduce the varus angle and decrease the knee adduction moment which characterizes osteoarthritic gait [3]. However, the reduction of contact loading on the medial compartment and shift of those loading into lateral compartment of knee after medial opening-wedge HTO are also necessary to fully understand mechanism of HTO to the OA knee.

In this study, the effect of medial opening wedge HTO on medial-lateral contact force balance in tibiofemoral joint was quantatively evaluated during stance phase of gait. Since the muscle force is determinant to calculation of contact force, we also tried to demonstrate difference between muscle forces in OA patient and subject with HTO surgery. The muscle forces and joint contact forces were obtained by two-step modeling technique that combined with conventional inverse dynamic analysis and multibody dynamic simulation (Fig. 1).

METHODS

Five patients, who have moderate medial knee OA (Mean age: 57.6 years, weight: 67.4 kg, and height: 157.2 cm), participated in this study. 3D motion data of lower extremity was recorded by motion analysis system (Hawk® Digital Real Time System, Motion Analysis System, Santa Rosa, CA, USA) using ten cameras and reflective skin markers. The external ground reaction forces were measured by four force plates (MP4060, Bertec Corporation, Columbus, OH, USA) during walking. The participants performed 5 trials of motion with a self-selected walking speed along six meter walk-way. All procedure described above was repeated for each individuals 12 month after the HTO surgery.

At the first step, the muscle forces, joint forces and moments were calculated based on the recorded joint motion and ground reaction forces using an inverse dynamic lower extremity model [4]. The lower extremity was modeled as a 6-segment, 18 degree of freedom (DOF) articulated linkages actuated by 52 muscles. The output of inverse dynamic model such as predicted muscle forces, ankle joint forces and moments were used as the input to the multibody lower limb model with anatomical representation of the knee joint.

At the second step, a multibody lower extremity model of each subjects before and after HTO were developed in a dynamic analysis software (RecurDyn ver.7, Function Bay Inc., Korea). The previously developed and validated knee joint model [5] with bones (femur, tibia and patella), cartilage layers, non-linear ligaments, and deformable contact in both medial and lateral tibiofemoral compartment was placed in the symptomatic leg.

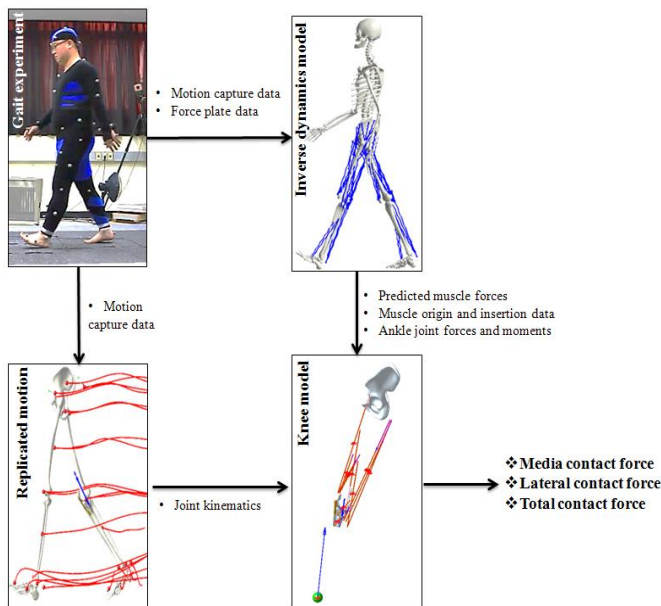
For the contact force estimation, the quasi-static analysis was run at the time step of 0.05 second during the stance phase of gait. The muscle forces from inverse dynamic analysis were applied constantly via muscle force actuators and ankle joint forces/moments which calculated in inverse dynamic analysis were applied as external forces on the distal tibia. The compressive contact forces on the medial compartment, lateral compartment as well as the total tibiofemoral joint force were investigated. The contact force result of each subject was normalized to the body weight and the results for OA subjects were compared to those of post-HTO. The estimated quadriceps and hamstring muscle forces, and medial to lateral compartment load ratio were also analyzed.


Figure 1: Diagram to explain the procedure for the estimation of tibiofemoral loading as well as muscle forces during normal walking

RESULTS AND DISCUSSION

Medial opening wedge HTO dominantly decreased the compressive contact force on the medial compartment during stance phase of gait (Fig. 2). The reduction in the first and second peaks of contact curve were about 0.8 BW. HTO increased the compressive loads on the lateral compartment, however the lateral compartment contact force was not higher than the medial contact force (Fig. 2).

The total tibiofemoral compressive force decreased after HTO due to reduction of quadriceps muscle activation. The medial to lateral load ratio showed that HTO significantly balanced the knee joint loading during normal walking. Our result indicates that the HTO surgery could improve the tibiofemoral contact force balance.

COMPARATIVE ANALYSIS OF STRESS AND STRAIN OF SPINAL CORD
IN VARIOUS POSTERIOR DECOMPRESSION EXTENTS
FOR CERVICAL OSSIFICATION OF THE POSTERIOR LONGITUDINAL LIGAMENT

Batbayar Khuyagbaatar, Won Man Park, Kyungsoo Kim and Yoon Hyuk Kim

Kyung Hee University, Yongin, KOREA
email: yoonhkim@khu.ac.kr

INTRODUCTION

Ossification of the posterior longitudinal ligament (OPLL) is a common cause of cervical myelopathy due to compression of the spinal cord. Patients with multiple levels of OPLL usually require the posterior decompression surgery. Clinical studies have reported that the decompression extent play an important role in the clinical outcomes [1, 2]. Thus, there is a need to better understand the optimal surgical extent with which sufficient decompression without excessive posterior shifting can be achieved. However, few quantitative studies have clarified this optimal extent for decompression of cervical OPLL. In this study, we used finite element (FE) modeling of the cervical spine and spinal cord to investigate changes in stress, strain, and posterior shift of the spinal cord for posterior decompression extent that occur with three different surgical methods.

METHODS

The FE model of the human C2-C7 cervical spine was reconstructed from the CT images. The FE model of spinal cord consisted white matter, gray matter, dura mater with nerve roots, denticulate ligamnets (DLs), and a cerebrospinal fluid (CSF) layer (Fig 1). Material properties of white and gray matter obtained from Ichihara's study [3] then fitted to hyperelastic model. A single tangent modulus for dura mater derived from the Persson's study [4]. The DLs were modeled as 22 triangular extensions, using link element at each spinal level that attached laterally from the cord to the dura mater, and material property was obtained from a previous study [5]. The CSF layer was demonstrated Newtonian fluid characterized by viscosity of CSF derived from previous literature [6].

Three type of posterior decompression models for laminectomy, laminoplasty and hemilaminectomy were developed based on conventional surgical protocols with different extent of decompression (Fig 2a). The extent of decompression ranged from one- to five- levels: C5, C4-C5, C4-C6, C4-C7, C3-C6, and C3-C7 for each types of model, where the continuous OPLL placed through the C4 to C6 vertebral bodies (Fig 2b). The OPLL was modeled as simple rigid body model, and an OPLL occupying ratio of 20% to 60% was imposed to the spinal cord based on plain radiographic findings. Under various OPLL occupying ratios, the von-Mises stress and maximum principal strain in the spinal cord as well as the posterior spinal cord shift were analyzed for pre-operative and various posterior decompression models using FE analysis (ABAQUS^{TM}, ABAQUS Inc., Providence, RI, USA).

(a) Superior view of C5 vertebra model showing three types of decompression

(b) FE models of extent of posterior decompressions
Figure 2: FE models and types of posterior appraoches

RESULTS AND DISCUSSION

The von-Mises stress and maximum principal strain in the cord decreased as the extent of posterior decompression increased, regardless of the occupying ratio and the type (Table 1). The maximum stress in the cord was decreased by 30% to 90% from 1- to 5-levels of decompression by laminectomy and laminoplasty. The C3-C6 and C3-C7 in the laminectomy and laminoplasty at the 60% occupying ratio of OPLL had a maximum posterior shift of greater than 3 mm, which was associated with positive clinical outcomes after laminoplasty [2] and which showed substantial reductions in stress and strain. In contrast, the stress and strain reductions of hemilaminectomy differed from the values of laminectomy and laminoplasty due to

maximum values at the lateral column arising from lateral decompression of the spinal cord. Our results showed that hemilaminectomy is inferior to laminectomy and laminoplasty in terms of cord decompression.

In conclusion, stress and strain in the spinal cord decreased and posterior shifting of the cord increased as posterior decompression extended. The location of the decompression extent also influenced shifting, depending on the patient's anatomy. Laminectomy and laminoplasty were very similar in terms of decompression results, and both were superior to hemilaminectomy in all parameters tested. Decompression to the extents of C3-C6 and C3-C7 of laminectomy and laminoplasty could be considered sufficient with decompression itself. Our findings provide fundamental information regarding the treatment of cervical OPLL and can be applied to patient-specific surgical planning in the future.

DYNAMICAL FINITE ELEMENT ANALYSIS TO REPRODUCE THE TYPICAL PATTERNS OF PELVIC INSUFFICIENCY FRACTURES

INTRODUCTION

Pelvic insufficiency fracture (PIF) is caused by the reduction of bony elastic resistance due to aging. It is known that there are many typical fracture patterns [1]. The relations between the patterns and static loading conditions have been analyzed by using finite element model [2]. However, dynamical analysis of stress is needed to simulate the actual *in vivo* conditions. The purpose of this study is to analyze dynamical stress changes and to elucidate the relation between the fracture patterns of PIF and loading conditions.

METHODS

The model was based on the CT images of a female suffering from L1 vertebral compression fracture (76 years old). The sacrum, hip bones, and public symphysis were modeled with tetrahedral meshes (HyperMesh 10.0, Altair, USA). The sacroiliac joints were filled with soft elastic meshes to model the micro motion due to the joints and surrounding ligaments. Although PIF is caused by the bony porosis, the distribution of the bone material property in the pelvis is not necessarily clear. Thus, the isotropic materials as healthy model were used to reproduce the typical fracture patterns of PIF in this study.

The material properties were referred to the previous literatures (Cortical Bone (E=18000 MPa, v=0.3), Cancelous Bone (150 MPa, 0.3), Public Symphysis(5 MPa, 0.3), Sacroiliac Joint(1000 MPa, 0.3)) [3, 4]. Also, the sacrospinous ligaments were modeled because they are large and work to transmit loads the pelvis. Therefore, the ligaments were modeled as to generate force only when they were extended (spring constant: 45.0 N/mm) [5].

In this study, the base of sacrum was constrained completely. Also, total of 16 loading conditions were simulated as shown in Figure 1. The loads were applied to the iliac crest, acetabular surface and the ischial tuberosity. To generate surface loads, rigid surfaces were attached to those parts and the loads were applied to the rigid surfaces. The load of 2000 N was applied to the each of the iliac crest and acetabulum, while 1000 N was applied to both sides of the ischial tuberosity. In this study, RADIOSS (Ver.12, Altair, USA) was used as an explicit solver.

Acetabulum	A2000M, A2000M-S, A2000M-I, A2000M-A, A2000M-P		A2000P, A2000P-S, A2000P-I			A2000M, A2000M-S, A2000M-I, A2000M-A, A2000M-P	A2000M-A
ischial tuberosity	IT1000S-A, IT1000S-P		IT1000S			IT1000S, IT1000S-A, IT1000S-P	

RESULTS AND DISCUSSION

The simulated fractures patterns were classified as shown in Figure 2. All loading conditions had stress concentration on the sacrum and pubic rami. This means that the combination fractures of the sacral and pelvis could be happened regardless of the loading conditions.

The fracture patterns of H, U and L characters on the sacrum were looked like each other well, and this could mean that it is difficult to identify a mechanical cause of PIF from the sacrum fracture. This also shows that a slight difference of loading condition could change the fracture patterns.

The superior area of the acetabular roof showed the stress concentration only under the conditions of I2000M-I or A2000M-A. This agrees with the clinical findings in which that the fracture of the area is observed rarely. Therefore, the starting point of the fracture on the superior area of the acetabular roof could be identified when the fracture is diagnosed.

While the classification showed the most of the typical fracture patterns of PIF, the inferior horizontal fracture pattern was not confirmed with our model [1, 3]. Actually, through whole of the loading conditions, the lower part of the sacrum did not show the stress concentration. The reason for this was that the finite element model did not necessarily simulate the distribution of the material property, muscle loads and realistic loading conditions. These are limitations in this study, and the model might be modified in the future work.

Although our study had some limitations, the simulated fracture patterns were almost similar to clinical patterns of PIF. Therefore, the model and loading conditions could be constructed adequately. Also our model and the results of this study could be useful to elucidate the mechanism of PIF.

HIGH-DIMENSIONAL ANALYSIS REVEALS PATTERNS OF LOWER LIMB MUSCLE VOLUME DISSIMILARILITIES ACROSS CLINICAL AND ATHLETE POPULATIONS

[1] Katherine R. Knaus, [1] Geoffrey G. Handsfield, and [1] Silvia S. Blemker

[1] The University of Virginia, Charlottesville, VA, USA
email: ker4e@virginia.edu

INTRODUCTION

Muscle volume is a major determinant of force generating capacity. Recent *in vivo* measurements demonstrate that in healthy individuals, lower limb muscle volumes scale linearly with the product of height and mass [1], making it possible to compare body-size-independent muscle sizes between different subjects. We have used this normative database in order to identify differences in body-size normalized lower limb muscle volumes between a healthy normative database and subjects ranging in functional capacity from children with cerebral palsy (CP) [2] to collegiate athletes [3]. In all these (and other similar studies), analyses of muscle volumes are performed on a muscle-by-muscle (or functional group) basis. The goal of this work was to explore the applicability of high-dimensional data analysis approaches that would allow a more holistic understanding of how muscle volumes across the entire limb vary across populations.

METHODS

Using high resolution MRI, we imaged the lower limbs of 23 active healthy individuals [1], 10 patients with cerebral palsy [2], and 35 collegiate athletes [3], of who competed in track and field (10), football (5), baseball (5), and basketball (10). We manually segmented 35 unique muscles in these images to compute volumes, which were normalized for body size differences by dividing by height*mass.   Z scores were computed by comparing the normalized volumes for each subject to the mean and standard deviation of the healthy normative database.

Using hierarchical clustering to calculate the multi-dimensional Euclidean distance between each vector of normalized volumes, individual subjects and muscles were sorted based on statistically similar patterns of muscle size.   Principal component analysis was used to reduce the data to only two dimensions that captured the most significant portion of the original variance. Subjects were plotted in these dimensions, defined by the first principal component, which described 52% of the original variance, and the second component, which described 9% of the variance. Finally, the contribution of each muscle to the different components was computed.

RESULTS AND DISCUSSION

Clustering along the subject "axis" resulted in three main groupings [Fig. 1A]: the first group (top) included athletes, the second group (middle) included primarily healthy non-athletes, and the third group (bottom) included primarily cerebral palsy patients, revealing the intrinsic differences in the muscle volume patterns between these subject populations. Furthermore, when plotted along the first two principal components, regional similarity was observed in subject groups, including athletes competing in the same sport [Fig. 1B].

Clustering along the muscle "axis" revealed that four subgroups of muscles contributed to this organization of subjects [Fig. 1A]. The first group included mostly distal ankle muscles, which tend to be small in CP patients and relatively normal in athletes. Group 1 muscles had average contributions to the first principal component, and large positive contributions to the second principal component [Fig. 1C]. The next group included gluteal muscles and small hip and ankle muscles, which tended to be normal in both CP patients and athletes. Group 3 muscles had small contributions to both first and second principal components [Fig. 1C]. The following group included mainly hip and knee extensors, which tended to be very large in athletes, and relatively normal in CP patients. Group 4 muscles had large contributions to the first principal component, and negative contributions to the second principal component [Fig. 1C]. The last

group included miscellaneous "other" muscles, which tended to be small in CP patients and large in athletes. Group 2 muscles had average contributions to the first principal component, and a small mostly negative contribution to the second principal component [Fig. 1C].

High-dimensional clustering and principal component analysis revealed patterns of muscle volumes across individuals and muscles. The subgroups of muscles that contribute most to the principal components and distinguish the CP patients or athletes from the healthy subjects corresponded with several of the reported modules of co-activation during walking [4]. For example, muscles in Module 1 that were responsible for body support during stance were primarily members of Group 4. The muscle clustering results demonstrate

regionally specific variations in muscle size that would be indicative of certain muscles and regions showing altered functional capacity. Future work will reveal if these regions of diminished capacity correlate with muscle functional demands relevant to these subject populations (such as high speed running in the athlete populations [5] and movement abnormalities in the cerebral palsy population [6]).

ANALYSIS OF 3D STRAIN IN MEDIAL MENISCAL ALLOGRAFT TRANSPLANTS FOLLOWING TWO SURGICAL TECHNIQUES

INTRODUCTION

At present, there is a deficiency in the understanding of the biomechanical characteristics of meniscal tissue in meniscal allograft transplantation (MAT), and how these may be affected by surgical techniques.[1, 2] A novel in-vitro loading device capable of applying physiologically relevant loads has been developed, enabling 3D strain measurements in meniscal tissue.[3] The objectives of this study were to investigate the 3D strain in intact and transplanted medial menisci, with and without an additional peripheral 3rd point of fixation on the tibial plateau.

METHODS

Ten human cadaveric knees (average age approximately 67, 5 male, 5 female) were evaluated. Eight teflon beads (0.8 mm) were inserted in two tetrahedral formations in the middle 1/3 and posterior 1/3 of the medial meniscus under arthroscopic guidance. The joint was positioned at 5^0 flexion and loaded to 1x body weight (650 ±160 N) during CT image acquisition using the custom loading device. MicroView 3D image viewer was used to obtain 3D bead coordinates to calculate the principal strains.[4] The same process was repeated for a medial MAT, utilizing soft tissue anterior and posterior root fixation via transosseous suture, and a 3rd transosseous suture tied over a button providing peripheral fixation on the tibial plateau. Strain data was collected for loaded and unloaded menisci, with and without the peripheral fixation.

Statistical analysis using repeated measures ANOVA (IBM SPSS Statistics 22) was conducted to determine differences in strain results between intact or MAT with either surgical technique.

RESULTS AND DISCUSSION

Figures 1-3 show the average 3D strain found in 10 knees for the middle 1/3 and 8 knees for the posterior 1/3 of the meniscus. Medial-Lateral (ML), Anterior-Posterior (AP) and Superior-Inferior (SI) principal strains are shown. Directions ML/AP, ML/SI and AP/SI indicate shearing strains.

In the intact knee, ML (-0.94% Middle, -6.62% Posterior) and SI (0.09% Middle, -8.14% Posterior) are both negative (compressive) strains while AP (8.44% Middle, 10.05% Posterior) is positive (tensile). These results are expected as tibiofemoral loading of the meniscus causes hoop stresses, resulting in, fibres in the ML direction to be compressed and fibres in the AP direction to be pulled as the meniscus is mainly anchored at the anterior and posterior horn attachments. [7]
Figure 1: Strain profile in an intact meniscus
Figure 2: Strain profile in a MAT using soft tissue anterior and posterior root fixation via transosseous suture
Figure 3: Strain profile in a MAT using soft tissue anterior and posterior root fixation via transosseous suture, and a 3rd transosseous suture tied over a button

This is the first study to quantitatively study regional 3D meniscal strain in a large number of human knees under simulated physiological loading regimes. The values obtained are within reason of previous literature where strain was quantified through linear strain gauges or elongation tests of resected tissue. [5, 6]

The strain profile is changed following allograft replacement, but due to the high variability in these measurements no statistical difference has been uncovered. The current results indicate no differences in strain measurement between any of the surgical conditions tested and the intact meniscus. The efficacy of the peripheral anchor may require a cyclic loading protocol rather than static as was conducted in this study. More testing is required to assess differences in strain between these fixation techniques.

CONCLUSIONS

There is no significant difference in strain between the native meniscus and a MAT without an additional peripheral anchor. The addition of a peripheral anchor conferred no significant benefit in this model. These results suggest that a peripheral anchor in medial MAT may not be necessary to replicate native tissue strain or improve the chondroprotective effect of MAT.

INTRODUCTION

The morphological and biomechanical evaluation of the musculoskeletal structures of animals is essential to the evaluation of orthopedic devices. Bones of various animal species have been used in biomechanical research, including the femur, tibia and vertebrae [1-6]. Ovine, porcine, bovine and canine models are commonly used, but there has been little research on cervine (deer) species as a suitable animal model. A recent study in New Zealand assessed the red deer (*Cervus elaphus*) femur as a potential model [4]. Given that tibiae and vertebrae of white-tailed deer (*Odocoileus virginianus*) have been shown to be appropriate models for human tibiae and vertebrae [2, 5], and are regionally abundant in North America, the objective of this study is to quantify and compare the morphomeric and biomechanical properties of the *Odocoileus virginianus* femur to those of the human femur and other animal models.

METHODS

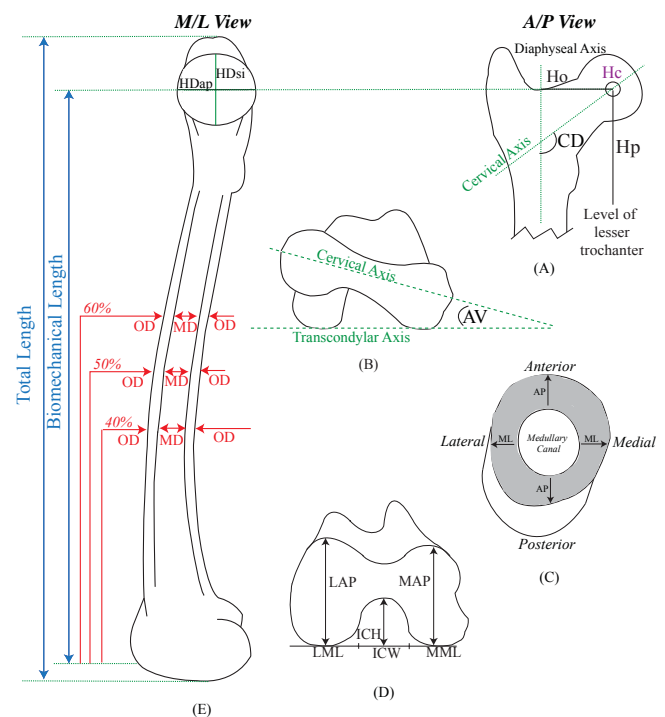
Sixteen pairs (10 male, 6 female) of fresh frozen *Odocoileus virginianus* femora (average age 2.1 ± 0.9 years) were obtained from Nolt's Custom Meat Cutting (Lowville, NY). Right femora were used for the morphometric study while left femora were used for biomechanical testing. Dimensions measured (Figure 1) include total and biomechanical lengths (L_T, L_B), anteversion and cervicodiaphyseal angles (AV, CD), head diameter in AP and SI planes (HD_{AP}, HD_{SI}), head offset and position (H_O, H_P), outer and medullary diameters (OD, MD) in AP and ML planes, cortical cross-sectional area (CSA), cortical thickness (CT), AP and ML dimensions of lateral and medial condyles (LAP, LML, MAP, MML) and intercondylar height and width (ICH, ICW). MD, OD, CSA and CT were reported as the average of the values measured at 40%, 50% and 60% of L_B. L_T, AV, CD, HD, H_O, H_P and CSA were measured via scaled photos (Fujifilm FinePix Z33WP camera) of specimens in ImageJ (ImageJ 1.48, nih.gov) while the other dimensions were measured by hand with inside/outside calipers with the exception of L_B, which was measured with a flexible tape measure to the nearest mm. MD dimensions were measured at incremental percentages of the total length by transecting the bone at each of these locations with a hacksaw. Each dimension was measured three times by three different people and recorded in mm (lengths) or degrees (angles).


Figure 1: Morphometric dimensions. *(A)* AP view of proximal femur showing H_O and H_P relative to H_C (head center), and CD angle; *(B)* AV angle; *(C)* Cross-sectional view of diaphysis showing CT in AP and ML planes; CSA is also represented by the shaded area; *(D)* Distal femoral dimensions; *(E)* ML view showing L_T and L_B as well as head diameter in AP and SI planes, and OD and MD at each % of L_B.

The diaphysis of the 16 left femora were potted in Bondo^{TM} (Auto Body Filler, 3M, St. Paul, MN) at a 10° angle in the frontal plane [3, 6]. Half were monotonically compressed and the other half were torqued to failure in a load frame (MTS 809 Axial/Torsional Test System, Eden Prairie MN). Rates of compression and torsion were 0.1 mm/sec and 0.2^o/sec respectively. Stiffness and ultimate strengths were calculated ($K_{Axial}=\Delta F/\Delta\delta$ & $K_{Torsional}=\Delta M/\Delta\theta$) using a custom MATLAB code (R2012b, MathWorks, Natick, MA).

RESULTS AND DISCUSSION

Although markedly shorter than the human femur, the cervine femur has a length closer to that of the human femur than other species [3, 4] (Fig. 2). Average cervine AV and CD angles were closer to human values than canine species [1]. Average values for HD_{AP}, HD_{SI}, H_O and H_P were all smaller than human dimensions [1]. This is expected, as the cervine pelvis is much smaller than the human pelvis, and thus requires smaller head dimensions overall [1].
Figure 2: CSA, length, and head angles
Figure 3: Diaphyseal and shaft dimensions

Figures 2 and 3 compare mid-diaphyseal averages for CSA, CT, MD and OD. The average LML, ICH and ICW were smaller than human values but

follow similar trends to other animals. The cervine femur has a greater torsional stiffness than the human femur, which has a higher torsional ultimate strength: 106.83 Nm for cervine compared to 170.00 Nm for human femurs (Fig. 4). In addition, the cervine femur was found to have an axial stiffness within range of previously-reported human values [4,6].
Figure 4: Axial and torsional stiffness of deer femora compared to human, pig, and sheep femora [4]

CONCLUSIONS

Cervine femora have average length, angular, distal femoral and endosteal values closer to human values than some other animal models and also have similar biomechanical properties. Therefore they may be suitable analogs for human bone in the testing of orthopaedic devices. These results may have important implications for orthopaedic device development and may offer an inexpensive, locally-abundant and sustainable source of suitable animal models for the human femur.

ADJUSTING THINKING ABOUT IM NAILS: MECHANICAL EVALUATION OF AN ADJUSTABLE INTRAMEDULLARY NAIL PROTOTYPE

[1]Mark J. Hedgeland, [1]Alexander D.W. Throop, [2]Alexander Martin Clark Jr., and [1]Laurel Kuxhaus

[1]Clarkson University, Potsdam, NY, USA
[2]Canton Potsdam Hospital, Potsdam, NY, USA & Sharon Hospital, Sharon, CT, USA

email: lkuxhaus@clarkson.edu web: http://people.clarkson.edu/~lkuxhaus/

INTRODUCTION

The fixation of a long bone fracture via intramedullary (IM) nailing is a common orthopaedic surgical procedure. To ensure rigid fixation, the IM nail must be the proper length for the patient's bone [1]. Improperly sized IM nails can lead to complications such as non-union which can eventually result in mechanical failure [1]. The currently available IM nails come in discrete sizes, (up to 98 sizes for one model) which often do not fit a patient's IM canal length exactly [1]. Alternatively, an adjustable-length nail would offer improved patient outcomes. In addition, the adjustable nail would reduce hospitals' need to stock many discrete sizes of nails, and therefore reduce stocking costs and procedure time. This work aims to improve on the four previously designed adjustable tibial IM nail prototypes' stiffness values with a new design and compare these values to currently-in-use nails. This will be done in cervine tibiae, which have already been shown to be suitable models for human tibiae [1].

METHODS

A new adaptation to previous IM nail prototypes was designed in Creo Parametric 3.0 (PTC, Needham, MA) and SolidEdge (Siemens PLM Sofware, Plano, TX) and then machined from surgical stainless steel (316L). The machined "Prototype 5" was able to extend through its full range of adjustability (approximately 290-410 mm) and lock into place securely with a flattened locking nut and thread-locking set screw. To provide greater torsional resistance than previous prototypes, the new design also incorporated a thicker overall structure. Prototype 5 had the largest total cross-sectional area of any of the prototypes thus far, but

Figure 1: X-ray of Prototype 5 inserted into a cervine tibia.

was still comparable to the size of currently-in-use nails[1]. Prototype 5 was then tested in torsion and four-point bending according to the ASTM standard to determine its stiffness values [2]. For torsion testing, Prototype 5 was inserted into three right cervine tibiae specimens (2 male and 1 female, 2.1 ± 0.6 years) according to standard surgical procedures and under the direction of a certified orthopaedic surgeon [AMC] (Figure 1). The tibiae were from white-tailed deer donors, *Odocoileus virginianus,* obtained from Nolt's Custom Meat Cutting (Lowville, NY). After insertion, the tibia/Prototype construct was potted vertically in Bondo™ (Auto Body Filler, 3M, St. Paul, MN) for support around the diaphysis. They were then tested in torsion at a rate of 0.1/sec at 1° increments up to 10° (MTS 809 Axial/Torsional Test System, Eden Prairie MN). The bending test was performed in a non-articulating four-point

bending fixture. Prototype 5 was tested alone (not inserted into a tibia) at a rate of 1 mm/sec until 5 mm of displacement had been reached. The load-displacement data from each trial of torsion and bending tests were analyzed, and the stiffnesses of each construct were calculated as in Equations 1 and 2 using a custom MATLAB code (R2012b, Mathworks, Natick, MA).

$$K_{Torsional} = \Delta M / \Delta \theta \qquad (1)$$

$$K_{Bending} = \frac{(L+2c)(\Delta F/\Delta \delta)s^2}{12} \qquad (2)$$

where L, s, and c are based on roller geometry [2]

RESULTS AND DISCUSSION

The device performed better than its predecessors in bending stiffness (Figure 2). Note that its bending stiffness is much greater than the currently-in-use nail, Synthes (Tibial Nail EX, Johnson & Johnson, New Brunswick, NJ), and within range of human tibia values [3,5]. In addition, the torsional stiffness of Prototype 5 is within the range of the Synthes nail.
Figure 2: Torsional and bending stiffness of Prototype 5 compared to previous prototypes [1], the currently-in-use Synthes [4], and human tibia [5].

CONCLUSIONS

The higher bending stiffness of Prototype 5 is not surprising as it has the largest overall cross-sectional area of any of the previous prototypes. The aforementioned prototypes employed a design which consisted of a single threaded rod screwed into a bent proximal end with adjustability at the distal end. These designs were locked by nut, set screw, or pin, but never a combination of these [1]. The high torsional stiffness of Prototype 5 indicates that the combination of the locking nut and set screw as a locking mechanism, coupled with the rearrangement of the Prototype's region of adjustability, better resists rotational forces while implanted in the tibia. Prototype 5 also more closely resembles the overall structure and appearance of currently-in-use nails. Future work will include axial compression, and a larger sample size. These initial findings indicate that this device may be comparable in mechanical behavior to that of currently-in-use devices.

An adjustable IM nail that could serve as a viable alternative to current discretely-sized models would have significant positive clinical impacts. The addition of adjustability to IM nailing, made possible by a device such as this, could improve patient outcomes from fracture fixation surgeries and drastically reduce healthcare costs associated with the procedure by eliminating the need to stock several dozen discretely-sized nails.

ACTIVITIES OF DAILY LIVING INDUCE VERTEBRAL FRACTURES DESPITE HEALTHY BMD

Nicole C. Corbiere, Stacey L. Zeigler, Kathleen A. Issen, Arthur J. Michalek, and Laurel Kuxhaus

Clarkson University, Potsdam, NY, USA

email: lkuxhaus@clarkson.edu, web: http://www.people.clarkson.edu/~lkuxhaus/

INTRODUCTION

Osteoporotic vertebral compression fractures are a growing problem and the micromechanical origin of these fractures remains unclear. Patients with osteoporosis often can't recall an extreme event that caused a compression fracture, suggesting that activities of daily living (ADLs) could contribute to these fractures. Repetitive small movements during ADLs affect the vertebrae; the study of these movements could provide insight on fracture initiation. The effects of lower angle motion ADLs on vertebral compression fracture development is unknown, despite the fact that flexion of less than 15° is the most common motion of the lumbar spine during ADLs [1].

This work will mechanically simulate vertebral fractures under low-load low-angle loading conditions in cervine lumbar vertebral motion segments. Cervine vertebral motion segments have a similar mechanical response to human vertebral motion segments [2-4]. Characterizing the hysteresis loops from loading that simulates ADLs is an important first step towards quantifying the effects of ADLs on fracture initiation and propagation.

METHODS

Six 5-vertebra motion segments (male, 2.67 ± 0.52 years) were harvested from cervine donors (Nolt's Custom Meat Cutting, Lowville, NY).   X-rays (Multix X-Ray System, Siemens, Berlin, Germany) and DXA scans (Lunar Prodigy Advance DXA System, GE Healthcare, Little Chalfont, Buckinghamshire, United Kingdom) were performed at Canton Potsdam Hospital to rule out any bone pathologies and obtain bone mineral density (BMD).   The average BMD for all specimens was 1.182 ± 0.155 g/cm^2, comparable to healthy human bone. Specimens were potted in Bondo™ (Auto Body Filler, 3M, St. Paul, MN) to create end-caps to interface with a pinned end loading fixture.

Cyclic loading with this fixture simulated repeated flexion; the pinned end conditions more accurately represent physiologic loading conditions than fixed end conditions. Eccentric compressive loading of the fixture (eccentricity of 10mm) induced flexion (Figure 1). Specimens were cyclically loaded at 2Hz between displacements corresponding to approximately 0° and 15° flexion for 40,000 cycles. Periodically, the loading rate was slowed to 0.1Hz to capture images for digital image correlation (not discussed here) and motion analysis. A 4-camera Qualisys (Oqus 500 cameras, Qualisys Inc., Sweden) motion capture system, with an accuracy of 0.1mm and a capture rate of 120Hz, was used to measure the intervertebral flexion angles; for this, four retroreflective markers were secured to each vertebral body with cyanoacrylate adhesive.
Figure 1: Pinned end conditions.

After 40,000 cycles of loading, specimens were monotonically compressed to further failure at a rate of 25.4 mm/min [5] and again X-rayed. These data were processed to compute the intervertebral angles (during the motion capture), load-displacement during monotonic compression, and peak load during the cyclic compression. Number of cycles to first observable failure and monotonic compression failure loads were also determined.

RESULTS AND DISCUSSION

All specimens failed at the articular facet joints (Figure 1); the fracture continued through the intervertebral disc interface. In 5 of the 6 specimens, facet fracture was observed prior to monotonic compression as early as 1,400 cycles (range: 1,400-35,000 cycles). During this cyclic flexion, the peak load decayed nonlinearly by an average of 73% (range: 57-84%), indicating that damage occurred. During monotonic compression to catastrophic failure, the average failure load was 240 ± 146N, substantially smaller than previously-reported failure loads ($7,244 \pm 1,795$N) using fixed end conditions [6]. These results demonstrate that fractures can be created under cyclic low-angle flexion (e.g., during ADLs).

As expected, the early cycle hysteresis loops (not shown) exhibit relaxation of the motion segment: the load decreases with increasing cycles. Figure 2 shows the hysteresis loops for a representative specimen for the 500th and 40,000th cycle of loading. This specimen failed at both the L2/L3 and L3/L4 articular facet joints. The peak compressive load decreased 84% during the cyclic loading and the intervertebral flexion angles (not shown) changed markedly after fracture occurred, indicating that the structure accumulated considerable damage.

In addition to decreased peak load, the difference in hysteresis loops from the 500th to the 40,000th cycle shows accumulation of damage: the shapes of the loops change. The specimen shown in Figure 2 visibly failed at approximately 7,000 cycles. The articular facet failure caused this change in mechanical response as evidenced by the undulations in the 40,000th cycle hysteresis loop.

Given the known articular facet joint fracture, the change in shape and slope of the last loop suggests that the facet joints may be catching, causing the undulations in this loop.
Figure 2: Hysteresis loops for the 500th and 40,000th cycles from a representative specimen.

CONCLUSIONS

These preliminary data suggest that the cyclic loading of small movement ADLs can contribute to fracture formation, despite healthy BMD. Future analyses, including calculating cortex surface strain and intervertebral angles during cyclic loading, may elucidate vertebral fracture mechanisms. Despite the limitations of a small sample size and the use of cervine specimens, these results suggest that health care providers may need to consider small movement ADLs in fracture prevention education.

MONITORING ACOUSTIC EVENTS IN BONE DURING SCREW INSERTION

[1] Evan R. Langdale and [1] Stephen M. Belkoff

[1] The Johns Hopkins University, Baltimore, MD, USA
email: sbelkoff@jhmi.edu

INTRODUCTION

No objective standard exists for optimal bone screw tightening during the application of fracture plates. Proper tightening is necessary to maintain fracture reduction and prevent malunions and nonunions, yet surgeons strip up to 20% of screws in osteoporotic bone [1]. The patient dependent variation in the material properties of bone has made previous attempts at predicting optimal screw purchase difficult. Loss of screw purchase is likely a result of bone failure in the bone-screw-thread interface. Damage to the bone has been identified by acoustic emissions [2]. The goal of the current study is to use acoustic emissions as a measure of bone damage and a predictor of subsequent loss of screw purchase.

METHODS

Cadaveric humeri were stripped of soft tissue and mounted in a custom testing fixture. Pilot holes were drilled to their appropriate size and a 1/3 tubular bone plate instrumented with strain gages was placed on the bone. The plate was calibrated to measure the force that a screw applies to the plate and has been used previously to measure screw purchase [3]. A 3.5mm cortical bone screw (Synthes) was inserted into the bone manually until the screw head was close to seating in the plate. Further screw tightening was achieved using a servohydraulic testing machine that rotated the screw at 20°/s until the screw was stripped and lost purchase.

During the test, a piezoelectric transducer, attached to the bone, recorded acoustic data at 200 kHz. Torque, angle and plate strain were recorded at 1 kHz.

An acoustic event was defined as any signal that was ≥2 times the average noise that was recorded during manual screw insertion. Cumulative acoustic events and force on plate were plotted against screw angle of rotation to identify a relation between the number of acoustic events and loss of screw purchase as indicated by loss of plate compression against the bone.

RESULTS AND DISCUSSION

Acoustic events began occurring at the end of the linear region of the plate strain vs. angle of screw rotation curve (Fig. 1).
Figure 1: Plate strain and cumulative acoustic events plotted as a function of angular rotation. Dashed vertical line signifies end of linear region.

The onset of acoustic events initiated at 89% of peak compression.

As plate compression versus screw rotation continued beyond the linear region, the additional screw rotation did not result in an appreciable increase in plate compression. The results suggest that the onset of acoustic events may be indicative

of bone failure leading to loss of screw purchase and concomitant loss of screw force applied to the plate. These findings are consistent with acoustic events observed in bone loaded in compression [4].

CONCLUSIONS

Acoustic events correlate with loss of screw purchase in bone and may indicate damage at the bone-screw interface.

VALIDATION OF THE SUBJECT-SPECIFIC FINITE ELEMENT ANALYSIS
UNDER QUASI-STATIC AND DYNAMIC GAIT CONDITIONS

INTRODUCTION

Finite element (FE) foot modeling is a useful tool for investigating foot and ankle biomechanics. Such models can provide insight into internal soft tissue behavior of the foot and are ideal for conducting parametric analyses [1, 2]. Many of the previous FE foot models simulated quasi-static loading and imposed major simplifications on anatomy and material properties [1, 2], which could compromise their accuracy and usefulness. The purpose of this study was to develop and validate a subject-specific FE foot model of a healthy normal subject capable of accurately simulating both quiet stance (quasi-static loading) and the stance phase of gait (dynamic loading), and to explore the plantar pressure and internal soft tissue stress distribution under these two loading conditions.

METHODS

A right foot of a 43-year-old male (945 N body weight (BW)) subject was scanned using high resolution partially-loaded computed tomography (CT) and unloaded magnetic resonance imaging (MRI). The scan data were segmented to obtain subject-specific bone, skin, muscle and fat anatomy using custom software. Boolean operations were performed using ScanIP (Simpleware, Exeter, UK) to generate joint capsules and skin thickness, and eliminate gaps and volume overlaps (Figure 1). Models were meshed with linear tetrahedral elements using ANSYS ICEM CFD (ANSYS Inc, Canonsburg, USA) and preprocessed in LS-Prepost (Livermore Software, Livermore, CA). Bones were assumed rigid due to their small deformation relative to the soft tissue. Subject-specific Ogden hyperelastic material properties of the skin, fat,

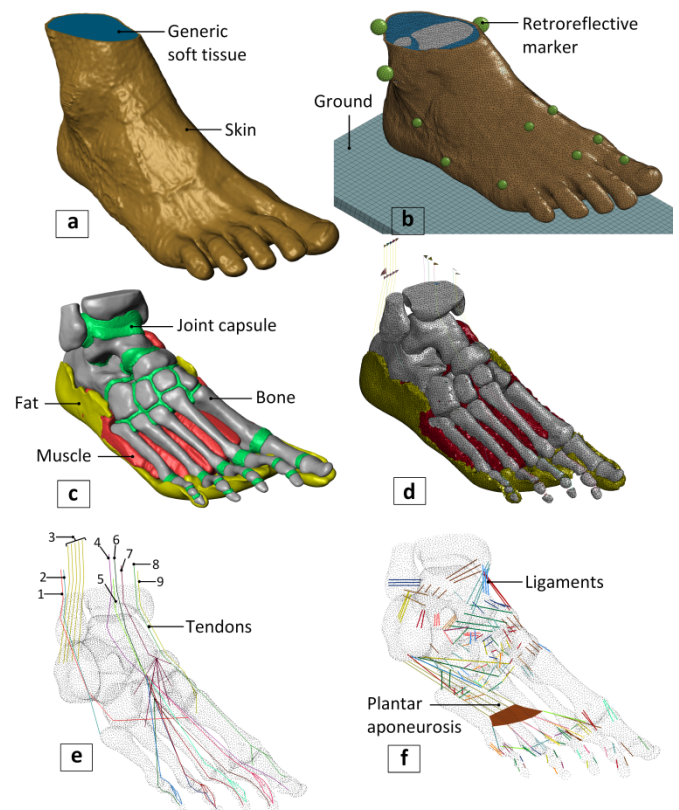
muscle and generic soft tissue (Table 1) were determined from inverse FE analysis of gated MRI compression experiments [3, 4]. A total of 102 ligaments, 9 extrinsic muscle tendons [5], and joint cavities were accurately modeled based on the medical images. The plantar aponeurosis component was divided into four different regions, with non-linear material properties obtained from cadaveric mechanical testing [3].


Figure 1: (a, c) Surface model of the foot showing skin (brown), generic dorsal soft tissue (blue), plantar fat (yellow), intrinsic muscle (red), bones (gray) and joint capsules (green). (b, d) Solid model components. (e) 9 extrinsic muscle tendons, (f) 102 ligaments and the plantar aponeurosis.

The models were validated under three loading conditions: passive 10% BW compression, quiet stance, and the stance phase of gait. The passive compression loaded the tibia and Achilles tendon (zero and 20% BW) in the vertical direction such that the GRF was 10% BW. In quiet stance, the tibia was oriented based on *in vivo* motion capture data collected in-house for this subject. The model was loaded by the tibial force, Achilles tendon force (54.5% BW) and gravitational acceleration to apply 50% BW at the ground. For gait simulation, the tibial kinematic time history from motion capture was prescribed, as were eight tendon force-time histories (taken from literature [6]). The initial ground position and Achilles tendon force were tuned to achieve physiologic vertical ground reaction force (GRF). All models were solved in LS-DYNA (v971d R5.1.1 explicit analysis). Bone kinematics, dynamic GRF, plantar pressure, plantar aponeurosis force and ankle joint force were compared with the *in vivo* experimental data for this subject and with literature data [7, 8].

Table1: Material models and properties.

Material	Model	Properties[†]
Bone	Rigid	ρ = 0.449e-6 kg/mm^3, E = 20,100 MPa, v = 0.3
Skin	Hyperelastic	ρ = 1.142e-6 kg/mm^3, μ = 0.158 kPa, α = 185.20, v=0.4990
Fat	Hyperelastic	ρ = 0.916e-6 kg/mm^3, μ = 1.874 kPa, α = 8.29, v = 0.4999
Muscle	Hyperelastic	ρ = 1.047e-6 kg/mm^3, μ = 0.161 kPa, α = 31.95, v = 0.4999
Dorsum tissue	Hyperelastic	ρ = 1.000e-6 kg/mm^3, μ = 0.787 kPa, α = 21.11, v = 0.4999

[†] Density (ρ), modulus of elasticity (E), Poisson's ratio (v), Ogden hyperelastic coefficients (μ_l and α_l). Poisson's ratios were estimated from tissue properties: longitudinal ultrasound speed, density and elastic modulus. Detailed calculations (Poisson's ratio) and data references (ligament, tendon and plantar aponeurosis) are listed in [3]

RESULTS AND DISCUSSION

The subject-specific model was capable of simulating physiologic compression, quiet stance and dynamic gait conditions. The difference between the simulated and experimental data from passive compression validation ranged from 0.4% to 52.3%. The quiet stance experimental and simulated plantar pressure distribution were similar, but did not exactly match (Figure 2).

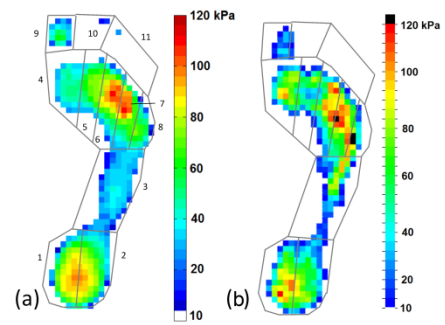
The simulated gait vertical GRF (Figure 3) agreed with our *in vivo* data (RMS error of 13%), partially due to tuning. The predicted anteroposterior and


Figure 2: Quiet stance plantar pressure (divided into 11 regions) from (a) experimental measurement and (b) FE simulation.

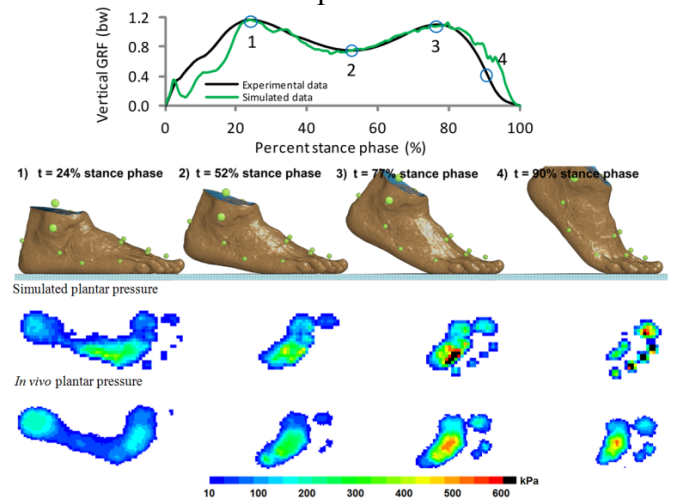
mediolateral progression of the center of pressure, mean pressure, contact force and contact area also agreed with *in vivo* data. Peak pressure was over-predicted, possibly due to numerical artifacts. The bone-to-ground and segment-to-segment angles showed physiologic movements in the sagittal plane, but implied an overly stiff transverse deformation. The pattern and magnitude of the simulated plantar aponeurosis force and ankle joint resultant force were comparable to the literature.


Figure 3: Predicted foot deformation and plantar pressure distribution compared to the corresponding *in vivo* plantar pressure measurement at four instances of gait.

PATIENT-SPECIFIC MECHANICAL PROPERTIES OF DIABETIC AND HEALTHY PLANTAR SOFT TISSUE FROM GATED MRI

Williams, ED[1,2], Stebbins, MJ[1,2], Cavanagh, PR[2,3], Haynor, DR[4], Chu, B[4], Fassbind, MJ[1], Isvilanonda, V[1,2] and Ledoux, WR[1,2,3]

INTRODUCTION

The Hydraulic Plantar Soft Tissue Reducer (HyPSTR) is an MRI compatible device that applies dynamic loading profiles to a subject's foot while gated MRI captures soft tissue deformation. The combination of force and image data is used to calculate plantar soft tissue stiffness, which has been shown to be significantly different in subjects with/without diabetes [1]. Diabetes mellitus can lead to ulceration in the foot, and eventually amputations [2]. Ulcers may form at regions of high internal stress, which motivates the use of MRI to obtain volumetric information, as opposed to external deformation measurements [3,4] or one-dimensional ultrasound probing [5,6]. Finite element (FE) models can use this force and three-dimensional image data to conduct inverse FE analyses to determine patient-specific material properties, which in turn can be used to improve foot simulations under a variety of loading scenarios.

METHODS

Verification data and calibration curves were obtained to ensure that the motor and control electronics could accurately transmit displacements through plastic, water hydraulic tubing to the loading platen in the MRI core. Applied force was measured indirectly from system pressure and matched with the appropriate MRI time stamps for 16 loading/unloading phases during a periodic (5s) sine-wave displacement protocol. Gated MRI was synchronized with a peripheral pulse unit signal so that cardiac MRI gating protocols could be used to obtain 16 images of the tissue deformation at custom rates. Distances between anatomical landmarks were measured in pixel units with segmentation software and converted to mm.

An ankle foot orthosis (AFO) was designed from carbon fiber and leather to secure the foot and lower leg to the loading apparatus during testing (Figure 1). The HyPSTR can be fitted with an ultrasound adapter, for pilot testing or adjusted to test forefoot tissue properties, or left or right feet.
Figure 1: HyPSTR slave cylinder (black) and loading jig. The ultrasound probe adapter (bicolor, yellow/red) is connected to the loading platen.

Two subjects were tested. Subject A had no history of diabetes and was 93 kg in mass, 180 cm tall, and 43 years old. Subject B had type II diabetes and was 70 kg in mass, 170 cm tall, and 31 years old.

RESULTS AND DISCUSSION

Image data (Figure 2) for Subject B shows maximum tissue compression near the tenth acquisition phase. The first three phases appear to be unloaded (force data from the HyPSTR was 0N). This is due to the heel preconditioning that occurs after the subject is secured in the AFO. The gap that forms between the platen and foot is not completely avoidable, without pre-loading the subject.
Figure 2: Subject B (diabetic) center slices of the calcaneus from each of the 16 image volumes.

A loading/unloading stiffness curve was obtained for both subjects (Figure 3 for subject B, subject A not shown). The magnitude (approx. 200N) and velocity (approx. 3.5 mm/s) of the deformation was mostly elastic (i.e., there was no significant hysteresis, Figure 3). Fat pad stiffness is generally thought to increase exponentially with strain [3], which could still be true for these subjects at higher strains. Subject B tissue was 2.65 times more stiff than Subject A (data not shown here) in the final 0.06 mm of compression. This agrees with trends in the cadaver sample data from Pai and Ledoux [1].

$$y = 0.1225x^4 + 7E\text{-}12x^3 + 10.506x^2 - 6.3013x + 2.2658$$
$$R^2 = 0.9773$$
Figure 3: Stiffness curve for Subject B with polynomial fit.

CONCLUSIONS

The HyPSTR represents progress toward measuring patient-specific, dynamic heel pad stiffness. Currently there are limitations in platen velocity (0.2 Hz) that need to be addressed in order to test compressibility at a more physiologic rate (1 to 10 Hz). Still, the data indicate that the HyPSTR can differentiate between dynamic stiffnesses of subjects with and without diabetes.

INTRODUCTION

Individuals who have had a stroke routinely experience long-term motor and sensory impairments. Decreased strength and range of motion contribute greatly to decreased mobility. In conjunction with neurological changes, muscle properties, including architecture and material properties such as stiffness, may also progressively change. Prior descriptions of muscle material properties in stroke survivors have observed increased muscle stiffness [1]. However, these previous measures are estimates derived from individual joint stiffness or whole muscle groups. In addition, current standard clinical examinations cannot readily distinguish between active reflex and passive tissue components [2]. Thus, the purpose of this study was to compare material properties, by measuring shear wave velocity (SWV) which is related to shear modulus, in spastic paretic muscles at rest and at different activation levels with contralateral muscles in stroke survivors and in age-matched control subjects.

METHODS

Fourteen stroke survivors participated in this study (age: 58.9±7.4yrs; height: 1.68±0.10m; body mass: 85.5±18.2kg; time post-stroke: 11.4±11.6yrs.; Fugl-Meyer: 4-48, 19±15). We tested nine subjects who were gender and age-matched to the stroke survivors (age: 57.9±7.1yrs; height: 1.64±0.10m; mass: 74.4±11.2kg;).

Subjects were seated upright with their upper arm resting on a plastic support, the forearm secured in a fiberglass cast, and the wrist and forearm held in a neutral position in a ring-mount interface mounted to the table. The shoulder was positioned so that the humerus was abducted 45 degrees and the elbow

positioned at 90 degrees. Subjects performed a series of isometric elbow flexion contractions at different activation levels (0, 10, 25, 50, 75, 100% maximum voluntary contraction (MVC)) while force and torque were measured at the wrist (load cell). During each trial, muscle activity (electromyography), and ultrasound images (Aixplorer, SuperSonic Imagine) of the biceps brachii were captured. Mean SW velocity was calculated from a 12mm by 12mm region of the ultrasound images. Here we use shear wave ultrasound elastography which measures the velocity at which shear waves propagate through the tissue [3]. Shear waves will propagate faster in a tissue that has a higher elastic shear modulus:

$$\mu = \rho v^2$$

where μ is the elastic shear modulus, ρ is the muscle mass density ($\rho \approx 1000$ kg m^{-3}), and v is the SW velocity. We calculated the slope and r^2 of the linear fit between SWV and % MVC until 50%MVC as the SWV at 75% and 100%MVC reached the maximum the ultrasound system is capable of measuring (16m/s). An Analysis of Variance was used to compare the SWV at the different % MVC levels, slope, and r^2 of the non-paretic and paretic muscles, and those of the gender, age-matched controls.

RESULTS AND DISCUSSION

Our main findings show that at rest, the SWV was on average 40% greater in the paretic muscle compared to either the contralateral non-paretic muscle or the muscle of control subjects (Fig.1, p=0.003, p=0.002), and no significant difference in SWV between the non-paretic muscle and control muscle. In active muscle (10, 25, 50%), there was no significant difference in SWS between the non-paretic, paretic, and control muscles (Fig.1). The

slope of SWV versus %MVC (up to 50%MVC) and R^2 values was 10% and 15% greater, respectively, in the non-paretic muscles compared to that of the paretic muscle, but was not significant (Table 1, $p = 0.06$).
Figure 1: Mean shear wave velocity at rest and at 50 %MVC (force) for the non-paretic (black) and paretic (gray) muscle of individuals who have had a stroke and muscle of gender, age-matched controls (white). Brackets indicate the same control subject.

CONCLUSIONS

We demonstrate that SW velocity is faster in the biceps brachii of the paretic limb than in the contralateral non-paretic limb of stroke survivors and age-matched individuals with no neurological impairments when the muscle is at rest. This

suggests that paretic muscles have potentially altered muscle material properties, specifically stiffness in both passive and active muscles, but primarily in passive states. This can be a result of increased collagen in the perimysium and abnormal accumulation of the extracellular matrix[4].

Interestingly, this difference in SWV between three muscle groups disappears once the muscle was active. One source of active stiffness is short-range stiffness. Thus, it is possible that the non-contractile elements contribute minimally to stiffness in active muscle and the active short-range stiffness is not altered in stroke-impaired muscle.

These results offer us insight and a first look into active and passive stiffness of stroke muscle. Quantitative measurements of muscle material properties, in particular stiffness, in individual muscles is important for accurately evaluating muscle function and for understanding the fundamental mechanisms of impairment that occur after a stroke. This knowledge has the potential for aiding clinical decisions, and for guiding rehabilitation interventions that may specifically target altered passive and active stiffness.

INTRODUCTION

The wrist structure is primarily composed of irregularly shaped carpal bones interconnected by numerous ligaments, resulting in complex structural mechanics. The mechanical characteristics of the wrist have an immense impact on wrist stability and function. Previous studies of wrist biomechanics were mainly limited to uniaxial and planar experimentation but the mechanical properties in 3D are not well understood. The purpose of this study was to examine the 3D stiffness characteristics of the wrist with displacement perturbations applied to the carpal arch.

METHODS

A custom stationary apparatus held five (n = 5) cadaveric hands in a vertical position (Fig. 1). For each specimen the hamate was fixed to the stationary apparatus and the trapezium was free to be displaced in 3D. An instrumented 6 DOF robot arm displaced the ridge of the trapezium and

Figure 1: Experimental setup for applying displacement perturbations to the trapezium.

measured 3D reaction forces. A ball-socket interface between the trapezium and robot allowed for free rotation without torque constraints. The displacement perturbations were implemented with various magnitudes (0.5, 1.0, 1.5, and 2.0 mm) from its initial position towards 14 directions that were equally spaced in 3D with respect to an anatomically defined coordinate system – X, Y, Z axes corresponded to the lateral(+), distal(+),and volar(+) directions, respectively. Prior to data collection, the carpal arch was preconditioned by displacing the trapezium 2 mm in each direction ten times. The force-displacement data were used to determine a stiffness matrix K according to $\mathbf{f} = K\mathbf{d}$, where $\mathbf{f}$ and $\mathbf{d}$ are force and displacement vectors, respectively. The matrix was determined by fitting the force-displacement data with least-squares optimization procedures.

The stiffness matrix was separated into symmetric (K_S) and antisymmetric (K_A) components, where $K_S = (K + K^T)/2$ and $K_A = (K - K^T)/2$ (^{T} denotes matrix transpose). The determinates of K and K_S, det(K) and det(K_S) respectively, were calculated to provide a scalar quantity of the overall stiffness values. K_A was a 3x3 skew-symmetric matrix and subsequently det(K_A) = 0. An elastic index was calculated as det(K_S)/det(K) where an elastic index of 1 indicates pure elasticity, i.e. spring-like behavior. Eigendecomposition of K_S was then used to determine the magnitudes and directions of principal stiffness components.

RESULTS AND DISCUSSION

The optimization procedures to determine the stiffness matrix resulted in a goodness of fit of $R^2 = 0.815 \pm 0.070$. The stiffness matrix and its decomposed symmetric and antisymmetic matrices were:

$$K = \begin{bmatrix} 11.7 \pm 2.4 & 0.5 \pm 0.9 & 5.7 \pm 1.0 \\ -0.9 \pm 0.7 & 2.9 \pm 0.5 & -0.6 \pm 0.6 \\ 6.7 \pm 1.5 & 0.5 \pm 0.6 & 7.4 \pm 1.0 \end{bmatrix} \text{N/mm}$$

$$K_S = \begin{bmatrix} 11.7 \pm 2.4 & -0.2 \pm 0.7 & 6.2 \pm 1.2 \\ & 2.9 \pm 0.5 & 0.0 \pm 0.5 \\ & & 7.4 \pm 1.0 \end{bmatrix} \text{N/mm}$$

$$K_A = \begin{bmatrix} 0 & 0.7 \pm 0.4 & -0.5 \pm 0.4 \\ -0.7 \pm 0.4 & 0 & -0.6 \pm 0.2 \\ 0.5 \pm 0.4 & 0.6 \pm 0.2 & 0 \end{bmatrix} \text{N/mm}$$

The determinates of K and K_S were 151.3 ± 70.4 N^3/mm^3 and 146.1 ± 67.0 N^3/mm^3, respectively. The subsequent elastic index was 97.0 ± 2.0%. Eigendecomposition of K_S resulted in the three principal components of 16.2 ± 2.9, 3.1 ± 0.6, and 2.8 ± 0.5 N/mm (Fig. 2, Table 1).

The wrist structure had a high elastic index demonstrating a spring-like characteristic. In other words, the force vector field for the displacement perturbations was essentially conservative. Generally, the specimens varied in stiffness magnitude (See Determinant of K_S, Table 1), but their principal directions and relative principal component magnitudes were more comparable. The principal stiffness components of the wrist structure differed in magnitude indicating that the wrist had an anisotropic stiffness behavior. Specifically, the maximum principal stiffness component was 5.8 times greater than the minimum principal stiffness.

The direction of the wrist's maximum principal stiffness was within the transverse plane and was pronated 36° relative to the medial-lateral axis. This may be due to wrist ligament orientation and the tightly bound distal carpal row that is predominately within the transverse plane. The minimum principal

stiffness occurred in a direction oblique to the anatomical axes and was situated in the plane of dart thrower's motion, i.e. radial-extension to ulnar-flexion.
Figure 2: Specimen specific principal stiffness components. The 1st, 2nd, and 3rd principal components are shown (green, red, and blue respectively) with length corresponding to stiffness magnitude.

CONCLUSIONS

The wrist structure exhibited spring-like and anisotropic stiffness behaviors. The maximum principal stiffness occurred in the transverse plane while the minimum principal stiffness was situated in the plane of dart thrower's motion. This study provides advanced characterization of the wrist's 3D structural stiffness for improved insight into wrist biomechanics, stability, and function.

INTRODUCTION

The carpal tunnel is comprised of eight carpal bones held together by a network of interosseous ligaments. Previous studies have demonstrated relative movement of the carpal bones with force application on aspects of the wrist [1, 2]. Narrowing of the carpal arch width (CAW), measured from the hook of the hamate to the ridge of the trapezium, has been demonstrated by applying force across the wrist [3, 4]. However, the time dependent effects of applying compressive force across the wrist on CAW narrowing have not been studied. Therefore, the purpose of this study was to investigate the change in CAW over time while external compressive force was applied across the wrist *in vivo*. Given the viscoelastic nature of the soft tissues that bind the carpal bones, we hypothesized that prolonged force application to the carpal tunnel would result in creep of the carpal tunnel deformation, which would be manifested by increased CAW narrowing over time.

METHODS

Fourteen (n=14) female participants (24.5±4.2 years old) participated in this study. Study exclusion criteria included history of musculoskeletal or neurological disorders affecting the hand and wrist. Each subject placed the hand in a splint in a supinated position, and an ultrasound probe was placed on the volar aspect of the wrist at the level of the hamate and trapezium. A carpal compression device powered by linear air pressure actuators and a surgical tourniquet provided an external compressive force across the wrist of 15 N for 5 minutes. The device and setup are demonstrated in Fig. 1. Ultrasound video was captured throughout the 5 minutes of wrist compression.

The ultrasound video was decomposed into individual frames and analyzed using a custom LabVIEW program to track the most volar aspects of the hook of the hamate and the ridge of the trapezium over time. The CAW magnitude for each frame was then calculated based on the coordinates of the hamate and trapezium (Fig. 2). Then, a creep function of the CAW was determined by fitting a standard linear solid (SLS) viscoelastic model. The model consisted of a spring (K_1) in parallel with a Maxwell element that included a spring (K_2) in series with a dashpot (η) (Fig. 3). The creep function of the SLS model was of the form

$$\varepsilon(t) = \varepsilon_0 \left(1 - Ae^{-Bt}\right)$$

where $\varepsilon_0 = \frac{F}{K_1 L_0}$, $A = \frac{K_2}{K_1 + K_2}$, $B = \frac{K_1 K_2}{[\eta(K_1 + K_2)]}$, F was the applied compression force, L_0 is the initial CAW, and $\varepsilon(t)$ was the strain at time t.
Figure 1: Experimental setup of ultrasound imaging and wrist compression to narrow the CAW.
Figure 2. Representative ultrasound image with the hook of the hamate and ridge of the trapezium identified for tracking (red boxes), and the CAW (yellow line) between the two bony landmarks.
Figure 3. Schematic of the SLS model.

RESULTS AND DISCUSSION

Data from 11 of the 14 subjects were analyzed; the remaining three subjects were unable to be used due to poor image quality. Over the 5 minutes of force application, the mean CAW increasingly narrowed as time increased (Fig. 4). Significant narrowing from baseline CAW was observed after 1, 2, 3, 4, and 5 minutes of force application ($p < 0.05$). The amounts of CAW narrowing were 2.56% (SD 1.8%), 3.6% (SD 1.95%), 4.07% (SD 1.91%), 4.26% (SD 2.0%), and 5.15% (SD 2.44%) from baseline, at times of 1, 2, 3, 4, and 5 minutes, respectively. The best-fit of the viscoelastic model to the average CAW data produced a curve with a R^2 value of 0.938 (Fig. 4). The values for the springs and dashpot in the SLS model fit were $K_1 = 0.526 \times 10^6$ N/m, $K_2 = 6.74 \times 10^5$ N/m, $\eta = 70.3 \times 10^6$ Ns/m.
Figure 4. Average CAW narrowing from all subjects over the 5 minutes of compression and the SLS model fit curve (R^2=0.938).

During the 5 minutes of continuous compressive force application across the wrist, the CAW progressively narrowed over time. This suggests that when external forces are used to manipulate the carpal bones, time dependent effects should be taken into account to ensure accurate manipulation of these bony structures. To better characterize this viscoelastic pattern of observed deformation, the data was fit to an SLS viscoelastic model. This model characterized the observed narrowing of the CAW well. Using this model, it was further predicted that the maximum amount of CAW narrowing would be 5.8% as time approached infinity when the wrist is under 15N of compressive force application. Therefore, at 5 minutes of force application the CAW had narrowed by 88.8% of its maximum predicted narrowing at this force level.

CONCLUSIONS

CAW narrowing due to external compressive forces occurs in a viscoelastic fashion over time. Future studies looking into manipulation of the carpal structures from external force application should account for this time dependent deformation.

CARPAL ARCH COMPRESSION DECREASES MEDIAN NERVE FLATTENING IN CARPAL TUNNEL SYNDROME PATIENTS

[1]Tamara L. Marquardt, [2]Peter J. Evans, [2]William H. Seitz, Jr., [1,2,3]Zong-Ming Li

INTRODUCTION

The carpal tunnel in the wrist is formed by the interconnected carpal bones and the transverse carpal ligament (TCL). The tunnel contents include the median nerve, which is susceptible to entrapment in the space-limited tunnel leading to carpal tunnel syndrome (CTS). CTS patients have increased flattening of the median nerve which is alleviated after surgically transecting the TCL to increase carpal tunnel space and decrease tunnel pressure [1]. Recent studies support that the carpal tunnel space can be augmented by narrowing the carpal arch width [2-4]. Furthermore, it has been shown that applying radioulnar compression to the wrist decreases median nerve flattening in asymptomatic controls [4]. However, the implications of wrist compression on the carpal tunnel and median nerve in CTS patients have not been examined. Therefore, the purpose of this study was to investigate the morphological changes of the carpal arch and median nerve in response to wrist compression in CTS patients.

METHODS

Five (n=5) female volunteers diagnosed with CTS (54.6±7.5 years; 4 right, 1 left) participated in this study. Each patient placed the arm in a custom compression system, palm side facing up (Fig. 1). The system applied radioulnar compressive forces of 10 N and 20 N across the distal carpal tunnel level for 3 minutes and then three cross-sectional ultrasound images at this level were acquired. Three unloaded (0 N) ultrasound images were also captured prior to each force application. Each force condition was repeated four times in a randomized order. A 5-minute rest was provided between consecutive trials.

The three unloaded (0 N) and three loaded (10 N or 20 N) ultrasound images from one trial for each load condition were analyzed. *ImageJ* was used to determine the coordinates of the most volar point of the hook of hamate and the ridge of trapezium, as well as the volar boundary of the TCL. Additionally, *ImageJ* was used to trace the median nerve's border and calculate its shape descriptors including perimeter, area, and flattening ratio (major axis/minor axis of fit ellipse). The *ImageJ* coordinates were transformed into an anatomically relevant coordinate system, and carpal arch width (CAW) and carpal arch area (CAA) were calculated. CAW was defined as the distance between the hamate and trapezium. CAA was the area bounded by the volar TCL boundary and the CAW line.
Figure 1: Experimental setup with the compression system and outline of ultrasound probe footprint indicating the location of imaging.

One-way repeated measures ANOVAs were performed to investigate the effect of force magnitude (0, 10, and 20 N) on CAW and CAA, as well as the median nerve's perimeter, area, and flattening ratio. Post-hoc Tukey's tests were used for pairwise comparisons and $p < 0.05$ was considered statistically significant.

RESULTS AND DISCUSSION

Ultrasonography captured changes of the carpal arch and median nerve in response to compressive force applied across the wrist of CTS patients (Fig. 2). CAW and the nerve's flattening ratio were significantly affected by force (p<0.01).
Figure 2: Representative images at 0, 10, and 20 N with the hamate (HH, #), trapezium (TM, +), TCL boundary (dotted line), and nerve (solid line) identified.

Specifically, CAW decreased by 0.9±0.5mm with 10 N of applied force and by 2.0±1.3mm with 20 N of force, relative to the initial CAW of 22.7±2.4mm at 0 N (Fig. 3). Pairwise comparisons revealed a significant difference between CAW at 0 N and 20 N (p<0.01). Although CAW decreased, CAA remained relatively constant (17.6±6.2mm^2 at 0 N) when compressive forces were applied (17.4±6.6mm^2 at 10 N and 18.2±5.6mm^2 at 20 N), and the changes were not statistically significant (p=0.88).
Figure 3: Carpal arch width (CAW) at force magnitudes of 0, 10, and 20 N. *p<0.01

Force did not significantly affect the nerve's perimeter (p=0.07) or area (p=0.68) which were initially 16.3±0.9mm and 11.1±1.3mm^2, respectively. However, the nerve's shape became more round (Fig. 4) as reflected by decreases in its flattening ratio with force application (p<0.01). The flattening ratio of the nerve was 3.90±0.79 at 0 N, and it decreased by 0.54±0.57 at 10 N and by 1.06±0.44 at 20 N. Pairwise comparisons found that the flattening ratio was significantly different between 0 N and 20 N (p<0.01).
Figure 4: Median nerve outlines for individual patients at 0, 10, and 20 N with the dashed line indicating the average fit ellipse.

This study revealed that radioulnar compressive force applied across the wrist affected the morphology of the carpal arch and the median nerve in CTS patients. Previous studies have demonstrated that CAW can be narrowed [2, 3], and that this narrowing can be achieved *in vivo* [4]. The changes in CAW of CTS patients from wrist compression in the current study agree with the findings from a previous study with control subjects [4]. Even though CAA did not increase with force application, flattening of the median nerve decreased. It has been shown that the nerve undergoes shape changes to minimize insult within the tunnel space [5]. Nerve flattening in CTS patients also decreases after carpal tunnel release surgery. Therefore, radioulnar wrist compression may provide relief of nerve compression in patients with CTS.

PREDICTORS OF PATELLOFEMORAL JOINT STRESS: AN EXAMINATION OF PATELLOFEMORAL JOINT MORPHOLOGY

[1] Tzu-Chieh Liao, [2] Shawn Farrokhi and [1] Christopher M. Powers

[1] University of Southern California, Los Angeles, CA, USA

email: powers@usc.edu, web: http://pt.usc.edu/labs/mbrl/

INTRODUCTION

Patellofemoral pain (PFP) is a common condition seen in orthopedic practice, accounting for approximately 25-40% of all knee injuries [1]. A commonly cited hypothesis as to the cause of PFP is elevated patellofemoral joint (PFJ) stress [2] secondary to abnormal PFJ structure. With respect to the morphological factors that influence PFJ stress, previous studies have shown that persons with PFP exhibit altered patella position [3], abnormal femoral morphology [4], and decreased patella cartilage thickness [5] when compared to healthy individuals. However, the influence of the abnormal morphology on PFJ stress is unknown. Using finite element (FE) analysis, the purpose of the current study was to assess the relationship between PFJ morphology and elevated PFJ stress in persons with PFP.

METHODS

Nineteen subjects (10 PFP and 9 pain-free controls) were recruited for this study. Each subject completed 2 phases of data collection: magnetic resonance imaging (MRI) assessment and biomechanical testing. Each subject underwent 4 different scans on a 3.0 T General Electric scanner. These scans were necessary to obtain subject-specific data used for the FE modeling and for the measurement of morphological variables (patella height (Insall-Salvati ratio or ISR), lateral trochlear inclination angle (LTI), and patella cartilage thickness). For the biomechanical testing, kinematic, kinetic, and electromyographic were obtained during a static squatting task (45° of knee flexion).

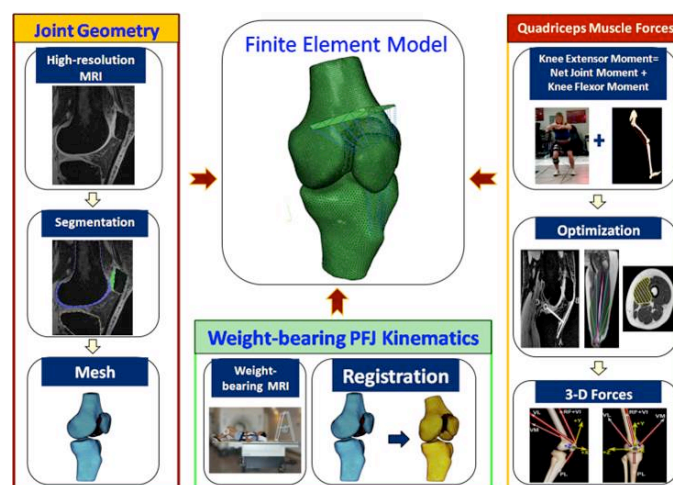
Patella cartilage stress profiles were quantified utilizing a subject-specific FE model of the PFJ (Fig. 1). Input parameters for the FE model included: (1) joint geometry, (2) quadriceps muscle forces, and (3) weight-bearing PFJ kinematics [2]. Using a nonlinear FE solver, quasi-static loading simulations were performed to quantify patella cartilage stress during the squatting maneuver (45° knee flexion).


Figure 1: Finite element modeling pipeline.

Pearson correlation coefficients were used to examine the associations between peak hydrostatic pressure between ISR, LTI angle, and patella cartilage thickness. Variables that were significantly correlated with PFJ stress were put into a stepwise regression model to determine the best predictor of elevated PFJ stress.

RESULTS AND DISCUSSION

Pearson correlation coefficients revealed that only patella height (r=0.48, p=0.018) and patella cartilage thickness (r=-0.58, p=0.005) were significantly correlated with peak hydrostatic

pressure (Table 1). Results of the stepwise regression analysis revealed that patella cartilage thickness was the single best predictor of peak hydrostatic pressure, followed by patella height. Together, these 2 variables explained 50% of the variance in peak PFJ stress.

Table 1: Relationship between peak hydrostatic pressure and morphological variables of interest.

	Correlation Coefficient
Patella height (ISR)	0.48*
Lateral trochlear inclination	-0.29
Patella cartilage thickness	-0.58*

*$p < 0.05$.

The results of the current study support the premise that PFJ stress is associated with PFJ morphology. Patella height was the best predictor of PFJ stress with greater degrees of patella height being correlated with greater stress. This is logical given that a higher positioned patella articulates with the more shallow portion of the trochlear groove, thus decreasing PFJ contact area [6]. The finding that patella cartilage thickness was negatively correlated with PFJ stress is in agreement with the results of Li et al. [7], who demonstrated that a reduction of cartilage thickness causes increase cartilage stress. Furthermore, our findings revealed that 50% of the variance in PFJ stress could be explained by morphological factors.

CONCLUSIONS

Identifying the underlying factors that contribute to elevated PFJ stress is an important step in developing effective interventions for persons with PFP. Although abnormal morphological may not be correctable through conservative measures, it is important to recognize the role abnormal structure may play in contributing to pain and pathology.

INTRODUCTION

Due to the inherent lack of stability provided by the bony, ligamentous, and capsular structures, dynamic control of the muscles plays an important role in stabilizing the shoulder during dynamics motions. The rotator cuff muscles, including the supraspinatus, infraspinatus, teres minor, and subscapularis, serve as the chief stabilizers of the shoulder. The rotator cuff muscles produce compressive forces to center the humeral head in the glenoid fossa, as well as generate inferior and posterior shear forces to counterbalance the superiorly directed deltoid force [1].

Scapular muscles, including the trapezius and serratus anterior, rotate the scapula to coordinate with humerus during arm elevation [2]. The rotator cuff and scapular muscles are essential to producing smooth shoulder movement. While many studies have investigated which exercises result in higher elelctromyography (EMG) activity during exercises, few studies have focused on if the changes in muscle activation happen after exercise training. The purpose of this study is to assess the effect of exercise training on shoulder kinematics and EMG during arm elevation.

METHODS

Twelve healthy subjects were recruited (4 males and 7 females, 18 – 26 years old). They received exercise training three times per week for four weeks, with an average duration of 30 minutes per session. All training sections were supervised to ensure compliance with the training protocol. The exercise protocol consisted of six exercises, including full can, prone full can, external rotation in sidelying, diagonal exercise, push up with plus, and push up on exercise ball. The training consisted of three sets of 10 repetitions using variable resistance: one set at 50% of the 10-repetition maximum (RM), one at 75% of the 10 RM, and one at 100% of the 10 RM [3].

A magnetic tracking device (Polhemus Liberty, Colchester, VT) was used to measure scapular, humeral and thoracic kinematics. The Myopac Jr (Run Technologies, Mission Viejo, CA) was used to collect raw surface EMG data. Paired fine wire electrodes were inserted into supraspinatus and infraspinatus muscles. Surface electrodes were used for the middle deltoid, upper trapezius, lower trapezius and serratus anterior. The subjects were instructed to conduct three arm elevation trials in the scapular plane with their dominant arm (Figure 1). The EMG during the arm elevation was synchronized with the kinematic measures and normalized by a MVC during a five second contraction.

Figure 1. The experimental setting

The scapular kinematics and root mean square EMG data were calculated over four 30° increments of motion during arm elevation from 0° to 120°. A two-way repeated measures ANOVA was used to examine the changes after the training.

RESULTS AND DISCUSSION

Figure 2 and figure 3 show the scapular kinematics and shoulder muscle activation during arm elevation. After training, scapular upward rotation tended to increase at higher humeral elevation angles (interaction effect, $p = 0.06$). The upper trapezius EMG tended to decrease throughout the rang of elevation (main effect, $p = 0.07$). No significant difference was found in other parameters.

This study is still ongoing. The preliminary results show the exercises focusing on training rotator cuff and scapular muscles may increase scapular upward rotation and decrease upper trapezius muscle activity during arm elevation.

THE EFFECTS OF ENTHESEAL SHAPE ON STRAIN FIELDS IN A PLANAR MODEL OF THE ANTERIOR CRUCIATE LIGAMENT

Callan M Luetkemeyer, Ellen M Arruda, James A Ashton-Miller

The University of Michigan, Ann Arbor, MI, USA
email: cmluetke@umich.edu

INTRODUCTION

The posterolateral (PL) bundle of the anterior cruciate ligament (ACL) is susceptible to failure at its femoral enthesis [1,2], where it resembles a ribbon [3]. Dissimilar tidemark profiles of the femoral enthesis were recently described and categorized in a histological study (Figure 1) [2].
Figure 1: Human ACL femoral enthesis profiles and their respective frequency in 60 sample sections. Reproduced from Figure 5.3 in [1].

A knowledge gap is whether these entheseal profiles affect ligament mechanics. We therefore developed a model to examine the differences in strain fields among these characteristic tidemark profiles in order to determine whether certain profiles may be more advantageous than others.

METHODS

The ACL femoral enthesis was modeled as a 2D trapezoidal body of width *w* rigidly attached to a fixed curve, *y=A(x)*. This curve characterized the entheseal shape, and had an overall slope of *a/w*, such that the insertion angle of the enthesis (ϕ) was 30 degrees [1]. The opposite edge of the body (*y=L*) represented the ligament proper, and it underwent a uniform displacement δ.
Figure 2: Diagram depicting the relationship among variables used in the model. The open arrow indicates the displacement of the boundary *y=L*.

Assuming homogeneity and no Poisson's effect, the displacement field is characterized by Equation 1.

$$u_y(x,y) = \frac{\delta}{L - A(x)}(y - A(x)) \qquad (1)$$

Entheses A-F (Figure 1) were modeled using Equations 2-4.

$$A_{A,B}(x) = \frac{a}{w}x \pm [x^2 - wx] \qquad (2)$$

$$A_{C,D}(x) = \frac{a}{w}x \pm [4x^4 - 8wx^3 + 5w^2x^2 - w^3x] \qquad (3)$$

$$A_{E,F}(x) = \frac{a}{w}x \pm [2x^3 - 3wx^2 + w^2x] \qquad (4)$$

The Lagrangian strain fields and Von Mises strain field were computed for each displacement field.

RESULTS AND DISCUSSION

Contour plots for the Von Mises strain fields are shown in Figure 3 with red indicating the highest strain region and blue, the lowest. The yellow line indicates the fixed enthesis boundary. The area

below this line is not part of the ligament and is not of interest.
Figure 3: The Von Mises strain fields for entheseal profiles A-F as defined in Figure 1.

While a parabolic convex (A) enthesis increased the longitudinal strain throughout most of the ligament, it simultaneously reduced the maximum Von Mises strain by 32.3% compared to the parabolic concave (B) enthesis. This is due to a shift in the shape of the shear field; the point of maximum shear strain switches from the obtuse angled corner (most inferior attachment point in the ACL) to the acute angled corner (most superior attachment point). Clearly, shear effects play an important part in the concentration of strain within the femoral enthesis.

The most important feature of entheseal shape in determining the maximum Von Mises strain was the convexity near the most inferior attachment point of the ACL. If this part of the curve was convex (as in A, C, and E), the Von Mises strain was reduced.

Maximum Von Mises strain also increased with increasing polynomial order.

A parabolic convex tidemark seems to be the most advantageous shape for an angled ligament enthesis. It likely experiences less shear stress and Von Mises stress than other entheseal shapes. The present results lend insight into why ACL failures often occur at the femoral enthesis [2,3] and suggest the site of failure initiation might lie at the inferior corner. These results are also useful for establishing one of the variables in an ideal ACL enthesis. A future experimental study might examine whether the femoral entheseal shape can be remodeled in response to particular exercises, thereby reducing ACL injury risk. Likewise, tissue engineers might consider optimal entheseal shape when designing artificial ligaments with angled attachments.

This study is limited by the assumptions of homogeneity and zero Poisson's ratio. A finite element study incorporating realistic ACL geometry and a nonlinear, viscoelastic, anisotropic constitutive model or a well-designed experimental study with high imaging resolution would yield more realistic results. Still, there is valuable insight contained in this simple 2D analytical model.

While shear strain clearly plays a critical role in ligament mechanics, most studies have focused on the tensile properties of ligaments. More research is needed to characterize their shear properties and to determine the role of shear in ligament failure.

CONCLUSIONS

The profile of the ACL femoral enthesis affects its strain field and thereby the strain concentration at its most inferior point of attachment. A parabolic convex shape reduces the shear strain at this point and thus reduces the maximum Von Mises strain.

A COMPREHENSIVE META-ANALYSIS OF SKELETAL MUSCLE ARCHITECTURE IN HUMANS

[1]Lydia A. Luu*, [1]Sibo Zhang*, [1]Catherine M. Pelland, [1]BME 4280, [1]MAE 4280, [1]Silvia S. Blemker

INTRODUCTION

Skeletal muscles are the motors for all voluntary movements in the body, from walking to speech to breathing. The last few decades of biomechanics research have led to breakthroughs in our understanding of structure and function of individual muscles in the upper and lower limb. However, a holistic understanding of the diversity of muscle structure and function of all skeletal muscles of the human body remains lacking. Studies of muscle architecture have been performed for various groups of muscles such as the upper extremity [1] or lower extremity [2], but there is no comprehensive single source of muscle architecture data for all skeletal muscles in the human body.

This study aimed to perform comprehensive meta-analysis of the architectural properties of the nearly 300 skeletal muscles in the human body in order to (i) explore relationships between muscle form and function across all skeletal muscles across the body, (ii) examine subject demographics (age, gender, etc.) and the experimental means of collecting data across muscle architecture studies, and (iii) identify key gaps in our understanding of muscle architecture that provide future avenues of research.

METHODS

As part of an upper-level undergraduate Movement Biomechanics course, students were instructed to search PubMed and Web of Science for published values (in existing literature) of four skeletal muscle architecture parameters: physiological cross-sectional area (PCSA), optimal fiber length (L_0^M), volume (V), and pennation angle (α). Each muscle was researched by at least two undergraduates independently and their data compiled into a shared document for analysis. The data submitted by the class was examined to verify the values and sources. Data acquired from non-peer reviewed articles, estimations made by students, and modeling studies were omitted. Further research was conducted to fill in missing muscle architecture parameters with data from cadaver or *in vivo* studies. When volume, PCSA, or optimal fiber length was missing in data acquired from the same source, the other two were used to calculate the missing value.

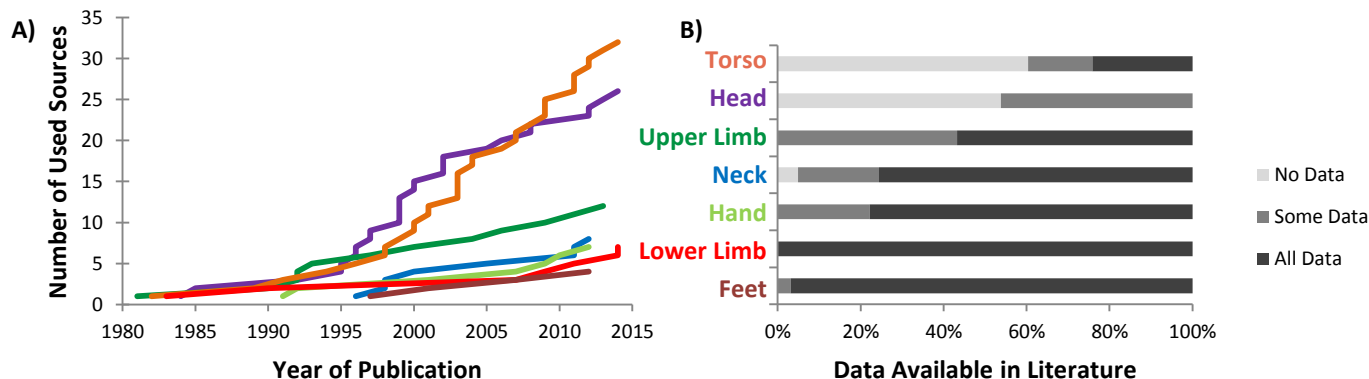
For the purpose of muscle architecture analysis, all non-optimal data points (fiber length, muscle length, anatomical cross-sectional area, etc.) were eliminated from the data set. Average PCSA, optimal fiber length, and pennation angle were calculated for each muscle (with available data);


Figure 1 - *Muscle Architecture Literature Meta-analysis*: **A)** depicts a timeline of the cumulative number of muscle architecture studies for each muscle region. **B)** represents the percentage of muscles in each region of the body for which we have found all, some, or none of the four architecture parameters (PCSA, L_o^M, V, and α).

each data point was weighted based on the number of subjects in its respective study. Average volume for each muscle was calculated by multiplying the average PCSA and average optimal fiber length. For comparison between cadaver and *in vivo* studies, only muscles with both cadaver and *in vivo* volume data were included. Lastly, each study was evaluated based on the amount of information provided on subject age, weight, height, and gender.

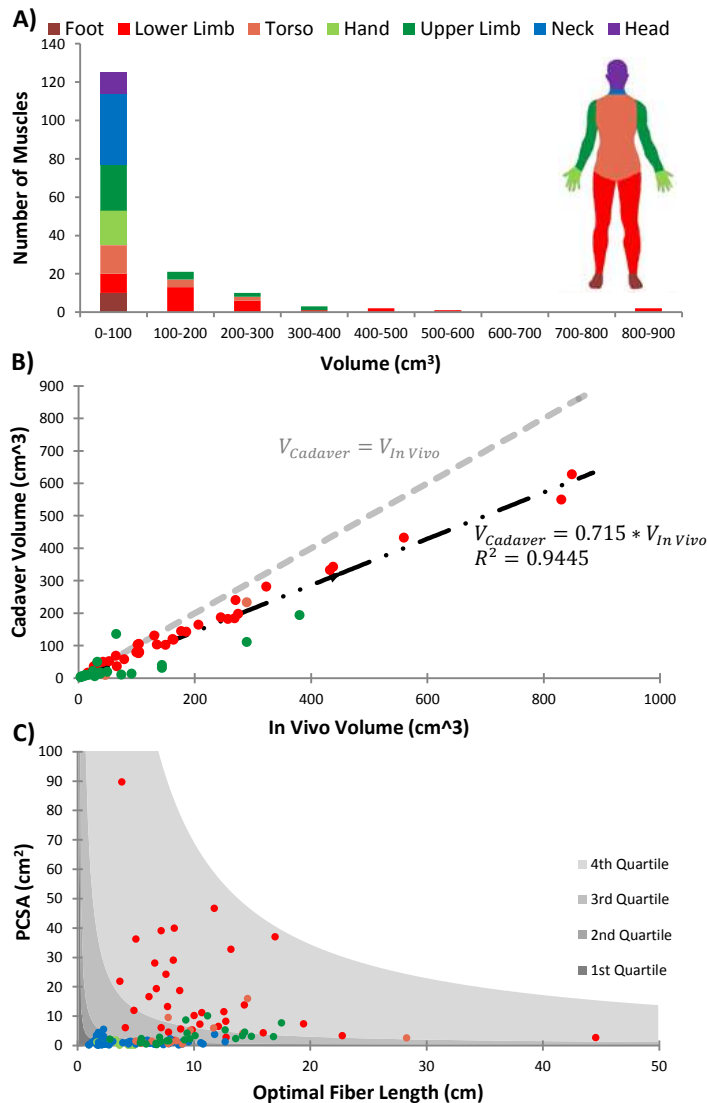
RESULTS AND DISCUSSION


Figure 2 - *Muscle Architecture analysis*: **A)** a histogram of average cadaver volumes throughout the human body. **B)** is scatterplot of muscles with recorded cadaver and *in vivo* muscle volumes. The fitted trend line shows loss of volume in cadaveric samples when compared to the unity line. **C)** presents the average PCSA and L_o^M of all muscles for which architectural data was found. Shading represents volume quartiles.

A timeline of the cumulative number of muscle architecture sources for each muscle region reveals several key observations concerning muscle architecture research (Fig. 1A). First, finding head and torso architecture data required searching through a significantly larger number of sources, partly due to the fact that there are more muscles in those regions. However, fewer sources that cover a large number of muscles in those regions exist, compared to the upper and lower extremities. While the studies used to compile the data for this analysis do not necessarily represent all muscle architecture studies, our timeline implies that the emergence of architecture studies has been linear over time for muscles of all body regions. Studies of limb and torso muscles were found at earlier time points as compared to the other regions. The four desired muscle architecture parameters were not found for every single muscle (Fig. 1B). All of the muscles in the upper limb, lower limb, hand, and feet have been measured to some extent with the lower limb being the most thoroughly studied muscle region. Conversely, the head and torso have a large number of muscles for which we no architecture data could be found. Future work should more rigorously characterize muscle architecture in these regions.

Muscles throughout the body range in volume (Fig. 2A). Of the muscles for which data was found the smallest is the interspinalis cervicis in the neck (0.16 cm^3) and the largest is the gluteus maximus in the lower limbs (849 cm^3). Reported muscle volumes in the head, neck, hand, and foot are less than 100 cm^3, whereas muscles in the torso and upper limbs can be larger (up to 290 and 380 cm^3, respectively). Muscles of the lower limb encompass the greatest range of volumes (from 16 to 849 cm^3). Volumes collected from cadavers are 71% of *in vivo* MRI volume measurements (Fig. 2B). We observed an inverse relationship between PCSA and L_0^M, and the maximum volume of every muscle falls under a hyperbolic curve (Fig. 2B). The trade-off between PCSA and length was observed for both large muscles (primarily in the lower limb) as well as smaller muscles (e.g. the foot and hand) .

KINETICS AND KINEMATICS OF THE ANKLE DURING FOOT EXTERNAL ROTATION

[1] Alexander Mait, John Paul Donlon, Adwait Mane, Jason Forman and Richard Kent

[1] The University of Virginia, Charlottesville, VA, USA
email: arm7sb@virginia.edu, web: www.centerforappliedbiomechanics.org

INTRODUCTION

High ankle sprains are a debilitating injury in athletics. They typically involve excessive external rotation of the foot causing diastasis between the fibula and tibia, thus injuring the syndesmotic ligaments [1, 2]. Other motions of the ankle such as dorsiflexion and eversion have also been shown to contribute to the injury [1, 3]. The goal of this study was to collect kinematic and kinetic data of specific ankle bones during external rotation of the foot to better understand high ankle sprains and to refine an existing finite element (FE) model of the ankle.

METHODS

A custom rig was designed to test lower limbs from human cadavers. Preliminary tests were performed with a left lower limb of a male 46 year old cadaver with a statue of 177 cm and mass of 113 kg. The test device was designed to rotate the leg about the long axis of the tibia to ±20° of foot rotation. The proximal portion of the tibia was potted in a cylindrical cup which was rigidly attached to an index table that could be rotated internally or externally. In order to not constrain the axes of rotation, the foot was allowed to translate in the x, y, and z directions via a system of rail bearings attached to the calcaneus (Fig. 1). A lockable gimbal device was attached between the calcaneus mount and rail system to provide an ability to pre-set the foot in eversion (10°) and/or dorsiflexion (20°) prior to applying foot rotation.

In order to capture the kinetics of the lower limb, a load cell was rigidly attached to the potted tibia. A quasi-linear viscoelastic (QLV) model [4] was then developed for each test to describe the relationship between the applied rotation and the moment recorded about the long axis of the tibia. From the QLV models, the instantaneous elastic moment (Mz_0) and steady-state moment (Mz_∞) were calculated for external rotation of the foot initially in neutral, eversion, and dorsiflexion.
Figure 1: Schematic of experimental test rig.

To capture the kinematics of the bones of the ankle, an aluminum cube was screwed into the fibula and talus using wood screws set a certain distance off the bone with a spacer. For each test these cubes were scanned at the initial position (neutral) and final position (rotated) using a 7-axis, three-dimensional laser scanner (ROMER Absolute Arm, Hexagon Metrology, Inc., Surrey, Great Britain). Based on computed tomography (CT) scans and coordinate transformations [5], the yaw, pitch, and roll angles as well as x, y, and z displacements of each bone were calculated.

RESULTS AND DISCUSSION

When the foot was initially placed in neutral, the instantaneous moment Mz_0 observed under 20° external rotation was 9.87 N-m. This dropped slightly to 8.97 N-m when the foot was initially everted by 10°. When the foot was initially placed into dorsiflexion, the Mz_0 observed under 20° external rotation was 7.03 N-m. For all three foot initial position conditions, Mz_∞ was approximately

3.0 N-m (Fig. 2). The drop in Mz_0 from neutral foot to everted foot is consistent with [3], where approximately 37 N-m was measured at 20° external rotation for neutral foot and 19 N-m for everted foot; however the magnitudes vary significantly from the current study. The Mz_0 for the neutral foot in Fig. 2 is more consistent with [6], where about 15 N-m was measured for the "strongest" specimen at 20° external rotation.
Figure 2: Instantaneous elastic and steady-state moment about tibia axis based on QLV models of each test [4].

The changes in yaw, pitch, and roll angles as well as x, y, and z displacements of the fibula and talus relative to the tibia global coordinate system are listed in Table 1. Talus lateral translation relative to the tibia was found to be 2.88 ± 1.13 mm in [3] at 30° of external foot rotation when the foot is everted 20°, yet the current study found only 0.83 mm of y (lateral) translation. Fibula rotations about all axes (relative to the tibia) were found to be less than 0.6° on average for a neutral foot under 10° of external foot rotation in [7]. The current study, with applying 20° of external foot rotation, found two angles of rotation greater than 1° for the fibula, namely the change in yaw angle at -4.705°.

The differences in the kinetics and kinematics from the current study to previous studies can most likely be attributed to the difference in boundary conditions for the experiments. Previous studies have typically disarticulated the tibia and fibula at mid-shaft and did not allow the foot to translate when foot rotation was applied [3, 6, 7].

The current study focused on using quasi-static rotation loading of the lower limb. In future studies, a more dynamic loading should be considered to capture the nonlinear kinematics of the ankle bones. Also, the current study focused on one specimen. More specimens should be tested in order to gather a better confidence in the results. To expand the scope of the study, more initial foot motions should be explored, higher degrees of external rotation should be used, and capturing data on other ankle bones should be completed.

CONCLUSIONS

This study demonstrates that capturing detailed kinematics of the bones of the ankle during a combination of foot motions is possible. Using these methods, data may be gathered to refine a computational model of the ankle to accurately reproduce bone kinematics and boundary forces. Such a model may then be used to study effective strains in ankle ligaments that are not accessible to observe experimentally.

BIAXIAL QUANTIFICATION OF TRANSVERSE CARPAL LIGAMENT ELASTIC PROPERTIES BY SEX AND REGION

[1]Bryan Mathers, [2]Anne Agur, [1]Michele Oliver, [1]Karen Gordon

[1]School of Engineering, University of Guelph, Guelph, ON, CA
[2]Division of Anatomy, Department of Surgery, University of Toronto, Toronto, ON, CA
E-mail: bmathers@uoguelph.ca

INTRODUCTION

Carpal tunnel syndrome (CTS) is a widespread peripheral neuropathy which occurs more frequently in women than in men [1]. While a great deal of research has been conducted, CTS etiology is not clearly understood. The transverse carpal ligament (TCL) makes up the volar border of the carpal tunnel. The TCL acts as a pulley for the flexor tendons running through the carpal tunnel, anchors the thenar and hypothenar muscles and is thought to play a role in the stability of the carpus. As a result of these important roles, the material properties of the TCL are of great interest. Recent studies of the TCL have shown its properties vary with location and depth due to the complex orientation of collagen fibers [2-5]. Brett et al., found that the TCL strains significantly more radially than ulnarly when under uniaxial load [2]. In addition, the study reported a trend that female specimens experienced more strain on the radial side of the TCL compared to male specimens [2]. Given the increased incidence of CTS in women, further work evaluating this trend, specifically a comparison of regional sex based differences in properties, is warranted.

Material properties derived from biaxial loading more closely reflect the in-vivo behavior of tissue. Based on the uneven loading of layers and difficulties in clamping thicker tissues, Sacks et al. [6] recommended that biaxial sample thickness should not exceed 3 mm with 1 mm being the optimal thickness to obtain valid results. As TCL thickness can approach 3 mm, biaxial testing of this ligament can become problematic. Histological and mechanical studies of the TCL have found that load bearing fibers in deep layers of the TCL become more organized, providing greater mechanical strength in comparison to superficial layers [4,5]. Testing only deep layers of the TCL would ensure

that sample thickness approaches the recommended 1 mm and that the TCL fibers contributing to mechanical strength are evaluated.

The purpose of this study was to quantify deep TCL layer biaxial moduli to evaluate differences in between males and females, and radial and ulnar locations. The results of this work could impact our understanding of the etiology of carpal tunnel syndrome, and may improve treatment options, specifically related to non-surgical manipulative therapy.

METHODS

22 (13 Male (71±14.3 years) and 9 Female (81±2.8 years)) cadaveric wrists, were used in this experiment. Human ethics approval to conduct the study was obtained from the University of Toronto as well as the University of Guelph. Visual assessment of the tissue showed no discernible pathologies. Each wrist was dissected to expose the TCL. Two, 7 x 7 mm squares of the TCL were obtained from each specimen, centered through the proximal distal thickness and on either side of the medial lateral midline of the ligament. A layer of superficial tissue was removed from each sample. The final thickness was measured using a custom micrometer. Biaxial testing was performed using a CellScale BioTester (Waterloo, ON). Samples were mounted using four 5 mm rakes such that the predominant medial lateral fibers were aligned with the X axis. Samples were preconditioned over 10 cycles to 9% strain at 1%/s before undergoing biaxial strain to 12% at 1%/s. Axial forces and displacements were collected at a rate to 15 Hz. Cross sectional area was calculated based on tissue thickness and distance between rakes. Cross sectional area, force and rake displacement were used to determine stress-strain relationships for each

axis. The linear region of this plot was identified, and its slope was calculated to generate the elastic modulus. Statistical analyses were conducted using the GLM procedure in Minitab 17.1.0 (Minitab, State College, PA, USA) where specimen was included in the model as a random effect. Moduli were assessed by region (radial or ulnar), testing direction (medial-lateral or proximal-distal) and sex (male or female). When appropriate, differences were assessed using Tukey post-hoc analyses. In all analyses, $p \leq 0.05$ was required to declare a significant difference between means.

RESULTS AND DISCUSSION

The mean thickness of the tested samples was 1.14 ± 0.18 mm. Elastic moduli in the medial-lateral direction were significantly larger than the proximal-distal direction for both radial and ulnar samples ($p=0.013$). Medial-lateral and proximal-distal elastic moduli of the ulnar samples were significantly larger than those of the radial samples ($p=0.001$). No significant differences were found in elastic moduli between male and female specimens for any combination of region and/or direction (Figure 1). This lack of significance suggests that the increased incidence rate of CTS in females may not be a result sex based differences in mechanical properties of the TCL. Significantly lower medial-lateral transverse elastic moduli for radial samples compared to ulnar samples support the findings of Brett et al. [2]. These results may be useful in improving manipulative therapy techniques used to treat CTS. The TCL may stretch more radially than ulnarly so manipulative therapy may benefit from focusing stretching on the radial side of the TCL.

This study is not without limitations, with an average specimen age of 81 in women and 71 in men, results may differ from results obtained from younger specimens. Sectioning the TCL does disrupt the fibers and may affect results, however, this effect would be consistent across all samples.. Finally, while every effort was taken to keep the tissue moist during sectioning and testing, dehydration of the sample over the course of testing may have impacted results.

AXIAL ROTATION CAUSES BILATERAL DIFFERENCES IN THE SIZE RATIO OF INTERVERTEBRAL FORAMEN TO NERVE ROOT

Graham Mayberry and Janessa Drake

York University, Toronto, ON, CANADA
email: mayberr1@yorku.ca, jdrake@yorku.ca

INTRODUCTION

Axial rotation in the lumbar spine can lead to potential injury and pain development. Therefore, our understanding of transverse spinal rotation is critical to research in functional anatomy disciplines. Previous research has been conducted to measure nerve compression *in vitro*[1] while the foramina heights and widths have been measured *in vivo* [2]. The relationship between the size of the intervertebral foramen (IVF) and the spinal nerve root (NR) that exits through it has not been quanitified, though it may play a significant role in how or whether individuals experience low back pain (LBP) [3]. Additionally, it is known that facet joints of the left and right side of the same functional spine unit (FSU) experience different degrees of motion during axial rotation [4]. The purpose of this study was to compare the left and right sides of the spine by quantifying the size ratio between the intervertebral foramen and associated nerve root in supine and axially rotated postures.

METHODS

Two healthy males (24.0 +/- 2.0 yrs) were recruited for this study with no history of LBP over the previous 12 months and successfully pass the MRI screening process. A Siemens MAGNETOM 3T Trio MRI scanner was used to acquire 3D MRI scans, using a T2SPC imaging protocol, with a slice thickenss of 0.781mm.

During the imaging session, the participants were asked to lie in a supine position with their shoulders strapped down while 3D MRI scans were acquired. The participants then moved to their maximal axially-rotated position (with their knees pointing to the left). Wedges were placed at the hips and between the knees, and straps were fastened around the shoulders, knees and hips to ensure they were comfortable and would not move during imaging. The lumbar spine was imaged, focusing on the levels of L4-L5, providing a complete FSU.

The images were analyzed using OsiriX (© Pixmeo Sarl, V 5.0.1) to measure cross-sectional area (CSA) of the NR and IVF from a series of subsampled slices that represent the best view of both features. The CSA for both the NR and IVF of the left and right sides were calculated by averaging the seven smallest CSAs from the entire series of slices along an axis that was manipulated to run directly through the center of the IVF perpendicular to the saggital plane. The NR:IVF ratio was then calculated and compared for both the left and right sides.

RESULTS AND DISCUSSION

The CSA of the right and left IVF and NR, in addition to the NR:IVF ratio, were quantified for the L4-L5 FSU in both the supine and axially-rotated positions for both subjects (see Table 1). These preliminary results do not suggest any predictability or trend when looking at the IVF and NR independently, though a greater sample size would help verify that claim. However, focus on the NR:IVF ratio reveals that the behavior of the left and right sides are in the same direction though with very different magnitudes. A graphical representation of the NR:IVF ratio allows a much easier comparison (see Figure 1). In both subjects, the NR:IVF decreases on the right side but increases on the left side when going from supine to right axial rotation.

The greater the NR:IVF ratio seen would suggest a greater probability of nerve root compression or impingement which may result in behavioural changes.   One study investigated this relationship

in rats and found that the amount of mechanical compression in the nerve root was proportional to amount of behavioural change exhibited in rats [5]. The relatively low NR:IVF ratios acquired in this study would likely lead to the development of low back pain and associated periphery pain, however it has been found that this NR impingement occurs in 50% of patients with LBP [6].
Figure 1: NR:IVF ratio of the left and right side of L4-L5 in the supine and axially rotated positions of two pilot subjects.

The two subjects exhibited different trends of the NR and IVF if analyzed independently, which we attributed to morphological variation and possibly different strategies while rotating, despite being given the same instructions. For instance, if one shifts the hips dorsally or ventrally in an effort to remain comfortable (ie. Following the instruction to maximally rotate while being comfortable) then the left and right IVFs may open or close to accommodate the movement. For this reason, the choice to measure the relationship between the NR and IVF is more functionally appropriate.

CONCLUSIONS

The quantification and comparison of the NR and IVF between sides and positions will aid in our understanding of the left to right behaviour during axial rotation and supplement the *in vitro* work that has been completed to date in that regard. Our results suggest that there is a tradeoff between the left and right sides in terms of NR:IVF ratio and that they do seem to behave conversely to one another.

Due to the fact that this study provides novel data in an area in which our understanding of LBP still lacks a definitive mechanism, this research is extremely valuable. With more subjects currently being scanned, we can provide a database for which asymptomatic baseline measurements can be compared. Future research should examine females, various age groups, and perhaps even patients suffering from LBP to fully understand the left to right behaviour of the NR:IVF relationship during axial rotation in the lumbar spine.

INTRODUCTION

The design of radial head prostheses for cases of comminuted radial head fractures enables a surgeon to restore the native length to the radius and approximate the appropriate kinematic relationships for supination and flexion. Unfortunately, not all patients can tolerate these prostheses and revision surgeries may be required. The current designs of prostheses consider head diameter and length and offer few choices with respect to the foveal radius of curvature. The possible problems of a capitellar-radial head mismatch have been recently considered with respect to the increased pressures on capitellar cartilage.(Kim, 2014) The possible problems related to shear loads on the capitellum have not received the same attention. The current work sought to demonstrate *in vivo* axial and shear loading by quantifying the amount of radial head translation due to a maximal biceps contraction during a supination resistance loading, working from the null hypothesis that at 90 degrees of shoulder abduction and 90 degrees of elbow flexion there would be no difference between the head positions during a maximal supination effort and during a relaxed pose.

METHODS

Instituitional Review Board approval was received to obtain six radiographs of the elbow of the dominant arm in 14 men(age 34.8±10) and 14 women(age 39.5±12). Each subject sat in a chair with the shoulder abducted to 90 degrees, the elbow flexed to 90 degrees and with her/his elbow on the surface of an x-ray table.(Expert 4000, Swissray, Piscataway, NJ) Each subject first relaxed the arm musculature with the forearm in neutral rotation while a technician imaged the elbow. The subject then gripped a fixed handle connected to a torsional loadcell and performed a maximal supination effort while the loadcell recorded the torque and the technician again imaged the elbow. Two additional trials with accompaning radiographs of the unloaded and loaded elbow were performed.

Each digital radiograph was then processed to find the relative locations of the center of the capitellum and the radial head. Rouleau et al. (2012) used the center of the face of the radial head to locate the radius but the current work judged the centroid of the head to be less sensitive to error. Radiographs were imported into MatLab(MathWorks, Natick, MA). Three trained medical personnel then outlined the capitellum and radial head in each image and identified the center of the radial canal at the canal narrowing of the bicipital tuberosity. A custom MatLab program then established an orthogonal coordinate system by connecting the radial head centroid and the center of the radial canal and finding the perpendicular to this first line segment.

A line segment was formed by connecting the centroids of the radial head and capitellum and this line segment located the capitellum with respect to the radial head. Upon finding the capitellar radial head locations for the unloaded and loaded cases, the averages of each and the differences between them were computed. The difference in the locations between the loaded and unloaded cases represented the displacement of the radial head, with the movement along the radial head axis representing proximal/distal translation and the movement along the perpendicular to the radial axis representing vertical movement, described as superior/inferior translation. The differences of locations of the unloaded and loaded positions and, second, the differences of the displacements for men and for women, were compared with paired t-tests in Minitab(Minitab Inc., State College, PA).

RESULTS AND DISCUSSION

The vertical locations of the radial head with respect to the capitellum in the loaded condition were statistically different than the unloaded locations in both men and women (men, $p<0.026$; women, $p<0.001$) while the horizontal positions were not statistically different in men ($p>0.200$) but were in women ($p<0.010$). Women had greater vertical movement ($p=0.040$) but there was no difference in axial movement (proximal-distal) towards the humerus ($p=0.390$). (s. Figure) A comparison of the findings of three raters with an ANOVA found no differences due to the rater ($p = 0.409$).

Radial Head Translation
The radius moved with respect to the humerus, which one would expect when the directions of the muscle forces acting during maximal supination effort are considered. At 90 degrees of elbow flexion, the biceps pulls the radius upward, while the forearm musculature pulls the radius toward the capitellum. Compression of the cartilage of the capitellar-radial head interface provides one possible measureable movement, but the cartilage on the radial head and captellum combined is two millimeters thick. Thus in the average, the axial movement of the radius towards the humerus of less than 0.5 mm could be cartilage compression if the load were very large, but the vertical movement of the radius towards the shoulder is more than could occur due to this compression.

The resistance to translation toward the shoulder could be provided by forces from several sources. Foremost, ligaments of the forearm are likely to contribute, with the annular ligament especially well placed for this purpose. The annular ligament constrains the radius laterally and the fibers should also resist the vertical biceps load under consideration. The load sustained by the annular ligament under these circumstances is not yet carefully quantified, but the fibers at the medial insertion of the annular ligament are not oriented directly toward shoulder. Nonetheless, fibers could certainly resist the load, although not efficiently. The interosseous membrane could also resist the translation in question. Its fibers are most effectively oriented to resist axial movement of the radius, but their obliquity and the central band could play a role in constraint of vertical translation. Muscle activity could also play a direct role, particularly the supinator, which can not only work with the biceps to effect supination: a component of its force on the radius would act in a distal direction. The other muscles act primarily along the longitudinal axis of the forearm. Lastly, the radial head could resist upward movement by contact between the posterior side of the fovea and the capitellum. Given that the radius moved upward, the capitellum certainly adds to the vertical translation constraint on the radius. Force due to this contact would add to the pressure between the radial head and capitellum and create additional design considerations for radial head prostheses. The shear loading could have a particular importance to the ability of the capitellar cartilage to survive radial head replacement. The difference between men and women could be due to larger axial muscle forces which lead to greater capitellar/radial head contact and therefore greater shear loads but no certain evidence currently exists.

CONCLUSIONS

The results show that the radial head does translate towards the shoulder during supination so that both compressive and shear forces are applied to the capitellum, adding to the demands on any radial head replacement.

INTRODUCTION

Individuals with knee osteoarthritis (OA) commonly exhibit abnormal mechanics during gait, including altered knee joint angles and moments, which may contribute to the initiation and progression of the disease [1]. Quadriceps weakness is common in individuals with knee OA and has been suggested to contribute to abnormal knee joint mechanics. However, 1) prior studies have found no significant associations between quadriceps strength and knee joint mechanics and 2) quadriceps strengthening has not been shown to influence knee joint mechanics in these individuals [2,3]. Conversely, quadriceps muscle power (force x contraction velocity) has been found to be significantly associated with the peak external knee adduction moment (KAM), a measure of frontal plane knee loading, in patients with knee OA [4]. The association between quadriceps power and sagittal plane knee joint mechanics such as peak knee flexion angle (KFA) and external knee flexion moment (KFM) have not been explored in this population.

The purpose of this study was to examine the contributions of quadriceps strength and power to knee mechanics (peak KFA, KFM, and KAM) during gait in individuals with knee OA.

METHODS

Thirty-three adults (age > 40 years) with physician-diagnosed knee OA and moderate impairment in physical function participated in this study (23 females, 10 males, 59.79±9.02 years; 100.08±24.98kg; 1.70±0.95m; WOMAC function subcale: 29.32±8.06 out of a possible 44 with higher scores indicating greater dysfunction).

Quadriceps strength was quantified as the one repetition maximum (1RM) assessed on a pneumatic knee extension machine with the involved limb positioned at 90° of hip and knee flexion. The resistance from the last full repetition of knee extension was recorded as the 1RM (kg) and normalized to body mass. Quadriceps power was assessed at 40%, 50%, 60%, 70%, 80%, and 90% of 1RM in a random order. The participants were instructed to extend their knee as hard and fast as possible, pause at end range, and return to the starting position over two seconds. Three trials at each resistance were performed and the peak power (W) produced at 40% 1RM (low intensity), 70% 1RM (moderate intensity), 90% 1RM (high intensity), and overall regardless of external load was recorded (W) and normalized to body mass.

Gait trials were collected using a three-dimensional, 12-camera passive marker motion capture system synchronized with an embedded force platform. Participants were outfitted with 35 retroreflective markers on the trunk, pelvis, and lower extremities and walked along a 10m walkway at a self-selected speed. After the gait trials, participants were asked to mark the pain in their knee on a visual analog scale (VAS). Kinematic and kinetic data were normalized to 100% of stance phase. Peak KFA, KFM, and KAM during the first 50% of stance phase were averaged over 3 trials and used in the analysis.

Pearson correlation coefficients were used to examine the relationships between each dependent variable, independent variable, and potential covariates (sex, pain, and gait velocity). If any covariates were significantly associated with the dependent variables, they were entered into the regression analysis prior to the muscle variable.

Separate linear regression analyses were used to assess the amount of variance in peak KFA, KFM, and KAM explained by each measure of quadriceps strength and power.

RESULTS AND DISCUSSION

Quadriceps strength and all measures of power were significantly, positively correlated with peak KFA (r=0.42-0.56). Strength explained 15% of the variance in peak KFA while power explained 20-29% of the variance (Table 1). Only quadriceps power at 90% 1RM was significantly correlated with peak KAM, explaining 9% of the variance in peak KAM (Table 1). No measures of quadriceps strength or power were significantly correlated with peak KFM. None of the covariates were significantly correlated with the dependent variables and were therefore not entered into the regression analysis.

A novel finding in the present study is the positive association between quadriceps power and peak KFA, suggesting individuals who generate more power also have greater KFA during stance. These results suggest that not only does the force generating capacity of the muscle influence knee joint position during stance phase of gait, but also the speed at which that force is generated.

Peak KAM was not significantly correlated with quadriceps strength but was significantly correlated with power at 90%1RM (r=-0.35). These results indicate that individuals who generate greater power at a higher intensity also have higher medial compartment loading. Additionally, all measures of quadriceps power explained more of the variance in peak KFA than strength (Table 1). Taken together, these results suggest that muscle power may play a larger role in knee kinematics than strength alone.

CONCLUSIONS

Quadriceps muscle strength and power both influence knee joint mechanics in individuals with knee OA. Since knee joint mechanics have been associated with the initiation and progression of knee OA, it is important to consider the possible consequences that increasing quadriceps strength and power may have on overall joint health. Future studies should examine the effects of interventions aimed at improving quadriceps strength and power on knee joint mechanics in individuals with knee OA.

SENSITIVITY OF CARTILAGE PRESSURE TO LIGAMENT STIFFNESS DURING SHOULDER ABDUCTION

[1] Hafizur Rahman and [1] Mariana E. Kersh

[1] The University of Illinois at Urbana-Champaign, Urbana, IL, USA
email: mrahman3@illinois.edu, web: http://uitbl.mechse.illinois.edu

INTRODUCTION

Rotator cuff tears are considered one of the primary causes of shoulder pain and dysfunction in adults [1]. Statistics show that more than 50% of patients over the age of 60 and 80% of patients over the age of 80 have a cuff tear [2]. Unfortunately, the success rate of rotator cuff repair is variable with many resulting in a re-tear. The chance of persistent tears or re-tears has been documented to be 35% for small tears and 94% for larger multi-tendon tears [3-5]. Similarly, revision surgeries can be as high as 30% for isolated supraspinatus tendon tears [6].

The aim of our research is to provide orthopedic surgeons with specific recommendations that will improve the outcome of rotator cuff surgeries. It is therefore important to understand the biomechanical properties of the ligaments, capsule, and dynamic properties of the muscles of the shoulder joint. Of note from the literature is the variation in the measured stiffness of shoulder joint ligaments [7-8]. It is essential to know how the variation of ligament stiffness affects the cartilage pressure in the glenohumeral joint. To investigate this, we developed a three-dimensional finite element (FE) model of the shoulder joint that includes the major ligaments and glenohumeral cartilage.

METHODS

The geometries of the humerus and scapula were created from computed tomography (CT) data of the shoulder (voxel size: 0.34 x 0.34 0.49 mm). The CT files were imported into Amira (v5.6, Visualization Sciences Group, France, and Zuse Institue Berlin, Germany) for segmentation of the bones using a semi-automated method. After segmentation, surfaces were generated and exported as an STL file and then imported into Geomagic Studio (v2014, Geomagic Inc., USA). The bone surfaces were smoothed, refined and noise was reduced. Finally, a solid model was created and exported as an STPAP203.

Construction of the FE model and all simulations were performed using Abaqus (v6.13, Daussalt Systems, France). Quadrilateral dominant surface meshes were used for the humerus and scapula (E=17GPa, ν=0.35) [9]. The cartilage mesh was a layer of elements offset from the surface of the proximal and distal ends of the humerus and scapula, respectively. Scapula cartilage was defined as 1 mm thick and the humerus cartilage as 0.5 mm thick (E=30MPa, ν=0.45) [10]. Frictionless contact was defined between the humerus and scapula cartilage.

The coracohumeral ligament (CHL), superior glenohumeral ligament (SGHL), middle glenohumeral ligament (MGHL), and inferior glenohumeral ligament (IGHL) were modeled as axial springs (Fig. 1).

Figure 1: Finite element model of shoulder joint with ligaments (red)
The model was kinematically constrained along the scapula, and a 15 degree abduction was enforced on the humerus while translational components of the humerus were left unconstrained. The simulation was run with ligaments at three stiffness values: (1) the average value reported in the literature, (2) low: the average value minus the reported standard deviation, and (3) high: the average stiffness plus the reported standard deviation (Table 1). No stiffness values were found for the MGHL, therefore the average of the SGHL and IGHL were used. The kinematics of the humerus and cartilage contact pressure was recorded under the three stiffness levels.

Table 1: Stiffness for ligaments, K (N/mm) [7-8]

	CHL	SGHL	MGHL	IGHL
Low	30.8	15.9	15.6	15.4
Avg	36.7	17.4	21.4	25.4
High	42.6	18.9	27.1	35.4

RESULTS AND DISCUSSION
From the simulation results, it is interesting that the translational motion of the humerus remained almost the same for the first 5° of abduction. After 5° of abduction motion, the medial-lateral translation began to change for low, average and high ligament stiffness. By 15°, medial translation for average stiffness ligaments was 16.6% higher than low stiffness ligaments and 7.9% lower than high stiffness ligaments (Fig. 2). On the other hand, at 15° abduction, anterior translation for average stiffness ligaments was 1.7% higher than high stiffness ligaments and 4.3% lower than low stiffness ligaments (Fig. 3).
Figure 2: Humerus medial-lateral translation
Figure 3: Humerus anterior-posterior translation

The average contact pressure of the scapula cartilage was nearly constant for all stiffness values until 5° of abduction, as expected, since there was no change in translation motion of humerus until 5° of abduction (Fig. 4). But after 5°, the changes in cartilage contact pressure was abrupt – possibly because of differences in the topology of the scapula cartilage surfaces that were in contact. After 13° of abduction, the cartilage contact pressure rose sharply and varied for all three stiffness values. The

medial-lateral and anterior-posterior translation changes observed after 10° might be contributing to the cartilage contact pressure differences. A similar phenomena was also observed for the humerus cartilage contact pressure.
Figure 4: Scapula cartilage contact pressure during abduction

Our results suggest that the translation of humerus can be sensitive to ligament stiffness. This sensitivity of the humerus translation motion also has contributing effects on how the contact pressures are generated in cartilage. This is important for both experimental studies where care should be taken to not disturb the ligaments when measuring cartilage mechanics and modeling studies that make use of this experimental data. To date, we have not validated our model, but experimental procedures are going on to validate the simulation results.

ARTHROKINEMATIC EFFECTS OF JOINT MOBILIZATION OF THE TALOCRURAL JOINT: AN IN VITRO STUDY

Anthony R. McNally, Stacie I. Ringleb, Cameron P. Powden and Matthew C. Hoch
Old Dominion University, Norfolk, VA, USA
email: sringleb@odu.edu

INTRODUCTION

Ankle injuries, resulting in damage to the lateral ligamentous complex, are often associated with limited dorsiflexion (DF) range of motion (ROM). Deficits in dorsiflexion ROM may be the result of arthrokinematic restrictions, specifically in posterior talar glide [1]. To restore normal ankle arthrokinematics and ROM, clinicians often use manual therapy techniques referred to as joint mobilization (JM). Anteror-to-posterior joint mobilization techniques are frequently employed to increase dorsiflexion ROM of the talocrural joint [2]. Several studies have identified immediate improvements in dorsiflexion ROM following JM treatment; however, these studies failed to confirm the arthrokinematic alterations that were involved[3, 4]. Therefore, the mechanisms underlying the effect of talocrural JM have not been satisfactorily explored.

Examining the effects of JM using in vitro testing methods may provide a model to capture subtle changes at the arthrokinematic level. Distal tibiofibular JM was simulated in vitro and was able to detect increased ankle dorsiflexion after treatment [5]. However, arthrokinematic changes at the talocrural and subtalar joints remain unclear [3, 4] and an in vitro model examining kinematics following talocrural joint mobilization has not been investigated. Therefore, the purpose of this preliminary in vitro study was to examine changes in talocrural arthrokinematics and dorsiflexion ROM after performing Maitland Grade III anterior-to-posterior JM to the talocrural joint.

METHODS

Three fresh frozen cadaver lower extremities (3 left limbs, age 68.3 ±8.08, one male) with no documented history of ankle injury were secured to a custom 6 degree of freedom ankle loading device.

A certified athletic trainer with 3 years of experience performed two sets of Maitland Grade III anterior-to-posterior JM to the talocrural joint with 200 oscillations per set. The Grade III JM was defined as a 1-second large amplitude rhythmic oscillation applied from the mid-range of accessory motion to the area of tissue restriction. Data were collected at baseline and after each set of JM.

A six camera Motion Analysis Eagle System (Motion Analysis Corporation, Santa Rosa, CA) was used in combination with the MotionMonitor (Innovative Sports Training, Chicago, IL) to track and collect 3D motion of retroreflective sensors installed directly to the talus, calcaneus and tibia bones during dorsiflexion and posterior translation of the ankle joint. Kinematic motion of the foot during data collection included neutral to anterior to posterior translation and neutral to maximum dorsiflexion. Two separate data sets were collected at each interval with each data set containing two cycles of rotational and translational motion.

Dorsiflexion data were exported from the MotionMonitor using an Euler sequence of Z-X'Y''. Data were post processed using a custom Matlab program (The MathWorks, Inc., Natick, Massachusetts V7.12.0, 2011).

The dorsiflexion ROM and posterior talar translation collected following each set of JM treatment were qualitatively compared to the baseline measures for each specimen. The mean and SD for both variables was calculated across subjects for each time point to examine preliminary data trends.

RESULTS AND DISCUSSION

This preliminary study suggests that talocrural JM did not increase dorsiflexion ROM or posterior talar translation. On the contrary, a slight decrease in dorsiflexion ROM and posterior talar

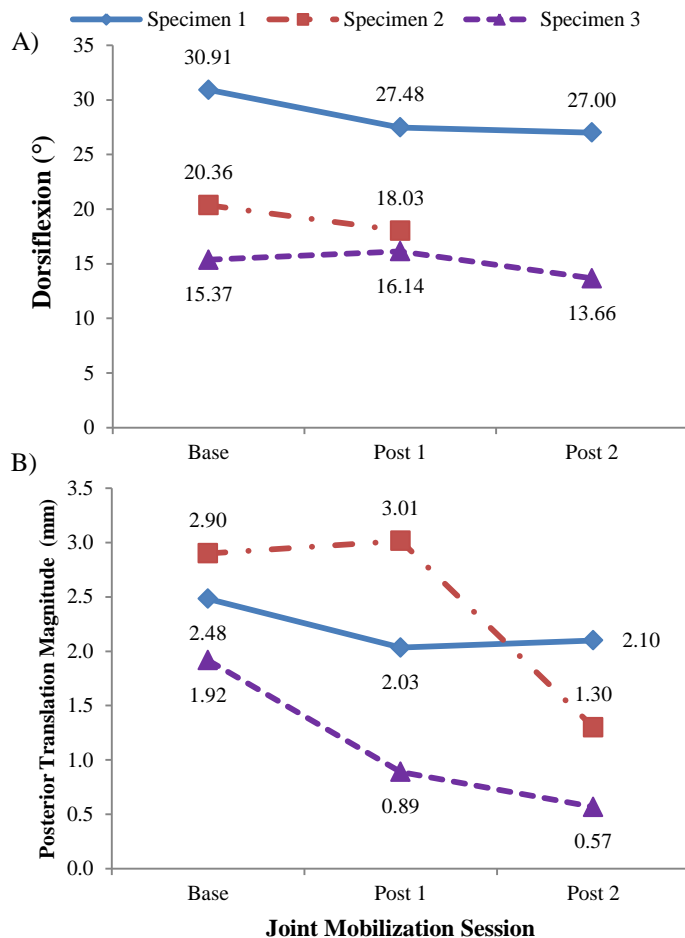
translation was observed across all three specimens. These results are in opposition to many in vivo studies that determined talocrural JM can effectively increase dorsiflexion ROM [3, 4] and in vitro research which identified dorsiflexion improvements following tibiofibular JM [5].


Figure 1: Effects of talocrural JM on ankle dorsiflexion ROM (a) and posterior translation (b). * The talus bone cracked during Post 2 testing in Specimen 2 and was not included in this aspect of the analysis.

Interval Relation	Dorsiflexion (°)	Posterior Translation (mm)
Base to Post 1	1.66±7.07°	0.45±0.83
Post 1 to Post 2	1.48±8.76°	0.66±0.93
Base to Post 2	2.81±10.24°	1.11±0.64

Table 1: Mean ±SD of dorsiflexion and posterior translation of the talocrural joint. Positive values represent gains in range of motion.

Several factors may account for the unanticipated results of this study. The primary explanation for the decreased posterior translation dorsiflexion ROM may be associated with the open kinetic chain model used for assessing motion in this study. The decrease in posterior translation may actually represent a posterior shift in the location of the talus with each subsequent JM session, creating a new starting point for the beginning motions of dorsiflexion and posterior translation. While we tracked motion of the talus during anterior and posterior glides, we were unable to account for the starting position of the talus between JM treatments. A posterior migration of the talus in an open kinetic chain may alter the contact between the talar dome and ankle mortise which could change the axis of rotation. A weight bearing model observed that JM expanded the range of ankle dorsiflexion[5]. Therefore, if a closed kinetic chain test were implemented, the talus may not shift posteriorly and an increase in dorsiflexion may be observed. Furthermore, the use of an open chain versus a closed chain model may explain the opposing effects of the JM between the two studies. Additional exploration which may include advanced imaging and closed kinetic chain models may clarify relationships between boney positioning and ROM and elucidate the underlying mechanisms of talocrural JM.

CONCLUSION
Further investigation should be performed to clarify the effects of JM including closed kinetic chain in vitro models or radiographic imaging to examine changes in boney positioning.

INTRODUCTION

Although ISB recommendations for reporting shoulder joint motion were published in 2005 [1], these recommendations are difficult to follow using video-based motion capture since they rely on knowledge of the location of the glenohumeral joint center, which is not visible or palpable. As a result, marker sets used to quantify upper extremity motion often vary widely from the ISB proposal.

For years, lower extremity biomechanics studies have used functional methods for identifying joint centers, and the process is standard in some clinical gait protocols. In functional methods, the subject performs a specific movement that allows the joint center of rotation to be inferred from the pattern of motion of one segment relative to the other. In some subjects, accuracy of hip joint center location can be improved significantly compared to regression or anatomical landmark methods [2].

Accurately identifying the location of the glenohumeral joint center could improve both kinematic and kinetic analysis at the shoulder. In this study, we compare two different protocols for functionally locating the glenohumeral joint center. This study is the first step in an attempt to develop an accurate glenohumeral joint center representation for use in video-based motion capture.

METHODS

Trunk and humerus motions were captured using a video-based motion capture system in six adult subjects (4M, 2F) with no existing symptomatic pathology of the right shoulder. A total of 10 retroreflective markers were placed on the trunk (C7, T8, sternal notch, xiphoid process) and right upper arm (acromion, lateral epicondyle of the elbow, medial epicondyle of the elbow, three-
Figure 1: Marker placement for tracking motion of the humerus relative to the thorax. Red markers are placed on the back at C7 and T8.

marker triad). The seven skin-mounted markers were located according to the ISB recommendations for tracking motion of the humerus relative to the thorax [1]. An additional rigid three-marker triad was secured distal to the insertion of the deltoid muscle on a tight Velcro strip (Figure 1).

After performing a calibration in the "T" position (both shoulders abducted 90°, palms facing forward), subjects performed functional calibration movements in two different positions. In the 0° abduction position subjects performed small circumduction motions (approx. 15°) with the arms held in anatomical position. A second functional circumduction motion was performed with the shoulders in 90° of abduction (arm circles). In each case, three to five full cycles of motion were captured. Finally, subjects performed two trials each of full shoulder flexion and full shoulder abduction (both nominally from 0° to 180°).

Motion data were captured at 120 Hz using an eight-camera Vicon Nexus (Oxford, UK) motion capture system and reconstructed marker

trajectories were smoothed using a second order Butterworth lowpass filter with 6 Hz cutoff frequency. Post-processing was completed using Visual3D software (C-Motion, Germantown, MD). For each subject, Euler angles of the humerus relative to the trunk were computed using the plane-elevation-rotation (Z-Y-Z) rotation sequence described by An et al [3]. Location of the functional shoulder joint center relative to the acromion marker was computed using the finite helical axis algorithm [4] for each functional motion. These data are presented below.

RESULTS AND DISCUSSION

Mean computed locations of the functional shoulder joint center were similar for the two functional motion positions (Table 1). The mean position in the A-P direction was essentially the same for the two motions. However, the mean M-L positions were 6 mm apart and the mean S-I positions were 7.5 mm apart.

Both functional motions resulted in computed shoulder joint center locations that were posterior, medial, and inferior to the acromial marker. These results are consistent with the anatomy of the glenohumeral joint. With the shoulder abducted, the functional joint center moved superiorly relative to the acromion by about 7 mm.

Sangeux et al. [2] found that location of the functional joint center at the hip was highly dependent on the range of motion performed and whether the motion was performed voluntarily or with assistance. Therefore, much more work still needs to be done to optimize the specific protocol for functional joint center determination. In this study, subjects were allowed to select a comfortable range of motion, with no attempt to control either the exact magnitude of the motion or the speed at which is was conducted.

While much more validation data is needed to ensure that the functional joint center computed using this technique corresponds to the true glenohumeral joint center, the technique yielded reasonable results for both different motions, at least in this small group of subjects without shoulder pathology.

CONCLUSIONS

Accurate glenohumeral joint kinetics, and to a smaller extent kinematics, require accurate location of the glenohumeral joint center. This technique, when fully developed, should help improve estimates of glenohumeral joint mechanics. In future studies we will attempt to validate the procedure with medical image data. We will also focus on optimizing the functional joint center protocol. It is likely that the optimal position of the functional motion will depend on the specific motion to be studied, and whether it contains a significant amount of shoulder abduction.

VIBRATION OF QUADRICEPS MUSCLE AFFERENTS AFFECTS BOTH IPSILATERAL AND CONTRALATERAL QUADRICEPS AND HAMSTRINGS RATIO OF TORQUE, POWER, AND ACCELERATION TIME

INTRODUCTION

Arthrogenic muscle inhibition (AMI) is a devastating side effect to joint injuries such as anterior cruciate ligament (ACL) rupture. A chronic inability to fully activate the ipsilateral quadriceps and subsequent contralateral atrophy of the quadriceps results from AMI [1,2]. Possible mechanisms for these effects of AMI include flexor withdrawal reflex, gamma-loop, or Ib inhibitory pathways.

Previous studies that utilized vibration to affect muscle afferents stimulated the muscle tendon for 20-30 minutes to discharge vesicular release and theoretically block all neurotransmission available from the Ia fibers [3]. However, recent microneurography findings regarding vibration and sensory afferents indicate that vibration will activate Ia, Ib and II afferents to varying degrees and thus caution should be utilized to distinguish the afferent input specifically affected via vibration [4].

The aim of this study was to determine whether real-time inhibition of muscle forces occurred from muscle afferents and to specifically identify whether these afferents can affect contralateral musculature as a basis to model AMI.

METHODS

Ten healthy participants (mean age: 27.7, ± SD 5.3) were tested bilaterally (4 females, 6 males). We examined the effect of vibration during isokinetic knee extensor and flexor at 60°/s and 300°/s using Biodex dynamometer. Each subject performed 3 sets at each speed and the vibration modality was randomized to the contralateral, ipsilateral, and control (no vibration) conditions.

Vibration (43 Hz) was applied via a medical-grade percussor to the belly of the quadriceps muscle (localization of Ia and II afferents). Prior to each trial, the subject was permitted two practice reps for familiarization. During each trial, the subjects were given verbal encouragement. Five reps of the isokinetic strength measures were averaged for the 60°/s trial and ten reps averaged for the 300°/s trial. Measures of agonist/antagonist ratio of acceleration time, deceleration time, avg. torque, peak torque, and avg. power of quadriceps and hamstrings in both ipsi- and contralateral vibration were compared to control conditions for statistical analysis. Agonist/antagonist ratios were calculated and utilized in order to determine the holistic effects of vibration on the musculature (hamstring = agonist; quadriceps = antagonist). In addition, data was normalized to control measures for analysis of individual musculature effects. Data was analyzed via paired t-tests and multivariate linear regression in JMP Pro 9.

RESULTS AND DISCUSSION

t-tests revealed lack of significance between left and right limbs on similar trials ($p > 0.05$), thus data from both limbs were combined to increase sample size (n=20).

At 300°/s, contralateral vibration of the tested leg demonstrated significance of decreasing agonist / antagonist acceleration time ($p=0.0427$), decreasing agonist/antagonist ratio of peak torque ($p=0.0242$), and decreasing agonist/antagonist ratio of avg.

torque (p=0.0497). In addition, contralateral vibration of the tested leg demonstrated significance (p=0.0448) for increasing agonist/antagonist ratio of deceleration time. This data demonstrates that aberrant afferent input (in this case, from the contralateral limb) can affect efferent output of the other limb. Thus, the aberrant afferent input (vibration) from the contralateral limb moved these values in the opposite direction of desired outcomes, demonstrating that the contralateral limb can influence outcomes of the other limb in both injury and recovery mechanisms. The 300°/s trial speed is a physiologically relevant speed of movement during sporting activity and thus is important for measuring criteria simulating real-world scenarios of acceleration, deceleration, avg. torque, and peak torque.

At 60°/s, ipsilateral vibration of the tested leg only demonstrated a trend toward statistical significance (p=0.0532), but this difference may be a clinically significant decrease in the agonist/antagonist ratio of avg. power. This value may reach significance with an increased sample size.

Standard least squares multivariate linear regression with categorical predictors of group, sex, and group*sex revealed significance for control group vs both ipsi- and contralateral vibration (p=0.0268) for avg. power of hamstrings at 60°/s normalized to control measures (**Fig. 1**).
Figure 1: Avg. power of hamstrings at 60°/s decreases with both ipsilateral and contralateral vibration (values normalized to control measures).

CONCLUSIONS

This is the first study to observe effects of real-time vibration (causing aberrant afferent input) on ipsilateral and contralateral muscle efferents, either agonist or antagonist. The current results indicate that contralateral aberrant afferent input is an inhibitory factor of the muscle efferents of the other limb in control subjects. This serves as a possible model for AMI as deafferentation that occurs either post-injury or post-surgery can have a contributing factor on muscle efferents ipsi- or contralaterally. In addition, this data serves as a neuromuscular model for the importance of proprioceptive afferent input to the muscles from both limbs for injury prevention.

Similar to the crossed extensor reflex, interneuron linkage to contralateral alpha motor neuron and subsequent gamma motor neuron co-activation may exist to regulate muscle efferents. Thus, this data provides evidence for a possible model for AMI to pursue the underlying mechanisms of and the relevance of these effects on neuromuscular control in the ACL injured population.

INTRODUCTION

In vitro cadaveric testing allows invasive instrumentation, testing in various states of injury, and application of multiple surgical techniques to the same specimen; but without the central nervous system present, motion requires external actuation. A joint motion simulator (JMS) fixes a cadaveric joint's proximal side and loads the tendons inserting on the joint's distal side. An elbow JMS fixes the humerus and actuates the freely moving radius and ulna through their tendonous insertions. Loads applied repeatably at physiologic levels actuate a cadaveric elbow in as natural a way as possible yielding meaningful insights into elbow behavior.

Specimen variation, muscles affecting multiple degrees of freedom (DOF), and orientation dependent gravitational loading complicate JMS control. Current JMSs use EMG based muscle loading ratios [1], angle dependent muscle activation [2], and specimen specific movement scaling [3] to manage these problems. Specimen specific controller modifications may still be necessary with these methods to achieve highly accurate motion. The purpose of the following work is to show that the addition of iterative learning control (ILC) to antagonist source switching decoupled feedback control achieves highly accurate JMS control with no specimen or orientation specific modifications.

METHODS

The Allegheny General Hospital (AGH) elbow JMS (Figure 1) [4] actuates the elbow's two kinematic DOFs through the insertions of the biceps, brachialis, pronator teres, and triceps. The brachialis and triceps affect the flexion / extension (FE) DOF. The biceps and pronator teres affect both the FE DOF and the pronation / supination (PS) DOF. Encoders (US Digital) and load cells (Transducer Techniques) feed back joint positions and tendon loads, respectively. The elbow JMS's control system contains three layers: decoupled feedback control, antagonist source switching [5], and ILC [6]. Antagonist tension control is included to prevent tendon slack. Two muscles, maintained at small but positive tensions, are designated antagonists: one for FE and one for PS.
Figure 1: AGH elbow JMS

Decoupled feedback control maps errors in FE position, PS position, FE antagonist tension, and PS antagonist tension into combinations of tendon velocities. For example, FE position error creates simultaneous triceps extension and biceps, brachialis, and pronator teres retraction. Moment arms and stiffnesses determine the decoupling map.

Motion with low antagonist tension precludes a dedicated antagonist tension source. For instance, moving from full supination to full pronation with a vertical humerus and horizontal forearm is impossible with a small antagonist biceps tension. When the gravitational moment changes from aiding supination to aiding pronation, a low biceps tension and accurate position control require the pronator teres to reduce its tension, but tension in

the pronator teres can only be reduced so far. Switching the antagonist tension source to the smaller of the two tensions solves this problem. In this case, the source closing the tension control loop switches from the biceps to the pronator teres.

ILC, a method using past errors to reduce future errors, is used here to overcome specimen specific dependence. The current decoupled feedback controller's dependence on moment arms and stiffnesses, both of which vary between specimens, prevents accurate control for all but the parameter sourcing elbow. With ILC, an average elbow's decoupling map suffices for any elbow. As more trials are run, the ILC modifies the inputs improving joint position and tendon tension accuracy.

An ILC generating references for an antagonist source switching decoupled feedback controller was implemented and evaluated over three cyclic motions using a mechanical elbow: a 60° flexion motion with fixed 30° of pronation, a 120° pronation motion with fixed 90° of flexion, and a simultaneous 60° flexion and 120° pronation motion. Antagonist tension references were set to one pound. The three motions were performed with the humerus and flexion plane both horizontal and vertical. Five second periods were used for all motions. Performance was quantified with maximum absolute error and RMS error.

RESULTS AND DISCUSSION

Forty control iterations reduced maximum errors for all motions below 1° in position control and 0.3 lbs in antagonist tension control (Figure 2, Table 1). For comparison, a successful, validated elbow JMS [2] designed for motion in all orientations tracked

FE motions from 10° to 120° at 10°/s with RMS errors of 1.7° (vertical) and 2.2° (horizontal).
Figure 2: Maximum position error reduction over 40 trials during horizontal, simultaneous motion

CONCLUSIONS

A combination of ILC for specimen variation, decoupled feedback control for actuator interaction, and antagonist source switching for varying gravitational loading achieves accurate JMS control. Future work will apply the approach to a range of real elbows proving it manages specimen variation.

CHANGES IN TIBIOFEMORAL CONTACT FORCES FOLLOWING ALTERATIONS IN JOINT CAPSULE STIFFNESS

[1]Gannon University, Erie, PA, USA; email: schmitz005@gannon.edu
[2]University of Kentucky, Lexington, KY, USA

INTRODUCTION

Post-traumatic osteoarthritis (OA) affects the knee more than any other joint in the human body [1]. While the cause of this disease is multifactorial, one component may be abnormal tibiofemoral joint loading that occurs after knee injury or surgery [2,3]. The number of joints that become arthritic as a direct consequence of traumatic events is unquantified within the literature, due to the difficulty of collecting such data. One common surgery, for a traumatically unstable knee, is reconstruction of the anterior cruciate ligament (ACL), with over 200,000 of these reconstructions occurring each year in the United States [4]. In fact, in some studies, OA occurs in over 50% of these ACL reconstructed individuals 10-20 years after surgery [5].

The effect of ACL graft placement and tension on tibiofemoral function is well-studied. In contrast, the effect of anterior capsule properties on joint loading is largely understudied. This anterior restraint is important to investigate because the structural integrity of the capsule is altered during the initial trauma to the knee joint and secondarily changes during the post-surgical course. To aid in minimizing OA, it is important to understand the effect of joint capsule properties on tibiofemoral loading. Therefore, the goal of this work was to investigate the effects of knee joint capsule stiffness on tibiofemoral loading. We hypothesized that increased capsule stiffness would lead to increased joint loading.

METHODS

A parametric modeling study was conducted on a previously developed discrete element model of the knee [6] implemented in the open-source software OpenSim [7]. The tibiofemoral joint contained six degrees-of-freedom (dof) while the patellofemoral joint contained one dof. Twenty-two ligaments were included as non-linear springs, as well as an elastic foundation model for tibiofemoral contact.

The knee joint capsule was added using four non-linear springs in the anterior portion of the knee joint. These elements included two parallel elements running from the distal femoral metaphysis to the proximal tibial metaphysis, along with two crossing elements connecting the insertions of the parallel elements to each other (Figure 1). The knee joint capsule springs were constrained by a cylindrical wrapping surface to simulate sliding of the knee capsule on the femur distal surface during knee flexion. The capsular elements were modeled with stiffness values equal to 30% of the stiffness of other ligaments.
Figure 1: Discrete element knee model in OpenSim

A forward dynamic simulation was used to passively flex the knee joint from an extended position to 75 degrees of flexion for two cases: 1) normal condition and 2) stiff condition where the stiffness of the capsule was increased by 20%. For each of these simulations, the tibiofemoral contact force was calculated as the vector sum of the forces

in the muscles and ligaments (expressed in the femoral reference frame) [8]. The simulation was run at a speed such that inertial forces were negligible.

RESULT AND DISCUSSION

The magnitude of the tibiofemoral contact force (i.e. resultant force) increased with knee flexion, reaching its maximum at peak knee flexion (Figure 2). Our hypothesis was supported in that a 20% increase in joint capsule stiffness caused a 16% increase in maximum contact force. This implies that increased joint capsule stiffness may be a factor in OA progression.

There are some limitations and study design factors that should be considered when interpreting this work. First, the tibiofemoral contact force was not decomposed into the medial and lateral compartments. Therefore, it is unclear which compartment is more sensitive to changes in joint capsule stiffness. Second, the joint capsule stiffness was set to 30% of the stiffness of the other ligaments. This was approximated due to the paucity of literature data on joint capsule properties. This would affect the quantitative results of the study but not the trend or interpretation.

CONCLUSIONS

Clinically, increased joint capsule stiffness may occur either as a consequence of an original traumatic insult to this structure or due to secondary changes subsequent to a surgical intervention. The quantifiable change, in either circumstance, to the joint capsule commonly appears to be a stiffer joint capsule. Our results show this increase in stiffness may lead to increased tibiofemoral cartilage loading, thus predisposing the joint to OA. Therefore, preserving the structural integrity and minimizing scar tissue in the knee joint capsule may be an important consideration when treating a traumatic injury to the joint and when considering the rehabilitation following an ACL reconstruction.

EXPERIMENTAL ANTERIOR KNEE PAIN AFFECTS ACTIVATION OF CERTAIN MUSCLES DIFFERENTLY DURING LANDING AND JUMPING

INTRODUCTION

Anterior knee pain (AKP) is a common problem that is associated with abnormal lower-extremity movement neuromechanics [1]. The independent effects of AKP are difficult to study due to other simultaneous effects of knee pathology (e.g., knee effusion or degradation). The purpose of this study was to evaluate the independent effects of AKP during landing and jumping on activation of lower-extremity muscles during two land and jump tasks performed at two different intensities.

METHODS

Thirteen healthy subjects (7 males, 6 females; mass = 70 ± 15 kg; height = 1.74 ± 0.11 m; age = 22 ± 2 yrs) gave informed consent and completed a control and pain data collection session, 48 hours apart. For each session, subjects performed two land and jump tasks at a low and high intensity: a forward double-leg land and jump task (FDJ) and lateral single-leg land and jump task (LSJ). The FDJ task required subjects to jump off of two legs, forward over an obstacle, and land on two legs, on a force platform; then, immediately jump forward off of two legs over a second obstacle. Low and high intensities for this task involved obstacle heights that were standardized to each subject. The LSJ task required subjects to jump off of the left leg, laterally, and land on the right leg on a force platform; then, immediately jump back to the beginning location, landing on the left leg. Low and high intensities for this task involved lateral jump distances that were standardized to each subject. Surface electromyography (EMG; 1000 Hz) was recorded for the right gastrocnemius (GA), vastus medialis (VM), medial hamstrings (MH), gluteus medius (GMD), and gluteus maximus (GMX) while subjects contacted the force platform during each trial. First and second halves of the time that subjects contacted the force platform defined landing and jumping.

For both sessions, subjects first completed three trials of both tasks, at both intensities, to provide reference EMG values. Next, for the pain session, 1 ml of hypertonic saline (5.0% NaCl) was injected into the right-leg infrapatellar fat pad, to induce experimental AKP, and subjects performed three more trials of both tasks at both intensities; these were the experimental trials. The control session was the same as the pain session, except the injection was omitted. Subject perceived AKP was measured every two minutes of both sessions using a 10-cm visual analog scale.

Functional linear models were used to evaluate the effect of session and intensity on normalized EMG amplitude throughout the time that the subjects contacted the force platform for each trial. Also, mixed-model repeated measures ANOVA and Tukey-Kramer *post hoc* tests were used to compare subject perceived AKP between sessions. All alpha levels were set to 0.01.

RESULTS AND DISCUSSION

Subject perceived AKP was greater for the pain-session trials, relative to the control-session trials (Figure 1; $p < 0.01$). The AKP significantly altered EMG amplitude for all of the observed muscles, at varying parts of both tasks, except for the VM during the FDJ ($p < 0.01$). Effects of the experimental AKP on EMG amplitude were admittedly varied, in direction and timing, and did not reveal a consistent pattern, and the space required to describe all of these effects is not

presently available. Three muscles (GA, MH, and GMD), however, did display a similar interesting pattern, for both tasks, that we wish to emphasize here. This pattern is demonstrated by MH EMG amplitude during the LSJ (Figure 2): as a result of AKP, muscle activation decreased during landing and increased during jumping. This pattern was also observed for the GA and GMD, however, we do not now have space enough to present these data.

The cause of this inhibition and subsequent facilitation is unclear and will require additional research to elucidate. We now speculate, however, that the decreased muscle activation during landing could be due to greater reliance on force contributions from passive muscle components [2] or the skeletal system (i.e., a more upright landing position). We further speculate that the increased muscle activation during jumping could reflect an attempt to compensate for the preceding inhibition during landing and/or increased neural drive, via the group Ib pathway, resulting from the high forces associated with landing [3]. Regardless of the cause(s) of the observed inhibition and facilitation, these EMG alterations are important because they

likely result in altered tibiofemoral and patellofemoral joint loads.

INTRODUCTION

Proximal junctional kyphosis (PJK) and proximal junctional failure (PJF) are an increasingly recognized complication after long-segment instrumentation for the correction of kyphosis and scoliosis. Vertebral compression fractures (VCFs) at the upper instrumented vertebra (UIV) and the UIV + 1 have been described. Prophylactic vertebroplasty has been advocated to reduce the rate of VCFs but still results in the creation of a stiff "super vertebra". We hypothesize that utilizing a tapered dose of bone cement in the UIV, UIV + 1, and UIV + 2 eliminates the creation of a "super stiff" vertebra further decreasing the rate of VCFs and PJK.

METHODS

A biomechanical cadaveric study along with finite element analysis (FEA) was utilized.

Fifteen fresh-frozen ligamentous T6 - pelvis specimens were used. The spines were equally divided into three Groups of 5 specimens each: Group 1 - Bilateral pedicle screw and rod instrumentation from T10 to S1, no cement; Group 2 - Instrumentation + 4cc of cement injected into T10 (UIV) and 4cc into T9 (UIV + 1), 2cc of cement injected through each pedicle; & Group 3 - Instrumentation + 4cc total in T10 (UIV), 3cc total in T9 (UIV + 1), and 2cc total in T8 (UIV + 2). Dual-energy X-ray absorptiometry (DEXA) was obtained on all specimens. The pelvis and T6 vertebra of each specimen were fixed in bondo epoxy resin. The spines were mounted on a MTS biaxial load actuator and axial compression was applied eccentrically, 10 mm anterior to the center of the T6 vertebra, until failure occurred. Maximum load to failure was measured in Newton (N). The spines were also analyzed visually, fluroscopically, along with computed tomography (CT) scans for the presence of VCFs.

Finite element analysis (FEA) was utilized to simulate similar scenarios for the three groups as the cadaveric study using normal and osteoporotic bone models. An axial compressive load was applied perpendicular to the top of T6 vertebra, 10 mm anterior to its center just like the cadaver study. Stresses at the endplates and the posterior ligaments were analyzed.

RESULTS

Cadaveric Data

There was a significant reduction in the number of fractures (Fig. 1) observed in Group 3 vs. Groups 2 and 1 (p=0.0019). There was only one fracture in one specimen observed in Group 3; all five specimens suffered a fracture in Group 2; and five in Group 1. Posterior ligamentous rupture occurred in four specimens in Group 3; three in Group 2; and only one in Group 1. The mean peak load-to-failure values showed an increasing trend from Groups 1 to 3, but were not significant (p=0.38). Load vs. deformation plots in specimens that failed exhibited a peak load (inflection point) followed by an

obvious loss of structural integrity (Figure 2). There was no difference in DEXA values among the specimens in the three Groups (p=0.71). There was no hardware failure in any Group.

Finite Element Analysis (FEA) Data

Load to failure in normal bone was higher in comparison to osteoporotic bone, which followed the same trend as the cadaveric data. Specimens with higher bone mineral density (BMD) were stiffer and the maximum load to failure increased from Group 1 to Group 3. The T8 (Figure 3) and T9 (Figure 4) endplate stresses were reduced by 20% and 33%, respectively in Group 3. The stresses observed at the supraspinous (SSL) and interspinous ligaments (ISL) in Group 3 were higher at T6-T9 as vs. Groups 1 and 2. At T9-T10, the stresses observed in the SSL and ISL in Group 3 were lower as compared to Groups 1 and 2.

CONCLUSIONS

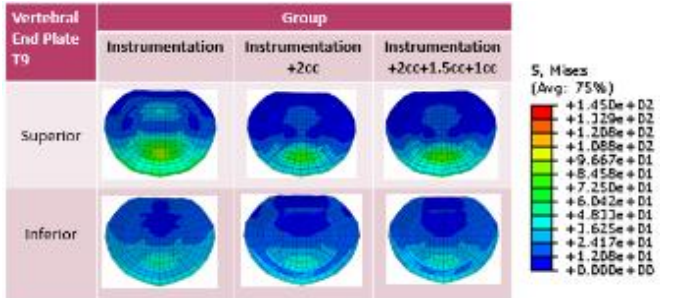
There was a significant reduction in VCFs in those specimens treated with a tapered dose of vertebral cement in the UIV, UIV + 1, and UIV + 2 (Group 3) as compared to spines treated with instrumentation only (Group 1), and those treated with the same amount of cement at the UIV and the UIV + 1 (Group 2). This tapering technique of cement increases the load required for failure decreasing the risk of VCF, the precursor of PJK.
Figure 1: Failure observed in the anterior column (T8) during compressive loading of a specimen in Group 1.
Figure 2: Load vs. displacement plot of a specimen exhibiting an inflection point (peak) indicating the failure load.
Figure 3: T8 endplate stresses


Figure 4: T9 endplate stresses

In both cadaveric and FEA models, this novel technique of using the tapering dose of prophylactic vertebroplasty cement in the UIV, UIV + 1, UIV + 2 decreased the endplate stresses, increased the load required for failure, and reduced the incidence of VCFs above long-segment instrumented constructs. Clinically, this technique may reduce the risk of PJK and PJF. Further biomechanical and clinical analyses are required.

THREE-DIMENSIONAL HUMERAL SHAPE MORPHOLOGY THROUGHOUT THE PEDIATRIC AGE SPECTRUM IN CHILDREN WITH UNILATERAL OBPP

INTRODUCTION

To understand the relationship between humeral morphology and pathology, developmental shape changes must be understood. Little data exist in regards to how pathology and development influence three-dimensional (3D) humeral shape. A pediatric cadaver study established that the humeral head anteverts through development [1], but the lack of an ossified head in younger children prevented direct measures of humeral head orientation. Closing this knowledge gap is crucial for treating pathologies such as obstetrical brachial plexus palsy (OBPP), where the current trend supports earlier intervention (physical therapy, botulinum toxin injections, surgery) to help prevent functional losses.

The purpose of this study is to quantify the 3D humeral morphology in children across the pediatric age span (6 months to 18 years old) with unilateral OBPP and internal rotation contractures in order to test the following hypotheses: 1) development is correlated with 3D humeral shape changes in the unaffected arm; 2) the impaired arm has significant multi-planar shape deformities, relative to the unimpaired arm, which increase with age.

METHODS

In total 29 bilateral 3D axial MR images of children/adolescents with unilateral OBPP were included in this study. The first set (n = 17, age = 1.5±1.2 years) was acquired as part of a pre-surgical evaluation protocol (author MLP). The second set of 12 subjects (age = 11.8±3.3 years), was taken from a previously published study [2]. Both centers had IRB approval.

The humeral head and shaft/elbow were segmented by manually outlining the outer cartilage and cortical bone surface, respectively [2]. The resulting point cloud was fitted with a 3D mesh and aligned to its principal axes. The epicondylar axis and the lesser tuberosity (LT) were identified on the 3D model (Fig 1).

The model was then converted back to a point cloud and imported into a customized Matlab program. This program determined the best-fit ellipsoid and cylinder to the humeral head and central shaft, respectively. From these data the inclination angle and two retroversion angles, V1 and V2 were calculated (Fig 1). Paired t-tests were used to identify significant (p < 0.05) differences between sides. Pearson's correlations were run to determine the relationship of specific variables to age.

RESULTS AND DISCUSSION

The humeral head was significantly less retroverted (ΔV1 = -10.3° and ΔV2 = -16.9°, p < 0.008), more elliptical (p < 0.001), and smaller in all three dimensions (p < 0.001) for the unimpaired arm. The decreased retroversion disagrees with the past 2D study in younger children [3], whereas all other results are supported by past 2D work [4]. Although V1 was strongly correlated to V2 (r = 0.83, p < 0.001), the variation in ΔV1 and ΔV2 and the more elliptical humeral head on the impaired side demonstrates that retroversion is associated with both the orientation between the humeral head and elbow and the shape of the humeral head itself. The level of pathology increased with age (r = 0.507, p = 0.012), which may explain the discrepancy in retroversion when comparing to past work [3]. A

longitudinal study is needed to identify how shape changes with age in individual subjects, yet the results indicate that intervening early may help prevent larger musculoskeletal pathologies later in life.

Although the inclination angle was not significantly different between sides, the results are noteworthy when analyzing patient-specific changes. Six and five subjects showed declination and inclination, respectively, greater than one standard deviation away from the control average. This discrepancy suggests that patient-specific, 3D morphometric analyses will support optimal treatment.

There was a significant correlation between humeral morphology and age for the control side (V1: r = -0.57; V2: r = -0.711; and inclination: r = -0.477, $p < 0.05$). Numerous factors such as increases in the variety of tasks performed and changes to the external forces on the arm (e.g., the initiation of crawling) may influence the relationship between shape and age on the control side. These natural developmental changes must be taken into account when assessing pathology. In addition, these changes in shape likely influence the musculotendon moment arms [5], confirming the concept that musculoskeletal models must be tailored to the pediatric population and not be derived by simply scaling adult models.

CONCLUSIONS

This study is the first to evaluate 3D humeral shape changes in OBPP across the full pediatric age span. It provides novel findings in terms of inclination. The increased understanding of 3D morphologic changes in both the control and impaired arms of children with OBPP can lead to improvements in determining the unique and optimal treatment options for an individual based on subject-specific 3D morphological analyses.

Figure 1 Left: an anterior to posterior view of the humerus. The shaft axis was the primary axis of the best fit cylinder to a predefined portion of the shaft (shown in mesh). The inclination angle was defined as the angle between the primary axis of the best fit ellipsoid to the humeral head (R1: see right) and the epicondylar axis of the elbow (see Epi Axis on right). **Right**: a superior inferior view of the humerus. V1 was defined as the angle between R1 and the Epi Axis. V2 was defined as the angle between the vector from the lesser tuberosity (LT) to the center of the best fit ellipsoid to the humeral head HC

INFLUENCE OF AGE AND GENDER ON LUMBAR SHEAR TOLERANCE

[1]Sean Shimada and [1]Nicholas Merrier

email: sean@motionsandforces.com

INTRODUCTION

A review of literature examining shear tolerance of the lumbar spine revealed that minimal research has been performed regarding the failure mechanism to external loading situations. Studies have been conducted on lumbar functional spinal unit tolerances; however, this method is not representative of the dynamic failures typically seen in a motor vehicle collision. The Hybrid III Anthropometric Test Device (ATD) lumbar spine has been designed to be biofidelic. Despite this fact, the ATD family assumes that the mass densities and elastic moduli of human tissue are the same for all individuals, regardless of size, age and gender. Additionally, biomechanical studies report that males on average are stronger and have higher injury tolerances than females. Furthermore, variables such as age and gender need to be considered as maintained by the literature in order to increase the biofidelity of ATDs. This study proposes a method to calculate the lumbar spine shear tolerance for any size occupant of varying age and gender for accidental injury reconstruction. If implemented, the methodology and result can benefit biomechanists and injury reconstructionists by providing higher physiological specificity to injury tolerance models.

METHODS

A review of the current literature revealed that the number of studies concerning lumbar shear tolerance is very limited; much of the specimens are older males and a constrained number of female specimens are reported. To the best of our knowledge, the only study that tested whole cadaver specimens was Begeman et al. (1994). Begeman et al. reported that anterior lumbar failure began at 1292 N and 1767 N for 0.5 mm/s and 50 mm/s, respectively. Complete failure of the posterior ligaments was defined as soft tissue failure. Pathologic examination revealed that the predominant injuries were tearing of the interspinous and supraspinous ligaments as well as the ligamentum flavum. Taking into consideration the Hybrid III spine was designed to duplicate a 50th percentile male spine, data points from the spine comparison tests by Begeman et al. (1994) were also utilized for the subject study. An analysis of the load-deflection curve of the complete Hybrid III lumbar spine matched quite well with that of the average unconstrained cadaver specimen with maximum forces of 1560 N for a loading rate of 0.5 mm/s and 2225 N for 50 mm/s.

The lumbar soft tissue properties for males and females were additionally deduced from the literature. Compilations of data related to the effect of age and gender on spinal muscle and ligament strength were used to establish linear regressions.

The lumbar shear tolerances for the 50th percentile male were assessed to the 5th percentile female by adopting the anthropometric scaling procedure expressed by Mertz et al. [1]. Geometric properties such as height and weight were used to determine proportional sizes and tolerance. Linear regressions of 1st percentile, 50th percentile and 99th percentile population representatives of each gender were used to establish erect sitting height. The mass ratio and sitting height were used to determine the scaling factors. Regressions of age and gender were applied to the current Mertz et al. anthropometrically scaled models injury tolerance in order to determine their effects. The models altered with age and gender were then quantitatively compared to the impact and injury tolerance of the Mertz et al. anthropometrically scaled models.

RESULTS AND DISCUSSION

The influences of age and gender on lumbar shear impact response and injury tolerance were compared to the current anthropometric scaling of Hybrid III ATDs. Conservatively, the average soft

tissue failure is expected to occur at 1430 N at 0.5 mm/s and 2000 N for 50 mm/s for a 50th percentile male. The 5th percentile female shear tolerance for soft tissue injury was determined to be approximately 785 N at 0.5 mm/s and 1100 N for 50 mm/s. The effect of age and gender on the 50th percentile male and 5th percentile female soft tissue shear failure is presented in the following figures.
Figure 1: Comparision of 50th percentile male injury tolerance between the anthropometrically scaled models and the influence of aging and gender.
Figure 2: 5th percentile female anthropometrically scaled impact and injury tolerance with the influence of aging and gender.

The existing anthropometric scaling technique for a female and male of the same height and weight results in nearly identical tolerances. The small variation seen in the anthropometric scaling tolerance is a result of females having naturally taller erect sitting heights. Implementing the regressions revealed that tolerances have higher variation when accounting for the differences in age and gender. The regressions demonstrated that the female strength was approximately 75 percent of the male counterparts; however, strength decreased with age for both genders. Strength decreased more so for males and most rapidly after middle age.

CONCLUSIONS

Low back pain is one of the most common and growing health problems. The information and method proposed in the subject study will provide a basis for determining the likelihood of lumbar injury due to shear loading. These tolerance values and the ability to scale to numerous individuals will provide a higher physiological specificity to injury tolerance models, as well as present a foundation for assessing the likelihood of lumbar shear injury given the loading dynamics during a motor vehicle collision. Low back pain costs billions in health care and a basis for determining the likelihood and prevention of lumbar shear injury could advance biomechanical and injury analysis.

AGE-RELATED DIFFERENCES IN MECHANICAL RESPONSE OF LOWER BACK TISSUES AND THE RESULTANT SPINAL LOADS DURING LIFTING

[1]Iman Shojaei, [1]Milad Vazirian, [1]Emily Croft, and [1]Babak Bazrgari
[1]University of Kentucky, Lexington, KY, USA

Email: shojaei.iman@uky.edu

Introduction

Among identified risk factors for low back pain (LBP), age is becoming increasingly important due largely to the increasing population of older workers in the US. Given the important role of lower back biomechanics in development of LBP, the objective of this study was to investigate differences in the active and passive mechanical responses of lower back tissues and the resultant spinal loads when persons of different age complete the same manual material handling (MMH) task.

Method

Experimental procedure

53 individuals between 22 and 68 years old participated in this study after completing an informed consent procedure approved by the University of Kentucky IRB. During experimental session, participants completed a symmetric MMH task by lowering a 10 lb load from upright standing posture to their knee height and lifting it back to their initial upright posture. Each participant also completed a maximum voluntary isometric trunk extension (MVE) test and a passive trunk stress relaxation test as explained elsewhere [1].

Trunk kinematics and electromyography (EMG) of select trunk muscles were collected using respectively accelerometers (Xsens Technologies, Enschede, Netherlands) and surface electrodes (DE-2.1 Differential EMG sensor, Delsys, Natick, MA). Trunk kinetics during MVE and stress-relaxation tests, was collected using a load cell (Interface, Scottsdale, AZ) while ground reaction force during MMH task was collected using a force plate (AMTI, Watertown, MA). The raw collected data were filtered according to literature recommendations.

Modeling procedure and analysis

Active tissue response to task demand was calculated using a simple EMG-assisted model including a single extensor and a single flexor muscle with respective fix moment arms of 6 cm and 10 cm with respect to L5-S1 joint. Active muscle response was calculated using the following relation

$$F_a = \frac{EMG}{EMG_{max}} * G * f(l) * f(v)$$ wherein

EMG denotes mean EMG of four extensor/flexor muscles, EMG_{max} denotes the maximum mean EMG of the same four muscles during MVE test, f(l) and f(v) represent length-tension and velocity-tension coefficients. G, as a gain factor, is calculated for each person such that the error between the moment of predicted active force and measured moment during MVE is minimized. Passive tissue response at any given angle was considered to be the required force in the extensor muscle of the model such that its moment around L5-S1 to be the same as the measured passive moment for the same angle during stress-relaxation test. The

resultant spinal loads (i.e., compression and shear forces) were calculated using both active and responses. A multivariate analysis of variance (MANOVA) was used to determine the effects of age on the maximum values of the ratio of active to passive tissue responses, and estimated compression and shear forces.

Results and discussion

For younger participants, sum of moments from the active and passive responses of lower back tissues with respect to the L5-S1 joint matched well with the net external moment obtained using a link-segment model (Table 1). For older participants, though, the error between the aforementioned moments increased due to inability of our model to account for active response of abdominal muscles; an event that was present at larger trunk flexion of older participants. To account for such contribution from abdominal muscles to active tissue response and the resultant spinal loads, the difference between the aforementioned moments were considered as the contribution of abdominal muscles. Compared to younger participants (Table-1), older individuals (20s, 30s and 40s vs. 50s and 60s) developed higher ratio of passive to active moments in the extensor muscles (P=0.0174). Further, older versus younger individuals completed the task such that a similar compression force (P=0.1286) but higher shearing demands (P=0.0393) were imposed on their lower back.

Increased shearing demand of task with aging was due to higher/lower contribution of pelvis/lumbar spine to trunk flexion among older vs. younger participants and may result in a higher risk of LBP due to excessive pressure on the facet joints.

ADVANCES IN HYPERELASTIC FINITE ELEMENT MODELING OF BIOLOGICAL TISSUES: EXPLICIT STRAIN ENERGY FUNCTION SPECIFICATION

[1] Joshua M. Inouye and [1] Silvia S. Blemker

[1] University of Virginia, Charlottesville, VA, USA
email: ssblemker@virginia.edu

INTRODUCTION

Finite element modeling (FEM) is a suitable method to study the mechanics of biological tissues, but its utility for studying soft tissues has been limited by problems with numerical stability at large, complex deformations. Here, we describe a new paradigm for finite element tissue modeling that greatly increases numerical stability: explicit specification of a strain energy density function using Sefea[TM] (Strain-Enriched FEA, AMPS Technologies). This method relies on numerical differentiation of the strain energy function to calculate the stress and tangent tensors for each integration point (instead of using complex analytical expressions). We create an image-based model of a hamstring musculotendon unit—the biceps femoris longhead—to demonstrate this method's utility and stability.

METHODS

Typically, FEM of hyperelastic materials relies on a strain energy density function. For example, a simple isotropic, quasi-incompressible hyperelastic material model is a Mooney-Rivlin solid, whose strain energy function is given by the expression

$$W = C_{10}(\tilde{I}_1 - 3) + C_{01}(\tilde{I}_2 - 3) + W(J)$$

Where W is the strain energy (a scalar), C_{10} and C_{01} are material constants, $\tilde{I}_1$ and $\tilde{I}_2$ are scalar deviatoric invariants that are functions of the deformation tensor, and $W(J)$ is a volumetric strain energy term of the relative volume J in order to enforce a nearly-incompressible material response. More complex strain energy functions can be used for transversely isotropic biological tissues. Most solvers require calculation of the stress and tangent tensors that are functions of the derivatives of the strain energy density with respect to the right Cauchy-green deformation tensor C:

$$\sigma = f\left(\frac{\partial W}{\partial C}\right)$$
$$C = f\left(\frac{\partial^2 W}{\partial C^2}\right)$$

where σ is the Cauchy stress and C is the tangent tensor. These tensors are typically calculated analytically, but Sefea[TM] calculates them with numerical differentiation of the strain energy density function.
Figure 1: We integrate the force-length relationship of muscle [1] to obtain an explicit strain energy function for muscle.

The advantages of Sefea[TM] include i) using enhanced 4-node tetrahedral elements to enable automatic meshing and ii) specifying an explicit strain energy density function rather than the stress and tangent tensors. We determine the along-fiber strain energy function of muscle by integrating the force-length curve of muscle [1] (Figure 1). The active force curve scales with muscle activation. The same operation is performed to determine the

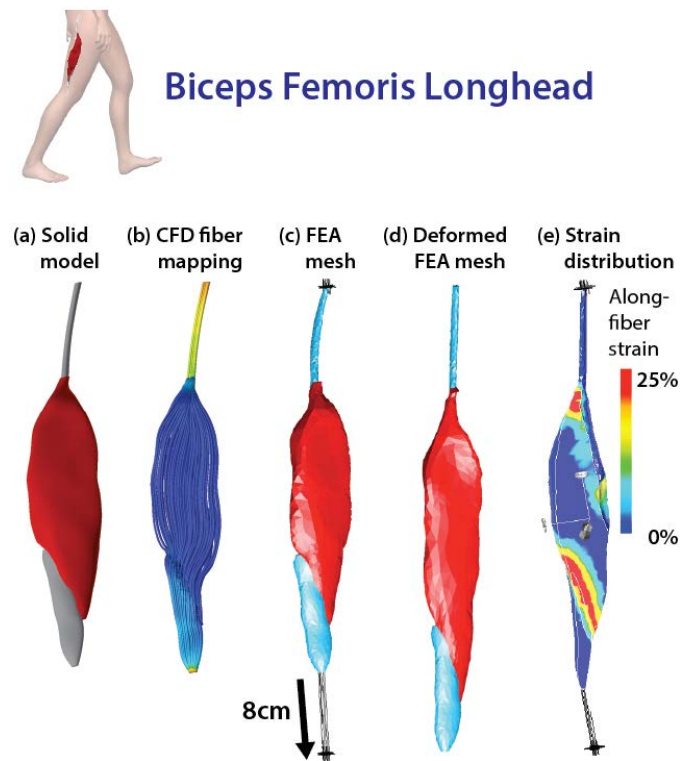
tendon strain energy function. We used material parameters for muscle and tendon from a previous study [1].


Figure 2: (a) MRI-based solid model of the biceps femoris longhead [2]. (b) Computational fluid dynamics determines the fiber directions for the transversely isotropic formulation [3]. (c) The solid was meshed automatically with enhanced 4-node tetrahedral elements and the distal tendon was displaced by 8cm. (d) The deformed mesh reaches full convergence. (e) Strain distributions within the muscle are non-uniform.

We created a 3D model of the biceps femoris longhead based on MRI data [2] (Figure 2a). We used used computational fluid dynamics to specify fascicle trajectories for the transversely isotropic material models [3] (Figure 2b). We used automatic tetrahedral meshing and simulated a long eccentric

contraction by ramping the muscle activation from 0 to 1 while displacing the distal tendon by 8cm (well above the stretch during sprinting of 5cm [4]) (Figure 2c).

RESULTS

The model was numerically stable using Sefea^{TM}, reaching full convergence (Figure 2d). The deformed model at a physiological 2cm displacement (approximately 40° of knee extension [2]) shows non-uniform strain distributions (Figure 2e). Non-uniform strain distributions have been shown characteristically in previous finite element studies of eccentric contraction [1,2,4].

DISCUSSION

Our new finite element modeling paradigm of explicit strain energy function specification within Sefea^{TM} significantly enhances numerical stability. Furthermore, it enables fully automatic meshing of biological tissues of arbitrary shape and complexity using 4-node tetrahedral elements. These elements are also stable in contact scenarios—typically not the case for non-linear elements. This new paradigm and technology will empower hyperelastic finite element studies of biological tissues that would be otherwise unfeasible.

ISOMETRIC SQUAT PEAK FORCE IN RANGE OF KNEE FLEXION ANGLES STRONGLY RELATED TO COUNTERMOVEMENT JUMP PEAK FORCE

Mitchell L. Stephenson, Harry Fisher, Kyle K. Graves, Taylour J. Hinshaw, and Boyi Dai

University of Wyoming, Laramie, WY, USA
email: mitch.stephenson@gmail.com, web: http://www.uwyo.edu/kandh/

INTRODUCTION

The one-repetition maximum (1RM) is considered the gold standard of dynamic peak strength, commonly used in squat competition and training. Due to the methodology, 1RM testing has a relatively large time requirement and poses injury risks to the athlete. In comparison, isometric squat (IS) testing has often been proposed as an alternative that would reduce the time requirement and risk to the athlete. While both performances are strongly related, IS testing was found to introduce error in the 1RM predictions [1].

Previous research has identified the importance of the specificity in testing when relating IS to squat 1RM, as the removal of the dynamic movement in IS testing only allows for the quantification of strength at a single knee flexion angle (KFA) of the 1RM range of motion [2]. A similar phenomenon should also exist when relating IS force testing to countermovement jump (CMJ) force output; as an athlete moves through a range of motion in a CMJ, testing a single angle in an isometric test may not best reflect CMJ peak force [3].

The purpose of the current study was to assess the relationship between isometric force output at a range of KFAs in a squat and the peak force during a CMJ. It was hypothesized that the force output at deeper KFAs in the IS would be positively correlated with the peak force output in the CMJ.

METHODS

Thirty-one physically-active, uninjured recreational athletes (sex: 14 males and 17 females; age: 20.2 ± 1.7 years; height: 1.73 ± 0.12 m; mass: 72.8 ± 17.7 kg) participated in the current experiment. Participants provided informed consent and then performed a warm-up protocol. Participants completed three trials of a countermovement jump task and then four maximal isometric squats. Vertical ground reaction force (GRF) data were collected by one FP4060 force plate (Bertec Corporation, OH, USA) sampling at 1600 Hz and subsequently filtered with a 100 Hz low-pass filter.

For the jump, participants stood with the testing leg on the force plate, performed a countermovement jump with an arm swing for maximum height and landed back in the initial position. Participants then performed an isometric squat (Figure 1) for maximal effort against a weighted squat rack while standing with the testing leg on the force plate in each of four external KFA ranges: 35-45º, 55-65, 75-85, and 95-105, set by manipulating the top catch pin of the rack and identified by 2D kinematics. Each isometric squat was performed for a total of 5 seconds, with a minimum of 3 minutes of rest between trials. The order of different isometric squats was randomized.

Pearson correlation tests were used to assess the relationship between the peak 1s average vertical GRF from the squat and the peak takeoff force in the CMJ with using SPSS v21 (IBM Corporation, Armonk, NY, USA) with a type I error rate of 0.05.

Figure 1. Isometric squat with different knee flexion

RESULTS AND DISCUSSION

Significant and strong correlations were found between the IS peak force and CMJ peak force in all IS KFAs (Table 1). The peak force at 80º KFA in the IS was most strongly correlated with the peak force in the CMJ.

The current results are consistent with previous research that has investigated fewer IS KFAs' relationship with a dynamic squat [2]. The current finding of the strongest correlation at 80º KFA is possibly explained by the proximity of this KFA to just above the "sticking region" in a squat and CMJ movement [4], as this may be related to the muscle stretch-shortening cycle and represent the critical performance instance in the CMJ.

The current results contrast with previous research investigating a similar relationship with an isometric leg press, in which the investigators did not find a significant relationship between isometric peak force at 90º knee flexion and jump performance [3]. This is possibly due to the necessity of specificity in testing similar postures between the movements [5] and a small sample size in the previous study [3]. Furthermore, as research [6] has indicated that squat depth, not barbell load, predominantly loads the knee, kinematic assessment of CMJ KFAs as they relate to peak force and IS peak force at specific KFAs may better illuminate the dynamic relationship between these variables and the value of IS performance in predicting CMJ kinetics and kinematics.

CONCLUSIONS

Strong, positive correlations were observed between IS peak force at a range of KFAs and CMJ peak force, with the IS peak force at 80º relating the strongest to CMJ peak force. This is possibly due to the relation of this KFA and the sticking point in the movement. The findings provide implications in using isometric squat for assessing jumping performance and lower extremity strength. Subsequent kinematic analysis of both the IS and CMJ is necessary for elucidating individual differences in this relationship and how it is associated with the maximum knee flexion angle during the CMJ.

It should be noted that the relationship between the investigated variables only accounts for 26-43% of the variability in performance, and as such utilizing one to predict the other may introduce error in estimation. As the IS does not allow for expression of other factors such as the utilization of muscle stretch-shortening cycle, muscle coordination, and differing motor control programs, it represents only one perspective of assessment.

INTRODUCTION

Tearing the anterior cruciate ligament (ACL) has been identified to be a significant threat to athletes, resulting in the implementation of intervention programs to counter the threat. However, most current programs are based on investigations with unrealistic research environments that do not reflect the dynamic nature of sport performance.

Previous investigations attempted to contend with this by introducing an unanticipated component in their protocols, resulting in increases of biomechanical factors associated with ACL loading [1]. But these investigations did not control the timing of the directional stimulus. Further research manipulated the timing of the stimulus in regards to landing, but found no difference in ACL loading factors between the unanticipated conditions [2]. It is possible that participants sacrificed performance to counter ACL loading [3].

As the previous research only investigated manipulating the timing of the stimulus 600ms to 400ms before landing [2] while evidence indicates lower extremity reactions can be significantly faster [4], the current research proposes to investigate the change in injury and performance kinetics when manipulating the timing of directional stimulus through a range of 0ms to 400ms.

METHODS

Thirteen physically-active, uninjured recreational athletes (sex: 11 males and 2 females; age: 20.6 ± 1.7 years; height: 1.77 ± 0.07 m; mass: 76.2 ± 11.7 kg) participated in the current experiment. Participants provided informed consent and then performed a warm-up protocol. They then performed a series of successful practice trials before 45 block-randomized recorded trials.

Participants jumped forward from a 30cm tall block, instrumented with a Bertec forceplate (FP4060-05-PT, Bertec Corporation, Columbus, OH, USA) sampling at 1000hz, landing bilaterally with the dominant foot on a second Bertec FP4060-10-2000 forceplate sampling at 1600hz. In a fluid motion, participants jumped forward and upon landing either performed a vertical jump for maximum height or a left/right jump at 90° for maximum distance depending on the directional stimulus.
Figure 1: Example of right lateral jump (posteriolateral perspective) and vertical jump (anteriolateral perspective).

The directional stimulus was presented by three LEDs mounted in front of the landing forceplate: Left and right yellow LEDs indicated their medial and lateral jumps relative to their dominant leg and a center red LED indicated the vertical jump. Stimuli were sent in one of four conditions: 1) anticipated (AN) condition, well before movement was initiated; 2) classically unanticipated (CU) condition, the moment the participant left the jump block; 3) timed unanticipated condition at 300ms (TU300) and 150ms (TU150) before landing; and 4) at the instant of landing (LA). Stimuli and timing were controlled via an Arduino Uno microcontroller (Smart Projects, Strambino, Ivrea, Italy) connected to the forceplates.

Participants performed three trials in each direction at each stimulus timing condition. Peak vertical landing force (FZ_{LA}) and peak vertical takeoff force (FZ_{TO}) were identified, averaged between the three trials, and normalized to bodyweight (BW). Contact

time (CT) was also extracted and averaged amongst the three trials. A one-way repeated measure analysis of variance was performed to analyze differences in dependent variables amongst the stimuli timing, with a Type I error rate of 0.05. Greenhouse-Gesier corrections were used for sphericity violations. Bonferroni-corrected pairwise comparisons were performed when significant main effects were detected.

RESULTS AND DISCUSSION

Results are presented in Table 1. Differences in FZ_{LA} and FZ_{TO} were found in the lateral jump condition, with stimuli presented at LA resulting in a larger FZ_{LA} than the other conditions and a smaller FZ_{TO} with stimuli presented at TU150 than AN and CU. These differences only in the lateral jump may be due to a unilateral reliance on the tested limb in this direction. Respectively, these results indicate a possible increase in ACL loading and decrease in performance. Significant differences in CT were found in all three jump directions, with LA resulting in a longer duration CT than all other stimuli timings.

No significant kinetic differences were found between the AN and CU conditions for any jump direction, contrasting with previous literature [2]. An increase in sample size may be necessary to better elucidate possible differences. Generally, FZ_{TO} decreased and CT increased as available time for reaction before landing was reduced via the stimulus timing. This implicates a reduction in performance as time for reaction is reduced. Further

research is necessary to determine whether performance was sacrificed to specifically reduce ACL loading, however.

Error in the exact timing of each stimulus was not quantified with the current statistical technique and the exact timing may better determine possible effects on the kinetic variables. Furthermore, the current results are limited to ground reaction force; kinematic analysis would provide a more holistic analysis when performed in conjunction.

CONCLUSIONS

Preliminary data from the current research indicates an increase in vertical landing force before a lateral jump when directional stimuli are presented at the instant of landing, as well as an increase in contact time for any directional jump as available time for reaction before landing decreases. This decrease in performance may be countered with reaction time training, but further research on the changes of combined kinetics and kinematics is necessary before intervention programs are implemented.

INTRODUCTION

Brachial plexus birth palsy (BPBP) is a peripheral nerve injury affecting about four in 1,000 births annually [1], leading to impaired function of the neonatal upper limb. The resulting denervation of muscles often causes gross morphological changes in surrounding bone structures, exacerbating limb impairment that is observed clinically [2]. Effects to bone due to altered musculoskeletal loading requires an in-depth understanding of changes in bone mineralization and microstructure in developing joints, which is currently not well understood. Examining changes in bone will provide clinicians with additional information to optimize treatment plans and minimize or circumvent onset of permanent shoulder deformity.

The purpose of this study was to determine whether changes in cancellous bone mineralization and microarchitecture of the proximal humerus occur with the altered musculoskeletal loading characteristic of BPBP injuries using a rat model.

METHODS

Sixteen male Sprague-Dawley rat pups were separated into two groups (*n*=8 each). Group 1 (neurectomy) underwent neurectomy of the left brachial plexus upper trunk, representative of the C5 and C6 nerve root injuries most commonly observed in clinical cases of BPBP [3]. Group 2 (sham) received a sham surgery including division of the left pectoralis major with no injury to the nerve. Surgical interventions were applied five days after birth and approved by the Institutional Animal Care and Use Committee. Animals were sacrificed eight weeks post-operatively, and the left (affected) and right (control) humeri were excised and imaged using micro-computed tomography (micro-CT) (SCANCO μCT 80). One animal from each group was excluded from analyses due to specimen damage following excision.

Micro-CT scans were reconstructed at a 10-μm isotropic voxel size, and a global threshold of 441 mg/cm^3 of calcium hydroxyapatite (HA) (3891 Hounsfield units, or HU) was applied. A region of interest (ROI) equal to 5% of the overall humeral length was selected in the proximal metaphysis immediately distal to the growth plate. The ROI was evaluated using the SCANCO proprietary software to assess tissue mineral density (TMD) and 3D trabecular thickness (Tb.Th), separation (Tb.Sp) and number (Tb.N), as well as trabecular connectivity and orientation. Two-tailed t-tests (α=0.05) were used to compare bone mineralization and microstructure between groups (SAS 9.4).

RESULTS AND DISCUSSION

The affected limbs in the neurectomy group experienced trabecular thinning with a tendency for reduced tissue mineral density relative to sham affected limbs (Fig. 1). Tb.Th was reduced by 12% (p=0.046) in the neurectomy group (Fig. 2).
Figure 1: Sagittal view of the proximal metaphyseal region (bottom half of the bone profile, separated from the top by the dark curvature representing the growth plate) shows reduced trabecular thickness with neurectomy (left) compared to sham (right).
Figure 2: Trabecular thickness decreased with neurectomy (white) versus sham (black).

Clinically, radiographic evidence of muscle atrophy in all rotator cuff muscles following BPBP injury has correlated with anterior humeral head subluxation and changes in glenoid shape [5]. Prior analyses using the same animals from our study showed postural (reduced external rotation) and osseous (glenoid declination, inferior humeral head translation) deformity of the glenohumeral joint for animals experiencing neurectomy. Deformity was significantly correlated with reduced optimal fiber length for muscles, including teres major and subscapularis, thereby simulating mechanical conditions capable of altering normal bone growth [4]. Other studies have also suggested that impairment to the longitudinal growth of muscles can induce postural constraints, causing increased passive forces of muscles crossing the glenohumeral joint [6].

In addition to gross changes in bone morphology, altered musculoskeletal loading with disuse has been associated with trabecular thinning in mice [7]. The present study suggests that altered mechanobiological effects on bone following peripheral nerve injury, compounded with the resulting changes in load transferred from paralyzed muscle to bone, may disrupt normal bone remodeling processes. We are currently examining bone cell activity in histologic sections from these humeri. Simulations of load distribution in cancellous bone have shown that changes in trabecular microarchitecture lead to reduced stiffness [8]. Likewise, changes in bone tissue mineralization represent significant alterations in cancellous bone tissue that are associated with large changes in bone elastic modulus and resistance to loading [9]. While not a direct indicator of bone strength, reduced bone mineral density has been associated with higher fracture risk clinically [10]. Currently, we are analyzing the right (control) humeri to assess trabecular differences between the unaffected (right) and affected (left) limbs in the same animal. Future computational and animal model studies are necessary to isolate the extent of changes in trabecular mineralization and microarchitecture associated with limited use of the affected limb alone and in the presence of denervated muscle. While the etiology of osseous deformity in BPBP remains unclear, understanding changes in bone microstructure resulting from injury may present a foundation for understanding the progression of deformity and offer targets for interventions and treatments.

Influence of Fatigue on Lower Extremity Biomechanical Variability during Forward Lunge

Amanda E. Stone, Diana M. Alonso, Kyle C. Norder, Austin C. Norden, Kaitlyn T. Girard, and Chris J. Hass

University of Florida, Gainesville, FL, USA
email: stonaman@ufl.edu; web: http://apk.hhp.ufl.edu/index.php/departments-centers/center-for-exercise-science-ces/applied-neuromechanics-laboratory/

INTRODUCTION

Soft tissue injuries to the knee stabilizers most often occur during landing and cutting types of activities where the knee flexes under eccentric control of the quadriceps muscles. Fatigue of the stabilizing muscles is also thought to contribute to an increased injury risk. Investigations implementing applied dynamic fatigue protocols have shown that high fatigue levels cause significant alterations in lower limb kinematics [1]. Additionally, changes in performance after fatigue may be attributed to alterations in force generation capacity, as well as changes in muscle coordination patterns [2]. Several studies argue that fatigue may be an integral component of some sports-related injuries [3, 4, 5]. During rehabilitation, lunge exercises are often used as a perceived safe exercise to train the muscles in a manner that mimics the lower extremity mechanics observed during sport-related injuries. It is unknown, however, how fatigue may affect the ability to safely perform lunge exercises. Thus, the purpose of this study was to investigate which, if any, biomechanical changes occur during a fatigued state when completing a forward lunge task.

METHODS

Eight healthy subjects (age 19 to 24 years) comprised of four males (age 21±2, weight 73±9 kg, height 177±8 cm) and four females (age 21±1, weight 56±4 kg, height 162±4 cm) were recruited to participate in this study. At the time of recruitment, all subjects were physically active as defined by at least 30 minutes of physical activity at least three times per week. Subjects were excluded from the study if they had any surgery to their back or lower extremity, or an injury within the last six months that limited their physical activity for more than three days. Subject were required to have previous experience performing a lunge.

Reflective markers were placed bilaterally over the lower extremities in accordance with the Vicon Plug-in Gait marker set. Three dimensional kinematics (eight camera Vicon Motion System, 120 Hz) and ground reaction forces (Bertec, 360 Hz) were collected while participants completed lunge repetitions until a maximum state of fatigue was reached; maximum fatigue was defined as a 9 out of 10 on the modified BORG rating of perceived exertion scale for two consecutive trials (Figure 1). The first and last two trials were used to analyze pre- and post-fatigue data. Three-dimensional kinematics were calculated for the lower extremity joints and angle variability was calculated at the hip, knee and ankle in the frontal plane using the root mean square error (Equation 1); this variable was chosen because it is a strong indicator of instability.

$$Variability = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(x_i - \bar{x}_i)^2} \tag{1}$$

Rating of Perceived Exertion (RPE)- Modified Borg Scale	
0	Rest
1	Really Easy
2	Easy
3	Moderate
4	Sort of Hard
5	Hard
6	
7	Really Hard
8	
9	Really Really Hard
10	Maximal effort

Figure 1. Modified BORG rating of perceived exertion scale.

Dependent samples t-tests were used to determine if behavioral changes were present in the dependent variables of interest between pre- and post-fatigue conditions (SPSS, $P \leq 0.05$).

RESULTS AND DISCUSSION

Results revealed an increase in variability in the frontal hip and ankle angles ($P=0.04$ and $P=0.02$, respectively), as well as decreased variability in the frontal knee angles ($P=0.03$) from pre- to post-fatigue when the non-dominant leg was forward (Table 1). Lower extremity kinematics and kinetics revealed no significant trends between pre- and post-fatigue for hip, knee, and ankle angles and moments.

Table 1. Mean ± SD of pre- and post-fatigue variability for hip, knee and ankle joints.

	Pre-Fatigue	Post-Fatigue	P
Variability (°)			
Frontal Hip	4.7 ± 1.6	5.6 ± 2.1	0.04*
Frontal Knee	12.2 ± 9.1	10.9 ± 8.5	0.03*
Frontal Ankle	3.1 ± 1	3.5 ± 1	0.02*

*Indicates trend between pre- and post-fatigue conditions, $P \leq 0.05$

Previous studies have suggested insufficient proprioception caused by muscle fatigue may increase postural instability [6]. Furthermore, hip and ankle fatigue have been specifically shown to decrease postural control [7]. Related to postural stability, joint angle variability is also affected by muscle fatigue and may be a contributing factor to increased injury in a fatigued state.

These findings demonstrate that certain biomechanics are compromised in a fatigued state while performing a forward lunge task. When ignored, these changes in variability could potentially lead to injury.

CONCLUSIONS

This study is one of few to investigate biomechanical changes due to muscle fatigue and is the first to provide an analytical comparison pre- and post-fatigue during a commonly used rehabilitation exercise, the forward lunge. Our findings have identified an increase in frontal hip and ankle angle variability, as well as a decrease in frontal knee angle variability, in the non-dominant leg during the lunge task. These changes in variability may be a target for rehabilitation interventions and future investigations to limit frontal angle variability in lower extremity joints and decrease the likelihood of sport-related injuries.

INTRODUCTION

Spinal fusion has been the gold standard for treatment of degenerative disc disease. Over the years, numerous surgical techniques and various implants (expandable versus non-expandable) have been developed to increase fusion rates and decrease operative and recovery time. The purpose of this study was to evaluate the stability of TLIF standard surgical technique and cage versus the PLIF surgical technique with expandable cage. Kinematics and endplate stresses will be recorded to evaluate which implant might better promote bone fusion.

METHODS

Six L23 (TLIF) and six L45 (PLIF) ligamentous functional spinal units (FSUs) were used for the study. The caudal end was fixed to the testing apparatus while pure moments up to 10 N*m were applied to the cranial end in extension (Ext), flexion (Flex), left (LB), and right (RB) lateral bending, and left (LR) and right (RR) axial rotation. Specimen motion was recorded using Optotrak motion capture (NDI, Waterloo, Canada). A previously validated whole spine model was used to obtain the necessary L23 and L45 segments for finite element analyses, wherin respective surgeries were simulated. TLIF simulation involved complete facetectomy and nucleotomy. PLIF simulation involved bilateral partial laminectomy and bilateral cage placement. In each surgical simulation, the disc space was distracted until the cage was in contact with both endplates, after which a 10 N*m pure moment was applied. Cadaveric and finite element range of motion results and endplate stresses were compared.

RESULTS AND DISCUSSION

Cadaveric results demonstrated standalone TLIF increased motion in extension, left and right bending, left and right rotations, and flexion with pre-load

(Fig. 1). Finite element analysis revealed that the TLIF group showed increased extension, flexion, left and right bending, extension with preload, and flexion with preload but decreased axial rotation. The PLIF group demonstrated decreased motion in all loading conditions (Fig. 2) as was further substantiated by finite element analysis. The differences in motion between cadaver and finite element motion are listed in Table 1.
Figure 1: TLIF range of motion results for cadaver and finite element model
Figure 2: PLIF range of motion results between cadaver and finite element model.

Motion	Ext	Flex	LB	RB	LR	RR	WP Ext	WP Flex
Cadaver TLIF	+21%	-8%	+13%	+9%	+20%	+27%	-20%	+14%
FEA TLIF	+33%	+20%	+15%	+19%	-30%	-37%	+45%	+14%
Cadaver PLIF	-36%	-70%	- 64%	-58%	-22%	-5%	-41%	-71%
FEA PLIF	-70%	-79%	-42%	-47%	-53%	-55%	-74%	-74%

Table 1: Table below shows the reduction in motion for all of the loading conditions between cadaver and finite element.

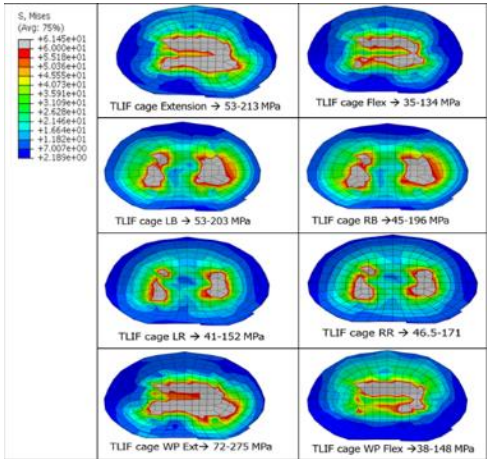
Differences in range of motion can be attributed to surgical technique and implant type. The TLIF approach required total facetectomy. As the facets, in conjunction with the capsular ligaments, are responsible for limiting motion in extension, left and right bending, and left and right axial rotation, performing the facetectomy altered the center of rotation for all loading conditions. The bilateral expandable cage placement has two advantages: endplate contact and fit. The cage can be expanded for proper fit with both endplates and provides a greater surface contact area.


Figure 3: Endplate stresses for TLIF group. Minimum and maximum stress reported were 35 MPa and 275 MPa respectively.
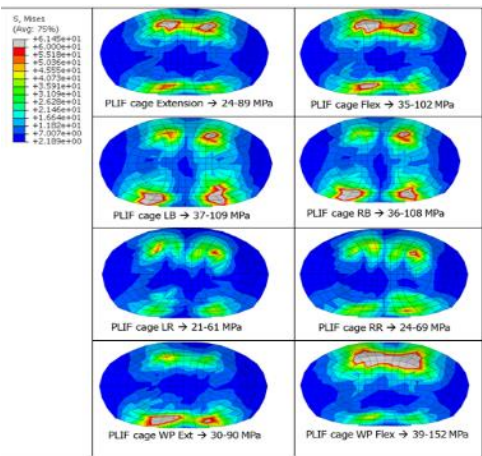

Figure 4: Endplate stresses for PLIF group. Minimum and maximum stress reported were 35 MPa and 275 MPa respectively.

The TLIF group (Fig. 3) demonstrated higher endplate stresses than the PLIF group (Fig. 4). The TLIF model yielded an average stress of 186.5 MPa as compared to 97.5 MPa in the PLIF model. Under higher stresses, bone growth is more likely occur. However, higher stresses may be problematic if the bone is osteoporotic; leading to cage subsidence

CONCLUSIONS
The results showed that the PLIF expandable cage stabilized the functional unit better than the non-expandable TLIF cage. Furthermore, the TLIF non-expandable cage demonstrated higher contact stresses than the expandable PLIF cage. Future work will focus on interrogating the pedicle screw system via a similar approach and on the effect of device contact footprints on the endplate stresses and load transfer.

MODELING OF HUMAN INTENT FOR CLASSIFICATION OF A WEIGHT LIFTING TASK

Deema Totah, Lauro Ojeda, Daniel Johnson, Deanna Gates, Emily Provost, Kira Barton

The University of Michigan, Ann Arbor, MI, USA
email: deema@umich.edu, web: http://brg.engin.umich.edu/

INTRODUCTION

Back injury is one of the leading causes of missed work days in the United States, with musculoskeletal disorders forming 33% of all reported work injury and illness cases in 2013 [1]. Lifting is known to be a major cause of these injuries and lifting belts are a common solution for their prevention. Research suggests, however, that these passive braces are biomechanically ineffective at unloading the lower back and merely serve as a reminder to the user to keep an upright posture [2].

To gain a better understanding of these injuries, researchers are using instrumented braces and wearable sensors to collect spinal motion data [3, 4]. Given the limitations of current braces however, robotic assistive devices and adaptive exoskeletons could provide more adequate biomechanical support through actuation and relieve some of the back muscle loading. In particular, the efficacy of these devices would be greatly improved if they are able to alter their level of supplied assistance in time to meet task-specific demands of the user (e.g. trunk motion alone vs with an external load). In order to integrate these devices with the user, better models of human intent must be developed. Human intent models that can recognize a task, and do so earlier, allow devices to have faster response times and more targeted control. In this work, we investigate whether phenomena indicative of anticipatory activity, occurring in muscles prior to loading [5, 6], can be used to predict a human's intent to lift a specific load. While the majority of research in this area investigates anticipatory activity in cases of sudden loading, our pilot study considered anticipatory activity during dynamic lifting of different loads.

METHODS
Figure 1: Experimental setup with subject lifiting 12-lbs dumbbells (left). EMG sensors (middle). IMU sensor attached to a soft brace around the upper-back (right).

A 33-year old, healthy male subject was recruited for this pilot study and all protocols were approved by the University of Michigan IRB. The subject was positioned in front of a table at hip height. Three pairs of objects were placed on the table (two 12-lbs dumbbells, two 2-lbs dumbbells, and two sticks with negligible weight), as shown in Figure 1. A display screen placed at eye level in front of the table informed the subject which pair of weights he should lift. During each task, which was paced according to audible and visual cues, the subject assumed a series of poses according to a specific sequence (see Figure 2): sagittal flexion of the trunk to 30° with arms hanging vertically, hand contact with the weights while holding the trunk stationary ("pre-onset" of loading), lifting of the weights to the shoulders while holding trunk stationary ("early-onset" and "post-onset" of loading), and extension of the trunk to a neutral erect posture with weights held at the shoulders. The sequence was then reversed, and the subject rested for 10 s. During each experimental session, the subject lifted each pair of weights thirty times (for a total of 90 lifts per session). The order of the weights was randomized. A total of six identical data collections were conducted over 6 days.

Muscle activity of the erector spinae and multifidi muscle groups was collected at 1kHz using four bipolar surface electromyography (sEMG)

Pre-onset	Early-onset	Post-onset
	Pre-onset	Early-onset	Post-onset
No weight	47.1%	88.2%	94.1%
2 lbs	35.3%	76.5%	76.5%
12 lbs	44.4%	100%	100%

Figure 2: Successful classification percentages for each weight class are shown for the three neural network models (before and after the onset of weight lifting).

electrodes (Ambu, Copenhagen, Denmark) placed on the subject's lower back at L3 level, with a single reference electrode placed over the right iliac crest. Additionally, motion was tracked using two inertial measurement units (IMUs) (Invensense Inc., Sunnyvale, CA) placed on the upper-back at the middle of the thoracic curvature and sampled at 150 Hz.

sEMG signals were filtered, rectified, and then run through a low-pass filter (4Hz cutoff frequency) to form linear envelopes. We then constructed three-layer neural network models for prediction (pre-onset) and classification (early and post-onset) of a given weight. The first layer consisted of varying time windows of EMG linear envelope data as an input to the network. The second layer contained half the number of units as the input layer. The output layer contained the three weight classes (no weight, 2-lbs, and 12-lbs).

The pre-onset prediction model used a 1-second EMG time window beginning 1 s before the subject lifted the weight from the table, ending at the transition to lifting (i.e. before the onset of lifting). The early-onset classification model used a 100-ms time window starting 300 ms after the onset of weight lifting. This time window was found to be the best window for early-onset identification by performing a 100-ms sweep across the first second of lifting. Finally, the third model, termed 'post-onset' classification, used a 1-second window after lifting was initiated. We leveraged the Matlab Neural Network Toolbox (Mathworks, Natick, MA) to construct the models. Data from three trial days were used to train the network, while data from one other day and two different days were used to validate and test the models, respectively. This created user-specific, inter-day models.

RESULTS AND DISCUSSION

The 'pre-onset' prediction model obtained 42.3% accuracy. The 'early-onset' classification model obtained 88.5% accuracy. The 'post-onset' classification model obtained 90.4% accuracy. Figure 2 shows success percentages for each weight case along with markers on the torso flexion angle curve showing the time windows of the input data for each model. The light weight class (2-lbs) resulted in the least accurate prediction or classification. Incorrect assignment of this class generally resulted in a classification of no weight.

CONCLUSIONS

This pilot study demonstrates that prediction from anticipatory muscle activity lacks accuracy; yet early load identification is possible with accuracy rates on par with a 'post-onset' classification model. Early-onset classification, achieved within the first 400ms of lifting, shows promise for developing smart assistive and rehabilitative devices with faster response times; a requirement for real-time, user-driven control. Future work should focus on early-onset prediction, as a potential identification model. Further work is needed to validate this model and generalize it with multiple subjects. Incorporating muscle fatigue effects would further improve the performance of this model.

INTRODUCTION

The research on the effects of matrix water on the fracture resistance of bone is accelerating [1]. This understanding may be central to improving fracture risk assessment. Water in bone exists in unbound state in the pore spaces or in the bound state to the matrix. Recently, we developed a custom designed short-wave infrared (SWIR) Raman spectroscopy to identify the bound and unbound water compartments of bone [2]. Using this novel technique, for the first time, we identified four peaks which associate with various water compartments in bone (Fig. 1). The current study investigated the relationship between various water compartments in bone and the mechanical properties. Distinguishing the contributions of various water compartments on bone's mechanical properties would help to further elucidate the function of water compartments on the bone fracture resistance.

METHODS

Mechanical properties: The cortical bone beams (N=30) with the dimension of 30 mm in length, 3 mm in width and 1.1 mm in thickness were subjected to three-point bending test under displacement control (1 mm/sec) to measure elastic modulus, maximum flexural strength, toughness and post-yield toughness (PYT).

Selective dehydration: Contributions of different water compartments were probed by a sequential dehydration process: 1) drying in ambient condition following by oven drying at 40 °C for 48 h, 2) partial replacement of remaining bound water by ethanol for 36 h followed by a vacuum treatment for

40 h to remove the remnant ethanol. Also, the water loss was recorded by using gravimetric analysis.
Figure 1: The breakdown of band intensities between bound water, unbound water and bone matrix (see reference for details[2]).

SWIR Raman spectroscopy: Raman spectra were collected immediately after each step of dehydration episode to record the reductions in OH-band intensities using our custom SWIR Raman system. All spectra were normalized to the protein related CH stretch band. Intensity ratios (I_{OH}/I_{CH}) of different OH peaks in the range of 3100-3800 cm^{-1} were qualified in terms of correlation with mechanical properties of bone.

Statistical analysis: Linear regression analyses were conducted to study associations between mechanical properties and Raman biomarkers. Statistical significance was set at $p < 0.05$ for the resulting R^2 value.

RESULTS AND DISCUSSION

Using the four peaks that we previously identified, we developed four new spectroscopic biomarkers: I_{3220}/I_{2949}, I_{3325}/I_{2949} and I_{3453}/I_{2949} reflect status of collagen-related water compartments and collagen portion of bone while I_{3584}/I_{2949} reflects status of mineral-related water compartments and mineral portion of bone (Figure 1). The overall results herein support the notion that there are different sorts of bound water compartments in bone and the bound water layer that was partially removed by ethanol treatment is the critical portion for bone mechanics since R^2 correlation coefficients between mechanical properties and spectroscopic biomarkers mostly peaked after oven dried and decreased after ethanol treatment. We found that two new biomarkers (I_{3220}/I_{2949} and I_{3325}/I_{2949}; $R^2=0.81$ and $R^2=0.79$, respectively) are appropriate predictors of bone toughness whereas the I_{3584}/I_{2949} had moderately strong positive correlation with strength ($R^2=0.46$) and strong negative correlation with the modulus ($R^2=0.78$), indicating this biomarker can be used to assess bone stiffness and strength.

CONCLUSIONS

As a complementary tool to assess bone fracture risk, Raman-based water measurement can potentially provide risk assessment because even in wet condition of bone (bone's natural condition), 37%, 45% and 39% of total variance of toughness, strength and stiffness, respectively can be explained independently from bone mineral density (BMD) and porosity.

For the first time, it was revealed that Raman-based water measurement has a strong correlation with mechanical integrity; therefore, this novel approach may help assess bone quality and improve the current diagnosis of those who may be at risk of bone fracture due to aging or disease.

INTRODUCTION

Raman spectroscopy has become a powerful tool in the assessment of bone quality. However, the use of Raman spectroscopy to assess collagen quality is less established than mineral quality. The only specific spectroscopic biomarker for collagen quality in bone is the ratio of underlying sub-bands of amide I region (1660/1690 cm^{-1}) corresponding to enzymatic collagen cross-links [1]; however, the validation of this ratio is still controversial [2]. Toughness and post-yield toughness (PYT) of bone are mostly determined by collagen rather than the mineral phase. Therefore, it is essential to identify new spectroscopic biomarkers which help infer the status of collagen quality in bone and other collagen-rich tissues. The first aim of this work was to identify the regions of amide bands in collagen to determine new spectroscopic biomarkers which are sensitive to denaturation. The second aim was to assess whether there is an association between the new spectroscopic biomarkers and toughness of cortical bone.
Figure 1: Changes in Raman peaks of pure collagen sheets due to the thermal denaturation.

MATERIALS AND METHODS

Sample set 1: Pure collagen sheets were prepared from bovine collagen type I solution at 37°C as the reference. Sheets were kept at 100 °C for 2 h to induce thermal denaturation. *Sample set 2:* Cortical bone wafers from bovine femur with V-notch were used in thermal and mechanical denaturation experiments (N=3 in each experimental group). *Sample set 3*: Cortical beams for three-point bending test (N=25) were used to assess the correlation between toughness and new spectral biomarkers. Thermal denaturation of bones was attained by boiling the samples in water for ~ 90 min. Mechanical denaturation was attained by loading notched bone wafers using a miniaturized tensile loading device to induce an extensive damage zone at the notch tip [3].

Raman spectra of pure collagen sheets were collected at 10 randomly selected points using a 785 nm Raman system (Xplora, Horiba). Raman mapping of each cortical bone wafer was conducted before (control) and after the denaturation (thermal or mechanical) on the same area of the notched region to investigate changes in target spectroscopic ratios due to denaturation. On three-point bending specimens, an average of 12 Raman spectra was collected in the vicinity of the region where tensile fracture occurred. Three notched bone wafers were utilized as negative controls from which spectra were collected in a similar time frame with mechanically loaded specimens, but without any mechanical loading. Spectral ratios of experimental groups were compared using one-way ANOVA followed by Tukey's post-hoc test. Linear regression analyses were also performed between Raman

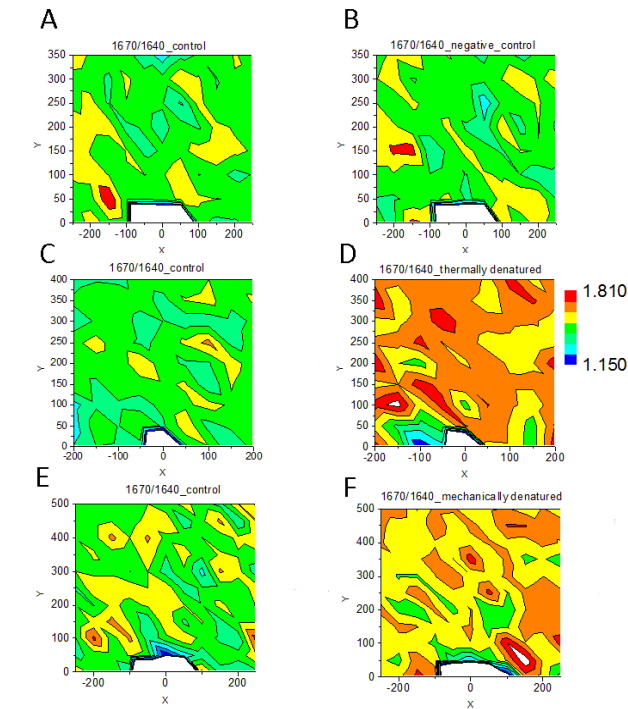
spectroscopic biomarkers and the mechanical properties. Statistical significance was set at p< 0.05


Figure 2: 2D Raman maps of bone wafers corresponding to 1670/1640 ratio. (A-C-E) Control samples before denaturation, and (B) negative control sample assessed secondarily without denaturation, (D) thermally and (F) mechanically denatured samples.

RESULTS AND DISCUSSION

Four intensity ratios were calculated using five peaks (Fig. 1) whose intensities were sensitive to thermal denaturation: 1670/1640, 1320/1454, 1245/1270 and 1245/1454. These ratios were significantly affected by thermal denaturation (p < 0.001 compared to pure collagen at 37 °C). Raman analysis of negative controls revealed that there were no significant differences in Raman spectral markers (p>0.05) (Fig. 2A-B).

Table 1: R^2 pairwise correlations between mechanical Properties and Raman biomarkers

Linear Regression Analyses (R^2)	Raman Analysis			
	1670/1640	1245/1454	1245/1270	1320/1454
Toughness	0.38 p<0.001	NS	NS	NS
PYT	0.54 p<0.001	0.22 p<0.05	NS	0.22 p<0.05

NS = not significant

The results of thermal and mechanical denaturation experiments of cortical bone wafers showed that all these four ratios to be sensitive to both thermal and mechanical denaturation in cortical bone samples (Fig. 2C-F). The cumulative result showed the 1670/1640 peak intensity ratio as a novel biomarker to assess collagen quality (Table 1). The changes in this ratio with denaturation may reflect alterations in the collagen secondary structures, specifically a transition from ordered to unordered structure since the Raman study of collagen type I indicated that the peak at ~1640 cm^{-1} is associated with ordered (triple helix or α-helix) structure whereas ~1670 cm^{-1} is associated with random/unordered structure [4]. So far, the literature utilized the ratio of ~1245/1454 ratio based on FTIR studies. However, current results indicate that 1245/1454 ratio have a weak correlation with PYT and no correlation with toughness (Table 1).

CONCLUSIONS

To the best of our knowledge, the current work is among the first thorough analysis of the Raman amide bands in terms of providing spectroscopic manifestations of collagen integrity and bone toughness. These new spectral information can be used to understand the involvement of collagen quality in the fragility of aging and in diseased bone.

SHORTER HEELS ARE ASSOCIATED WITH STIFFER PLANTARFLEXOR TENDONS

Herman van Werkhoven, Daniel Lidstone, and Jeffrey M. McBride

Appalachian State University, Boone, NC, USA
email: vanwerkhovenh@appstate.edu

INTRODUCTION

The foot and ankle plays an important role in many activities. Understanding how foot and ankle anthropometry affect ankle musculoskeletal properties allows us to better understand the capabilities of the musculature to successfully perform motor tasks. Previous research have shown that ankle plantarflexor moment arm, or heel length as external estimate of plantarflexor moment arm, is negatively correlated with running economy [1]. Furthermore, it has been shown that sprinters have shorter plantarflexor moment arms compared to controls [2]. Results from these studies suggest that heel length influences the biomechanics associated with better performance in different tasks. Apart from the relationship between heel length and certain performance criteria, it is also reasonable to consider potential relationships between heel length and other musculoskeletal properties of the ankle muscles. Heel length affects the force transmitted by the plantarflexor muscles, as joint moment is a product of muscle force and muscle moment arm. The internal muscle-tendon unit (MTU) therefore experiences different forces dependent on properties associated with the heel length.

Recently, [3] showed that subjects with better running economy have shorter heels and that heel lengths were associated with an external measure of dynamic stiffness. In this study, stiffness was calculated by dividing peak force produced during a straight leg vertical jump by the distance covered during the jump. It is unclear whether a similar association exists between heel length and more direct measures of muscle-tendon unit stiffness. The purpose of this study was to investigate the relationship between heel length and tendon stiffness. We hypothesized that heel length would be negatively correlated with tendon stiffness.

METHODS

Ten healthy male subjects participated in this study. Subjects' height, weight and foot length was recorded. Photographic images were taken of their feet from which heel length (average horizontal distance from lateral and medial malleolus to back of heel), as well as first toe length were calculated.

Subject performed three isometric maximal voluntary contractions (MVC) while standing with a stationary rigid bar across their shoulders and their knees straight. The balls of the subjects' feet where placed on a wooden block and the block was situated on top of a force plate. Isometric maximal voluntary plantarflexor force (MVPF) was estimated by multiplying MVC ground reaction force by ankle gear ratio (forefoot length divided by heel length).

Tendon stiffness was estimated using the free oscillation method [4]. Subjects stood with a bar resting on their shoulders. The bar was able to rotate freely about an axis at the same height as the shoulders. Subjects were instructed to remain in a stationary position without moving as a medicine ball was dropped onto the bar on their shoulders. The impact caused measurable ground reaction force oscillation, similar to a spring–damper system experiencing damped oscillations. The medicine ball drop was repeated over several trials. Spring–damper model parameters were estimated using a least-square curve fitting method. System stiffness was converted to a single-leg MTU-specific tendon stiffness by taking ankle gear ratio into account.

Correlation analyses were performed between heel length and tendon stiffness, tendon stiffness and MVPF, as well as MVPF and other anthropometric measures.

RESULTS AND DISCUSSION

Results showed a significant negative correction between heel length and tendon stiffness (Figure 1, r = -0.76, p = 0.011). Tendon stiffness was positively correlated with MVPF (Figure 2, r = 0.75, p = 0.012). MVPF was not significantly correlate with any of the other anthropometric measures (Table 1)

Table 1: Correlations between MVPF and anthopometric measures – no significant correlations

measure	r	p-value
body mass	0.24	0.50
height	0.33	0.35
toe length	0.13	0.72
heel length	-0.32	0.37
Figure 1: Heel length vs. tendon stiffness. A significant negative correlation was observed.
Figure 2: Tendon stiffness vs MVPF. A significant positive correlation was observed ($p < 0.05$).

Previous research have shown the potential link between tendon stiffness and force production, as sprinters appear to have stiffer tendons [5]. The researchers hypothesized that that larger forces might cause adaptations to the tendon allowing it to perform at lower strain values for a given force, reducing the risk of tendon damage [5]. For a specified joint moment related to a given task,

shorter heels would also cause larger plantarflexor forces. It could be expected that the tendon adaptations that would occur due to higher forces might similarly reduce the likelihood of tendon damage. A potential link between heel length and tendon damage should be further investigated. Previous studies have shown that more efficient distance runners have shorter heels [1], which given the current findings suggests stiffer tendons. It has also been suggested that muscle stiffness is associated with better running economy [6].

Further analysis of muscle and tendon stiffness, potentially using more direct stiffness measures, such as the ultrasound technique, could give further insight into the relationship between MTU stiffness and anthropometric measures, and their association with performance and injury.

RELATIONSHIP BETWEEN ACL GRAFT GEOMETRY AND TIBIOFEMORAL KINEMATICS

[1] Michael F. Vignos, [1]Jarred Kaiser, [1]Geoffrey S. Baer, [1]Richard Kijowski, [1]Darryl G. Thelen,

email: mvignos@wisc.edu, web: http://uwnmbl.engr.wisc.edu/

INTRODUCTION

ACL reconstruction (ACL-r) surgeries are normally successful at restoring knee stability. However, >50% of reconstructed knees exhibit osteoarthritis at long-term follow-up [1]. One theory is that ACL-r is unable to restore normal knee mechanics, resulting in abnormal cartilage loading that leads to tissue degeneration [2]. Indeed, studies have shown bilateral differences in ACL-r knee kinematics, with greater external tibia rotation and progressive anterior tibia translation observed in downhill running [3]. It is important to assess how ACL graft placement may contribute to such asymmetries.

Studies investigating the relationship between graft geometry and knee mechanics have taken two main approaches. The first approach is cadaveric studies. One such study found that anterior femoral attachment location was correlated with anterior tibia translation [4]. However, cadaver studies are inherently limited by an inability to consider functional loading scenarios. A second approach is to bilaterally compare joint level mechanics in ACL-r subjects during locomotion. With this approach, Scanlan et al. found that ACL graft orientation in the frontal plane was negatively correlated with the knee extensor moment [5]. However, the net knee moment is inherently influenced by many factors including knee structure, neuromuscular coordination and movement patterns. Hence, it may be preferable to study links between ACL-r geometry and knee kinematics using simpler tasks.

In this study, we used static and dynamic MR imaging to investigate the relationship between ACL-r graft geometry and tibiofemoral kinematics during an isolated knee flexion-extension task. We hypothesized that graft orientation would be the best predictor of bilateral differences in anterior tibia translation and external rotation.

METHODS

We tested eight subjects that underwent a primary unilateral, isolated ACL-r (4 F, 25.8±4.9 yrs, 86.3±18.2 kg, 2.3±0.6 yrs post-surgery, 5 patellar tendon grafts, 1 partial lateral meniscectomy). Bilateral MR images of the knee were collected using a 3D SPGR sequence (0.37x0.37x0.90 mm resolution) and a 3D FSE Cube sequence (0.31 mm isotropic resolution). We manually segmented femur, tibia, and ACL geometries for both the reconstructed and contralateral knees. We then measured the area and location of the ACL attachments, and the orientation of the ACL relative to the tibia plateau in the sagittal and frontal planes (Fig 1). We computed the bilateral difference for each metric by subtracting the contralateral value from the reconstructed.
Figure 1: Geometry measurements shown on a representative non-ACL-r knee. (α) Sagittal plane angle, (β) frontal plane angle, (a) anterior-posterior and (b) medial-lateral tibia attachment, and (c) anterior-posterior and (d) cranio-caudal femur attachment.

Each subject then lied supine in the MR scanner with their lower leg secured to a loading device. Subjects performed cyclic knee flexion against an inertial load at 0.5 Hz, which induced quadriceps loading with knee flexion. Subjects continuously performed this task for 5 min. while SPGR-VIPR images were collected for both knees [6].

Six degree of freedom tibiofemoral kinematics were measured using model-based tracking [6]. The metrics computed were the tibiofemoral translations

and rotations at peak flexion angle, as well as translation and rotation ranges over a motion cycle. Bilateral differences in kinematic metrics were computed for each subject. We then computed the correlation between the bilateral difference in ACL geometry metrics and the bilateral difference in kinematic metrics. Significance was set at $p<0.05$.

RESULTS AND DISCUSSION

We found that bilateral differences in kinematics were most significantly correlated to differences in the sagittal plane ACL orientation (Table 1). At peak knee flexion, an increase in the sagittal plane ACL orientation was positively correlated with anterior and medial tibia translation and internal tibia rotation. Sagittal plane orientation was also correlated with internal tibia rotation range of motion over a motion cycle (Fig 2). These results suggest that an ACL graft that is oriented more vertically than the native ACL may be associated with greater anterior-posterior and rotational laxity, such that the quadriceps induce greater anterior tibia translation and internal rotation with contraction.

We also found that bilateral differences in the femoral attachment area was negatively correlated with anterior tibia translation and internal tibia rotation. A bigger femoral footprint may reflect a larger graft cross-section, and hence greater resistance to anterior tibia translation and rotation.

The initial results in this study suggest that ACL geometry may be predictive of knee kinematic behavior under simple *in vivo* loading conditions. However, increased subject numbers are needed to assess the robustness of the relationships observed. Further analysis is also needed to consider potential multifactorial interactions between graft types, geometry metrics and kinematics.

BICEPS BRACHII AND BRACHIALIS CROSS-SECTIONAL AREAS ARE MAJOR DETERMINANTS OF MUSCLE MOMENT ARMS

INTRODUCTION

Changes in strength are often attributed to changes in muscle morphology and architecture [1-4], in addition to neural adaptations [5]. However, changes in muscle moment arm (MA) as a result of hypertrophy are less described. Sugisaki, et al. [6], Akagi, et al. [7], and Akagi, et al. [8] described the positive correlation between muscle cross-sectional area (CSA) and muscle MA, and Sugisaki, et al. [9] noted a small increase in triceps brachii moment arm following hypertrophy. Therefore, the purpose of this paper is to develop a two-dimensional mathematical model to describe how changes in muscle architecture of the biceps brachii (BIC) and brachialis (BRA) may influence the MA of each muscle.

METHODS

A position-elbow flexor anatomical CSA (ACSA) hyperbolic cosine regression equation was extrapolated from West, et al. [10], wherein an MRI was taken with the elbow in extension and a neutral radioulnar joint position.

The radius of the proximal elbow flexors was assumed to be the average of the muscle group's force vector field. A coefficient was applied to all equations to represent the degree of hypertrophy (or atrophy) from baseline, which assumes uniform growth.

A tangent line was calculated to represent the distal BIC and BRA tendons, which originated from the distal-most section of each muscle belly. Because the original hyperbolic cosine regression equation was representative of both the BIC and BRA, it was assumed that both muscles had equal ACSAs, and that the BIC lay directly superficial to the BRA. Previous research has described the similar sizes of the BIC and BRA [3].

The muscle belly of the BIC was set to begin 1.1 cm proximal to the joint center in order to control for insertion point, which was fixed 4.51 cm distal to the axis of rotation (capitulum). This was assumed to be about where the center of the insertion site is, as the capitulum has a 10.6 mm radius [11], the bicipital tuberosity is 25 mm distal from the radial head, and the insertion site is 22 mm long [12].

The muscle belly of the BRA was set to begin 0.69 cm proximal to the joint center in order to control for insertion point, which was fixed 3.17 cm distal to the axis of rotation (trochlea). Like the BIC, it was assumed that this was the center of the insertion site, as the trochlea has a 7.5 mm radius [13], the coronoid process is about 11.0 mm from the trochlea, and the insertion site is about 26.3 mm long [14].

The joint center of the elbow was represented by the origin (0,0), and the perpendicular distance from the tendon to the joint center was then calculated as the MA.

RESULTS AND DISCUSSION

The hyperbolic cosine regression equation showed a strong correlation with the length-ACSA relationship described by West, et al. [10] ($p < 0.001$; $r = 0.911$). The calculated MAs of the BIC and BRA were within previously reported ranges [15] (Figure 1).
Figure 1: Relationship between biceps brachii anatomical cross-sectional area and muscle moment arm. Negatively sloped lines are normal BIC MAs, and positively sloped lines are normal BRA MAs [15].

To the authors' knowledge, this is the first model to describe the effects of muscle hypertrophy on MA length, which demonstrated remarkable changes in MA of the BIC and BRA with increases in ACSA. Previous research has only attributed increases in torque production to the effects of hypertrophy on muscle force [2, 3], while ignoring potential changes in MA, as described by our model.

Intuitively, this change in MA is a function of the change in insertion angle, as the insertion point cannot shift. This increase in insertion angle occurs when the size of the muscle belly increases, thus shifting the muscle's resultant vector further from the humerus and joint center (Figure 2).
Figure 2: Illustration of the changes in BIC and BRA MAs with increases in ACSA.

The modeled change in MA is proportional to the square root of the change in ACSA ($\Delta MA \propto \sqrt{\Delta ACSA}$). Coincidentally, a similar relationship was observed by Sugisaki, et al. [9], wherein a 33.6% increase in triceps brachii ACSA was accompanied by a 5.5% increase in MA, although the authors did not note this mathematical relationship. More training studies are warranted to examine both the validity of this model and the hypothesis that changes in BIC and BRA MAs are proportional to the square root of changes in ACSA.

INTRODUCTION

Multidirectional instability can result due to multiple factors like the increased retroversion, a hypoplastic posteroinferior rim, and decreased scapular abduction during arm elevation [1]. Biomechanical studies are often used to understand the changes in the shoulder biomechanics [1-4]. During a biomechanical study setup misalignment of the scapula can occur leading to anterior or posterior tilt, which is rotation around the glenoid height (superior-inferior axis) as shown in Figure1. In past only one study has investigated the effect of scapular inclination [1-4]. However, to our knowledge there is no other study that has evaluated the influence of scapular misalignment/tilt. This study aimed to understand the relationship between glenoid tilt/misalignment and glenohumeral joint stability. We hypothesized that the shoulder stability would not change with variation in very small variations of glenoid tilt.

METHODS

Eight fresh-frozen cadaveric specimens were tested using a custom dislocation simulator. The specimens were thawed overnight and dissected before experimentation. All experiments were performed at glenohumeral abduction angle of 60°and 0° external rotation. After potting the scapula in a rectangular box, a line was drawn on glenoid from superior to inferior aspect of the glenoid. This line represented the height of the glenoid and was determined by using circumcircles. After the glenoid superior-inferior aspect was aligned parallel to the Y-axis of the simulator, it

was then verified using a microscibe digitizer. However, the accuracy of a microscribe is 0.3mm, so we chose a 3° tilt for both anterior (red) and posterior (blue), because it represented three standard deviation of the error ("d") that can occur as shown in Figure 1.
Figure 1: Different orientations of the glenoid fossa tilt, black shows the normal tilt at 0°, red glenoid shows the 3° anterior tilt, and the blue glenoid is the 3° posterior tilt evaluated in this study, d represents the two st.dev of error that occurred on each side.

Distance to dislocation and stability ratio was the primary measurement for every trial. Each experiment comprised of translating the glenoid in a posterior direction to cause an anterior dislocation. Firstly, experiment was performed in the right orientation verified by a microscribe shown as black. Then, both an anterior or posterior tilt was performed at 3° in a randomized manner. A centering medial load of 50N was applied on the humeral head, which was kept constant throughout each trial. This compressive load simulated the

static load of soft tissue that was removed for this study. Translational distance of the glenoid and medial-lateral displacement of the humeral head, along with horizontal reaction force were recorded for every trial. Repeated measures analysis of variance (ANOVA) was performed with statistical significance set at $p < 0.05$.

RESULTS AND DISCUSSION

The distance to dislocation for each specimen was determined as the point at which the tangential reaction force was zero. The distance to dislocation was similar at all three orientations. The results from ANOVA showed no effect on distance to dislocation for change in glenoid orientation (Table I). Similarly, the results for reaction force and stability ratio had same mean values. The stability ratio for normal, 3° anterior, and 3° posterior tilt were 0.25 ± 0.07, 0.24 ± 0.07, and 0.25 ± 0.07, respectively. Change in tilt or glenoid orientation mismatch did not affect any measured variable.

To our knowledge no study has evaluated the effect of glenoid tilt. The present study demonstrated that the small mismatch in the glenoid alignment (tilt) did not affect the shoulder stability in terms of both translation and stability ratio. These findings were in agreement with our hypothesis. This study examined the sensitivity of the scapula alignment during potting process for a biomechanical experiment. In conclusion, a digitizer device like microscribe can be used to verify the scapula potting.

CONCLUSIONS

This study demonstrated that very small variation in glenoid tilt does not affect the stability of shoulder.

MINIMAL EFFECT OF COMPRESSIVE LOADING ON THE GLENOHUMERAL JOINT STABILITY RATIO

INTRODUCTION

Anterior dislocation accounts for approximately 98% of all shoulder dislocations [1]. Most common pathologies associated with shoulder dysfunction include rotator cuff tears, labaral tears, and bony pathology [2]. Many biomechanical studies and computational studies are often conducted to investigate the changes in shoulder instability due to either bone defects or surgical repair [3-6]. Many cadaveric studies of shoulder instability use stability ratio (peak horizontal force/compressive load) as an outcome measure [4-7]. It is critical for readers to compare and understand results among different studies. However, many of these studies used different axial load for the compressive force [3-7]. This variation in compressive load sometimes poses a challenge to compare force or stability ratio results across past studies. The aim of the present study was to investigate if the stability ratio changes with variation of compressive force. We hypothesized that the shoulder stability ratio would not be affected with increasing compressive force.

METHODS

Eighteen fresh-frozen cadaveric specimens were tested using our custom dislocation simulator. The specimens were thawed overnight and dissected before experimentation. All experiments were performed at glenohumeral abduction angle (ABD) of 60° and 0° external rotation (ER). Each experiment comprised of translating the glenoid in a posterior direction in order to perform an anterior dislocation. Four different medial loads of 50N, 100N, 150, and 200N were applied on the humeral head and were kept constant throughout the trial. These forces were randomized for each specimen. This compressive load simulated the static load of soft tissue that was removed for this study. Translational distance of the glenoid and medial-lateral displacement of the humeral head, along with horizontal (tangential) reaction force were recorded for every trial. Stability ratio is calculated as the ratio of horizontal reaction force to compressive load. Every specimen was tested in an intact condition. One-way repeated measures analysis of variance ANOVA was performed at a significance level of $p < 0.05$ along with post-hoc Tukey HSD test.

RESULTS AND DISCUSSION

The relationship between the compressive force and stability ratio for all shoulders is shown in Figure 1. The repeated measures ANOVA revealed that the force had a significant effect on the stability ratio ($p < 0.001$). Stability ratio decreased significantly for 150N ($p < 0.05$) force and 200N force ($p < 0.05$). The average slope obtained from linear regression for all specimens was -0.00017 ± 0.00017. R square value for the fit was 0.57.
Figure 1: Relationship of stability ratio and compressive force for four different loading cases (50N, 100N, 150N, and 200N), * signifies significant difference from 50N with p<0.05.

This is the first study to show the effect of different compressive loading on the stability ratio of the glenohumeral joint. The important finding of the present study is that the increasing compressive force after 100N leads to significantly reduced values of the stability ratio. Lippit et al. [7] also showed the decrease in stability ratio in their study, even though these authors were measuring the effect of concavity depth in their study. This decrease in stability ratio shows that stability is reduced in terms of concavity compression after the compressive force surpass 100 N; however the decrease is so small that it should not cause any instability. Moreover, it will be a safe assumption to compare the results for stability ratio across different studies, if the compressive force used in those study were between the ranges of 50-200N.

CONCLUSIONS

The results from this study establishes that the effect of compressive force is minimal on stability ratio, however the stability ratio decreases contrary to the assumption of increasing stability with increasing force.

Effect of Musculoskeletal Model Choice on Muscle Activations During Landing, Running, and Lateral Cutting

Kevin C. Fontenot, Stacie I. Ringleb, and Joshua T. Weinhandl
email: jweinhan@odu.edu

INTRODUCTION

OpenSim is a platform for analyzing and understanding the effects of human locomotion mechanics through musculoskeletal modeling [1]. The three musculotendon models implemented in OpenSim 3.1 are the Thelen2003 (THE) [2], Millard Acceleration (ACC), and Millard Equilibrium (EQU) [3] models. The Hill-type model was used as the foundation for the models; however, each model utilizes a different approach for computing outputs. It remains unclear how predicted model activations between models vary for different tasks (i.e. landing, cutting, etc…). It is important to provide validation of models during tasks via surface electromyography (sEMG). The purpose of this study was to compare THE, ACC, and EQU musculotendon model activations to sEMG for landing, running, and lateral cutting. It was hypothesized that the Millard EQU model would be the best predictor of sEMG excitations and that the ability for all models to predict muscle excitation would decrease with task complexity.

METHODS

One healthy female (age 19 yr, height 1.63 m, and mass 65.08 kg) volunteered to participate. Data were collected synchronously using an 8 camera Vicon (Oxford Metrics, Oxford, England) motion analysis system (200 Hz), Bertec (Bertec Corporation, Columbus, Ohio) force plate (2000 Hz), and 7 Delsys (Delsys Incorporated, Natick, Maryland) surface electrodes (2000 Hz). Retro-reflective markers were placed bilaterally on anatomical landmarks [4], sEMG electrodes were placed on the vastus lateralis (VL), rectus femoris (RF), vastus medialis (VM), lateral and medial hamstrings (LH and MH respectively), medial gastrocnemius (MG), and tibialis anterior (TA). Electrode placements were confirmed by inspecting muscle excitations while conducting manual muscle tests.

For a single leg landing task the subject was instructed to cross their arms and fall from a box equivalent to their maximum jumping height, land with the dominant leg, return to an upright stance, and hold the landing for approximately one second. Running consisted of moving in a straight line at a speed of 4.5±0.2 m/s. The lateral cutting maneuver required the subject to run in a straight line at a speed of 4.5±0.2 m/s, plant the dominant foot on the force plate, and cut at a 45° angle. Five successful trials were completed for all tasks.

Kinematic and kinetic data were output using Visual 3D (v5.00, C-Motion Incorporated, Rockville, MD). Custom MatLab (MATLAB, Natick, MA) software was used to determine the initial weighting factors for each trial prior to input into a residual reduction algorithm (RRA) [4]. Kinematic and kinetic RMS residuals from RRA were compared to acceptable ranges as suggested by OpenSim before input into computed muscle control (CMC). A modified gait2392 model was utilized. Each model was implemented in CMC for every trial of each task to obtain muscle activations.

Model activations and sEMG excitations were time normalized to 101 data points defined as initial contact to maximum knee flexion for single leg landing and initial contact to toe off for running and lateral cutting. Activation and excitation data were normalized to the peak value of all trials for the respective task and averaged. Root-mean-squared difference (RMSD) was calculated between sEMG excitations and the OpenSim output activations.
Figure 1: RMSD values of the muscles for THE, ACC, and EQU during a single leg landing.
Figure 2: RMSD values of the muscles for THE, ACC, and EQU for running.
Figure 3: RMSD values of the muscles for THE, ACC, and EQU for lateral cutting.

RESULTS AND DISCUSSION

Model activations followed sEMG excitation patterns during all tasks for all models. During a single leg landing RMSD is lowest (RMSD ≤ 0.26)

in the VL, VM, MH, and MG (Figure 1). The ACC model displayed the greatest RMSD values for all muscles except the RF when running (Figure 2). During lateral cutting THE model displayed the lowest RMSD values for all muscles except the RF (Figure 3).

The purpose of the study was to compare the THE, EQU, and ACC musculotendon models; included in OpenSim, to sEMG during a single leg landing, running, and lateral cutting. Although model activations followed sEMG excitation patterns, THE model consistently produced lower RMSD values. An increase in task complexity did correspond to an increase in RMSD values for all models.

Limitations to the study include sample size. One subject was utilized and the study could be stronger with the incorporation of a more diverse population. The use of a one degree of freedom knee reduced model ability to accurately predict muscle activation. A three degree of freedom knee may better predict sEMG [5]. Tasks in the current study were anticipated resulting in pre-excitation. Constraining model activations to sEMG initial contact excitation may increase model accuracy.

Increasing task dynamics reduces model ability to predict sEMG excitation. THE displayed activation patterns which followed sEMG excitation with a lower RMSD than EQU and ACC models. Future research should consider constraining initial contact activation and incorporating a three degree of freedom knee. It is also strongly suggested that model type be reported in order to better understand how different models predict excitation patterns.

The Effects of Squat Depth on Right Leg Kinematics and Kinetics

Zachary A. Sievert, Stacie I. Ringleb, Laura C. Hill & Joshua T. Weinhandl

Old Dominion University, Norfolk, VA, USA
email: zsiev001@odu.edu

INTRODUCTION

The need to increase lower extremity power, strength and coordination can be found in many resistance training programs from Olympic athletes to the everyday exercise enthusiast. Traditionally the squat exercise is performed at four different depths: 45˚ of knee flexion (partial), 90˚ of knee flexion (normal), thighs parallel to the floor (parallel), and >120° of knee flexion (deep) [1]. There is a debate in the literature with regards to the optimal knee flexion angle during the squat exercise and how much loading is placed on the lower extremity throughout the various knee angles [1,2,3]. To help determine the optimal knee angle, the effect of squat depth on joint kinematics, moments, muscle activations, and ligamentous loading should be investigated. First, the kinetic and kinematic parameters of the squat exercise at various squat depths should be analyzed.

It is imperative to examine the differences in three dimensional joint kinetics and kinematics between normal and deep squats at bodyweight (BW), 50% one repetition maximum (1RM) and 80% 1RM. It was hypothesized that there would be significant increases in three dimensional peak joint moments about the right knee, hip and ankle during deep squats compared to the normal squats. This study had three hypotheses: 1) there would be significant increases in three dimensional joint moments about the right knee, hip and ankle as load increased; 2) there would be increases in all joint angles during deep squats compared to normal squats; and 3) as external load increased all joint angles would increase as well.

METHODS

Seventeen individuals participated in this study (age: 22.8±1.88 yrs, height: 1.69±0.06 m, mass: 73.5±12.72 kg). All participants were recreationally active, free of injury within the last six months and had no history of lower extremity surgery. Prior to data collection, participants provided written informed consent in accordance with institutional guidelines. The study was conducted over two testing days separated by no more than seven days in-between. On the first day of testing subjects reported to the laboratory for 1 repetition maximum (1 RM) [4].

On the second day of testing, the participants wore spandex shorts, a sports bra or form fitting shirt if applicable, and lab shoes. Eighteen retro reflective markers were placed bilaterally on anatomical landmarks [5]. Once the anatomical markers were placed on the skin, tracking plates with four markers were attached to the back, pelvis, bilateral thighs, shanks and shoes via elastic Velcro straps (McDavid, Woodridge, IL, USA). Three-dimensional marker coordinate data were collected at 200 Hz using an eight-camera motion analysis system (Vicon, Centennial, CO). All force data were collected at 2000 Hz using two Bertec force plates (Bertec Co., Columbus, OH).

When the participant was adequately warmed up they performed normal squats (90 ±10 ^{o}) with zero load (NBW), as well as at 50% 1RM (N50), 80% 1RM (N80). They also performed deep squats (120±10 ^{o}) with the same loads (DBW, D50, D80). Five repetitions were performed for each condition with 2-4 minutes of rest between conditions. The order of squat condition, normal and deep squats, was counterbalanced between participants. The order of loads, however, was the same for each participant.

Once all data were collected, a kinematic model was created in Visual 3D (v5.00, C-Motion Inc., Rockville, MD) for each participant from the standing calibration trial that consisted of eight segments: a trunk, pelvis, right and left thigh, right and left shank and right and left feet [5]. Marker data and ground reaction force data were filtered with a low-pass fourth order Butterworth zero lag filter with 12 Hz and 50 Hz cut off frequencies, respectively. 3D ankle, knee, and hip angles were calculated using a joint coordinate system approach [6]. After joint angles were estimated three-dimensional joint kinetics were calculated using a Newton-Euler approach [7] with body segment parameters estimated from De Leva (1996) and reported in the distal segment reference frame [8].

To analyze the data, separate two by three (condition (normal and deep) by load (BW, 50%, and 80%)) repeated measures ANOVA were conducted for each of the dependent variables. If two-way interactions were found, *post hoc* pairwise comparisons were conducted with a Bonferroni correction. Significance for all statistical analyses was set at $p < 0.05$.

RESULTS AND DISCUSSION

A weight*condition significant interaction was identified for knee internal rotation angle (p=0.05) (Table 2). Post hoc analyses revealed significant differences between NBW-DBW, N50-D50, and N80-D80 (p<0.001). No other joint angle had significant interaction of weight*condition. The only significant main effect for weight was observed in knee adduction angle (p<0.001), as weight increased knee adduction angle increased. It was also found that there was a significant main effect for condition across all joint angles.

A significant interaction was identified for peak hip extension moment (p=0.001) in which post hoc analyses revealed that all load and depth combinations were significantly different (p<0.001) (Figure 1). A significant interaction was identified for peak knee extension moment (p=0.043). All load and depth combinations were significantly different (p≤0.003) except for the NBW-DBW, N50-D50 comparisons. Significant main effects for weight and condition were identified for peak hip external rotation, knee external rotation, and plantarflexion moments (p≤0.001). Knee adduction moments were shown to have a main effect for the condition (p=0.001) but not for weight (p=0.080).

With regard to joint kinetics, hip extension moments were significantly different at each condition. The increased hip extension moments between normal and deep squat agrees with previous literature [1, 2] and may be explained by the observed increase in hip flexion as squat depth increased as this may place a greater demand on the hip extensors to return the body to an upright position. The increased demand would require increased force production from the hip extensors which would result in increased hip extension moments.

The interaction of the knee extensor moments may be explained by the increased demand the increased external resistance would place on the knee extensors to help return the body to an upright position. The increased depth would result in larger range of motion which may increase the joint moment as the demand increased to return the body to its resting upright position.
Figure 1. Mean Hip (top) and Knee (bottom) extension moments ($Nm·kg^{-1}·m^{-1}$) during 90˚ and deep squats at BW, 50% 1RM, and 80% 1RM.

CONCLUSIONS

From this examination of squatting mechanics it is apparent that there are many intricate components that differentiate normal and deep squats. Results of the current study indicate that there are significant changes in 3D lower extremity joint moments and angles as squat depth changes, and as external load increases. Further research is needed to determine if the increased joint loading exhibited during deep squats is harmful to the passive structures of the joints.

INTRODUCTION

Knee abduction moment (KAM), internal tibial rotation moment (ITR), and anterior tibial shear (ATS) all increase ACL strain, and are reportedly influenced by both modifiable and non-modifiable factors.[1] In recent literature, high medial and lateral tibial plateau slope (MTPS and LTPS, respectively) have gained attention as potential risk factors for noncontact ACL injury.[2] It is unclear whether non-modifiable factors preclude the efficacy of neuromuscular training (NMT) in ACL-reconstructed subjects. The purpose of this study was to determine the relationship(s) between provocative external knee loading and select modifiable and non-modifiable risk factors. We hypothesized that ITR and ATS would be significantly associated with non-modifiable factors, while KAM would be most strongly related to modifiable factors.

METHODS

Eleven ACL-reconstructed subjects were evaluated one year after surgery (7 male, 4 female, 20.5 ± 6.9 years old, 53.3 ± 1.27 weeks post-op). Another group of six subjects (4 male, 2 female, 23.5 ± 10.9 years old) were evaluated prior to and after participation in NMT (31.0 ± 6.5 and 45.0 ± 9.3 weeks post-operative, respectively). Instrumented knee laxity, medial and lateral tibial plateau slope (MTPS and LTPS, respectively), isokinetic quadriceps and hamstrings strength, and three-dimensional motion analysis during drop vertical jump were assessed.

Separate general linear mixed models were created to determine the effects of modifiable and non-modifiable factors on peak KAM, ITR, and ATS, and body-mass normalized values for these variables. Initial models included sex, MTPS, LTPS, LTPS:MTPS ratio, HQ ratios at 60 degrees per second (HQ_{60}) and 300 degrees per second (HQ_{300}), peak hip abduction moment, and peak vertical ground reaction force (vGRF) as predictors. Body-mass normalized values for vGRF and peak hip abduction moment were used in prediction models for body-mass normalized outcome variables. Only data from the uninvolved limb were utilized in the linear regression models. Models were finalized in an iterative fashion. Predictors with p-values below 0.2 from the first iteration were included in the second model. Variables in the second model with p-values below 0.1 were included in the third iteration. Final models for each variable were developed based only on predictors that demonstrated statistical significance at an alpha level of 0.05.

RESULTS AND DISCUSSION

For peak ATS, male sex (p=0.007) and MTPS (p=0.0226) accounted for 40% of the variance ($R^2=0.422$, p=0.0037; **Figure 1a**). LTPS accounted for approximately 30% of the variance in peak KAM ($R^2=0.29$, p=0.0051; **Figure 1b**). 80% of the variance in ITR was accounted for by combined measures of laxity (p=0.0023), MTPS (p<0.0001), LTPS (p=0.0142) and peak hip abduction moment (p<0.0001; $R^2=0.78$, p<0.0001) (**Figure 1c**). *Post-hoc* power analyses revealed greater than 80% power for all models.

The multivariate predictive models for peak internal tibial rotation moment and body mass-normalized peak internal tibial rotation moment were the strongest in this study. While the final models for this variable contained the most predictors of any outcome variable, the generalized linear mixed model for net ITR demonstrated an extremely large effect size of 4.55. This model accounted for nearly 80% of the variance in ITR, and a *post-hoc* assessment demonstrated that the
Figure 1: Relationship between model predictions and actual values for peak anterior tibial shear force (a), peak knee abduction moment (b), and peak internal tibial rotation moment (c).

four-predictor model was valid with over 99% statistical power at an alpha level of 0.05.

McLean et al. reported significant associations of MTPS and LTPS to knee kinematics and kinetics in all three planes of motion in active females.[3] Their results showed that LTPS could explain 60.9% of the variance in the inverse-kinetically calculated ATS. Furthermore, they reported that tibial and femoral geometry accounted for 75.4% of the variance in knee abduction angle, and nearly half of the variance in peak tibial internal rotation angle.[3] Further investigation is needed to determine the effect tibial geometry has on knee abduction and how much that relationship is affected by neuromuscular control strategy.

CONCLUSIONS

LTPS and MTPS predicted relatively small proportions of the variance in KAM and ATS, respectively. Non-modifiable factors accounted for a greater portion of the variance in ITR, though hip abduction moment, a modifiable variable, was also a strong predictor. Despite a relationship with non-modifiable risk factors, KAM, ITR, and ATS are modifiable and may be reduced through NMT in ACL-reconstructed subjects.

Risk of reinjury to the reconstructed limb, or injury to the contralateral limb is anywhere from five-to-twenty fold greater than risk of initial injury.[4] Recently-emerging literature indicates that the likelihood for second injury to occur on the non-reconstructed limb is greater than on the reconstructed limb.[4] The cohort utilized in this study represents a small, heterogeneous sample of ACL-reconstructed subjects. We are also limited by the fact that a handful of these subjects were measured both prior to and after participation in a neuromuscular training protocol. The rationale behind this approach was to utilize all subjects and time points for which we had data on all of our outcome and predictor variables. The relationships delineated by these preliminary models will need to be confirmed through analysis in an independent data set.

PROTECTIVE HIP AND KNEE KINEMATICS DURING UNILATERAL AND BILATERAL LANDINGS AFTER NEUROMUSCULAR TRAINING IN ACL-RECONSTRUCTED SUBJECTS

INTRODUCTION

Anterior cruciate ligament (ACL) injury leads to significant reductions in patient function, and biomechanical asymmetries that frequently persist for two years or longer after ACL-reconstruction. [1] Recent reports indicate that as many as one in four ACL-reconstructed patients will suffer a second ACL injury to either the affected or contralateral limb within their first year of return to sport. [2] Furthermore, patients who suffer a second injury have significantly poorer short-to-long term outcomes.

Hip, knee, and ankle kinematics are critical modifiable factors that affect ACL injury risk. Previous research indicates that landing with the hip and knee near full extension, and reaching lower levels of peak hip and knee flexion increase the likelihood for injury. In addition, stiffer landings transmit greater forces and torques through the joints, and likely contribute to increased injury risk. Neuromuscular training (NMT) protocols that target high-risk biomechanics and impairments in neuromotor control effectively reduce rates of primary ACL injury. [3] Furthermore, subjects that participate in these training protocols demonstrate a number of associated improvements in functional biomechanical control. [4] Despite success in large, prospective analyses of healthy athletes, few studies have investigated the impact of NMT on functional biomechanics in ACL-reconstructed subjects. The goal of this study was to quantify lower extremity kinematics during unilateral and bilateral landing in ACL-reconstructed subjects prior to and after participation in NMT.

METHODS

Twenty-one (9 males, 12 females, 20.2±7.3 years old) ACL-reconstructed subjects who were recently discharged from supervised physical therapy participated in this study (37.1±17.2 weeks post-operative). Subjects underwent two biomechanical testing sessions: One prior to participation in a twelve (12) session NMT program (Pre-test), and one after training (Post-test). Biomechanical testing consisted of 3D motion analysis using a 12 camera motion analysis system with marker data sampled at 240 frames per second. Subjects were outfitted with fifty-five (55) retro-reflective markers in a modified Helen Hayes configuration.

Subjects performed three successful trials of a bilateral drop vertical jump (DVJ) task, and a single leg drop landing (SLD) task off a 30.5 cm box in the motion capture volume. Knee, hip, and ankle angles in all three planes were averaged over the three trials. The NMT protocol consisted of twelve (12) training sessions. The program consists of biomechanical feedback from a certified trainer, and a multi-phase progression of task difficulty. The program is described in detail by Di Stasi et al. [5]

Discrete values for maximum and minimum angles, alignment at initial contact (IC), and joint excursions in all three planes were calculated and utilized for statistical analyses using 2x2 (limb-by-session) repeated measures analysis of variance (ANOVA). *Post-hoc* t-tests were used to determine differences between limbs and effects of training.

RESULTS AND DISCUSSION

Nineteen (19) of the 21 subjects performed the DVJ task at both biomechanics sessions. Twenty (20) of the 21 subjects performed the SLD task at both the sessions.

Hip Kinematics: Subjects demonstrated greater hip flexion at IC on the involved limb compared to the uninvolved limb during both tasks (DVJ: INV: 33.9±9.4 deg, UNIN: 31.5±10.1 deg; p=0.006), (SLD: INV: 26.2±5.8 deg, UNIN: 21.9±6.3 deg; p<0.001). After training, peak hip flexion during SLD increased (Pre-Test: 50.1±12.0 deg, Post-Test: 55.4±10.5 deg; p=0.02), as did hip flexion

excursion (Pre-Test: 26.3±8.6 deg, Post-Test: 30.9±9.1 deg; p=0.02). Subjects also demonstrated a strong trend toward decreased hip frontal plane excursion (Pre-Test: 17.1±6.0 deg, Post-Test: 15.4±4.8 deg; p=0.056).

Knee Kinematics: Knee flexion at IC after training increased for both tasks (DVJ: Pre-Test: -17.1±7.2 deg, Post-Test: -23.9±8.9 deg; p=0.001, SLD: Pre-Test: -9.4±4.8 deg, Post-Test: -11.8±5.7 deg; p=0.014). Peak knee flexion increased significantly after training for the SLD task (Pre-Test: -60.6±10.8 deg, Post-Test: -66.3±8.4 deg; p=0.006), and demonstrated a similar, but statistically insignificant trend during the DVJ task (Pre-Test: -88.0±11.0 deg, Post-Test: -93.1±12.2 deg; p=0.077). During the SLD task, subjects also demonstrated increased knee flexion excursion after training (Pre-Test: 51.1±9.6 deg, Post-Test: 54.5±8.67 deg; p=0.036).

Ankle Kinematics: Subjects demonstrated a decrease in ankle plantar flexion at IC during the DVJ (Pre-Test: -46.1±7.7 deg, Post-Test: -40.2±8.5 deg; p<0.001) and the SLD tasks (Pre-Test: -54.6±7.8 deg, Post-Test: -48.7±12.6 deg; p<0.001). Ankle flexion excursion also decreased after training for DVJ (Pre-Test: 51.6±8.4 deg, Post-Test: 46.0±8.7 deg; p<0.001) and SLD (Pre-Test: 49.8±8.4 deg, Post-Test: 46.6±6.5 deg; p=0.01).

This study demonstrates that the primary kinematic effects of NMT after ACL-reconstruction occur in the sagittal plane. Unpublished pilot data from our group demonstrates that the reported Post-Test hip and knee flexion values for peak and IC are likely greater than those of untrained ACL-reconstructed subjects at one year post-operative. Importantly, the tasks performed during the biomechanics sessions were not the same as the tasks performed during training. Thus, the biomechanical feedback provided to subjects during training appears to carry over into other landing tasks to which the subjects may not be accustomed.

Approximately 70% of ACL injuries occur via a non-contact mechanism, and are most frequently characterized by near full extension of the knee and hip at the time of IC. [6] Landing with the hip and knee in greater initial flexion, reaching deeper peak flexion, and exhibiting greater sagittal plane excursion are all likely protective of the native ACL and/or graft. [7]

While NMT did not affect coronal or transverse plane landing mechanics, the standard physical therapy regimen for ACL-reconstructed subjects at Ohio State, where most subjects performed their formal rehabilitation, is highly focused on controlled landing mechanics. At the time of Pre-Test, the patients in this study, on average, landed with their knees in slight adduction at IC for DVJ (INV: 1.9±3.4 degrees, UNIN: 1.6±2.0 degrees) and exhibited low values for peak knee abduction (INV:-2.2±3.6 degrees, UNIN: -1.98±3.3 degrees). Similar values were observed after training, and for the SLD task. These are representative of generally low-risk frontal plane mechanics, thus our cohort may not exhibit the frontal and transverse-plane control issues commonly observed in ACL-reconstructed subjects.

CONCLUSIONS

ACL-reconstructed subjects who participate in NMT after completion of formal rehabilitation exhibit ACL-protective adaptations in sagittal plane kinematics at the hip and knee during unilateral and bilateral landing tasks. The effects of NMT in ACL-reconstructed subjects as they pertain to second injury rates and joint kinetics will be investigated further and training programs should be optimized to maximize safe return to sport.

LACK OF ASSOCIATION BETWEEN SUBJECTIVE AND OBJECTIVE ASSESSMENT OF SPINAL STIFFNESS

INTRODUCTION

Spinal stiffness (SS) is routinely assessed by clinicians and utilized for clinical decision making [1]. However, manual assessment of SS has demonstrated poor reliability [2], likely due to the subjective nature of this procedure. Koppenhaver et al. reported that subjective rating of SS using manual assessment at L3 was uncorrelated with objectively assessed SS using an automated indenter [3]. The purpose of this study was to evaluate subjective SS ratings using 3 objective SS assessments: a clinician's palm with optical marker and force plate measurement, an instrumented hand-held probe, and an automated indenter.

METHODS

This was an observational study nested within a clinical trial on low back pain patients undergoing chiropractic spinal manipulative therapy (SMT). The local institutional review board approved the study protocol [4] and all participants signed a written informed consent document.

We performed 1 subjective and 3 objective assessments of lumbar spine SS before SMT delivery during the first treatment visit. For the subjective procedure, the clinician's impression of SS in the region directly under the assessing hand was rated using the following classifications: rigid (no joint motion), hypomobile (abnormally limited joint motion), normal, or hypermobile (greater than normal motion), for each of 5 lumbar segments.

We next performed 3 sequential objective SS assessment methods (Fig. 1). These methods included applying force in the posterior-to-anterior direction over lumbar spinous processes using the clinician's palm (P), an instrumented hand-held probe (I), and an automated indenter (A). The applied force was monitored using a force plate during P and a load cell during I and A. Displacement was monitored using an optical motion capture system during P and I and a linear variable differential transformer during A. P and I were performed over each of 5 lumbar segments while A was conducted only over the spinous process at or closest to the most anterior point of lumbar curvature. Details of these methods can be found in the study protocol [4].
Figure 1: Illustration of skin marks for spinous processes from L1-L5 (A) and 3 types of objective spinal stiffness assessment methods using the clinician's palm (B), an instrumented hand-held probe (C), or an automated indenter (D).

The SS value was calculated from the force-displacement curve using linear regression over the force range of 10 – 60 N. Each objective SS was classified according to the subjective ratings for each

of 5 lumbar segment levels (L1-L5). Mean objective SS differences compared with subjective SS ratings are reported with 95% confidence intervals.

RESULTS AND DISCUSSION

82 participants were enrolled with 39 (48%) as females, mean (SD) age of 44.9 (10.6) years, and a moderate mean pain intensity of 46.1 (18.1) on the visual analog scale (0-100) at baseline. Table 1 summarizes the mean differences between the subjective ratings for each of the 3 objective SS assessments according to the lumbar spine levels. Very few observations were classified as hypermobile or rigid, thus they are not presented. The magnitudes of all the mean differences are small and all 95% confidence intervals span 0.

There are a few limitations in the current study. The P method used a larger surface contact area than I or A measures causing paraspinal soft tissue compression that was not measured. Breathing instructions differed for the P, I, and A methods. The subjective and palm methods assessed stiffness at slightly different angles over different segments, whereas the automated and instrumented stiffness compressed at angles perpendicular to the examination table. Clinically or biomechanically meaningful magnitude of difference in spinal stiffness is currently unknown making it difficult to interpret measurement variability.

CONCLUSIONS

The results from the current study for A at L3 support the observations made by Koppenhaver et al. [3]. We performed two additional types of objective assessments at all five lumbar segment levels, but did not find evidence of a relationship with subjective SS ratings. Therefore, we conclude that these results have added support to the original work of Koppenhaver in showing that a subjective measures of stiffness do not correlate to other objective measures of stiffness. This work adds to a growing body of evidence that subjective methods of assessing spinal stiffness have important limitations.

A COMPARISON OF TWO SUPERFICIAL MCL RECONSTRUCTION INCLUDIING SINGLE-BUNDLE ANTERIOR CRUCIATE LIGAMENT (ACL) RECONSTRUCTION

[2] Zhu J, [1] Dong J, [2]Marshall B, [1] Linde-Rosen M, [1, 2] Smolinski P and, [1] Fu FH

[1] Department of Orthopedic Surgery, University of Pittsburgh, Pittsburgh, PA
[2] Department of Mechanical Engineering and Material Science, University of Pittsburgh, PA

INTRODUCTION

Anterior cruciate ligament (ACL) and medial collateral ligament (MCL) are the most commonly injured ligaments in the knee, which serves as the primary medial stabilizer to anterior translation and valgus stress [1]. It is not uncommon for superficial medial collateral ligament (sMCL) damage to occur with ACL injury. While conservative treatment of the MCL injury is often done, in cases of severe injury, reconstruction of the sMCL can be done in addition to the ACL reconstruction. There are two MCL reconstructions (parallel and tri-vector) in clinic. But we don't know which technique can better restore the biomechanics of the intact knee. The objective of the study was to compare knee biomechanics of two sMCL reconstructions combined with single-bundle ACL reconstruction using a porcine model.

METHODS

Twenty (n=20) fresh frozen unpaired adult pig knees were used for biomechanical testing. Specimens with a congenital abnormality or arthritis were excluded from the study and the existence of an intact ACL was confirmed arthroscopically. All specimens were frozen at -20 C^0, and thawed the night before testing at room temperature. The knees were kept intact and the specimens were kept moist with physiologic saline solution. The tibia and femur were sectioned ~15 cm from the joint line and the ends of femur and tibia were potted in heavyweight epoxy putty.
The specimens were divided into two groups, tested with the robotic testing system (CASPAR Orto MAQUET, Germany) under (1) an 89-N anterior tibial (AT) load at 30° (porcine full extension), 60°, and 90° of knee flexion, (2) 4-Nm internal and external tibial torques at 30° and 60°, and (3) a 7-Nm valgus torque at 30° and 60° of knee flexion [2, 3].

The groups were divided into either parallel or tri-vector group sMCL reconstruction and both groups had single bundle ACL reconstructions. The ACL reconstructions were performed with a 7 mm graft which was fixed with 60 N at 30° of flexion. The sMCL reconstructions were performed with 6 mm grafts and fixed with 44 N at 30° of flexion. The ACL reconstructions were done arthroscopically in an anatomic fashion with hamstring grafts and graft fixation was done with a screw and washer on the tibia and an extra-cortical button on the femur.

Differences in anterior tibial translation (ATT) displacement, internal / external rotation angles, and in situ forces at the different flexion angles where analyzed using one-way ANOVA with repeated measures, and statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

With ACL MCL co-injuries, ACL reconstruction alone can't restored ATT, valgus, internal or external rotation result. With ACL and two different sMCL reconstructions, no significant differences were found between two groups for ATT at 30° flexion, and both method restored intact knee biomechanics. At 60° and 90° of flexion, MCL tri-vector reconstruction can restore the ATT, while parallel MCL reconstruction cannot improve the ATT (Fig.1a). Under valgus loading, ACL reconstruction alone did not restore intact knee stability, the parallel sMCL reconstruction did restore stability while the tri-vector method did not (Fig.1b). Under the external tibial torque, parallel sMCL reconstruction does restore external rotation while tri-vector sMCL reconstruction does not restore (Fig. 1c). Under the internal tibial torque, both sMCL reconstruction techniques restored intact knee internal rotation (Fig. 1d).

Figure 1: Results comparison of displacement and rotation between two sMCL reconstructions (Tri-vector and Parallel) combined with single-bundle ACL reconstruction a) ATT; b) valgus; c) internal rotation; d) external rotation

THE RELATIONSHIP BETWEEN ARCH HEIGHT AND ARCH FLEXIBILITY

[1] Becky Zifchock, [1] Christal Theriot, [2] Howard Hillstrom, [3] Jinsup Song, and [1] Michael Neary

INTRODUCTION

Previous literature suggests that there is a relationship between foot structure and injury patterns [1]. The correlation between arch structure and injury may be related to the fact that foot structure influences its function. Several studies have considered both arch height and arch flexibility to be a defining characteristic of foot structure. In their recent study of high-arched runners, Williams et al [2] found varying levels of arch flexibility, which led to differing lower-extremity movement patterns and loading.

It is often assumed that high arches tend to be stiffer, while low arches tend to be more flexible. However, recent literature suggests that arch height does not necessarily dictate arch flexibility [2]. Therefore, the purpose of this study is to use a proposed arch stiffness classification system to categorize both the arch height and arch flexibility of individuals' feet and determine the tendency for certain arch height types to cluster toward certain arch flexibility types. Based on the assumption that high arches are stiffer while low arches are more flexible, a different distribution of arch flexibility types was expected for each of the arch height categories.

METHODS

Volunteers were drawn from pool of incoming military cadets, of whom 1124 agreed to participate in this study. All procedures were reviewed and approved by the Institutional Review Board, and all subjects gave informed consent prior to participation in the study. After the removal of erroneous data, a total of 1056 subjects, 882 men and 174 women, were included in the study (18.4

±1.4 years, 1.76 ±0.80 m, 76.1 ±12.7 kgs). The right foot was characterized for each participant: Arch height index was measured using the Arch Height Index Measurement System, and arch height index (AHI) was calculated [3]:

$$AHI = \frac{Dorsal\ Height_{50\%\ Total\ Foot\ Length}}{Truncated\ Foot\ Length}$$

Arch flexibility, (AHF) was defined as the change in arch height (distance from the dorsal surface to the ground) from sitting to standing due to the change in load borne by the arch during these activities [3]:

$$AHF = \frac{AH_{sitting} - AH_{standing}}{0.4\ x\ BW} \times 100\ [m/kN]$$

The data were then used to create a classification scheme for AHF. Due to the skewness of the AHF data, the median value was established and a system of quintiles was used to classify five AHF categories: Very Stiff, Moderately Stiff, Average, Moderately Flexible, and Very Flexible.

The distribution of AHF types was then compared amongst AHI categories. This was accomplished by identifying the number of individuals of AHF type in each AHI category. AHF type was based upon the classification system proposed in this paper, and AHI category was based upon previous cutoff values for cavus, rectus, and planus proposed by Hillstrom et al. [4]. The distribution was compared using a Chi-Square Test of Goodness of Fit.

RESULTS AND DISCUSSION

The classification scheme based upon the quintiles is shown in Table 1. The median AHF value was 14.75 mm/kN. Of the 1056 feet, an approximately equal distribution (range = 210 – 212 feet/category)

were classified in each of the five AHF types. For the AHI categorization, 68 feet were classified as cavus, 225 were classified as rectus, and 763 were classified as planus. The test of goodness-of-fit suggested that, amongst AHI types, there were a significantly disproportional number of feet that were classified in each of the AHF categories ($p <$ 0.01). As shown in Figure 1, the largest proportion of cavus feet was very stiff, and the smallest proportion was very flexible. This was also true of the feet in the rectus arch height category; although a large portion of the rectus feet also demonstrated neutral arch flexibility. Conversely, the largest proportion of planus feet was very flexible, and the smallest proportion was very stiff. The planus group demonstrated a very obvious step-wise increase in the proportion of individuals in each category from very stiff to very flexible. However the distribution of AHF categories within the cavus and rectus feet is less defined.
Figure 1: Distribution of arch flexibility types amongst arch height categories

The purpose of this study was to expand our understanding of arch flexibility as a measure of foot structure. From this study, we proposed a five-category classification scheme for arch flexibility.

It is important to note that the classification scheme proposed in the current study is based upon a population of healthy men and women between 18 to 25 years. Future studies should be carried out to determine whether the classification scheme can be applied to children, older adults, or a pathological population.

Despite the skew towards planus feet enrolled in the study, the results supported the hypothesis: there was a significantly different distribution of the arch flexibility types between arch height types. Specifically, the planus feet were much more likely to be very flexible, while the cavus and rectus feet were more likely to be stiffer. This relationship was most evident for the two extreme arch flexibility categories (very stiff and very flexible).

CONCLUSIONS

The results of the current research supports the common belief that cavus feet tend to be very stiff, while planus feet tend to be very flexible. However, the results of this study also demonstrate that there was a distribution of arch flexibility types amongst the arch height types. Therefore, at least two foot classification methods are useful to fully characterize foot structure.

Table 1: Proposed cutoff values for arch flexibility categories and distribution of feet (n = 1056) amongst arch flexibility and arch height categories

Arch Flexibility Category			Number of Feet		
	Quintile	Cutoff Value, mm/kN	Cavus	Rectus	Planus
Very Stiff	0 – 20%	AHF < 9.91	22	56	133
Stiff	20 – 40%	9.91 ≤ AHF < 13.54	17	51	142
Neutral	40 – 60%	13.54 ≤ AHF < 16.00	8	52	153
Flexible	60 – 80%	16.00 ≤ AHF < 20.54	15	32	164
Very Flexible	80 – 100%	AHF > 20.54	6	34	171

Long-range correlations of center of pressure are stronger for AP perturbations than ML perturbations in healthy young adults

[1]Venkata Naga Pradeep Ambati, [1]Troy Rand, [1]James Nielsen, [1]Mukul Mukherjee

Biomechanics Research Building, University of Nebraska, Omaha, NE, USA
email: vambati@unomaha.edu, web: http://cobre.unomaha.edu/

INTRODUCTION

Control of center of pressure in anterior-posterior and medial-lateral directions use different mechanisms [1]. This is because recovering stability requires activation of different joints in different directions [1]. Biological signals like COP have a fractal structure with long-range correlations (LRCs) such that postural sway at one point of time are related to postural sway at another point in time [2]. Recent studies have shown that the LRC of a healthy system can be driven towards a specific direction by administering a sensory input with the desired temporal structure [3, 4]. Hence we used signals with different temporal structures to perturb the support surface in AP and ML directions and examined the LRCs of resultant COP patterns. Due to the difference in the alignment of body segments and forces required to control stability in AP versus ML, we expected that LRCs for COP in AP perturbations will be greater than the LRCs for COP in ML perturbations. In addition to this, we also hypothesized that the root mean square (RMS) for COP during AP translations will be greater than RMS for COP during ML translations.
We also expected that LRCs and RMS for COP in response to different noise signals would be different because a healthy system shows flexibility in its responses to sensory input signals of varying temporal structures [3].

METHODS

10 healthy young adults stood in a side-by-side stance on a force platform that was subjected to translations in the AP and ML directions (figure 1). There were five separate translation conditions in each direction: no noise, white noise (WN), pink noise (PN), brown noise (BN) and sinusoidal wave (SW). Each condition other than no noise was created with 1800 data points and the frequency of platform translation was 10 Hz, which resulted in a three-minute trial. The COP data series used for further processing involved only the AP component of COP data during AP translations and the ML component of COP data from trials involving ML translations. We did not include the COP components orthogonal to the direction of perturbation. The COP data was processed using customized Matlab scripts (Mathworks Inc., Natick, MA) to generate root mean square (RMS) and DFA (detrended fluctuation analysis) measures of variability. DFA analysis results in a scaling exponent α that quantifies the long-range correlations in a time series. Repeated measures ANOVA was used to identify the differences in RMS and DFA α of the COP time series due to perturbation direction and noise conditions.
Figure 1. Schematic of experimental set up represent AP (A) and ML (B) perturbations produced in the force platform using waveforms with different temporal structures.

RESULTS AND DISCUSSION

DFA α values for COP during support surface translations in AP and ML directions were significantly different (p=0.001). DFA α values for COP were significantly different in the five noise conditions (p<0.0001). Post-hoc analysis showed significant differences in the DFA α values of COP from no noise condition when compared to corresponding values from white noise, pink noise and sinusoidal wave translations (Figure 2). Significant differences were also found between brown noise and white noise, pink noise, and sinusoidal wave translations. There was no interaction effect of perturbation direction and noise conditions on the DFA of COP time series.

There was a significant difference in RMS of COP during AP translations when compared to RMS of COP during ML translations (p=0.001). A significant difference due to noise conditions was observed in RMS of COP values (p=0.002). Post-hoc analysis showed significant differences in RMS values of COP from pink noise translations when compared to corresponding values from white noise and Sinusoidal wave translations. There was no interaction effect of perturbation direction and noise conditions on RMS of COP.

The results of our study strongly support our hypotheses. We observed that the LRCs of COP in AP and ML directions were different. We also observed that RMS for COP during AP translations was greater than ML translations. The linear measure used for analysis complements the findings of our non-linear analysis.

This may be due to differences in the alignment of body segments and muscles required for the activation of forces to maintain stability when perturbed in these directions.
Figure 2. Mean DFA α values of COP during AP and ML perturbations at different noise frequencies

CONCLUSIONS

Exploring the temporal structure of biological processes has provided many new insights into movement control. Because aging and disease are characterized by a degradation of this temporal structure it is important to investigate new ways to restore this highly complex structure. Our previous findings [4] have shown that healthy individuals show adaptive flexibility in their ability to entrain to different support surface inputs in the AP direction where the temporal structures of the inputs are different and alter their COP to match such variable inputs. Our current study shows that such entrainment is also possible in the ML direction. The different strategies used for control of posture in AP and ML directions might result in different temporal structures of COP variability in those respective directions. Future work should explore if the LRCs for COP variability remain different in AP and ML directions with increasing age and clinical conditions.

VIRTUAL TIME TO CONTACT IS MORE STRONGLY RELATED TO DISEASE SEVERITY THAN SWAY EXCURSION IN PEOPLE WITH DIABETES AND DIABETIC NEUROPATHY

INTRODUCTION

Individuals with diabetic neuropathy are significantly less stable during quiet and perturbed standing than individuals without diabetic neuropathy. They exhibit higher center of pressure (COP) sway velocity and sway excursion [1,2]. A second postural measure, Virtual Time-to-Contact (VTC) has been shown to be more sensitive than sway excursion in assessing postural stability in people with other neurological conditions, such as multiple sclerosis and concussions [3,4]. VTC establishes a boundary of support around a person's feet when standing and calculates how long it would take that person's COP to reach that boundary, given current instantaneous position, velocity, and acceleration. If the COP exceeds the boundary of support, the person will either fall or have to catch him or herself. The longer it takes the COP to reach the boundary of support, the greater VTC will be. A higher VTC is associated with greater stability [4]. VTC has not, as of yet, been used to assess postural stability in people with diabetes or diabetic neuropathy. Because of its previous success with other neurological conditions, VTC may provide a more sensitive measure of postural stability for people with diabetes and/or diabetic neuropathy compared to sway-based COP measures. To investigate this concept, we hypothesized that VTC will be more strongly correlated to severity of diabetic neuropathy than sway excursion. The purpose was to compare the relationships of VTC and sway excursion with severity of diabetic neuropathy in anteroposterior (AP) and mediolateral (ML) perturbations in people with diabetic neuropathy.

METHODS

3D motion capture and force plate data were collected on 10 participants (age: 50 yrs; 2 males; 8 females) using markers placed bilaterally on the 1st toe, 5th metatarsal head, and posterior heel. All participants had diabetes with 5 having diabetic neuropathy. Participants were perturbed on a NeuroCom Research Module. Perturbations were at 10 cm/s and 20 cm/s and lasted for 0.5 s. Force plate data were collected at 200 Hz during and 5 seconds following forward, backward, left, and right perturbations.

The severity of diabetic neuropathy was assessed via vibratory threshold using a biothesiometer on both feet. These tests were conducted at 5 plantar sites on both feet: 1st toe; 1st, 3rd, & 5th metatarsal heads; and the heel. The clinical vibratory threshold for neuropathy is 25 V with a biothesiometer.

VTC was calculated using center of pressure force plate data and a boundary of stability, as defined by foot marker locations in MATLAB. Sway excursion was calculated using center of pressure force plate data (Fig. 1). Minimum and average VTC and sway excursion were calculated during the perturbation, for the first 0.5 s after the perturbation, and for 1.0 s after the perturbation. Results for all AP perturbations were averaged for single assessments for VTC and sway variables as were the ML results. Both VTC and sway excursion variables were correlated and regressed with the both left and right vibratory threshold. Correlations greater than 0.632 were significant, $p < 0.05$. The study was approved by the ECU Institutional Review Board and the participants provided written consent.

RESULTS AND DISCUSSION

Four significant and strong correlations were found. During ML perturbations, both average (r = 0.72) and minimum (r = 0.79) VTC were strongly correlated with vibratory threshold on the right foot and minimum VTC was strongly correlated with vibratory threshold on the left foot (r = 0.65). During AP perturbations, average VTC was strongly correlated with vibratory threshold on the right foot (r = 0.78, Fig. 2). No significant correlations were found for sway excursion, both during and after perturbation or for VTC after the perturbation (Fig. 3). These data showed neuropathy severity is more strongly correlated to VTC than sway excursion. This is in agreement with research on other neurological conditions, particularly concussions, that VTC is a more sensitive measure of severity of a neurological condition [3,4]. However, the direction of the relationship is completely unexpected. Longer VTC with reduced sensation suggests that people with diabetic neuropathy may employ a safer and more restrained postural control strategy in response to perturbations. Similar findings have been found in gait in people with diabetic neuropathy while walking on different surfaces [5].

CONCLUSIONS

VTC had four significant relationships with severity of diabetic neuropathy, while sway excursion did not have any significant relationships with disease severity. These data suggest that Virtual Time-to-Contact may be more appropriate than sway excursion in assessing severity of neuropathy in people with diabetes and diabetic neuropathy. People with diabetes and diabetic neuropathy may use a more restrained postural control strategy in response to perturbations.

LEG STIFFNESS AND POSTURAL CONTROL IN CHILDREN DURING SINGLE-LEG HOPPING

Matthew Beerse and Jianhua Wu

Georgia State University, Atlanta, GA, USA. Email: mbeerse1@student.gsu.edu

INTRODUCTION

Hopping, described by a spring-mass model, demonstrates a linear relationship between vertical ground reaction force (GRF) and center of mass (COM) displacement [1]. Leg stiffness, important for movement performance and injury prevention, is commonly calculated from this relationship, but with inconsistent methods. Further, altering hopping frequency away from a preferred frequency requires the manipulation of leg stiffness and increases the demand on the musculoskeletal system [2, 3]. No study has been conducted to investigate how hopping frequency influences movement of the COM in the anterior posterior (AP) and medial lateral (ML) directions in children and adults. This study aimed to compare the kinetic and kinematic calculation methods on leg stiffness and investigate the COM movement in the AP and ML directions in children.

METHODS

Participants: There were 13 preadolescents with typical development (8 M/5 F). Mean (SD) of age, height, and body mass were 8.9 (1.8) years, 1.3 (0.1) m, and 32.7 (8.2) kg, respectively.

Experimental design: The subjects hopped at their most comfortable frequency three times and the average frequency was used to set the four metronome-guided frequency conditions: Preferred, Moderate (20% increase), Fast (40% increase) and Slow (20% decrease). A full body PSIS marker set was attached to the subjects to estimate the COM.

Data collection:
Three 20-second trials were collected for each condition. The order of condition presentation was randomized across the subjects. Because three subjects had an elevated preferred frequency, a fast condition was not possible. An AMTI force plate was used to collect vertical GRF data. A 7-camera Vicon motion capture system was used to collect kinematic data.

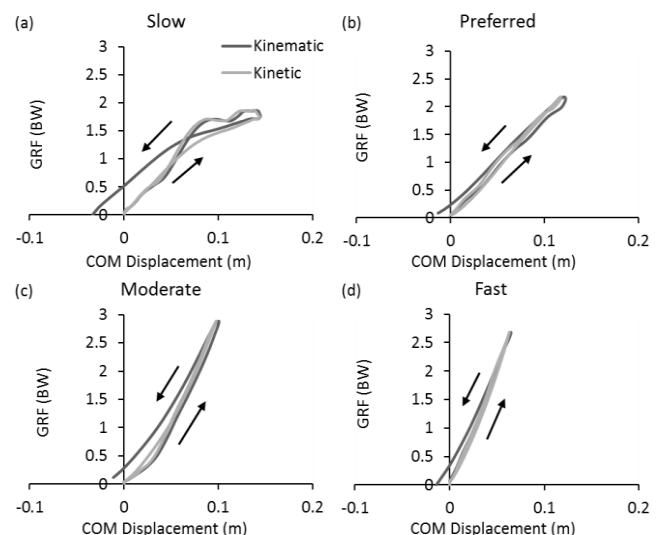
Data analysis: Two methods were used to calculate COM displacement, a kinetic method by double integration of acceleration from the vertical GRF data [1], using the central difference method and adjusted by position of COM at takeoff [4], and a kinematic method using the COM position marker estimated by the full body marker set. Leg stiffness was then calculated as the linear regression slope of the GRF plotted against the COM displacement throughout the entire stance phase (Fig. 1). COM range of motion in the AP and ML were calculated as the difference between the maximum and minimum position during stance phase and flight phase, separately.


Figure 1: Representative data highlighting similar maximum COM displacement but different COM position at take off between the kinematic and kinetic method.

Statistical analysis: Two 2-way (2 method x 4 frequency) ANOVA with repeated measures were conducted on leg stiffness and the maximum COM displacement to compare the kinematic and kinetic methods. Two-way (2 direction x 4 frequency)

ANOVA with repeated measures were conducted on the COM range in stance phase and flight phase. Post-hoc pairwise comparisons with Bonferroni adjustment were completed when necessary. A significance level was set at $p<0.05$.

RESULTS AND DISCUSSION

The maximum COM displacement during stance phase was similar between the kinematic and kinetic methods and decreased as frequency increased (Fig 1). There was a frequency effect $(F(3,33) = 103.96, p < .001)$.

Leg stiffness calculated by the kinematic method was generally lower than that calculated by the kinetic method (Fig. 3). There was a frequency effect $(F(3,33) = 122.46, p < .001)$ and a method effect $(F(1,12) = 39.96, p < .001)$.
In stance and flight phases, the COM range was smaller in the AP direction than in the ML direction. There was a frequency effect $(F(3,33) = 34.02, p < .001)$ and a direction effect $(F(1,12) = 22.84, p<.001)$, on the COM range in stance phase (Fig. 4). There was a direction effect $(F(1,12) = 9.01, p = 0.011)$ on COM range in flight phase (Table 1).

The maximal COM displacement was similar between the two calculation methods, but leg stiffness calculated from the kinematic method was lower than the kinetic method. The COM calculated

from the kinematic method in Fig. 1 shows that position at takeoff was generally higher than at foot strike in hopping of children. This implies that the trunk was more extended at takeoff compared to landing. Our integration for the kinetic method assumed similar COM position at takeoff and landing resulting in underestimated COM movement after mid-stance. Along with calculating leg stiffness over the entire stance phase using the same vertical GRF, the kinematic method produced lower leg stiffness than the kinetic method.

The COM range during stance increased at lower hopping frequencies challenging the children's balance. The COM movement demonstrated a greater range in the ML direction compared to the AP direction across all conditions. With only one leg supporting the body mass, the COM would need to shift towards the single support in the ML direction, thus causing a higher magnitude of the COM movement in this direction.

CONCLUSIONS

Both kinematic and kinetic methods show that children increase leg stiffness with hopping frequency. Horizontal movement is greater in the ML direction and increases with decreasing frequency requiring greater postural control in children.

ASSESSMENT OF KNEE MECHANICS AND MUSCLE ACTIVITY DURING BALANCE EXERCISES

Lauren C. Benson and Kristian M. O'Connor

University of Wisconsin Milwaukee, Milwaukee, WI, USA
email: lbenson@uwm.edu

INTRODUCTION

Patellofemoral pain (PFP) is the most common overuse knee injury [1], affecting people in a variety of tasks [2]. Risk factors for PFP are considered to be those that contribute to large patellofemoral joint contact forces at the lateral knee, including increased knee abduction moment [3], and an imbalance between vastus lateralis (VL) and vastus medialis oblique (VMO) [4].

Balance training has been successfully used as protection against recurring ankle sprains [e.g. 5]. The use of balance training to protect against traumatic knee injuries, however, has had conflicting results [6, 7]. Additionally, athletes with a history of knee injury had a greater incidence of overuse knee injury following a balance training program featuring the use of a wobble board [5].

If balance training elicits poor knee mechanics, repeating balance exercises throughout a training program may expose the athlete to large patellofemoral contact forces that, over time, could result in overuse injury. Since the moments at the knee and the timing of the vasti muscles during various balance exercises have not been reported, it is unclear how balance exercises may contribute to mechanics that could put athletes at risk for overuse knee injury. The purpose of this study was to quantify knee abduction moment and relative timing of VMO and VL during balance exercises for recreational athletes.

METHODS

Ten healthy recreational athletes (3 male, 7 female, 28 (4) years, 1.74 (0.12) m, 70.20 (15.40) kg) without functional ankle instability were recruited. Muscle activity of VMO and VL was recorded during maximum voluntary contraction (MVC) trials. Retroreflective markers were applied to the participants' skin to track the motion of the pelvis, thigh, leg and foot on the dominant side. In addition to muscle activity, three-dimensional kinematic data and ground reaction forces were recorded while balance exercises were performed.

The balance exercises consisted of barefoot, single-legged stance on firm ground with eyes open (EO) and eyes closed (EC), and on a rectangular wobble board allowing only medial-lateral motion (ML), only anterior-posterior motion (AP), and allowing motion in all directions (MULT). For each exercise, the participants completed 5 trials of 40 seconds. At the beginning of the trial, the participant was in bilateral stance, and then stepped forward with their dominant leg onto the balance surface. While balancing, the participants fixated their gaze on a target 2 m away at eye level, but had no restrictions for movement of the arms or the non-dominant leg. All trials of one exercise were completed before moving to the next exercise. The order that each participant completed the exercises was randomized to eliminate a learning effect.

The EMG data were full-wave rectified and root mean square values were calculated using a 120-ms window. The knee frontal plane angle and moment and the processed EMG signals, expressed as a percent of the maximal muscle activation from the MVC trials, were calculated for the final 30 seconds of the balance exercise trials. Each trial was assessed a balance score, defined as the percentage of time in the final 30 seconds of the trial that the participant maintained single-leg balance. Balance scores, peak knee abduction moment, and frontal plane knee moment variability while balance was maintained were averaged across all trials for each exercise. Additionally, the cross-correlation of VMO and VL activity was used to determine the similarity of the muscle activity throughout the balance task, as well as the relative time delay between the activity of the two muscles. The

influence of balance surface on each dependent variable was determined using a repeated measures ANOVA with $\alpha = 0.05$. When a significant effect of task was found, pairwise comparisons between tasks were performed.

RESULTS AND DISCUSSION

The balance score decreased as the instability of the task increased ($F_{(4,6)}$=8.379, p=0.012). There was no significant effect of balance surface on the delay ($F_{(4,6)}$=1.459, p=0.323) or cross-correlation coefficient ($F_{(4,6)}$=0.681, p=0.630) for VMO and VL. Peak knee abduction moment ($F_{(4,6)}$=6.441, p=0.023), and frontal plane knee moment variability ($F_{(4,6)}$=17.799, p=0.002) were greater for balance board tasks with instability in the medial-lateral direction (EC, ML, MULT). The results of the pairwise comparisons are illustrated in Figure 1.

CONCLUSIONS

Balancing in single-leg stance on surfaces with instability in the medial-lateral direction results in high knee abduction moment and variability. The goal of this study was to establish the knee loading patterns of healthy recreational athletes across different balance tasks. The next goal would be to determine if individuals with knee pain demonstrate disrupted muscle firing patterns and knee loading during balance tasks.

Hand and Foot Responses that Improve Ladder Fall Recovery

[1] Erika M. Pliner, [2] Na Jin Seo and [3] Kurt E. Beschorner

[2] Medical University of South Carolina, Charleston, SC, USA
[3] The University of Pittsburgh, Pittsburgh, PA, USA
email: beschorn@pitt.edu

INTRODUCTION

Ladder falls are the leading cause of fatal falls [1]. Previous research has revealed that ladder slip and fall risk is associated with the design of the ladder and climbing biomechanics [2, 3]. Furthermore, preliminary studies by our group have noted that the recovery response to a ladder fall event initially prioritizes reestablishing the hands back on to a ladder followed by the feet [4]. However, there is limited knowledge about the variability in the coordination between hands and feet during ladder climbing and in response to a perturbation. The effect of these different hand and feet strategies on recovery is not well understood. Thus, the purpose of this study is to investigate how hand and foot responses to a ladder climbing perturbation affect recovery.

METHODS

Thirty-five (10 female) participants between the ages of 18 and 29 were recruited for this study. Participant safety protocols were taken with IRB approval, written informed consent, and proper climbing attire which included a safety harness that was equipped with a load cell (1000 Hz). In addition, 47 reflective markers were placed on the participant's anatomical landmarks to record their kinematic data (100 Hz).

Participants climbed a vertical 12-foot custom ladder where they experienced a simulated ladder misstep perturbation. The perturbations were initiated using a rung that was unexpectedly released from under the subject's foot and subjects experienced a perturbation during ascent and descent while wearing high friction gloves, low friction gloves and no gloves. Five to eight unperturbed trials occurred between perturbed trials to reduce anticipation effects.

Recovery to the perturbation was measured based on the amount of weight support that the harness provided after the perturbation. A load cell attached in series with the harness rope was used to record the maximum force between the start of and end of fall. The start of the fall was determined based on the start of the perturbation and the end of the fall was determined based on when the pelvis reached the first local minimum in the vertical position [5].

Review of videos was used to categorize the hand and foot responses. When analyzing the hand responses, only the hand that was in motion (in the case of 2 points of contact) or the hand that would move next (i.e., the lower hand during ascent in the case of 3 points of contact) was analyzed. Four hand responses were observed: 1-Hand did not move; 2-Hand continued to the next rung as planned (i.e., moved 2 rungs up during ascent or 2 rungs down during descent); 3-Hand interrupted the planned path of motion and grasped the rung before the intended rung (i.e., grabbed one rung above the starting position for ascent or one rung below the starting position for descent); 4-Hand was in contact at the start of fall, but released the rung momentarily before re-grasping the same rung. Trials where the other hand released the rung and grasped a lower rung were excluded (n=4/171). Three types of foot responses from the perturbed foot were observed. A-hit the ladder rail or rung and fell to a hanging position; B-stopped on a lower rung; C-fell to a hanging position.

An ANOVA was performed to determine the effects of the hand response on harness forces. Because previous research had determined that gender was an important factor in ladder recovery, gender and the interaction between gender and hand response were also included. A second ANOVA was performed to assess the foot responses on recovery. This foot response model also included gender and the interaction. Both ANOVAs used harness force as the dependent variable. A Tukey's HSD post hoc analysis was performed on the hand and foot type responses. These ANOVA models were assessed separately for ascent and descent.

RESULTS AND DISCUSSION

The pathway for hand motions were variable across participants during ascent: 1) the hand did not move in 36% of trials; 2) the hand grabbed the target rung in 28% of trials; 3) the hand interrupted the planned path of motion and landed at the next rung in 13% of trials; and 4) the hand left the rung and came back down on to the same rung in 21% of trials. During ascent, harness force varied across hand response type ($p < 0.05$) and were higher for female participants ($p < 0.001$) but was not affected by their interaction ($p = 0.148$). Harness forces were highest when the hand interrupted the planned path of motion and grabbed one rung above the starting position. (Figure 1).

The pathway for hand motions were also variable across participants during descent: the hand did not let go of the rung in 11% of recoveries; the hand grabbed the target rung in 62% of trials; the hand interrupted the planned path of motion to grasp one rung above the target rung in 16% of trials; the hand let go of the rung and then reestablish position on the same rung in 8% of trials. During descent, harness forces varied with hand response type ($p < 0.01$) and were higher for females ($p < 0.05$) but were not influenced by response x gender interaction ($p = 0.457$). Harness forces were lower when the hand maintained contact with the rung during the entire fall or reestablished position on the rung that was just released than when the hand continued as planned to the next rung. Therefore, maintaining two hands on rungs or reestablishing the hand back to the same rung may offer benefits for ladder recovery during descent.

The response of the foot varied for ascent and descent trials. Specifically, the foot hit the ladder and fell to hanging position in 33% of ascent trials and in 39% of descent trials; stopped on a lower rung in 43% of ascent trials and in 22% of descent trails; and fell to hanging position without hitting the ladder in 22% of ascent trials and 36% of descent trails. Harness force varied between foot response for ascent ($p < 0.01$) and descent ($p < 0.001$) perturbations. In addition, higher harness forces were observed for female participants during ascent ($p < 0.01$) and descent ($p < 0.01$) but no response by gender interactions were observed in either climbing direction ($p = 0.785$ and $p = 0.576$,

respectively). Lower harness forces were observed when the foot reestablished placement onto a lower rung than when the foot hit the ladder side/rung and fell off or when the foot never made contact with the ladder. Therefore, the feet are an important component in recovering from a ladder fall event.
Figure 1: Harness force normalized to body weight for hand (numerical columns) and foot (alphabetic columns) responses during ascent and descent.

CONCLUSIONS

The results of this research indicate that the motion paths of the hands and feet during ladder recovery are important contributors to recovery. Maintaining both hands on the ladder during recovery was effective during ascent and descent. In cases where the hand left a rung, grasping a higher rung (i.e., not interrupting the hand path during ascent and interrupting the hand path during descent) increased recovery. This finding may be explained by previous research that found a more extended arm posture increases upper limb strength [6]. In addition, reestablishing the feet back on the ladder after a fall is critical to recovery. Thus, additional research that identifies means of improving foot placement after a fall may also offer protection against ladder falls.

CHANGES IN DYNAMIC BALANCE CONTROL AND POSTURAL STABILTY BETWEEN LEVEL AND SLOPED WALKING

[1,2] Scott P. Breloff and [2] Dwight E. Waddell

[1] University of Scranton, Scranton, PA, USA
[2] The University of Mississippi, University, MS, USA
email: scott.breloff@scranton.edu

INTRODUCTION

Injuries from falls, both fatal and non-fatal, constitute a majority of worksite related injuries each year [1]. In 2013 non-fatal construction falls were 16.1 falls per 10,000 workers [1]. Six hundred and ninety-nine workers lost their lives due to falls, slips, or trips in 2013 while falls from height accounted for 574 (82 percent) of those fatalities [1]. Fatigue induced by abnormal walking has a negative impact on balance control and individuals are less stable after walking along a sloped surface compared to a level surface for a prolonged period of time [2-3]. The purpose of this study was to determine if subjects balance control was compromised following a prolonged time on a non-level surface.

METHODS

Thirteen participants, all college age male students (Mass: 88.06±16.83kg, Height: 179.60±6.05cm), who were considered inexperienced walking on sloped surfaces, participated in the study.

Subjects completed two identical procedures on non-consecutive days consisting of one hour of walking on either a level (W) or sloped surface (S). Level walking trials required the subjects to walk on the laboratory floor. For the sloped condition, a pitched roof segment, measuring 24 feet by 8 feet at a 6/12 (26.5°) pitch was constructed for the participants to walk on (Figure 1). Subjects wore steel-toed work boots during all walking conditions.

As a baseline assessment, barefoot subjects completed two NeuroCom EquiTest® balance testing protocols - Sensory Organization Test (SOT) and the Motor Control Test (MCT) [4, 5].

Figure 1. Top: Roof Segment. Bottom: Subject traversing roof segment.

The participants would then put on steel-toed boots and complete a one hour walk for either of the two conditions. Following the one hour walk, subjects would again remove their boots and complete the balance testing protocols a second time. The NeuroCom EquiTest® was in the same room as the walking conditions therefore the transition time from walking to testing was almost instantaneous.

RESULTS AND DISCUSSION

Sensory Organization Test (SOT) and Motor Control Test (MCT) composite scores were statistically analyzed in a 2 x 2 x 2 (Test x Time x Condition) mixed analysis of variance (ANOVA), with repeated measures on the condition to determine if conditions differ between Pre- and Post-Condition composite scores. The SOT composite score is the weighted average of the scores of all sensory conditions which characterizes the overall level of performance. The MCT

composite score is the average of the individual latency scores for the two legs for the medium and large translations [5].
Figure 2: NeuroCom EquiTest® Pre-Condition and Post-Condition composite scores. '*' indicate group differences from post hoc tests

There was significant within subject interaction between Test x Time x Condition, $p<0.01$; Table 1. Follow up tests revealed no differences in the pre walking scores for either condition (MCT and SOT) indicating that subjects had the same composite postural control prior to the walking intervention. There were significant differences between the pre and post walking composite scores for both the MCT conditions (level and sloped); however the SOT composite scores were significantly different following only the sloped condition (Figure 2). Suggesting, the composite MCT postural control of the walkers who were inexperienced with sloped surfaces was altered due to prolonged walking while the SOT composite scores was altered following only sloped walking.

Walking on a sloped surface for one hour has a significant, detrimental effect on postural control which agrees with previous literature [3]. A decrease in postural control while walking on a sloped surface may be a contributing factor to the construction related falls suggested by the BLS. Data from the BLS did not provide the mechanism of the falls, or how long into a work shift when a fall occurred. Therefore, direct comparisons to deficits in postural may be difficult, but workers

should be educated regarding this change during the work day.

Flat-Pre	133.18	7.57
Flat-Post	137.45	11.00
Sloped-Pre	136.45	9.30
Sloped-Post	141.36	14.58

Table 1. Means and Standard Deviations for the Sensory Organization Test and the Motor Control Test for both conditions and over time.

CONCLUSIONS

The study results indicate that a sloped surface can lead to a decrease in composite postural control. The findings demonstrate a decrease in the influence of postural control from both the sensory and motor control systems. A decrease in postural control has been documented in previous literature to be one of the triggering events leading to falls. Balance control is maintained through the integration of sensory and motor control systems and a decrement in either of these systems can lead to a decrease in postural control.

COMPARING TRUNK PROPRIOCEPTIVE ABILITY AND MUSCLE RESPONSES TO SUDDEN TRUNK PERTURBATIONS BETWEEN ATHLETES AND NON – ATHLETES

[1] Grace O. Glofcheskie and [1] Stephen H.M. Brown

[1] University of Guelph, Guelph, ON, Canada
email: gglofche@uoguelph.ca

INTRODUCTION

Trunk control and stability is essential for athletic performance, as it is the centre of the kinetic chain and the base for all limb movements [1]. Previous studies have found that deficiencies in trunk neuromuscular control can predispose athletes to low back and lower extremity injuries [2, 3]. In order to produce an appropriate muscle response, three levels of motor control must be present. The spinal reflex pathway uses proprioceptive input from both muscle spindles and Golgi tendon organs. The brain stem pathway coordinates both visual and vestibular input using proprioception from joint receptors and mechanoreceptors in the skin [4]. Finally, cognitive programming is based on stored central commands, which lead to voluntary adjustments [5]. Therefore, if a lack of proprioceptive ability was responsible for delayed muscle response to perturbations and poor trunk postural control, a relationship between measures of these three contributors to motor control could be present. The purpose of this study was to determine if differences exist between athletes and non-athletes in neuromuscular response time to perturbations, seated postural control, and sagittal and axial trunk re-positioning ability. It was hypothesized that athletes would exhibit faster response to trunk perturbations, greater postural control and less error in trunk re-positioning tasks when compared to non-athletic controls.

METHODS

Male golfers (athlete group) competing at the collegiate varsity level (n=10), as well as male participants (control group) with no athletic background (n=10) were recruited. These groups were matched based on age, height and weight, with no significant difference between groups. An active marker motion capture system (Optotrak™ Northern Digital Inc., Ontario, Canada) was used to record 3D lumbar movement, with markers at vertebral levels T12 and S1. Electromyography (EMG) was recorded bilaterally to measure activation levels and response times of the thoracic and lumbar erector spinae, external oblique, and internal oblique muscles (AMT-8[TM] Bortec Biomedical Ltd., Alberta, Canada). Participants performed three separate testing protocols presented in a random order:
1) seated sagittal and axial trunk re-positioning tests to measure position sense; 2) a seated balance test to measure postural control using a wobble board placed on top of a force plate (True Impulse[TM], Northern Digital Inc., Ontario, Canada); 3) sudden trunk perturbations, applied with a mass of 10% of their maximum trunk extensor strength, in both the anterior and posterior directions, as well as with combined twist, while kinematic and EMG data were recorded. The dependent variables (3D lumbar spine motion, muscle responses, centre of pressure excursions and velocities, degrees of re-positioning error) were compared between golfers and controls. A significance level of $\alpha <0.05$ was used for all statistical comparisons.

RESULTS AND DISCUSSION

In sagittal trunk re-positioning tasks, golfers demonstrated significantly less absolute error (absolute difference between positioned target angle and re-positioned angle by participant) and variable error (standard deviation of absolute errors across trials). Significant differences were also observed in sagittal re-positioning to self-selected neutral posture, with less error in both absolute and variable errors in golfers (Figure 1). Similar trends were observed in axial re-positioning, as golfers showed significantly less error in absolute and variable error in both re-positioning to the target angle, as well as neutral posture (Figure 2).
Figure 1: Sagittal re-positioning absolute errors between golfers and controls in repositioning to target angles of 20°, 40° and 60° trunk flexion.
Figure 2: Axial re-positioning absolute errors between golfers and controls in repositioning to target angles of 10°, 20°, 30° and 40° trunk axial twist.

Golfers did not perform sagittal re-positioning at 60° of trunk flexion differently when compared to controls, however demonstrated significantly less error at 20° and 40° flexion. During the training and performance of their sport, golfers consistently adopt a posture of approximately 30° of trunk flexion and rarely position themselves near end ranges of trunk flexion. This is reason to suggest why golfers exhibit

less error at 20° and 40°, yet are no different than controls at 60° of flexion. In axial re-positioning tasks, golfers demonstrated significantly less error at 20°, 30° and 40°, yet no differences from controls at 10° of trunk axial twist. During the golf swing, these athletes are repeatedly twisting to their end ranges of motion in both the backswing and follow through. Due to this repetitive motor pattern that golfers develop, it is possible that they are more comfortable in these ranges of axial twist that are further away from neutral. In the seated balance task, golfers demonstrated significantly smaller ranges of centre of pressure (CoP) deviations in both the anterior-posterior and medial-lateral directions. Golfers also demonstrated significantly shorter cumulative path lengths, as well as significantly less path length velocity. Golfers also demonstrated faster neuromuscular responses to sudden trunk perturbations. This suggests evidence that greater proprioceptive ability is related to faster muscle responses and greater trunk postural control.

CONCLUSIONS

Golfers demonstrated less error in trunk re-positioning tasks, which suggests greater proprioceptive ability compared to non-athletic controls. Greater trunk postural control was also observed in golfers compared to controls in the seated balance task. Finally, faster neuromuscular responses to sudden trunk perturbations were observed in golfers compared to controls. Combined, these data suggest that golfers have enhanced proprioceptive abilities, which potentially lead to faster muscle responses to trunk perturbations, and therefore overall greater postural control compared to non-athletes.

COMPLIANT FLOORING AND ITS EFFECT ON POSTURE: DIFFERENCES BETWEEN YOUNG AND OLDER POPULATIONS

[1]Jessica Buschman, [2]Samuel Leitkam, PhD, [1]Tamara Reid Bush, PhD
[1]Michigan State University, East Lansing, MI, USA
[2]Ohio University, Athens, OH, USA
email: buschma5@msu.edu, leitkam@ohio.edu, reidtama@msu.edu
web: http://researchgroups.msu.edu/reidtama

INTRODUCTION

Thirty percent of older people (65 years and older) fall at least once every year [1]. Although there are many forms of preventative measures for falls, recent studies cite that compliant flooring is a new form of passive intervention for this issue [3]. Research has been conducted to analyze the relationship of flooring compliance and postural stability by measuring sway and/or Center of Pressure [2, 3], but there is currently a lack in research on how flooring compliance affects body kinematics. This study investigated how different flooring types impacted body posture in regards to the ribcage and pelvis orientations for young and older groups of individuals.

METHODS

The subject pool for this exploratory study consisted of 13 healthy participants. These participants were grouped into young and older age brackets: five participants were of the ages 19-29 (ave. 24.2, SD 3.96), and eight participants were over the age of 50 (ave. 69.1, SD 11.1). Qualysis motion capture was used to track markers at the seventh cervical vertebrae (C7), the two anterior superior iliac spine (ASIS) projections, and midway between the two projections of the posterior superior iliac spine (MidPSIS).

Four floorings included in this study were Airex; the flat surface of a force plate; a generic foam-core anti-fatigue mat produced by Hampton Bay; SmartCell; and SofTile. These floorings were labeled "air", "flat," "mat", "smart", and "soft", respectively. Airex is a soft foam material used in balance and training; SmartCell is a two inch thick rubber flooring designed to reduce impact and fatigue; and SofTile is playground flooring with a

hollow-core impact pedestal. Participants were seated on a backless stool with no arm supports and their feet placed on the flooring. Seat height was adjusted to ensure a knee angle of 90 degrees for each participant and flooring. The order of the floorings was randomized for each trial and each subject.

When instructed, the participants were asked rise to a standing position, all while keeping a forward gaze. Once in the standing position, participants were asked to maintain the standing posture for twenty five seconds. This method was repeated for all five types of flooring.

Posture was analyzed by evaluating the sagittal orientation of the pelvis and ribcage relative to vertical when standing. The ribcage orientation was defined by a vector starting at the sternum and pointing through the C7 marker. The pelvis orientation was a defined by a vector starting at the MidPSIS and passing through the midpoint of the ASIS markers. The ribcage angle was defined as the angle between the ribcage vector and vertical; the pelvis angle was the angle between the pelvis vector and vertical.

RESULTS

Figures 1 and 2 provide the average and standard deviations for the pelvis and ribcage values for both young and older subject groups. A noticeable increase in pelvis angle for the older participants occurred across all floorings. The ribcage angle decreased for the older participants.

A two-way ANOVA was computed to determine whether significant differences in ribcage and pelvis angles between young and older groups existed. The results show that there was a significant difference

(at the 95% confidence interval) between the young and older groups for both the pelvis and ribcage angles. The p values for this significance were 0.0087 and 0.0044, respectively. Between floorings, however, there was no significance found for either the pelvis or ribcage angles for either of the groups.
Figure 1: Standing pelvis angles for older and younger groups. All groups showed significance between age groups.
Figure 2: Standing ribcage angles for older and younger groups. All groups showed significance between age groups.

DISCUSSION

Based on the orientation of the pelvis vector, a larger pelvis angle represented a larger anterior rotation of the pelvis; whereas a larger ribcage angle represented a posterior rotation of the ribcage. The results showed that the older group had significantly larger anterior pelvic and ribcage tilt when standing than the younger group. In other words, the older populations rotated their pelvis and ribcage both forwards and downwards when standing, resulting in a "forward lean" of their standing position on the floorings. The lack of significance between floorings showed that neither group significantly changed their ribcage or pelvis orientations to account for the different floorings.

It was surprising that there were no significant differences seen between the "air" case and the other floorings, as it was a highly compliant flooring. This could be explained by the fact that this study did not look at *movement* of the pelvis and ribcage, but rather average postural angles.

Both Beach et al. and Wright et al. found that compliant floorings have a small but significant effect on postural stability amongst older populations [3, 4]. The forward rotation seen in our study could help explain the significant sway in the anterior/posterior (A/P) direction for these older populations, seen by Beach et al. This is important because this increased sway has been linked to an increase in postural instability, leading to falls [3].

CONCLUSIONS

Significant differences between the older and young postures existed across all floorings. However, no differences existed between floorings. Thus, this research does not indicate a postural difference due to type of flooring; rather the postural differences are age related. Understanding the postural changes in older populations and how different types of flooring compliances affect those postures will help in developing approaches for fall prevention.

LOWER EXTREMITY NET JOINT MOMENTS DURING LATERAL LOAD TRANSFERING: DIFFERENCES BETWEEN HIGH AND LOW SURFACE FRICTION

[1] Robert D. Catena and [2] Xu Xu

[1] Washington State University, Pullman, WA, USA
[2] Liberty Mutual Research Institute for Safety, Hopkinton, MA, USA
email: robert.catena@wsu.edu, web: http://labs.wsu.edu/biomechanics/

INTRODUCTION

Stress on the lower back is typically the concern in manual material handling tasks. However, when the load and frequency is sufficiently light, balance and falls become a concern. Reports indicate that falls are a leading cause of injury in manual material handling occupations, especially those performed outdoors where conditions aren't as controlled [1].

We have recently endeavored to study balance during the lateral transfer of a load [2]. In our most recent study we reported the differences in lower extremity joint kinematics between two transfer techniques [3]. One technique was successfully used in both high and low surface friction conditions, while another technique was just as successful (determined by transfer distance) in high friction conditions, but increased the likelihood of a fall when the same task and distance were performed on a slippery surface. In this study we sought to retrospectively determine if there is any kinetic benefit to either transfer technique. Toward that goal, we examined the changes in net moments at the lower extremity joints due to surface friction between these two transfer techniques.

METHODS

Thirty-five working aged volunteers with no substantial material handling experience provided informed consent to participate in this study. Participants wore a completely similar wardrobe (including shoes) and were harnessed during testing. Participants completed a 180° transfer of a load at their maximum desired distance (Fig 1). This distance was determined during practice trials in a high-friction ($\mu=0.86$) condition before 6 successful trials were recorded (HCOF). We then changed the

surface to a low friction surface ($\mu= 0.16$). Participants performed one trial using the same high-friction start position (LCOF1) before being allowed to practice and change the start configuration if so desired (LCOFp).
Figure 1: Start position and goal for the lateral load transfer

Participants wore a full-body passive marker set and marker motions were recorded with a 12–camera MotionAnalysis system. Ground reaction forces were recorded with Kistler force plates under each foot. An inverse dynamics method was used to calculate 3D internal net joint moments at the ankle, knee, and hip. Participants were retrospectively grouped by successful (SL) vs. unsuccessful (UL) completion of the LCOF1 trial. Joint moments were statistically compared between 2 groups and 3 tasks using a two-way ANOVA.

RESULTS AND DISCUSSION

There were two unique patterns to achieve the lateral load transfer in high friction conditions [3]. The SL individual used a narrow base that involved

pivoting the entire body, on the feet, towards the load as it was transferred. They did not substantially change their technique after practice in low friction conditions. The UL high friction approach to this task was a wide base of support, with greater motion at the lower extremity joints, but not the feet, resulting in motion of just the upper body towards the load rather than pivoting the whole body. However, after failing to use this technique successfully on a novel low friction surface and subsequent practice, UL individuals modified their transfer technique mostly toward that of the SL technique. The one exception was a newly adopted crouched posture throughout the task.

All subjects increased their starting hip, knee, and ankle adduction moments in low friction conditions compared to high friction conditions (Table 1), but surprisingly the greater UL stance width did not require any more of an increase in hip adduction moments compared to SL. The UL group did require a greater increase in start hip external rotation and extension moments compared to SL. These changes constitute those needed to merely hold a stance on the low friction surface in preparation for the transfer task. Only start moments could be examined in the LCOF1 task because UL individuals failed (fell or gave up) before completion of this task.

Table 1: Starting internal net moments (Nm).

		HCOF	LCOF1	LCOFp
Hip adduction	SL	2.98	22.58	15.48
	UL	9.11	29.24	19.24
Hip external rotation	SL	-0.30	1.64	0.83
	UL	0.59	7.90	4.74
Hip extension	SL	-0.13	7.75	8.09
	UL	7.57	31.30	24.68

While the two group transfer kinematics became more similar following practice on the low friction surface, there were only a few joint moments that became similar between the two groups (Table 2). Hip flexion, knee extension, and ankle adduction moments were originally different between groups in HCOF but converged to similar during LCOFp. Joint moment differences between groups during the transfer in high friction conditions typically

remained even after practice and convergence of the two transfer techniques in low friction conditions. Hip adduction, abduction, and extension moments increased from HCOF to LCOFp. Knee adduction and abduction moments also increased from HCOF to LCOFp. While ankle plantarflexion moment increased, ankle coronal and transverse plane moments decreased from HCOF to LCOFp.

Table 2: Transfer internal net moments (Nm). C = combined group values.

		HCOF	LCOFp
Max. hip flexion	SL	14.61	12.78
	UL	7.40	11.31
Max. knee extension	SL	20.24	23.76
	UL	19.46	23.82
Max. ankle adduction	SL	21.25	20.36
	UL	23.34	19.73
Max. hip adduction	C	35.12	44.26
Max. hip abduction	C	40.12	49.23
Max. hip extension	C	137.47	145.26
Ave. knee adduction	C	10.40	15.06

CONCLUSIONS

On a low friction surface, the lower extremity muscles are tasked to control the torso position and orientation in the load transfer and do this while avoiding a slip of the foot. The potential for movement at either side of the joint significantly increases many of the net moments at the lower extremity joints. We found that the transfer technique alone, and combined consideration of both transfer technique and surface friction influenced some joint moments. However, surface friction had a much larger effect on joint moments, regardless of the transfer technique used.

EFFECTS OF BLURRY VISION ON STANDING BALANCE

Mitchell Clough, Caitlin O'Connell, Rakié Cham
University of Pittsburgh, Pittsburgh, PA, USA
email: mac306@pitt.edu

INTRODUCTION

Vision loss, specifically the loss of visual clarity, leads to an increased risk of falls [1]. Individuals suffering from vision loss must rely more heavily on other senses to maintain their balance, and in particular the vestibular system and proprioception. These effects are more pronounced in older adults and may decrease their mobility and independence. Previous studies have compared balance between people with normal vision and people who were legally blind, and found a significant difference between balance in people with healthy vision and people with significant vision loss [2]. The purpose of this study is to examine the effect of acute, or sudden, blurry vision on balance of young healthy individuals. This will help determine whether impaired balance in individuals with vision loss is due to just the vision loss or other compounding factors such as age. Our hypothesis is that induced blurry vision in healthy subjects will cause balance impairment.

METHODS

Five subjects (age 20-25, 4 males) with healthy vision were recruited. Individuals with conditions affecting gait or balance were ineligible for the study.

Sensory organization tests (SOT) were conducted using an Equitest posture platform (Neurocom, Inc) [3]. The posture platform allows for sway-referencing of the floor and the visual scene. The platform is implemented with a force plate used to measure the center of foot pressure (COP). The SOT test consisted of 6 trials completed for both normal vision and blurry vision (Table 1). The subjects' eyes were dilated to induce blurry vision. Pupil size was measured before and after dilating drops were instilled to ensure that eyes were dilated.

COP data was collected for 60 seconds at a sampling frequency of 100 Hz for each trial.

Table 1: SOT trial descriptions including eye, vision and proprioception conditions.

Trial	Eyes	Vision	Proprioception
1	Open	Fixed	Fixed
2	Closed	--	Fixed
3	Open	Sway	Fixed
4	Open	Fixed	Sway
5	Closed	--	Sway
6	Open	Sway	Sway

COP data was processed with a low-pass Butterworth filter. The first ten seconds were removed to remove any transient effects. The data was resampled from 100 Hz to 20 Hz. The root mean square (RMS) of the processed COP data was calculated. The mean velocity (MV) of the COP was obtained from the derivative of the processed COP data. Because sway-referencing of the platform is in the anteroposterior (AP) direction, only the RMS and MV in the AP direction were included in analysis (RMS-AP and MV-AP, respectively).

A mixed linear regression model was used to analyze the data, with the outcome variable of interest being RMS-AP or MV-AP. The independent fixed factors included in the model included SOT trial (1-6), the dilation condition (baseline/no dilation, dilated) and the interaction of these effects. Subject was included as an independent random effect. Statistical significance was set at 0.05.

RESULTS AND DISCUSSION

The effect of the dilation on RMS-AP was found statistically significant ($p < 0.05$), with greater

movement noted in the dilated eyes condition. This finding was consistent across all subjects (Figure 1). While the impact of the dilation on MV-AP did not reach statistical significance, a similar trend demonstrating greater sway velocities was noted in the dilated eye condition compared to the baseline condition (p=0.1). As expected SOT trial was a statistically significant effect ($p < 0.01$), but the interaction of dilation and SOT trial was not ($p > 0.1$), suggesting the dilation effect was consistent across all SOT conditions (Table 2).
Figure 1: Average RMS-AP across all SOT trials for each subject for normal vision (baseline) and blurry vision (eyes dilated).

Table 2: Average COP RMS-AP across all subjects for each SOT condition.

SOT Trial	AP RMS (cm)	
	Baseline	Dilation
1	0.18 ± 0.04	0.21 ± 0.06
2	0.21 ± 0.05	0.30 ± 0.15
3	0.22 ± 0.06	0.31 ± 0.08
4	0.28 ± 0.10	0.37 ± 0.05
5	0.40 ± 0.10	0.57 ± 0.21
6	0.37 ± 0.08	0.43 ± 0.12

The findings of this study suggest that blurry vision or loss of visual acuity is associated with impaired balance. This finding agrees with epidemiological studies relating visual acuity loss with falls. The within-subject experimental design used in this study is a significant advantage of this study.

There are two potential mechanisms relating blurry vision or reduced visual acuity to falls. The findings of this study suggest that the loss of visual acuity is associated with an inability to rely on available and accurate sensory modalities. The second potential theory is that blurry vision reduces the ability to detect and avoid obstacles while walking, which was not tested directly in this study [4].

A limitation to this study is the small subject group, which limited the power of the statistical analysis. Additionally, all subjects were young and fit and thus may not have been affected by blurred vision to the extent that the elderly, who may have other comorbidities affecting balance, would have been. A future extension of this study could examine the effects of age on balance with blurry vision.

CONCLUSIONS

The differences in balance between the subjects when they had healthy vision versus when they had blurry vision suggest that vision loss does negatively impact balance. Further larger sample size studies are needed in order to understand the potential mechanisms mediating this effect.

Principal component analysis of human balance on a tunable balance board

[1] Denise Cruise, [2]Shirley Rietdyk, [2]Jeffrey M. Haddad, [2]Howard N. Zelaznik, [1,2]James R. Chagdes, [2]Joshua Liddy, [1] Arvind Raman

[1] School of Mechanical Engineering, Purdue University, West Lafayette, IN, USA
[2]Department of Health and Kinesiology, Purdue University, West Lafayette, IN, USA
email: drhickma@purdue.edu

INTRODUCTION

Understanding how many degrees of freedom are involved in human posture is important because it forms the basis for mathematical models of upright stance [4]. For quiet standing, it has been argued that one degree-of-freedom (DOF) models capture the dynamics of quiet standing [3,5,7]. Others argue that one DOF models cannot give a comprehensive description of human kinematics in upright posture, and that the model needs to be a multi-segment inverted pendulum [6].

Recently, there has been an interest in balance boards for training and rehabilitation of balance [1]. More recently, mathematical models of human balance on balance boards provided insight into how a person's region of stability (the parameters that lead them to be stable in an upright position) can be identified [2]. Thus mathematical models of humans on a balance board become important; however, little effort has been made to understand if the essential DOF of postural control on a balance board are related to the DOF on a rigid surface.

This work will act as a feasibility study to develop a protocol using principal component analysis (PCA) that will allow us to quantify the DOF of a person standing on a balance board transitioning from a stable to an unstable condition. Our initial results are presented here. Understanding the required DOF to maintain balance on an unstable rotational surface will help strengthen conclusions made about how people balance as they approach an instability, and inform models of human postural control.

METHODS

Participants
Fourteen healthy young university students (mean ± S.D.: height 171.8 ± 9.1 cm, weight 65.4 ± 10.1 kg), 3 male and 9 female, with no known balance pathology participated in this study.

Equipment
Kinematic data was obtained using 3D wireless sensors (YEI Technology, Portsmouth, Ohio, USA). These sensors use a 2.4 Gz signal to transfer orientation data. The location of each sensor is shown in Figure 1.
Figure 1: <u>Left</u>: Human diagram showing location of wireless IMU sensors: head, chest, pelvis, thigh, and shin. One wireless sensor was also placed directly on the balance board. <u>Right</u>: Human standing on tunable balance board.

Protocol
Participants were instructed to keep the balance board in a horizontal position, while looking straight ahead at a point on the wall. The torsional stiffness of the board linearly decreased in a continuous fashion, from a high stiffness value (similar to standing on a rigid platform), to no torsional stiffness; each trial lasted 50 seconds. Participants stood on the balance board with their feet side-by-side, approximately shoulder width apart, arms at their sides, and ankles aligned with the pivot point of the balance board.

Data Processing

Segmental angles were extruded from the sensors and used to calculate the following joint angles: ankle (shin – board), knee (thigh – shin), hip (pelvis – thigh), waist (chest – pelvis), and neck (head – chest) angles. The constantly changing demands of the balancing task due to the decreasing torsional stiffness of the balance board required us to analyze small segments of data. After looking at plots for various segment sizes, we chose one second as the length of each segment to analyze. The data were resampled to 30 Hz to ensure a constant sampling rate.

A covariance matrix was created for each second of data, and then PCA was performed on the covariance matrix. This procedure gives information about the modes of movement of the person: which mode is dominant (and by what amount), and which joint angles contribute to each mode.

RESULTS AND DISCUSSION

The PCA analysis provides information on what percentage of total sway motion can be attributed to a dominant mode, secondary mode, tertiary mode, etc. It also provides quantitative information on the contribution of various joints in each mode.

It was found that the movement of a person on a balance board can generally be described with two primary modes; the first mode accounts for the majority of the person's movement (~78% on average), and the second mode can account for 16%. Although there are other modes present, they only represent a small portion of the movement.

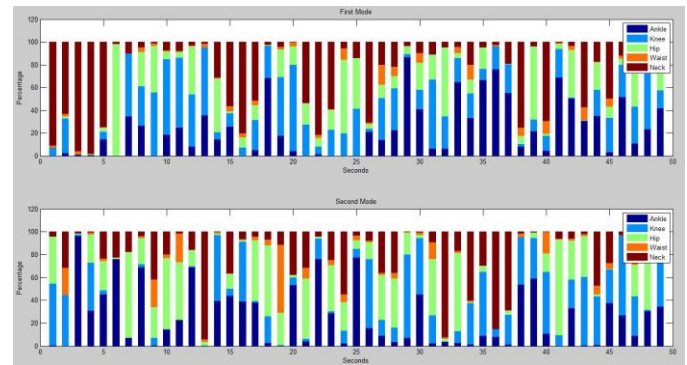
The PCA (Figure 2) also tells us what joint movements contribute to each of the modes. For example, at low torsional stiffness (time > 15 seconds), the primary mode features a greater contribution of ankle rotation. The opposite seems to be true of the secondary mode. Investigations into the variability of these modes and the joint contributions are ongoing. In addition, it can be seen that all of the joints contribute to each of the modes, but an analysis needs to be applied to determine which joint movements are statistically relevant.


Figure 2: Contributions to the primary (top) and secondary mode (bottom) of postural sway by each of the joints for one participant. Data are plotted as a function of linearly decreasing torsional stiffness of the balance board.

CONCLUSIONS

A feasibility study has been performed using PCA to determine the dominant modes of a human balancing on a balance board with tunable torsional stiffness. Preliminary results indicate that unlike balance on a rigid surface, secondary modes may also be important contributors to balance. The joint rotation contributions to each mode tend to change with board torsional stiffness. Future work will examine the variability of this data with larger populations and trials.

INTRODUCTION

Load carriage can be the most convenient way to transport items from point A to point B. Over 40 million students in the United States use backpacks on a regular basis [1]. Poor posture brought on by improper backpack use has led to alignment issues such as forward head posture, rounded shoulders, kyphosis, low back pain, and an asymmetrical axial skeleton during both standing and gait. In 2013 alone, over 28,000 backpack-related injuries were treated at medical practices [2].

The principal purpose of this study was to assess head and trunk position during static stance before and after walking between a traditional backpack and a nontraditional backpack designed to disperse the load across the body and close to the vertical axis. It was hypothesized that the nontraditional backpack would result in a more upright posture showing less forward head posture and forward trunk inclination than the traditional backpack.

METHODS

Following IRB approval, twenty-four healthy young adults (22.5±2.5 years, 12 male) participated in this study. Participants were free from injury and any other condition that would prevent them from carrying 15% and 25% of their body weight in a backpack. Participants also had a history of using a traditional backpack (3+ days/week). An informed consent and a health demographic questionnaire were completed prior to participating.

A 14-camera Vicon infrared motion capture system (VICON Inc., Denver, CO, USA) collecting at 120 Hz and an AMTI force plate instrumented treadmill (AMTI Inc., Watertown, MA, USA) collecting at 2400 Hz were used in conjunction with a modified Plug-In Gait marker set that included marker clusters on the thigh and shank of each leg. A traditional backpack (BP) and the BackTpack (BTP) (BackTpack LLC, Salem, OR, USA) were used for load carriage. Load was added to the backpacks to equal 15% and 25% of the wearer's body weight and was evenly distributed in the backpacks, placing the heaviest weight closest to the spine for the traditional backpack and balancing the weights between the two pockets for the BackTpack. Each participant was assessed under five conditions: static recordings with no backpack and each of the two backpacks at the two load percentages both before and after walking for 6 minutes at a speed of 1.4m/s. The order in which the backpacks were worn and the load was applied was randomized, although the no backpack condition always came first.

Head angle and trunk angle in the sagittal plane were assessed using Visual 3D software (Version 5.0, C-Motion, Germantown, MD, USA), and pre- to post-walk data was analyzed using two one-way RM ANOVAs to compare the load percentages back to the No Load condition. A two-way RM ANOVA was used to compare the backpack and load percentages to each other. Where appropriate, Bonferroni corrections were utilized. Analyses were conducted in SPSS (Version 22 for Windows, SPSS Inc., Chicago, IL, USA), and the alpha level was set at $p < 0.05$.

RESULTS AND DISCUSSION

For all individual pack conditions (No Load, BTP, and BP) at both load conditions (15% and 25%), there was a significant difference in head angle between pre- and post-walk ($p=.004$, $p=.014$). Both backpacks at 15% and 25% were significantly

different from each other (p=.002, p<.001) and from the no load condition (p<.001).
Figure 1: Trunk angle comparison in degrees for interaction effects between time (pre- to post-walk) and load percentage (dashed lines) and backpack type (solid lines). Abbreviations: BTP, BackTpack; BP, traditional backpack.

In comparing the two backpacks during both load percentages to each other, no significant differences were seen between time, load, or pack type for head or trunk angle. However, significant differences were seen in the time x pack interaction (p=.030) and in the pack x load interaction (p=.008) for trunk angle. These results can be seen in Figure 1.

Head angle was more negative (less hyperextension at the neck) and trunk angle was more positive (less forward flexion) for the BTP than the BP for both the 15% and 25% loads (Table 1). However,

following the walking period, the BP exhibited a slight reduction in trunk flexion while the BTP resulted in a slight increase in flexion. Overall, the more upright posture seen with the BTP may be due to the load placement along the vertical axis in conjunction with the line of gravity rather than being placed behind the wearer as with the BP. The findings supported the hypothesis, which was that the nontraditional backpack would result in a more upright posture than the traditional backpack.

CONCLUSIONS

In conclusion, the BTP more closely resembled the participants' natural stance as determined by the No Load condition for both head and trunk angle. The more upright posture supported by the BTP may help reduce characteristics of poor posture such as forward head positioning and forward trunk lean.

EFFECTS OF WHITE NOISE ACHILLES TENDON VIBRATION ON STANDING POSTURE

INTRODUCTION

We have proposed that proprioceptive feedback is used in the identification of economical movement patterns (1). Supporting this idea, we recently found that *disrupting* proprioceptive feedback from the plantarflexors during human walking reduces the rate of adaptation to a change in mechanical demand, and increases metabolic cost (2). This result raises the question of whether *enhancing* proprioceptive feedback could have beneficial effects for gait adaptation and economy.

Stochastic resonance, a phenomenon by which noise can increase a system's sensitivity, may hold promise for enhancing proprioceptive feedback. Recent work found that low-amplitude white-noise ankle tendon vibration improved passive movement detection (3). Similarly, low-amplitude electrical noise applied to the plantarflexors reduced postural sway due to enhanced proprioception (4). Such sensory stimulation may improve post-stroke function (5, 6). However, these benefits are strongly dependent on stimulation amplitude (see Fig. 1)
Figure 1. White noise stimulation can improve a system's sensitivity to an input signal, but only within a narrow range of noise amplitudes.

Our long-term goal is to investigate the effects of enhanced plantarflexor proprioception during walking. As a preliminary step, the purpose of these experiments was to test whether Achilles tendon white noise vibration influenced postural control, and to identify the optimal vibration amplitude. We quantified the effects of such vibration during: 1) quiet standing; and 2) sway toward visual targets, a task requiring more substantial active control of the plantarflexors. We hypothesized that vibration amplitudes just below the sensory threshold would have maximal beneficial effects.

METHODS

Eight healthy females (age=24±3yrs; height=168±7 cm; mass=65±8kg) participated. We applied vibration as 100Hz bandwidth white noise using C-2 tactors strapped over the bilateral Achilles tendons. These vibration characteristics were previously successful in enhancing the sensitivity of plantarflexor muscle spindles (3). For each participant, we determined the sensory threshold (**ST**) for white noise vibration applied to each leg using a standard method of limits technique.

Participants performed 27 quiet standing trials (30s long) on a force plate with their eyes closed, arms crossed, and listening to brown noise, following instructions to stand as still as possible. Participants performed 3 trials for each of 9 vibration conditions: No Vibration and 20%, 40%, 60%, 80%, 90%, 100%, 150%, and 200% ST. These vibration amplitudes were chosen based on the common result that beneficial effects of stochastic resonance occur just below the sensory threshold.

Participants also performed 27 trials using active control of their center of pressure (CoP) location (Fig. 2). Participants used visual feedback of their CoP location to sway to 3 consecutive targets. Once the anteroposterior (AP) CoP location remained within 5mm of the target for 3 seconds, the target moved to the next position. For the fourth target, participants were not provided visual CoP feedback,

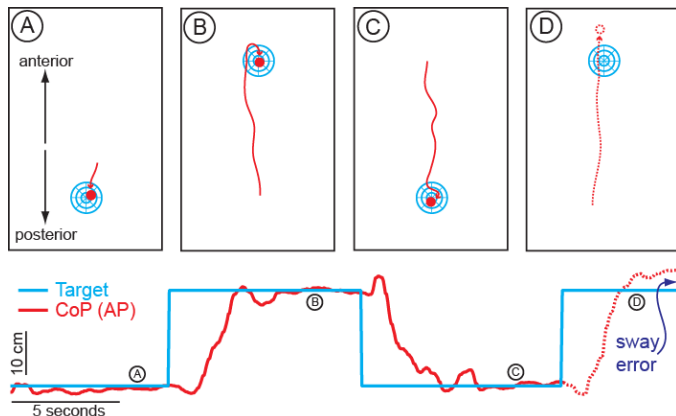
and pressed a push-button when they believed they were in the correct position. Participants performed 3 trials at each of the vibration levels listed above.


Figure 2. Sample illustration of the visual feedback provided to participants (top row), and CoP location relative to the target positions (bottom). Participants first swayed to a "home" target located relatively posteriorly using visual feedback of their CoP position (A). They then swayed to a variable-location anterior target (B) and back to the home target (C). Finally, participants swayed to the anterior target **without** visual CoP feedback (D).

Our analyses focused on AP CoP movement, where the effects of plantarflexor proprioception are strongest. For quiet standing, we quantified the CoP location standard deviation. For active sway, we quantified AP error at the final target position. We used repeated measures ANOVA to determine if these metrics were influenced by vibration level.

RESULTS AND DISCUSSION

Sensory thresholds varied widely across participants (range=10-28 μm rms amplitude). Contradicting our hypothesis, vibration amplitude (defined as %ST) did not have a significant effect on sway during quiet standing (p=0.37), and did not exhibit clear amplitude dependent modulation (Fig. 3A). Similarly, vibration amplitude did not have a significant effect on repositioning errors during active sway (p=0.24; Fig. 3B).

The lack of a clear vibration effect is surprising, as similar stimulation has had beneficial effects for other ankle tasks (3, 4). Our results may be due to the wide variation in the sensory thresholds used to

set individual stimulation intensity, which may be influenced more by cutaneous sensation than plantarflexor muscle spindles. As initial, indirect evidence for this possibility, grouping our results into quartiles of un-normalized vibration amplitude reveals a possible optimum around 20 μm (Fig. 4). Future experiments will test this possibility directly.
Figure 3. Changes in vibration amplitude did not have the expected effects on postural control during quiet standing (A) or active sway (B).
Figure 4. The effects of vibration amplitude may be more apparent if <u>not</u> normalized by threshold.

CONCLUSIONS

We were unable to define an optimal vibration amplitude in terms of the sensory threshold. Using un-normalized amplitude may be more appropriate (3) in order to define a stimulus likely to have future beneficial effects during post-stroke walking.

ELECTROMYOGRAPHIC ANALYSIS OF CORE MUSCLE ACTIVATION DURING LUMBAR STABILIZATION EXERCISES: IMPLICATIONS FOR REHABILITATION AND TRAINING

[1] Harshavardhan Deoghare, [2] Bhupinder Singh and [2] Barbara Chan
[1] Western University of Health Sciences, Los Angeles, CA, USA
[2] California State University Fresno, Fresno, CA, USA
email: hdeoghare@westernu.edu0

INTRODUCTION

Enhanced core stability, defined as "the ability to maintain or resume an equilibrium position (or trajectory) of the trunk (and pelvis) after perturbation", has been touted to improve injury-prevention in many sports. Additionally, with increasing amounts of evidence showing that neuromuscular activation is delayed in individuals with low back pain, it is important to determine which specific exercises, when utilized as a part of rehabilitation intervention, specifically target those muscles for motor control. There is no consensus as to which exercise elicits the largest activation magnitude for the core muscles, and subsequently, is most appropriate to be included in the exercise-training program for core rehabilitation. Previous EMG studies generally relied on trained eyes to ensure lumbo-pelvic alignment and no objective measure is provided which questions their validity. Using the 'LevelBelt' it is possible to objectively confirm lumbo-pelvic alignment during functional postures/exercises. In female college students with no history of low back pain we investigated activation of Transverse abdominis (TAr), external oblique (EO), multifidus (MF) and quadratus lumborum (QL) during three specific core stabilization exercises including static and dynamic stabilization on a physioball, and planking.

METHODS

15 healthy female subjects between the ages of 22-30 years old, with no recent complaint of low back pain, has normal flexibility of lumbar spine and lower extremity range of motion, were recruited from Fresno State for this study. Subjects were excluded if they reported previous fracture or surgery to the spine and/or lower limbs, gross postural deformities, pregnancy and current low back pain symptoms. All subjects were provided informed consent to participate. Following skin preparation and EMG instrument set up, all subjects were verbally and visually cued for the following exercises: sitting unsupported on physioball, and progress to dynamic stabilization (lifting a seven pound weight in seated position) followed by planking. 'LevelBelt' was strapped onto each participant across the upper sacrum and secured with the stabilization straps. The level belt was set to provide auditory and vibratory feedback with $\geq$ two degree of pelvic tilt. Each participant had a visual demonstration of the activity before performing a practice trial. EMG recording was collected three times for accuracy for each exercise. The order of the exercise sequence was randomized for each subject to avoid order effect and fatigue. Muscle activity recorded from the three exercises was normalized to MVIC by dividing the raw data by MVIC values. The percentage of all the exercise activity in each of the four muscles was then averaged and imputed into SPSS software to compute a one-way ANOVA.

RESULTS AND DISCUSSION:

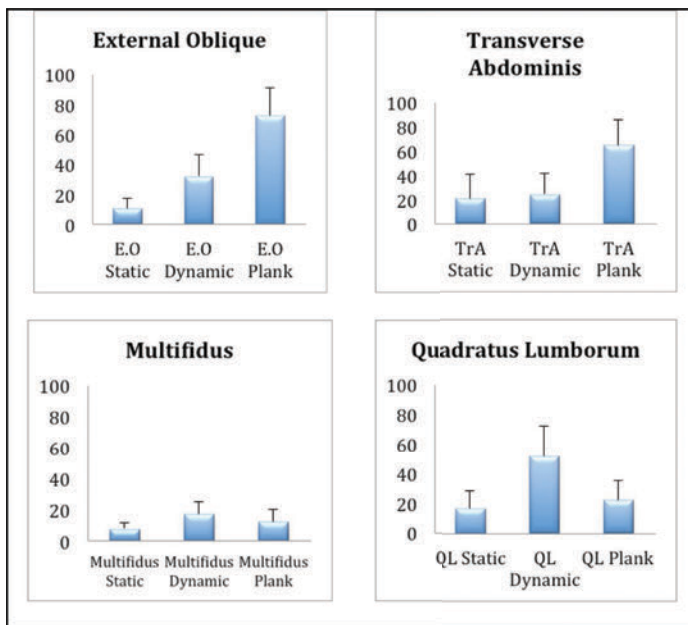
Table 1. Level of muscle activation during progressive core stabilization exercises			
	High (>60%)	**Moderate (21-40%)**	**Low (<21%)**
Static			Multifidus
			Transverse Abdominis
			Quadratus Lumborum
			External Oblique
Dynamic		Transverse Abdominis	Multifidus
		Quadratus Lumborum	
		External Oblique	
Plank	Transverse Abdominis	Quadratus Lumborum	Multifidus
	External Oblique		


Figure 1: EMG Activity of Core Stabilizers during common physical therapy exercises.

The results suggest that core muscle activity is dependent on the type of core stabilization exercise as some muscles are more heavily activated in one type of exercise than the other. The significant difference between muscle activity during exercise suggest that prescribing static exercise, progressing to dynamic and plank will elicit progressive activation for the TA and EO; however MF and QL are mostly activated with dynamic stabilization type activity and not with planking.

Limitation: The interpretation of this study should be with caution as we examined only healthy female subjects performing the exercises in an attempt to maintain consistency and determine accurate muscle activation, however muscle recruitment pattern will be different in subjects with low back pain and may require additional, if not different, techniques to accurately activate the targeted muscle.

CONCLUSIONS:

Accurate neuromuscular activation of core muscles ensures the stability of the lumbo-pelvic complex, which is required for optimizing sports performance and prevent injuries. This is the first pilot study investigating muscle activation during core

stabilization exercises where lumbo-pelvic alignment is objectively measured and confirmed using a novel device called level belt, a clinical tool that provides real-time biofeedback about the anterio-posterior and lateral pelvic tilt.

Tar and EO exhibited the most EMG activity during plank. Whereas, (MF) and QL demonstrated highest EMG activity during dynamic stabilization type exercises.

To construct an exercise regimen for treatment or prevention of low back pain or optimization of sports performance and prevent injury in healthy subjects consideration must be made for the desired target muscle and evidence based exercises that elicit the highest muscle activity must be utilized.

USING MUTUAL INFORMATION TO CAPTURE MAJOR CONCERNS OF POSTURAL CONTROL IN A TOSSING ACTIVITY

[1] Harshvardhan Gazula and [1] Simon M. Hsiang

[1] Texas Tech University, Lubbock, TX, USA
email: harshvardhan.gazula@ttu.edu

INTRODUCTION

In this study, to analyze the biomechanics of tossing, we hypothesize that an optimal toss is characterized by a sequence of decisions so that certain objective functions are optimized. The relationship among multiple objective functions when accounted for can lead to a greater explanation/control over the tossing behavior. The aim of this study is to show the logical relationship between different objective functions, using mutual information [1], and to provide an overview of how those relationships change as the tossing task comes to a termination under different experimental conditions. When viewed in this manner, differences between the major concerns in each phase of the activity become interesting as they are a reflection how the information is flowing from phase to phase and this information flow helps us identify optimal tossing behavior.

METHODS

10 adults (age: 26.92 ± 1.62 years; height: 166.6 ± 6.8 cm; weight: 64.2 ± 11.6 kg) without any history of musculoskeletal disorders participated in the study. All protocols were approved by Institutional Review Board and written informed consent obtained prior to enrollment. Test conditions were selected to mimic typical tossing tasks often observed in a warehouse. Participants picked a box of varying weights from the ground and tossed it to the target location (on the ground or on to a table right in front of them) in one smooth motion. A 2×2×3×3 (distance- 1 m, 1.5 m, height- floor, table (set to 53% of the subject′s stature, usually waist height), weight- 1 kg, 5 kg, 7 kg, and target clearance- 110%, 150%, 200%, respectively) factorial design was used in this study.

Passive retro-reflective markers on the main joints (wrist, elbow, shoulder, hip, knee and ankle) were affixed to each participant to track whole body motion. In addition, two markers were attached to the side of load. Marker trajectories were collected using a 6-camera motion capture system sampling at 60 Hz. A combination of bony landmarks, measured anthropometry and marker positions was used to calculate each segment position. We use three objective functions (concerns) viz., mobilization (M), stabilization (S) and strength utilization (T) in this study as identified in a previous study [2].
Figure 1: Identification of different phases of tossing using motion capture data.

Each trajectory is divided into three phases marked by four events [3]. These four events were the initial position (lift off), the load closest-to-body-position, the highest position (peak), and the final position (release). We calculated the three objective function values for each phase. To calculate mutual information (MI) we discretized each of the

performance measures into three categories, based on where they fell on the 33.33 (Lo-Low), 66.66 (Med-Medium) and 100 (Hi-High) percentiles scale, so as to build a conditional probability table. This discretization was performed separately for all phases.

MI is a quantitative measurement of how much one random variable tells us about another random variable [1]. In this study, information was thought of as a reduction in the uncertainty of a variable. Thus, more the MI between S and M (I), the less uncertainty there is in S knowing M or M knowing S. The formula to calculate the MI between two random variables S and M is given as follows:

$$I(S;M) = \sum_{s \in S} \sum_{m \in M} p(s,m) \log\left(\frac{p(s,m)}{p(s)\,p(m)}\right)$$

where p(s,m) is the joint probability distribution function of S and M are the marginal probability distributions of S and M, respectively, all obtained from the conditional probability table.

RESULTS AND DISCUSSION

Results of the study are presented as the primary concerns (pair of objective functions with the highest MI value) among the previously considered objective functions in each phase of the tossing activity under different experimental conditions. Cells with only one objective function mean that there's a tie between two pairs of objective functions and this objective function is common between the two pairs.

No clear patterns were found for Phases 1 and 2 for different load and clearance conditions. During Phase 3 more than 50% of the subjects resorted to a type of tossing pattern that showed 'mobilization' and 'strength utilization' as the most important concern under almost all the experimental conditions. These findings suggest that mobilization and torque utilization are the most important concerns at the moment the load is released from the hand.

Table 1: Major concerns in each phase of the tossing activity under different experimental conditions (with the percentage of subjects)

Condition	Phase 01	Phase 02	Phase 03
Tossing on Floor	MS (40%)	MS (30%)	MT (70%)
Tossing on Table	MT (60%)	ST (30%)	MT (40%)
Distance = 1m	MT (40%)	M (60%)	MT (60%)
Distance = 1.5 m	MS (30%)	ST (30%)	MT (50%)
Weight = 1kg	MT (30%)	M (60%)	MT (60%)
Weight = 5kg	MT (40%)	MS (40%)	MT (70%)
Weight = 7kg	MS (30%)	MS (30%)	M (60%)
Tolerance = 100%	M (60%)	MT (30%)	MT (60%)
Tolerance = 150%	MT (20%)	MT (30%)	MT (50%)
Tolerance = 200%	MS (50%)	T (60%)	MT (50%)

The key is to identify information regarding systematic relations that hold between objective functions that concern behavior and use such information in determining the right input needed to lead to a desired outcome. We hypothesize that knowing the systematic relations between actions and their outcomes in terms of the major concerns, the right action can be chosen at the right time for an effective control.

CONCLUSIONS

In this paper, we introduced a novel uncertainty reduction approach for the identification of body kinematic patterns and their logical organization based on different objective functions at different phases of a tossing task. The proposed research concept based on mutual information provides users with a useful diagnosis of the relevance of different objective functions and of the mutual dependencies in designing the task.

Relationship Between Thoracic and Lumbar Spinal Curvature During Unsupported Sitting

INTRODUCTION

Maintaining the natural curvature of the lumbar, thoracic, and cervical spine, or "neutral spine" posture while sitting is widely recommended for good spinal segment alignment.[1] A common clinical approach to correcting seated posture is to teach people to reduce posterior rotation of the pelvis in order to improve the lumbar lordotic curve and reduce mechanical stresses on the spine.

Changes in lumbar lordosis while sitting can result in compensatory adjustments in the cervical spine to maintain the orientation of the head, which have the potential to impact the spinal loading.[2] However, little is known of how the curvature and motion of the lumbar region correlates with the adjacent thoracic region while seated. Although the thoracic and lumbar regions have the potential to move independently and, therefore, respond to postural changes differently, we hypothesized that the curvatures of the thoracic and lumbar spine in the sagittal plane would be coupled during sustained, unsupported sitting.

METHODS

Forty individuals at the 37th Annual Meeting of the American Society of Biomechanics in Omaha, NE participated in this study. Study volunteers assented that they were free from back pain while sitting or standing for a period of 15 minutes. Thirty-five participants (21 males, 14 females, mean age=33.8 ± 10.6y) had complete data for analysis.

Each subject sat on a backless stool while wearing a chest harness and belt. Markers with moiré patterns and unique markings on them were placed over the spine and pelvis (Figure 1). Subjects were instructed to maintain an erect sitting posture for 15 minutes

while utilizing a hand-held iPad to play games that challenged the brain. The three-dimensional locations and orientations of each marker were obtained using a moiré pattern motion capture system at 1 Hz [MC 40180; Metria Innovation, Milwaukee, WI]. The Metria system has been validated to provide accuracy within 1mm and 0.05 degree.[3]
Figure 1. Subject and marker positions

The radius of curvature (RoC) in the sagittal plane for the thoracic spine was estimated using the intersection of vectors normal to the face of each marker, which were located on the proximal and distal aspect of the thoracic spine (yellow in Figs 1, 2a). The lumbar RoC was estimated similarly with a marker on the lumbar spine and the combined orientation of 2 markers on the posterior superior iliac spines (red in Figs 1, 2a). Spinal curvature was calculated from the inverse of each RoC.

RESULTS AND DISCUSSION

The medians and ranges for the thoracic and lumbar curvature were 2.20 [0.26, 4.81] m[-1] and 0.70 [-1.85, 5.96] m[-1], respectively. A Spearman's rank correlation coefficient (ρ) was calculated between the thoracic and lumbar curvature for each subject (Figure 2b). All ρ were different from 0 (p<0.01), with the exception of subject 6 (blue point in Fig. 1b, p=0.12). The range was from ρ = -0.74 to ρ = 0.86. When each subject's curvature data was normalized to his/her initial thoracic and lumbar

curvature, the thoracic and lumbar curvature were significantly correlated for the group, though the relationship was weak (overall ! for the group = 0.12, p<0.001).

These results suggest that thoracic and lumbar curvature may be coupled for most individuals, but the relationship varies widely in both strength and direction, even among these subjects without back pain during unsupported sitting.

CONCLUSIONS

These data suggest that monitoring and correcting the lumbar spine curvature tends to influence the thoracic spine curvature in most individuals without back pain during sustained, unsupported sitting. However, the relationship between lumbar, thoracic, and cervical curvatures is probably more complex than is generally accepted clinically. Lumbar curvature and pelvic rotation should be considered when improvement of thoracic posture is also desired. Future studies should investigate coupling patterns of the lumbar and thoracic spine in people with back pain during sustained sitting and in patients with musculoskeletal disorders of the spine.

THE RELATIONSHIP BETWEEN KNEE PROPRIOCEPTION AND BALANCE IN ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTED INDIVIDUALS

INTRODUCTION

The anterior cruciate ligament (ACL) of the knee is an important ligament that prevents anterior translation and medial rotation of the tibia relative to the femur. Non-contact ACL tears can occur via poor landing, planting, or cutting mechanics. Injury to this ligament causes changes in the somatosensory and proprioceptive capabilities of the joint [1,2]. Proprioception is the ability to sense the location of parts of the body in space without the use of visual assistance and is vital to maintaining neuromuscular control during movement. The loss of proprioception can result in neuromuscular deficits that may force the nervous system to increase dependence on visual feedback for motion [2]. Increased deficits in the ACL reconstructed (ACLR) leg increase the risk of re-injury [3]. These deficits may be displayed when moving into a complex athletic environment or restricting visual feedback. It is unknown how vision moderates the relationship between proprioception and postural control. The purpose of this study was to determine the relationship between proprioception and static balance in ACLR individuals under varying two visual conditions.

METHODS

2.1 Participants

Thirteen individuals who previously had an ACL reconstruction (6 males, 7 females; age = 25.5±1.37 years, height = 1.70±0.13 m, mass = 75.6±19.2 kg) participated in this study. Inclusion criteria were as follows: 18 to 39 years old, underwent an ACL tendon graft reconstruction, and currently physically active. Participants completed a Tegner activity [4] survey indicating their current levels of activity (Tegner score = 6.0±1.5). The mean time interval after reconstruction was 23±18 months.

2.2 Measurement of Proprioception

Proprioceptive capability was measured using a Biodex System 3 isokinetic dynamometer (Biodex Medical Systems, Shirley, NY). Active joint position sense (AJPS) and passive joint position sense (PJPS) were performed to determine proprioception. Both methods tested errors associated with movement into flexion and into extension to a knee position of 20º. For both sensing tests, participants were placed at 90º hip flexion, eyes were blindfolded and ears covered. The knee was placed in 45° of flexion and extended to 20º flexion, either by the dynamometer during PJPS, or by the subject during AJPS. The participant's knee was then moved by the dynamometer back to 45° of flexion, and the participant was instructed to mark when they returned to the 20° flexion position. During PJPS, the dynamometer moved at an angular velocity of 2°/s, and the leg was allowed to freely move during AJPS. The same procedure was repeated for both PJPS and AJPS, starting from an extended position (0° flexion) and moving into 20° of flexion. Error for proprioception tests was determined to be the absolute difference from 20º.

2.3 Single Limb Balance Measurement

Static single limb balance was performed on a tri-axial force platform (Bertec, Columbus, OH) collecting at 1500 Hz to measure center of pressure (CoP) excursion with eyes open and blindfolded. During testing, participants stood on the uninvolved limb first, and then repeated the task on the involved limb. Participants were instructed to maintain balance on the specified leg for 30 seconds. Processing of balance data was performed

through custom MATLAB scripts (MathWorks, Natick, MA) with all CoP data low-pass filtered at 100 Hz using a 4th order Butterworth filter. CoP excursion was calculated as the total path length of the CoP excursion during the first ten seconds of the balance task.

2.4 Statistical Analysis

Separate Pearson correlations were used to assess the relationship between proprioception and single limb postural control across different vision conditions with a significance level of $p<0.05$ *a priori*.

RESULTS AND DISCUSSION

There was a significant correlation between CoP excursion during eyes closed balance and AJPS into extension error in the involved limb ($r^2 = 0.34$, p = 0.038), meaning decreased single leg stability on the reconstructed limb was correlated with worse proprioceptive ability (**Figure 1**).
Figure 1: Scatter plot of CoP excursion and AJPS during blindfolded balance (r^2=0.34, p=0.038).

No significant correlations were found between proprioception and postural control in the involved limb for the eyes open condition. No significant correlations to joint proprioception were found in the uninvolved limb during the eyes open and blindfolded condition. Lee et al. observed that the threshold for detection of passive motion was strongly correlated with dynamic single leg balance after ACL injury [1]. Additionally, literature reviews have concluded that ACL injuries may

cause neuroplastic changes and knee proprioception deficits [2, 5]. As AJPS error decreased in the involved limb, CoP excursion was greater during the eyes closed condition, indicating vision may moderate the relationship between proprioception and static single limb balance on knees with reconstructed ACL's. The moderate r^2 value for this relationship indicates that there may be additional factors that contribute to balance. Some factors may include core control, leg strength, and/or vestibular influence. Future research is needed to further explore what kind of influence, if any, such variables may have.

CONCLUSIONS

After ACL reconstruction, individuals may experience changes or deficits in proprioception and neuromuscular control. To maintain postural stability, ACLR individuals may depend more on vision with decreasing proprioceptive capabilities, but without visual restriction proprioception does not seem to play a role.

These findings suggest that active joint proprioception in ACL reconstructed limbs may be utilized in moderating involved single leg balance when vision is impaired. Improving proprioception under varying visual conditions may be an additional rehabilitation tool to aid in reducing the risk of re-injury.

INTRODUCTION

Aging has been proven to affect both attentional processes as well as postural control. As falls in the elderly population continue to pose major public health concerns in the United States, investigating relationships between executive controls, stability, and attention becomes increasingly important. Through measurement of sway and reaction time in response to visual and auditory stimuli, many studies have explored the effects of challenging the balance system of young and older adults. These results confirm that attention is involved with sensory integration of visual and auditory stimuli as well as standing balance. Moreover, more attention is required to maintain balance when multiple senses are in conflict compared to a single contradictory sensory input [1]. Increased reaction time and increased sway with age indicate that these attentional challenges to the balance system affect older adults to a greater degree [2].

The effects of challenging attention by other systems, particularly the proprioceptive system, have been previously unexplored. In this study, we will explore the effects of a proprioceptive stimulus on reaction time and sway in younger and older adults. Through the results of dual-task experiments, with information processing and proprioceptive components, we hope to achieve a greater understanding of the mechanisms contributing to the interactions between balance and cognitive processes and how aging affects these mechanisms. The goal of this abstract was to develop a novel proprioceptive stimulus to be used in further evaluating sensory integration during standing balance.

METHODS

Reaction time (RT) trials were collected on a NeuroCom EquiTest platform controlled by a (insert DAQ here). Body sway was calculated using the position of a Polhemus magnetic tracking sensor attached to the subjects' waist compared to a measured baseline distance from the sensor to the top of the EquiTest platform. Subjects were tested in a darkened room and told to focus on a fixed, eye-level target approximately 2 meters in front of them.

Each subject completed a total of three trials in four conditions: fixed floor with eyes open (FIX-EO), fixed floor with eyes closed (FIX-EC), sway referenced floor with eyes open (SRF-EO), and sway referenced floor with eyes closed (SRF-EC). Data were collected for 2.5 minutes per trial. For each condition, two baseline trials were collected without an RT task (one with perturbations and one without). The third trial per condition included a simple reaction time (SRT) test in conjunction with the perturbation. Trial order was randomized for each subject.

The proprioceptive perturbations used for the experiment involve rotation about the ankle invoked by the EquiTest system. The perturbations consist of a random toe up or down ankle rotation of +/-0.5 degrees superimposed on the current rotational position of the platform (Figure 1).
Figure 1. A. No rotation of foot. B. Toes down rotation (5°), C. Toes up rotation (-5°).

To ensure minimal sway at the time of a perturbation, before a perturbation was given, a constraint on the anterior-posterior sway was met. This was termed dwell time and defined as the sway angle of the subject being within +/-2 degrees for at least 2 seconds before the next stimulus was presented (Figure 2). This would mean that the time between stimuli may be higher for subjects that have more unperturbed sway .
Figure 2. Degrees of subject anterior-posterior sway are shown. Dwell time requires that the subject's sway must be within the shaded area (+/-2 degrees) for at least 2 consecutive seconds before the next stimulus is presented.

Proprioceptive perturbations were randomly introduced 3 seconds plus or minus up to 2 seconds after the previous perturbation and once the dwell time constraint was met (Figure 3). The average perturbation was 0.125 seconds in length.
Figure 3. Visual representation of the signal driving the perturbations on the platform. The 0.5 degree triangular wave is added to the current position of the platform. The delay is calculated using a randomized wait period (3 seconds +/- up to 2 seconds) and the subjects dwell time. If the wait period has passed, but the dwell time has not been achieved; the perturbation will commence after the dwell time has been reached. Red dotted line = start of perturbation; blue solid line = maximum perturbation; red solid line = end of perturbation

Over the course of a 150 second trial we expected to see approximately 43 perturbations for a healthy

subject who does not typically sway more than +/-2 degrees.

RESULTS

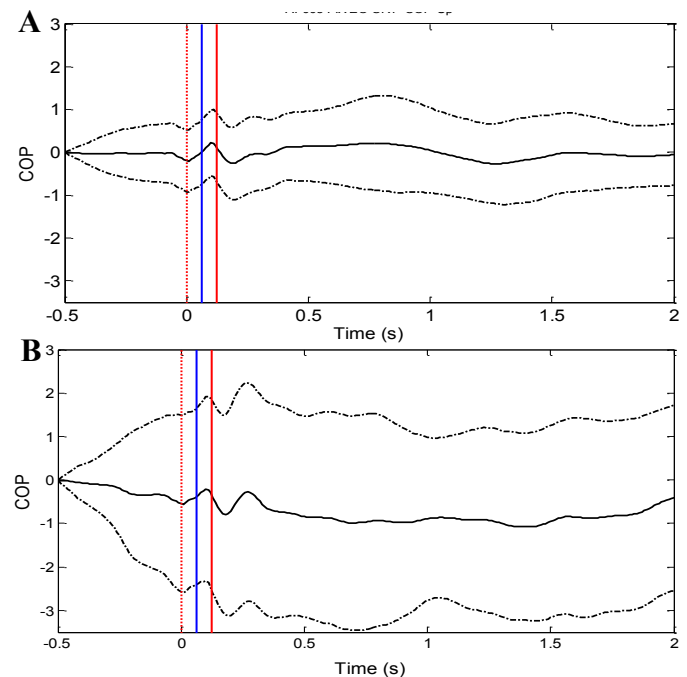
On average, there were 44 perturbations per 2.5 minute trial. Typical center of pressure time history plots are provided to demonstrate the impact of our novel perturbation on standing balance. Perturbations were averaged within condition, zero-meaned to the initial sway value before each perturbation, and the standard deviation was determined across perturbations within the trial.


Figure 4. Average COP with standard deviation for an older subject during "down" perturbations of (A) FIX-EO-SRT and (B) SRF-EO-SRT trials. Red dotted line = start of perturbation; blue solid line = maximum perturbation; red solid line = end of perturbation

DISCUSSION

A novel proprioceptive perturbation was developed that does not significantly alter sway. This paradigm will aid in providing a greater understanding of the mechanisms contributing to the interactions between balance and sensory integration as well as how aging affects these mechanisms.

RELATIONSHIPS BETWEEN HIP ABDUCTOR STRENGTH AND MEASURES OF SINGLE-LEG STABILITY IN FIT, YOUNG ADULTS

Gary D. Heise, Sutton Richmond, Austyn Resek, Brian Garcia, and Jeremy D. Smith

University of Northern Colorado, School of Sport & Exercise Science, Greeley, CO, USA
email: gary.heise@unco.edu, web: http://www.unco.edu/biomechanics/

INTRODUCTION

Postural stability, particularly static, whole-body stability in older adults, has received considerable attention in the research literature. Whole-body stability in younger, athletic populations has received less attention, primarily because typical static, two-legged postural assessments do not sufficiently tax a younger person's overall stability. Stability during one-legged standing is more challenging. Dynamic stability, usually tested on one leg, describes the process of transitioning from movement to a quiet, standing posture. Various measures, based on ground reaction forces (GRF) and center-of-pressure (COP) trajectories are often used to assess both types of stability. Clinicians have assessed dynamic stability in athletes with compromised joints (e.g., ACL injuries, ankle instability), but the influence of muscle strength has not been thoroughly examined [1].

Overall muscle strength, especially core and lower extremity muscle strength, is thought to enhance overall stability and reduce the risk of joint injury [2]. Previous work in our lab identified back extensor muscle strength as a significant predictor of static and dynamic stability, but knee and ankle muscle strength were not identified as predictors of static or dynamic stability [3,4]. Weak hip abductors have been associated in runners with iliotibial band syndrome [5], but this muscle group's influence on static or dynamic stability, especially in one-legged standing, has not been examined.

The purpose of this experiment was to explore the relationships between hip abductor muscle strength and various measures of single-leg static and dynamic stability among young, fit adults. It was hypothesized that greater hip abductor strength would be associated with better stability.

METHODS

Twenty people volunteered for this study (9 men; 11 women). All participants were young, healthy, and active (age, 26 ± 5 yr; body mass, 70.9 ± 9.8 kg; height, 173.2 ± 9.3 cm). At the beginning of a single test session, the protocol was explained and informed consent was obtained. Demographic and anthropometric data were collected in addition to some details about the frequency, duration, and intensity of weekly workouts.

Participants performed a brief, 10-15 minute warm-up (e.g., walk, stretch, low-intensity exercise). For static stability, ground reaction force (GRF) data were collected for 30 s at 1000 Hz and center of pressure (COP) coordinates were calculated for analysis. Trials were collected on each leg and for two floor conditions (rigid surface and compliant surface). COP mean velocity, 95% confidence ellipse area, and 95% power frequency were calculated [5]. Four dynamic, single-leg postural stability trials were collected: two from a forward hop; two from a medially directed hop. For dynamic stability, GRF data were collected for 20 s. A stability index (SI), based on root-mean-square values, was computed for both the medial-lateral (ML) and anterior-posterior (AP) GRF components [1]. The SI was calculated over 3 seconds, beginning 0.5 s after impact to avoid inclusion of the impact GRF peak.

Hip abductor muscle strength was determined with an isokinetic dynamometer. Maximal, isometric efforts were measured for right and left sides in a standing position. Correlations were used to evaluate the relationships between hip strength and measures of static and dynamic stability.

RESULTS AND DISCUSSION

Our hypothesis that stronger hip abductor strength would be associated with individuals displaying better one-legged stability was not supported. Two significant correlations that were identified in the present study resulted in the opposite relationship (i.e., greater hip abductor strength associated with greater COP movement). Figure 1 shows a measure of static stability and Figure 2 shows a measure of dynamic stability. These were the only significant correlations.
Figure 1: Scatterplot of hip abductor strength and the 95% confidence ellipse (CE) area for a left-footed, static stability trial. *$p<.05$

Previous work in our lab [3,4] investigated isometric muscle strength at the knee and ankle joints, but found no association between those measures, taken from a muscle dynamometer, and measures of static or dynamic stability. Furthermore our previous work identified several significant inverse relationships between back extensor muscle endurance and stability (i.e., longer endurance associated with lower metrics of stability). The only two significant correlations identified in the present study (Figures 1 & 2) show the opposite result. In addition, the significant correlations identified here show that hip abductor muscle strength explains only about 20-23% of the variance in stability.
Figure 2: Scatterplot of hip abductor strength and the medial-lateral stability index (SI) for a left-footed, medial landing (lower SI = better dynamic stability). *$p<.05$

Given that stability is governed by the equilibrial triad (vision, vestibular apparatus, and proprioception), it is not surprising that muscle strength at a single joint is not strongly related. Taken together with our previous findings, one-legged stability does not seem highly influenced by proximal or distal lower extremity muscle strength.

CONCLUSIONS

Overall, our hypothesis was not supported; individuals exhibiting greater stability in both static and dynamic conditions would be associated with greater isometric hip abductor strength. Only one measure of static stability and one measure of dynamic stability were significantly associated with hip abductor strength, but both relationships were in the opposite direction of our stated hypothesis.

THE RELATIONSHIP BETWEEN FOOT CONTACT AREA AND SINGLE-LEGGED POSTURAL STABILITY

Sutton B. Richmond, Kevin Dames, Jeremy D. Smith, and Gary D. Heise

University of Northern Colorado, School of Sport and Exercise Science, Greeley, CO, USA
email: sutton.richmond@yahoo.com, web: http://www.unco.edu/biomechanics/

INTRODUCTION

Postural stability, particularly static whole-body stability in older adults, has received considerable attention in the research literature. Whole-body stability in younger, athletic populations has received less attention, primarily because typical static, double-legged postural assessments do not sufficiently tax a younger person's overall stability. Stability during single-legged standing is more challenging and, when unshod, may be influenced by the actual contact area between foot and floor during quiet standing. This contact area is influenced by a number of anatomical and mechanical factors.

Hertel et al. [1] studied foot arch height and its influence on single-legged static stability. They reported that greater center of pressure (COP) excursions were found in participants with cavus feet (i.e., high arch height). They suggested that a higher arch height would result in a lower contact area and less range of motion in the subtalar and midtarsal joints. These joints are main contributors to pronation/supination movements, which are critical to single-legged stability. Their conclusions were based on classifying arch height with an approach that used linear and angular anthropometric measurements of the foot and ankle region while a person was lying prone. In addition, Hertel and colleagues only reported COP excursion and velocity as measures of static stability.

The present study addressed the limitations of Hertel et al. [1] by quantifying foot contact area and examining its relationship with single-legged static stability. Specifically, we hypothesized that greater foot contact area would be associated with more stable individuals. We also introduce a novel measure of foot contact area, which takes into account variations in foot morphology.

METHODS

Twenty healthy, active volunteers participated in this study (9 men, 11 women; age, 26 ± 5 yr; body mass, 70.9 ± 9.8 kg; height, 173.2 ± 9.3 cm). The participants were initially given time to stretch or warm-up for 5-10 min before testing began. Prior to stability testing, a physical trapezoidal measurement of the foot was taken using H, B1, and B2 which are shown on Figure 1.
Figure 1: Physical trapezoidal measurement of the foot (left) and pressure scan of the foot (right).

Next, a plantar pressure scan was taken at 50 Hz for 8 s (Tekscan, Boston, MA) while a person stood quietly on one leg. Average contact area was calculated from the Tekscan software. Contact area was divided by trapezoidal area to quantify a foot contact index (FCI). Static, single-leg postural stability trials were collected on each leg and for two floor conditions (rigid surface and compliant surface). Ground reaction force (GRF) data were

collected for 30 s at 1000 Hz and the COP coordinates were calculated for analysis. COP mean velocity, 95% confidence ellipse area, sway area, and 95% power frequency were calculated [2]. Correlation coefficients were used to evaluate the relationships between FCI and all measures of static stability.

RESULTS AND DISCUSSION

The novel measure of FCI yielded similar values for right and left feet with an average coefficient of variability of 8% (SEE Table 1), whereas the variability of the physical trapezoidal area of the foot and the variability of the scanned contact area were higher (~15%).

Table 1: Mean trapezoidal area (MTA), scanned area (SA), and foot contact index (FCI) for right and left feet. Standard deviations are included.

	RIGHT	**LEFT**
MTA (cm^2)	188.8 ± 25.7	187.2 ± 27.3
SA (cm^2)	140.6 ± 19.3	139.7 ± 20.9
FCI (%)	74.7 ± 5.8	74.8 ± 6.2

There were no significant correlations between FCI and any measure of static stability across all conditions of testing (Table 2). Values of COP mean velocity for the rigid surface found in the present study (3.5 cm·s^{-1}) were similar to those reported by Hertel et al. [1], but values of sway area (108-120 mm^2) were much less.

Table 2: Correlation coefficients between measures of static stability (first column) and the foot contact index for all four testing conditions.

	RR	**RL**	**CR**	**CL**
VEL	.35	.33	-.03	.21
ELLIP	.24	-.09	-.18	-.09
SWAY	.40	.16	.34	.09
POWER	.14	.22	.29	.25

VEL= COP mean velocity; ELLIP=95% confidence ellipse area; SWAY= sway area; POWER=95% power frequency; RR=rigid surface, right leg; RL=rigid surface, left leg; CR=compliant surface, right leg; CL=compliant surface, left leg.

The lack of a significant relationship between FCI and single-legged static stability measures are in contrast to the findings of Hertel et al. [1]. They used a discrete classification system for categorizing arch height, whereas the present study introduced a novel measure of foot contact area, a continuous variable. Although not significant in the present study, the positive correlation coefficients between sway area and static stability is also in direct contrast to Hertel et al. [1]. They found greater sway area in individuals who had high arch height (i.e., low contact area).

Our results question the notion that individuals with a high foot arch are less stable because of decreased contact area between the foot and the ground [1,3]. More specifically, no relationship seems to exist between foot contact area and stability.

Our study is limited to a young, healthy population. In fact, only five participants were considered overweight based on body mass index. In addition, we did not recruit people based on foot arch height or any other distinguishing, anthropometric characteristics. This may explain our relatively low variability in FCI.

CONCLUSIONS

Our hypothesis that greater foot contact area would be associated with better single-legged stability was rejected. This applied to both feet and two surface conditions.

IMPACT OF VISUAL GUIDANCE ON DIABETES' TOE ELEVATION DURING VIRTUAL OBSTACLE CROSSING TASKS

[1,4]Chun-Kai Huang, [2]Vijay Shivaswamy, [3]Pariwat Thaisetthawatkul, [2]Lynn Mack,[2]Amy Neumeister and [1,4]Ka-Chun Siu

email: chunkai.huang@unmc.edu

INTRODUCTION

People with more than 15 years of diabetes mellitus (DM) are at a high risk of suffering from diabetic neuropathy (DPN) with abnormal sensation and sensory loss of their feet [1], which increases the incidence of falling or tripping accidents. To maintain stability during locomotion, the reliance of body-based and visual senses (e.g. perception of self-motion) plays a very important role in DPN population to react on all kinds of external perturbations during walking [2].

Obstacle crossing is a common daily activity that might cause tripping accidents in diabetic population due to the insufficient toe elevation [3]. Our previous study indicated that through the perception of self-motion diabetic population decrease their gait variability during walking [4]; it is expected that toe elevation could be adjusted accordingly to cross obstacles successfully through the appropriate visual guidance that orientates body location related to the environment (i.e. exproprioception).

Therefore, this study investigated the effect of visual guidance on toe elevation during virtual obstacle crossing (VOC) tasks among people with Type 2 DM, DPN and age-matched healthy control. We hypothesized that the mean toe elevation in DPN would be significantly higher than other groups, and would be lowered when visual guidance was offered during VOC.

METHODS

Six subjects (two subjects in each Type 2 DM, DPN and age-matched group; one female; mean age: 50.17 years) were recruited to perform the VOC task, which was projected in the front screens and created with the dimensions of 45cm (width) x 20cm (depth) x 15% subject's leg length (height) using D-flow software (Motek Medical BV, the Netherlands). The virtual obstacles either showed up at the end of the corridor and moved towards subjects (Feedforward condition) or suddenly appeared two steps ahead of subject (Feedback condition). Two virtual markers that represented subject's toes were shown on the screen as their visual guidance. Subjects were instructed to elevate their dominant leg (leading leg) to step over the virtual obstacles (Fig 1). The collision event between virtual markers and the virtual obstacle was defined as the failure of obstacle crossing, and only successful trials were analyzed.
Figure 1: A subject performed a VOC task during treadmill walking (left); the movement of toe marker in sagittal plane during VOC (right).

After the familiarization of six-minute treadmill walking at each individual's self-selected pace, subjects completed four treadmill walking conditions in which consists of Feedforward/ Feedback and

with/without visual guidance conditions (three three-minute trials in each condition).

Three-dimensional spatiotemporal kinematic data were collected using VICON motion capture system at 100 Hz and processed along with Nexus software (Vicon, Oxford, UK). Toe elevation of leading leg during VOC task were calculated using MATLAB program (MathWorks, Inc., Natick, MA) and was defined as the vertical distance between the highest toe marker position and its position during quiet standing (Fig. 1). The mean and variability (coefficient of variance, CV) of toe elevation during VOC task were calculated.

The Kurskal-Wallis one-way ANOVA was conducted to examine the effect of visual guidance on toe elevation among three groups ($\alpha=0.05$).

RESULTS AND DISCUSSION

The preliminary results shown in Table 1 are in line with our hypothesis even though there was no significant finding ($p > .19$). Both DM and DPN lowered toe elevation during VOC without visual guidance which is expected to cause trip and fall; the visual cue assisted in increasing DM and DPN's toe elevation during VOC when compared to age-matched healthy controls in Feedback condition (Fig. 2). These findings are also in agreement that the leading leg is impacted prominently by the visual cue during obstacle-crossing task from a previous study [5]. The increased toe elevation in DM/DPN due to visual guidance can be inferred as the visual perception reliance that is expected to improve the balance during VOC.

More subjects are warranted to examine if the gait alternations found in the DM group is beneficial to stabilize their gait and reduce fall incidence.
Figure 2: The effect of visual guidance on mean toe elevation (mm) during VOC among age-matched, DM and DPN groups. FB: Feedback.

CONCLUSIONS

Overall, compared subjects with Type 2 DM with their age-matched healthy control, this study provides further evidence that visual guidance which offers the real-time location of individual's toe plays a prominent role on facilitating toe elevation and reducing fall risk in diabetic population during walking.

PERCEPTION OF SELF-MOTION IMPACTS THE VARIABILITY OF PLANTAR PROPULSION FORCE IN DIABETES

INTRODUCTION

Human movement variability generated in the neuromuscular locomotor system contributes to the stability of system, and an excessive movement variability of lower limb is seen as an indicator of fall risk [1].

People with more than 15 years of diabetes mellitus (DM) are at a high risk of suffering from diabetic neuropathy (DPN) with abnormal afferent nerve sensory inputs or efferent motor outputs [2], which causes higher spatiotemporal gait characteristics and increases the incidence of falling/tripping accidents. To maintain stability during locomotion, the reliance of body-based and visual senses (e.g. perception of self-motion) plays a very important role in DPN population to react on all kinds of external perturbations during walking [3].

The increased ground reaction force (GRF) in vertical direction and plantar propulsion force (PPF) in anteroposterior direction that will worsen the formation of plantar ulcer in DM population [4]. In addition, our previous study addressed that through the perception of self-motion (i.e exproprioception) diabetic population decrease their gait variability during locomotion [5].

Therefore, we speculate that the perception of self-motion will affect DM's plantar force generation by decreasing GRF/PPF and aim to further exam that whether the perception of self-motion will reduce the variability (i.e. coefficient of variation, CV) accordingly during locomotion.

METHODS

We recruited three chronic Type-2 DMs and three healthy controls to walk on an instrumented treadmill (FIT, Bertec Corp., Columbus, Ohio) with their self-selected pace. A six-minute treadmill walking was adopted as familiarization to stabilize the neuromuscular locomotor system. All subjects went through three no self-motion and three self-motion walking trials (120s/trial). The perception of self-motion was generated by presenting a virtual corridor that moved toward subjects with their matched velocity (Fig 1). Three-axis kinetic data during stance phase (heel-contact to toe-off) were recorded at 300 Hz and processed along with MATLAB program (MathWorks, Inc., Natick, MA) in vertical (i.e. GRF) and anteroposterior directions (i.e. PPF) respectively. The peak value and variability (CV) of GRF and PPF during treadmill walking were recorded.

Figure 1: A well-secured subject walks on the treadmill with his self-motion perceived through the rear projected virtual corridor moves toward himself.

Two-factor ANOVA with repeated measures were conducted to examine the role of self-motion impacts GRF/PPF in DM and age-matched healthy; The Bonferroni adjustment was adopted for the following analysis (α =0.05).

RESULTS AND DISCUSSION

The self-motion and group factors show significant interaction on PPF_{Peak} (toe-off) and PPF_{CV} whereas there is non-significant effect of self-motion on GRF. The following comparisons using Bonferroni adjustment show significant visual effect on reducing: (1) PPF_{Peak} in healthy controls; (2) PPF_{CV} in DM patients.

Firs of all, the decreased PPF_{Peak} and PPF_{CV} founded in this study were in line with previous study and can be explained as the optimization of neuromuscular locomotor system in the anteroposterior direction. Secondly, visual perception of self-motion shows its effect on reducing PPF_{Peak} during toe-off phase and PPF_{CV} in DM and healthy controls. Lastly, the significant decreased PPF_{CV} of DM in the following comparison illustrated that the reliance of exproprioceptive visual information improves to reduce human movement variability and to regain the stability in DM's neuromuscular locomotor system [1].

More subjects are warranted to consolidate if the gait alternations found in the DM group is beneficial to stabilize their gait and reduce fall incidence.

CONCLUSIONS

In summary, compared subjects with Type 2 DM with their age-matched healthy control, this study provides further evidence that the perception of self-motion (i.e. exproprioception) not only decreases gait variability during treadmill walking, but also plays a prominent role on reducing plantar propulsion force that may eliminate the cause of plantar ulcerations.

ACKNOWLEGEMENTS

ASSESSMENT OF SLIP-RISK USING A PORTABLE SLIP SIMULATOR

Arian Iraqi, Rakié Cham and Kurt E. Beschorner

The University of Pittsburgh, Pittsburgh, PA, USA
email: ari16@pitt.edu, web: http://www.engineeringx.pitt.edu/hmbl/

INTRODUCTION

According to the Bureau of Labor Statistics (BLS), falling events account for 25% of non-fatal occupational accidents [1]. A slip is likely to initiate when the friction required (RCOF) to sustain gait is less than the available friction at shoe-floor interface (ACOF) [2]. ACOF can be measured using a slipmeter on different floor surfaces, under both dry and contaminated conditions, whereas RCOF is measured on dry surfaces [3]. ACOF varies across different slipmeters [2], which makes the use of these devices to predict the risk of slips and falls challenging. Hanson et. al. developed a method to evaluate the relationship between slip resistance measurements and actual slips and falls. However, their study involved only one type of shoe. Different shoes have significantly different slip-resistant properties [4] and the ability of slip-testers to assess the slip risk across these shoes has not been sufficiently quantified. An in depth understanding of friction properties of shoes is required to minimize injuries due to falls from slips. The aim of this study is to test the ability of the Portable Slip Simulator, a whole-shoe tester capable of testing shoe-floor-coefficient of friction, to predict the outcomes of slipping accidents.

METHODS

Slip-resistance and slipping risk were characterized for three shoe and three boot conditions. In order to get a robust number of shoe/boot conditions, data from three similarly-conducted studies were combined for this post-hoc analysis [5,6]. The shoes included a standard work shoe (S1), a slip resistant shoe in new condition with full tread (S2T) and one in completely worn condition with not tread (S2NT), and three boot designs with identical tread but different hardness materials (Soft: B1, Medium hardness: B2; and Hard: B3, Table 1). The fluid contaminant was diluted glycerol for all conditions,

however, the concentration varied across the studies (Table 1).

Experiments to quantify ACOF were conducted using the Portable Slip Simulator [7]. This device tests an entire shoe heel and utilizes three vertical electromagnetic motors to apply a normal force and a linear motor to move the shoe across the flooring. Ground reaction forces (GRF) were measured using a 6DOF force plate (Advanced Mechanical Technology, Inc ®, Watertown, MA). Coefficient of friction (COF) values were measured at a sliding speed of 0.3 m/s, normal force of 250 N and shoe-floor angle of 7°. COF was quantified as the average ratio of resultant shear force to normal force during the first 200 ms after the normal force reached 250 N. Each test condition was repeated for 5 cycles.

Table 1: Shoe-floor-contaminant conditions and the number of subjects unexpectedly slipped.

Shoe #	Fluid Contaminant	Floor	n
S1	75% glycerol-25% water	Vinyl	26
S2T	90% glycerol-10% water	Vinyl	7
S2NT	90% glycerol-10% water	Vinyl	7
B1	50% glycerol-50% water	Vinyl	16
B2	50% glycerol-50% water	Vinyl	16
B3	50% glycerol-50% water	Vinyl	18

RCOF was calculated based on a method by Chang, et. al. [3] from baseline walking trials for previous studies conducted by our research group. The RCOF was considered only when the vertical force was above the 100 N threshold. Another criteria was that the longitudinal component of GRF had to be positive at the instant of the RCOF to correspond with the friction required for an anterior slip. Once the first two criteria were achieved, the RCOF was considered only when the instantaneous COF was increasing with time. This criterion bypasses peaks 1 and 2 of the COF data and considers the third peak.

All of the slipping trials were conducted by unexpectedly placing a liquid contaminant on the floor surface (Table 1 for different fluid contaminants) using a consistent method that obstructed the condition of the floor with dim lighting and distracting the subjects (Table 1 for number (n) of subjects for each shoe condition). The first and second unexpected slips were used for each of these studies. Slipping was tracked with a marker placed on the subject's heel. For slipping trials, occurrence of a slip event was considered when a slip distance was more than 1 cm [8].

A logistic regression model was used to determine if the mean difference between ACOF and RCOF (ACOF-RCOF) (Eq. 1) for each shoe was predictive of slip risk. The outcome was the occurrence of a slip and the prediction variable was the mean ACOF-RCOF, respectively.

$$Slip\_Risk = 1/(1+exp(\beta_0+\beta_1*(ACOF-RCOF))) \qquad Eq.1.$$

RESULTS AND DISCUSSION

The logistic regression demonstrates that as the ACOF-RCOF increases, slip risk is reduced ($p<0.0001$) (Fig. 1). The average difference between the logistic fit curve and the actual proportion of subjects who slipped was 3.95 % (standard deviation: 3.422 %).
Figure 1: Logistic regression model comparing ACOF-RCOF to the predicted probability of slip.

This study suggests that the average ACOF and RCOF should both be considered when predicting the overall slip risk. For example, Shoes 2T and B2 both had an ACOF (0.151) (Fig. 2) however, shoe 2T had a much lower RCOF (0.181) than B2 (0.209). The difference in RCOF may explain why

shoe 2T had a lower slip risk (14.29%) than B2 (50.00%) despite their similar ACOF values. The Tribometer used in this study showed a bias for slips of -0.058, i.e., ACOF-RCOF point where 50% of slips occur [4].
Figure 2: ACOF and RCOF across different shoes.

The Portable Slip Simulator provides valid measurements of slip risk for different shoes. Difference between ACOF and RCOF across the shoes and boots predicted the risk of slipping consistent with a logistic regression fit. Thus, the ACOF values from this slip-tester can be used to predict slipping risk as long as the RCOF for that shoe is known.

INTRODUCTION

The longitudinal arch of the human foot is an elastic structure with passive and active connective tissues that allow for energy storage and return during locomotion.[1] Activity of intrinsic muscles such as the abductor hallucis (ABDH) and flexor hallucis brevis (FHB) is necessary for arch support during standing,[2] and stimulation of these muscles results in arch lift and center of pressure (COP) movement.[3,4] Extrinsic muscles also activate during external arch loading, but show greater activation in posturally demanding tasks such as tandem stance[5] and unstable shoe wearing.[6] It has been proposed that intrinsic foot muscles behave as local stabilizers of the arch and extrinsic foot muscles as primary movers of the foot and ankle,[7] but it is unknown how these groups of muscles function during stances of varying postural demand and foot positions.

The purpose of this study was to evaluate activity of extrinsic and intrinsic foot muscles during common functional and sport postures of varying balance difficulty. It was hypothesized that these two groups of muscles would function differently, and that extrinsic muscles would be more active in single-leg stances due to the increased balance difficulty.

METHODS

Twenty healthy young adults free from pain and lower extremity injury for the past six months were recruited for the study (7 Males, 13 Females; Age: 27.5 ± 5.6 yrs; Weight: 669.8 ± 149 N) according to guidelines by the Institutional Review Board. The supporting foot, defined as contralateral to the preferred kicking foot, was examined. Paired fine-wire intramuscular electrodes were inserted into ABDH, FHB, flexor hallucis longus (FHL), and tibialis posterior (TP) muscles in the supporting foot of each subject. Surface electromyography (EMG) was collected from peroneus longus (PER) and tibialis anterior (TA). EMG data were collected using a wireless Noraxon system (Scottsdale, AZ) sampled at 3000 Hz, and bandpass filtered between 30 Hz and 500 Hz for surface data and 30 Hz and 1000 Hz for fine-wire data using a fourth-order Butterworth filter. Root mean square (RMS) signal amplitude was calculated over a 3 second epoch and normalized to the maximal voluntary isometric contractions for dorsiflexion, inversion, and eversion of the ankle, flexion of metatarsal-phalangeal (MTP) joints, and abduction of the first digit during manual muscle testing. Ground reaction force (GRF) data of each foot in each platform were collected with two force plates (Advanced Medical Technology Inc., Watertown, MA) in parallel setting. Sampling rate was 1500 Hz and synchronized with EMG. GRF were low-pass filtered using a fourth-order Butterworth filter with a 6 Hz low-pass cutoff. The postural demands of six balancing tasks were evaluated by COP velocity in a 3 second epoch of same duration for averaging EMG.

Subjects held six standing postures: bilateral stance (BLS), single-leg stance (SLS), bilateral squat (BSQ), single-leg squat (SSQ), bilateral calf raise (BCR), and single-leg calf raise (SCR) – in a random order for five seconds each. This sequence was repeated three times and measures were averaged for each posture. To keep the postures static in the three single-leg postures, the subjects were allowed light-touch on a supporting structure. A two-way analysis of variance (ANOVA) was conducted to compare differences between muscles and postures using Tukey post-hoc tests for pair-wise comparisons with significance set at $\alpha=0.05$

RESULTS AND DISCUSSION

The average COP sway velocity of six standing postures were, increasing in order, BLS (1.8 ± 0.9 cm/s), SCR (2.1 ± 1.0 cm/s), BSQ (2.4 ± 0.9 cm/s), BCR (3.4 ± 1.5 cm/s), SSQ (3.9 ± 2.4 cm/s), SLS (4.8 ± 1.6 cm/s). We would expect SCR to be the most challenging of the postures because of the greatly decreased base of support. But COP sway to be slower in SCR, likely because all subjects had to use a light touch cue to retain balance in this position.
Figure 1: Averaged RMS EMG of three muscle groups in six standing postures. Int: intrinsic foot muscles, Ext: extrinsic foot muscles, TA: tibialis anterior muscle.

RMS of each muscle of six standing postures was summarized in Table 1. The ANOVA revealed significant differences in muscle activation level across tasks (F=13.2, p<0.001) with post-hoc testing revealing three groups: (1) ABDH/FHB (intrinsic foot muscles), (2) FHL/TP/PER (extrinsic foot muscles), and (3) TA. Also, significant differences in muscle activation level within postural changes revealed BLS, BSQ < BCR, SSQ < SLS < SCR.

Figure 1 shows RMS EMG of three muscle groups in six standing postures. With increasing postural demand, intrinsic and extrinsic muscle groups increase activity in a similar manner. TA acts as a postural muscle only increasing in postures where it is demanded, primarily squatting.

CONCLUSIONS

Our results indicate the intrinsic and extrinsic foot muscles activate as unique groups. The activity of intrinsic and extrinsic foot muscles increases with postures of increasing balance difficulty in a similar manner.

INTRODUCTION

Postural stability is a fundamental skill of motor development. Children with Autism Spectrum Disorders (ASD) exhibit repetitive behaviors and difficulties maintaining postural stability [1]. These issues may be apparent from an early age. Current literature quantifies the magnitude of postural sway in anteroposterior (AP) and medio-lateral (ML) directions. However, this does not explain the inherent variability of posture, which has been shown not to be random, but deterministic in origin [2].

Postural variability can be examined using linear (i.e. mean, standard deviation) and non-linear measures (i.e. Lypunov Exponent, Sample Entropy), which aid in the understanding of postural control organization. Non-linear measures complement traditional linear measures and provide further insights when comparing typical and atypical development in children [3]. In the one study that used non-linear measures (multi-scale entropy), Fournier et al. [4] revealed that children with ASD had less dynamical complexity in their center of pressure (COP) when compared with healthy controls. In addition, children with ASD present greater postural sway than typically developing children [5]. Since, stationary stimuli have stabilizing effects on posture in healthy young adults, [6] we also wanted to examine whether a static-point target would have a stabilizing effect on children with ASD.

The purpose of this study was two fold: a) to determine postural control differences between typically developing children and children with ASD using linear and nonlinear measures of center of pressure (COP) and (b) to determine the effect of static stimulus on the postural sway of typically developing children and children with ASD. We hypothesized that children with ASD would have higher excursions in linear measures of COP when compared with typically developing children. Secondly, we expected to observe lower values of the nonlinear measures in children with ASD due to their restrictive and repetitive behavior. Lastly, we hypothesized that when children were presented with the static-point stimulus, both linear and non-linear measures would be reduced for both groups.

METHODS

Twenty-eight children participated; six diagnosed with autism (5.39±1.01 years old) and twenty-two typically developing children (5.49±0.77 years old). Participants attended a single session during which COP data was collected via force plate (AMTI, OR6) while looking at a blank TV screen or at a TV screen with a static-point target at eye level. Eye tracking equipment (Seeing Machines, faceLAB) was used to verify maintenance of attention during collection, ensuring that the children were looking forward.

Trials lasted for three and a half minutes each; with data recorded at 50 Hz. Post processing involved identifying segments during which the participant was not speaking or making overt motions with their head or arms. The longest common segment across all children was 750 data points, or 15 seconds of continuous data. The anterior-posterior (AP) and medial/lateral (ML) components of COP were further processed using custom Matlab scripts (MathWorks Inc.). The linear measures that we used were the mean, root mean square (RMS) and

velocity, and the nonlinear measures were the Lyapunov Exponent (LyE) and Sample Entropy (SampEn).

A 2x2 (Group x Visual Conditions) repeated measures ANOVA was used for statistical comparisons.

RESULTS AND DISCUSSION

Our analysis showed no significant differences between stationary stimulus versus no stationary stimulus conditions. However, significant differences were observed between the typically developing children and children with ASD with the nonlinear measures. Children with ASD exhibited significantly smaller ($p < 0.05$) LyE and SampEn for COP in AP direction when compared to typically developing children (Table 1). No significant differences were found for LyE and SampEn values for COP in the ML direction. There were also no significant differences found in any of the linear measures (i.e. mean, RMS, and velocity).

Although our initial hypotheses were not fully supported (in that were no significant differences in our linear measures), the hypothesis that children diagnosed with ASD would have lower LyE and SampEn values was supported ($p = 0.025$ and 0.044 respectively). The lower LyE and SampEn values indicated lower divergence and decreased predictability of posture in children with ASD. This confirms what was found in previous literature [1,3], that children with ASD have restrictive and repetitive movements.

Static-visual stimuli have been shown to have stabilizing effects on postural sway [6]. However, a surprising finding from our data was that providing the static-visual stimulus did not have any significant effect on posture for either group. This result could be due to the experimental set-up. The static stimulus was a small picture of Elmo in the middle of the TV screen while the only difference with the non-stimulus condition was the absence of Elmo. Possibly, the whole TV screen served a static reference point.

CONCLUSIONS

The present data indicates that postural control in children with ASD is more repetitive and dynamically less complex than children without ASD. These differences are particularly noticeable when using non-linear analysis to evaluate posture.

CHANGES TO FORCE CONTROL STABILITY AFTER ANTERIOR CRUCIATE LIGAMENT RUPTURE AND RECONSTRUCTION

[1] Amelia S. Lanier and [2] Thomas S.Buchanan

[1] The University of Delaware, Newark, DE, USA
[2] Delaware Rehabilitation Institute, Newark, DE, USA

email: alanier@udel.edu

INTRODUCTION

Rupture of the anterior cruciate ligament is a prevalent sports related injury. 70% of ACL injuries occur through a noncontact mechanism during sports requiring running and cutting. After ACL injury and reconstruction, patients experience altered neuromuscular control and reduced proprioception. Additionally, about 25% of those injured will experience a re-tear within the first year after returning to sports [1]. In an effort to reduce re-injury and return patients to activity, physical therapy aims to recover knee joint stability. Joint stability is measured in a number of different ways, including passively and dynamically. Recently, nonlinear analyses have been used to assess stability and have been able to provide valuable insight. These analyses are able to tap into the subtle time varying biomechanical changes that occur stride to stride, that current stability measures are unable to capture. One such example, called the Lyapnov exponent (LyE), utilized during gait analysis has shown reductions to kinematic knee joint stability after initial ACL injury and following reconstruction [2]. These changes to kinematic knee joint stability are present in all reconstruction types and in both the injured and uninjured limbs of patients [2].

However, the consequences of kinetic stability in this population have yet to be evaluated. The ability to stably produce multidirectional GRFs are crucial as patients return to running and cutting sports. Therefore, the purpose of this study was to evaluate force control stability after ACL rupture and subsequent ACL reconstruction using LyE. We hypothesized increased kinetic instability would be present after ACL rupture and ACL reconstruction when compared to healthy uninjured controls. We

also hypothesized all subjects would be less stable when tested in the anterior/posterior (AP) direction when compared to the medial/lateral (ML) direction.

METHODS

For this study we recruited 7 (2M) healthy uninjured individuals, 3(1M) who have experienced ACL rupture, and 2 (1M) who have undergone ACL reconstruction. All subjects were instructed to stand on two force plates with a foot on each force place. They were provided real time visual feedback of their force production, via a screen in front of them. Subjects were instructed alternatively and continuously to produce ±50% of their maximum force production in the AP or ML direction. LyE analysis was performed using the AP and ML force profiles as the variables of interest. To calculate the LyE two parameters were initially determined, time lag (τ) and embedding dimension (m). These parameters transformed our signal of interest into state space. Tau & m were calculated using an average mutual information (AMI) function and a global false nearest neighbor (GFNN) function respectively. Once in state space we used the Wolf algorithm [3] to calculate LyE. Further detail on AMI, GFNN, and Wolf algorithms is described in Stergiou et al. [4]. For this study we reported the maximum LyE value as it corresponds to the maximal instability.

RESULTS AND DISCUSSION

Our results support our first hypothesis that injury leads to reduced force control stability. Both ACL deficient (ACL-d) and ACL reconstructed (ACL-r) subjects had larger LyE values when compared to healthy uninjured controls (Fig.1, 2). However,

there is no difference in stability when comparing directions (Fig.1). Additionally, there appears to be no effect of limb (inv vs. uninv) (Fig 1).
Figure 1: Avg LyE ± SD (bits/sec) for healthy uninjured (gray), ACL-d (orange), and ACL-r (blue) subjects. Lower values for LyE indicate greater stability.
Figure 2: Representative force profile for a healthy subject (Plot A) and ACL-r subject (Plot B) in the anterior (+) and posterior (-) directions.

Being that ACL injury typically leads to muscular changes including quadriceps weakness we initially hypothesized force control stability would be more impaired in the AP direction compared to the ML direction. However, deficits to force control stability are present in both the AP and ML directions. This generalized reduction in force control stability may indicate upper level impairments are influential. Reduced proprioception and neuromuscular control is commonly seen after ACL injury.

Additionally, our results reflect those seen in studies that calculate kinematic stability. Using knee flexion/extension angle during gait Moraiti and colleagues found increased LyE values or reduced stability after ACL reconstruction [2]. Reductions to kinematic stability were equal in both involved and uninvolved limbs. Increased LyE present in both the involved and uninvolved limbs measured from both kinetics and kinematics may also indicate an upper level neuromuscular deficit. Diminished force control stability and kinematic stability in both the involved and uninvolved is important when considering there is a higher rate of re-injury in the contralateral limb [1].

CONCLUSIONS

After initial ACL injury and subsequent reconstruction there a large reductions to force control stability. Reduced force control stability is present in both the AP and ML directions. Our results indicate diminished stability in those with ACL injury and reconstruction when generating multidirectional ground reaction forces in both the injured and contralateral limb. Being that most injuries occur during running and cutting maneuvers a deficit to force control stability may be extremely detrimental. Reductions in force control stability may be contributing to re-injury rates in both contralateral and ipsilateral limbs as patients return to sports as it could lead to reduced running and cutting performance.

REDISTRIBUTION OF JOINT MOMENTS AND DYNAMIC BALANCE CONTROL OF PERSONS WITH PARKINSON'S DISEASE

Hyo Keun Lee, Jared W. Skinner, Chris J. Hass

The University of Florida, Gainesville, FL, USA
email: leehk82@ufl.edu

INTRODUCTION

One of the cardinal motor symptoms of Parkinson's disease (PD) is postural instability. Postural instability contributes to impaired balance control, ultimately leading to an increased incidence of falls during activities of daily living. Further, such deficits in balance control are especially prominent during challenging motor tasks where the individual transitions from one base of support to another.

The Sit to Stand (STS) is a challenging task for persons with PD because it requires significant momentum generation in the forward and upward direction at a time when the base of support reduces to the span of the feet. Thus, the STS task requires the execution of joint moments to produce the necessary momentum but this momentum must also be able to be constrained to prevent falling forward or backward after rising [1].

Previously, we have reported that individuals with PD have reduced torque generating capacity and express a redistribution of joint torques during locomotor tasks. Herein, we evaluate the torque generating capacity of persons with PD during a STS task and evaluate the contribution of the hip, knee, and ankle to the net support moment in comparison to performance of age-matched healthy older adults. In addition, we examined and compared postural stability during the stabilization period after standing. We hypothesized that persons with PD perform the STS task with redistribution of their lower extremity joint moment along with less dynamic balance control capabilities.

METHODS

Eleven participants with mild to moderate PD (mean ± SD age: 65 ± 8 years, mean height: 170.5 ± 7.2 cm, mean body mass: 77.3 ± 9.9 kg) and 9 age matched HOA (mean ± SD age: 66 ± 8 years, mean height: 171.2 ± 8.3 cm, mean body mass: 70.3 ± 12.9 kg) volunteered in this study.

Participants were instructed to perform 5 experimental STS trials from a standard height chair. The individuals' feet were positioned uniformly on a force plate in front of the chair. Joint moment data were calculated from inverse dynamics techniques using motion capture (120 Hz, Vicon, Oxford, UK) and force plates data (360 Hz, Bertec Corporation, Columbus, Ohio). The distribution of lower extremity joint moments was also examined as a percentage of the total support moment. The total lower extremity moment (TLEM) in sagittal plane following seat off was determined for STS task by summing the peak hip, knee, and ankle joint moments from both limbs [3]. TLEM provides a quantitative assessment of the support and propulsive effort of the musculature for both legs during the STS task [1].

Dynamic Postural Stability Index (DPSI) was calculated from ground reaction force data during stabilization of the STS task. A 3-sec interval starting from onset of STS was used for the evaluation of dynamic stability. Anterior-posterior, medio-lateral, vertical, and dynamic postural stability indices (APSI, MLSI, VTSI, DPSI) were calculated from ground reaction forces (Fx, Fy and Fz) [2].

All comparisons between groups were evaluated using independent T-tests. A traditional level of significance $p \leq 0.05$ was adopted for the investigation.

RESULTS AND DISCUSSION

Findings showed persons with PD produced smaller peak ankle moment ($p<.05$), while they produced significantly greater peak knee moment ($p<.01$) than HOA during STS. However, there was no significant group difference in peak hip joint moment. This indicates that contribution of the knee to the extension moment is greater while ankle flexor is less in PD, causing a redistribution of joint moments during STS (Fig 1).
Figure 1: TLEM joint distribution for STS

In addition, persons with PD exhibited similar DPSI score to the score of HOA ($p>.05$) whereas the APSI score was significantly higher in PD ($p<.05$). Our results support evidence from previous studies that PD patients have impaired ankle joint function producing relatively less joint moment during activities of daily living. Given that PD patients showed redistribution of joint moment and decreased balance control in the AP direction during STS, our result suggest that there may be a close relationship between muscular function and balance control capability in PD.

CONCLUSIONS

Persons with PD use a different strategy in lower extremity joint moment production during STS in comparison to HOA. This finding of redistribution of joint moments may indicate that the deficit of dynamic balance control in PD is closely related to muscular function. In the future study, correlation analyses should be performed to better understand the relationship between muscular function and balance control. This study further proposes the need of intervention like exercise training aimed on improved muscular function.

EFFECT OF WHOLE BODY VIBRATION ON CENTER OF MASS MOVEMENT IN HEALTHY YOUNG ADULTS

Huaqing Liang and Jianhua Wu
Georgia State University, Atlanta, Georgia, USA. Email: hliang2@gsu.edu

INTRODUCTION

Whole body vibration (WBV) has acute effects on postural control strategy. The degree of impact depends on the amplitude, frequency, and duration of WBV, and the difficult level of balance task as well as the reliability of sensory information to the individual [1, 2, 3]. Healthy young adults can return to the baseline level of postural sway for a simple balance task within 20 minutes after repeated exposure to WBV [4]. Still, little is known about the acute and residual effects of WBV on the center-of-mass (COM) movement after a single bout of WBV. The purpose of this study was to understand the COM movements of young adults pre-, during, immediately post-, and 5-minute post 40-second WBV during standing.

METHODS

Participants: Fourteen healthy young adults (6M /8F) participated in the study. Mean (SD) of age was 24.5 (3.9) years, height 1.68 (0.12) m, and body mass 70.6 (13.4) kg.

Experimental design: There were two vibration conditions: 0.5g and 0.9g (g is gravitational acceleration). These two vibration conditions represented WBV with amplitude less than 1mm at the frequency of 30 Hz and 50 Hz, respectively. There were two visual conditions: eyes open (EO) and eyes closed (EC). For each condition, data were collected for 40 seconds before vibration (phase *Pre*), during vibration (phase *Vib*), immediately after vibration (phase *Post_0*), and 5 minutes after vibration (phase *Post_5*). A Vicon full-body PSIS model was used to attach reflective markers on the subjects. A 7-camera Vicon motion capture system was used to record these markers.

Data collection and analysis: A total of four conditions (2 vibration x 2 visual) were tested and each condition was repeated twice. The order of the conditions was randomized and adequate amount of time was given between conditions. Customized MATLAB programs were used to calculate average velocity and range of the COM during each phase in the anterior-posterior (AP) and medial-lateral (ML) directions separately.

Statistical analysis: A series of 3-way (2 vibration x 2 visual x 4 phase) ANOVA with repeated measures were conducted on dependent variables. Post-hoc pair-wise comparisons with Bonforreni adjustments were conducted when appropriate. Statistical significance was set at $p<0.05$.

RESULTS AND DISCUSSION

Fig.1 COM AP Average Velocity
In the AP direction, average velocity increased from *Pre* to *Vib*, and reduced to the *Pre*-level after the vibration (Fig. 1). There was a vibration by visual by phase interaction (p=0.006). Post-hoc analysis revealed that average velocity was higher in the *Vib*-phase than the other three phases. Average velocity was higher in the EC than in the EO condition. Additionally, it increased to a greater extent from EO to EC condition in the *Vib*-phase than the other three phases. Average velocity increased from 0.5g to 0.9g in the EC condition, but decreased from 0.5g to 0.9g in the EO condition. For a higher level of vibration, participants may have intentionally restricted their postural sway in the AP direction and successfully did so in the EO

condition, but swayed at a faster velocity when visual information was not available.

Fig.2 **COM ML Average Velocity**
In the ML direction, average velocity increased from *Pre* to *Vib*, and reduced to the *Pre*-level after the vibration (Fig. 2). There was a vibration by phase interaction (p<0.001) as well as a visual by phase interaction (p=0.019). Post-hoc analysis indicated average velocity was higher in the EC than in the EO condition only in the *Vib*-phase. When the vibration increased from 0.5g to 0.9g, average velocity increased only in the *Vib*-phase. Additionally, average velocity was higher in the *Vib*-phase than the other three phases. A higher level of vibration elicited a faster postural sway in the ML direction, particularly when visual information was not available.

Fig.3 **COM AP Range**
In the AP direction, range was larger after vibration than before and during vibration, and increased from EO to EC condition (Fig. 3). There was a vibration by phase interaction (p=0.020) and a visual effect (p=0.002). Post-hoc analysis showed that range was larger during the *Post_0* and *Post_5* phases than the Pre-phase respectively. It seems that

vibration has an acute and residual effect on the COM range in the AP direction regardless of vibration and visual conditions.

Fig.4 **COM ML Range**
In the ML direction, range was larger 5-minute after vibration than before vibration (Fig. 4). There was a phase effect (p=0.009) and post-hoc analysis revealed that range during the *Post_5* phase was greater than the *Pre* phase regardless of vibration and visual conditions, suggesting a residual effect of vibration.

CONCLUSIONS

During vibration, young adults increase average velocity of the COM but maintain its range mostly in both the AP and ML directions regardless of visual conditions. After vibration, young adults return average velocity of the COM to its pre-vibration level in both the AP and ML direction; however, the vibration elicits a residual effect on the COM range in both directions. Young adults may need to constrain the range of sway to maintain balance during vibration, but increase the sway velocity to make sway corrections more frequently.

POSTURAL STABILITY IN ADOLESCENTS WITH EHLERS-DANLOS SYNDROME (HYPERMOBILITY TYPE) FOLLOWING AN EXERCISE INTERVENTION

[1] Jason T. Long, [2] Bailey A. Petersen, [1] Cailee M. Caldwell, and [1] Stephanie F. Sabo

[1] Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA

INTRODUCTION

Ehlers-Danlos Syndrome (EDS) comprises a group of disorders marked by abnormal collagen function. In the most common form of EDS (type III or Hypermobility Type, hereafter EDS-HT), major diagnostic findings involve joint hypermobility and chronic pain. The prevalence of EDS-HT is up to 10-30% of males and 20-40% of females [1, 2]. Current interventions for chronic pain in EDS-HT consist of physical therapy, orthotic arch supports for postural alignment, neuromuscular and proprioceptive training, joint protection, stability and strengthening [3-5].

Physical therapy has been recognized in practice for its benefits to patients with joint hypermobility. Although the literature focused on these benefits is limited, evidence suggests that mechanical interventions may improve fatigability, pain, and stability [1-4]. Pilot findings from our group suggest that participation in an intensive exercise intervention (IEI) may lead to improvements in joint motion, loading, and symmetry [5, 6]. This IEI is a current care option for these patients at our institution.

Our group has previously reported on changes in biomechanical factors during walking in patients with EDS-HT. While ambulatory parameters demonstrate minimal change following exercise intervention, underlying postural stability parameters have not been assessed. In a pilot study, Greenwood et al. [6] found that strategies for stabilization during balance tasks may be relevant to injury risk in EDS-HT populations. Therefore, the purpose of this study was to assess postural stability metrics in patients with EDS-HT before and after participation in the intensive exercise intervention.

METHODS

Adolescents with EDS-HT or hypermobility disorder were recruited from the roster of IEI participants (ages 6-17 years). Each participant made an initial visit to the Motion Analysis Lab (MAL) immediately prior to starting the IEI, and a second visit within five days of completing the IEI. Between lab visits, participants took part in the IEI. This is a 10-day program involving two hours of intensive therapy per day, focused in neuromuscular re-education, flexibility, strengthening, joint stabilization, and endurance. Therapy sessions are both land-based and pool-based

During each visit to the MAL, participants underwent postural stability testing on an OR6-500 force platform (AMTI; Watertown, MA). Participants were asked to assume a position of comfortable bilateral stance on the platform. Two trials were collected, corresponding to two different visual conditions--Eyes Open (EO) and Eyes Closed (EC). During each trial, ground reaction force data were collected at 1800Hz for 60 seconds and processed to obtain center of pressure (COP) information. Data were subsequently analyzed using custom Matlab software (The Mathworks, Inc.; Natick, MA). Measures of interest included linear (COP excursion, velocity, and standard deviation) and nonlinear (approximate entropy and sample entropy) metrics in the A/P and M/L directions. Data were compared between test conditions using paired t tests.

RESULTS AND DISCUSSION

Summary findings are presented in Table 1. Select findings with statistical significance and potential clinical relevance are highlighted in Figures 1 and 2.
Figure 1: Linear measures of COP excursion in ML and AP directions for EO condition pre- and post-intervention (*SD* standard deviation, *Exc* excursion, *Vel* velocity). Star indicates significant difference (p<0.05).
Figure 2: Approximate entropy (*ApEn*) and sample entropy (*SaEn*) of COP location in ML and AP directions for EO condition pre- and post-intervention. Star indicates significant difference (p<0.01).

Table 1: Velocity and entropy metrics for COP displacement in all conditions. † denotes significance for EO Pre vs EC Pre (p<0.01).

Measure	EO Pre	EO Post	
Vel-ML [cm/s]	7.55 ± 2.3	8.3 ± 2.39	
Vel-AP [cm/s]	9.84 ± 2.3	9.83 ± 2.46	†
Tot Vel [cm/s]	13.87 ± 3.24	14.44 ± 3.71	†
ApEn-ML	6.66 ± 2.08	6.06 ± 1.9	†
ApEn-AP	3.69 ± 1.22	3.51 ± 1.31	†
SaEn-ML	0.17 ± 0.05	0.25 ± 0.08	
SaEn-AP	0.17 ± 0.06	0.17 ± 0.07	†

Significant differences in SD-ML between the EO Pre and EO Post conditions indicate variability of COP excursion that decreases following participation in the IEI, indicating a reduced amount of ML position variability. Significant increases in nonlinear postural control metrics are observed in the ML direction for both approximate and sample entropy, indicating changes in the structure of the ML position variability. These findings are similar to those from studies of adolescent athletes recovering from traumatic brain injury [7, 8]. Collectively, these findings suggest that the patients improved their ability to stabilize in the ML direction, and that their patterns of balance demonstrated increased complexity. This increased complexity of sway control may point to an increase in the patients' postural adaptability, and an improved readiness for perturbation.

Additionally, significant differences between EO and EC conditions for AP velocity and entropy were noted both pre- and post-intervention. While these findings are similar to those in the literature, it may be interesting to assess patients' reliance on visual input for maintaining stability and the effect of the IEI on this.

CONCLUSIONS
Significant improvements in mediolateral postural stability have been observed in adolescents with EDS-HT following participation in an IEI. These findings stand in contrast to the absence of change observed in concurrent studies of gait metrics. Further study is warranted to learn how these changes are affected by patients' baseline characteristics (e.g. pain level, fitness level, etc.) Additional stratification by age and gender may also be useful in delineating the most appropriate intervention strategy for subsets of this population.

HEAD ACCELERATIONS AFTER SLIPPING AND TRIPPING EXCEED THOSE DURING WALKING

INTRODUCTION

Slipping and tripping contribute to a large number of falls and fall-related injuries among older adults [1]. Detecting the onset of a loss of balance after a slip or trip is critical in preventing a fall. The vestibular system provides sensory feedback on head orientation and motion. The purpose of this study was to compare peak linear head accelerations after slipping or tripping to those experienced during walking. This information can help determine whether vestibular information may be used to detect the onset of a slip or trip, and may guide the development of fall prevention strategies.

METHODS

Twelve young male adults (mean ± SD age: 20.9 ± 2.2 years) performed several walking trials along a 10m walkway at a prescribed gait speed (~1.5 m/s). After a minimum of 20 walking trials, an unexpected slip or trip (but not both) was induced to the dominant (right) foot.

Body segment positions of select anatomical landmarks on the head and feet were sampled at 200 Hz using a Vicon MX motion analysis system with T-10 cameras (Vicon Motion Systems, Inc., Los Angeles, CA). Head acceleration was sampled at 800 Hz using a lightweight six degree-of-freedom inertial measurement unit (IMU) (Memsense, LLC., Rapid City, SD) attached to the forehead. Marker position and acceleration data were low-passed filtered at 5 and 20 Hz, respectively.

Using methods similar to Startzell et al. [2] and Rivera et al. [3], head accelerations were converted to coordinate system aligned with the skull and transformed to an approximate location of the vestibular organ within the skull.

Peak accelerations in each direction (anterior/ posterior, rightward/leftward, superior/inferior) were determined over six time intervals following perturbation onset, and compared between tasks (walking, slipping, tripping) and time intervals using a two-way repeated measures analysis of variance on the ranks (due to non-normal distributions). In the event of a significant condition by time interval interaction, contrasts were performed within each time interval. Statistical analyses were performed using JMP Pro 11 (SAS Institute, Inc., Cary, NC) with a significance level of $p \leq 0.05$.

RESULTS AND DISCUSSION

Peak head acceleration after tripping (Fig. 1) and slipping (Fig. 2) both differed from walking. After tripping, (Fig. 1), peak head acceleration during the 0-50ms time interval after trip onset was 0.68 m/s^2 higher in the anterior direction ($p<0.001$), 0.47 m/s^2 higher in the posterior direction ($p=0.011$), 0.63 m/s^2 higher in the rightward direction ($p<0.001$), and 3.88 m/s^2 higher in the superior direction ($p<0.001$) compared to walking. Several other differences in peak head acceleration between tripping and walking were found over 50-300ms time interval after trip onset ($p<0.05$), and the magnitude of these differences tended to increase with time (Fig. 1).

After slipping (Fig. 2), peak head acceleration did not differ from walking until the 100-150ms time interval after slip onset, and was 2.00 m/s^2 higher in the inferior direction compared to walking. Several other differences in peak head acceleration between slipping and walking were found over the 150-300ms time interval after slip onset ($p<0.05$), and

the magnitude of these differences tended to increase with time, but the magnitude of these differences was smaller than those seen during tripping.
Figure 1: Peak head acceleration (m/s^2) after tripping (dark gray) and during walking (white). Time 0 indicates the instant of trip onset and mid-swing during walking. * denotes a difference between tripping and walking ($p<0.05$). # denotes a main effect of condition ($p<0.001$). The top of columns indicate the mean and SD in the positive direction (anterior, right, and inferior), and the bottom of the columns indicate the mean and SD in the negative direction (posterior, left, and superior).

Previous studies have shown muscle latency times of approximately 55-150ms [4] following trip onset Because differences in head acceleration between tripping and walking were seen within 0-50ms of trip onset, these results suggest that vestibular information may play a role in generating a balance recovery response from a trip. However, previous studies have shown muscle latency times following a slip to be 90-160ms following a slip [5]. Differences in head acceleration between slipping and walking were not seen until 100-150ms of slip onset, suggesting that the vestibular system is less likely involved in the initial neuromuscular response to a slip.
Figure 2: Peak head acceleration (m/s^2) after slipping (light gray) and during walking (white). Time 0 indicates the slip onset at heel contact, and heel contact while walking. * denotes a difference between slipping and walking ($p<0.05$).

CONCLUSIONS
Peak head acceleration after slipping and tripping differed from those during walking. Differences occurred sooner after tripping compared to slipping, and the magnitude of these differences was larger after tripping than those after slipping. These results suggest that vestibular information may play a role in initiating a balance recovery response to a trip, but it remains unclear if such information contributes to recovery from a slip.

OBESITY DOES NOT INCREASE LIKELIHOOD OF SLIPPING WHILE DESCENDING RAMPS

[1]John M. Scanlon, [1]Abigail M. Zadnik, [1]Maury A. Nussbaum, and [2]Michael L. Madigan

[1]Virginia Tech, Blacksburg, VA, USA
[2]Texas A&M University, College Station, TX, USA
email: mlm@tamu.edu

INTRODUCTION

Over the past several decades, there has been an increasing prevalence of adult obesity in the U.S. (22.9% in 1988-1994 [1] and 34.9% in 2011-2012 [2]). Obese individuals have a 27% annual fall rate compared to 15% for those of healthy weight [4]. The effects of obesity on the likelihood of slipping during level walking has shown mixed results [5,6]. Descending ramps has been found to increase the likelihood of slipping [7], and may influence how obesity affects the likelihood of slipping.

The purpose of this study was to investigate the effects of obesity on likelihood of slipping during ramp descent. Because obese individuals exhibit a higher annual fall rate [4], we hypothesized that the likelihood of slipping would be higher among obese participants. Understanding how obesity affects slipping could help guide the development of effective fall prevention strategies.

METHODOLOGY

Twenty-three young male adults were recruited from the university population including thirteen healthy weight (age 21.8 ± 2.1 years, BMI 22.1 ± 2.0 kg/m2) and ten obese (age 23.9 ± 3.5 years, BMI 32.0 ± 3.6 kg/m2) individuals. Participants descended five randomly-ordered ramp angles, including 0, 2.5, 5, 10, and 15 degrees, at a walking speed of 1.1-1.6 m/s. Five trials were performed at each ramp angle. Prior to the session, participants donned athletic compression shorts and standardized athletic shoes in their respective size, and were told that they were not at any risk of being slipped.

The ramp was 0.9-m-wide and 1.8-m-long, and covered in vinyl flooring. A force platform (Bertec, Columbus, OH) was integrated in the ramp and located halfway down the length of the ramp. A hand railing was attached to the left side of the ramp for safety, but was not used in any trials analyzed. Ground reaction force data were sampled from the force platform at 1000 Hz and processed using a customized Matlab program (The Mathworks Inc., Natick, MA). Acromion marker data and force platform data were filtered using 4th order low-pass Butterworth filters with cutoff frequencies of 5 Hz and 25 Hz, respectively. Walking speed was calculated as the mean velocity of the acromion marker while traversing the ramp. Resultant RCOF was calculated as the resultant shear force divided by normal force.

A four-way mixed-model ANCOVA was used with walking speed as a covariate. Independent variables included obesity group, ramp angle, ramp order, and trial number (an obesity group x ramp angle interaction was also included). Post hoc pair-wise comparisons were performed using Tukey's Honestly Significantly Different test. Analyses were performed with JMP v7 (Cary, North Carolina, USA), and statistical significance was concluded when $p \leq 0.05$.

RESULTS & DISCUSSION

RCOF exhibited an obesity group x angle interaction ($p=0.043$). Pair-wise comparisons indicated RCOF increased as ramp angle increased within each group, but no effects of obesity group at each ramp angle (Figure 1).

The RCOF values obtained in this study compared well with results from past studies.

Cham and Redfern [8] investigated gait during ramp descent on a vinyl surface for healthy weight subjects, and found RCOF values of: 0.18 (current: 0.19) for 0 deg, 0.26 (current: 0.27) for 5 deg, and 0.32 (current: 0.33) for 10 deg. Redfern and Dipasquale [7] and McVay and Redfern [9] also observed positive trends in RCOF with increasing ramp angles.

It should be noted that slip risk (which requires measuring the difference between the available COF and RCOF) was not directly measured. However, because the available COF was the same in all conditions, RCOF as reported here does indicate relative slip risk.

CONCLUSIONS

Although the risk of slipping increases as ramp angle increases, obese individuals are not at an increased risk of slipping while descending ramps. This result, combined with previous results [5,6,10], suggest modest, if any, increase in risk of slipping while walking among individuals who are obese.

Lumbar Spine Movement Patterns During a Clinical Test and a Functional Activity in People With Low Back Pain and People Without Low Back Pain

Marich AV, Bohall SC, Hwang CT, Sorensen CJ, Van Dillen LR

Washington University in St Louis School of Medicine,
Program in Physical Therapy, St Louis, MO, USA
email: maricha@wusm.wustl.edu

INTRODUCTION

Low back pain (LBP) is a common musculoskeletal problem with a complex etiology. One proposed movement-related mechanism contributing to the development and recurrence of LBP is the repeated use of stereotypic movement patterns. Previous research using clinical tests has identified early lumbar motion as one stereotypic movement pattern that is associated with LBP[1,2]. It is proposed that early lumbar motion used repetitively throughout the day results in an accumulation of tissue stress in the lumbar region, leading to microtrauma and eventually LBP symptoms. The movement patterns observed during clinical tests are assumed to reflect the behavior of the lumbar spine during daily functional activities.

The purpose of this study was to examine the lumbar movement patterns in people with LBP and back-healthy (BH) people during a clinical test and a functional activity. We hypothesized that (1) lumbar movement patterns during a functional activity would be similar to those observed during a clinical test, and (2) the amount of lumbar range of motion (ROM) used early in the movement would be greater in people with LBP compared to BH people, and be related to disability in people with LBP.

METHODS

Subjects. 32 people with chronic LBP and 16 age-, height- and weight-matched BH people participated. Subjects were excluded if they were in an acute flare-up or had a history of spinal trauma or certain spinal conditions. Subjects with LBP completed the modified Oswestry Disability Index (mODI). The mODI is a disease-specific disability measure.

Scores range from 0-100%. A score of <20% indicates low disability.[3] Thirteen LBP subjects had mODI scores < 20% (LBP-LOW, age 35.08 ± 12.28 yrs, 8 male), and 19 subjects had mODI scores ≥ 20% (LBP-HIGH, age 32.95 ± 8.57 yrs, 9 male).

Instrumentation. An 8-camera, 3-D motion measurement system (Vicon Motion Systems, LTD, Denver, CO) was used. All kinematic data were processed using Visual3D (C-Motion Inc., Germantown, MD) and variables calculated using custom written software in MATLAB (MathWorks Inc., Natick, MA).

Laboratory Based Testing. Kinematics were collected during the clinical test of forward bending (FWB) and the functional activity of picking up an object (PUO). For PUO, an empty plastic container was placed at a height equal to 100% shank length and a distance 50% of the trunk length away from the front of the knee. The variables calculated were maximum ROM of the lumbar spine and lumbar ROM at 25% increments of total movement time.

RESULTS AND DISCUSSION

Forward Bending. There were no differences in maximum lumbar ROM among the 3 groups. The LBP-HIGH group displayed significantly greater lumbar ROM from 0-25% of the movement time compared to the BH group (Table 1). There were no other differences among the groups.

Picking Up an Object. The LBP-HIGH group had significantly greater maximum lumbar ROM compared to the other 2 groups. The LBP-HIGH group also displayed significantly greater lumbar

ROM from 0-25% and 25-50% of movement time compared to the other 2 groups (Table 1).

Relationship of Movement Patterns to Disability: There was a moderate positive correlation between lumbar ROM in the early part of movement and mODI scores for all LBP subjects for both FWB and PUO (Table 2).

CONCLUSIONS

There were no differences in maximum lumbar ROM among the groups during FWB. Compared to the BH group, the LBP-HIGH group displayed significantly greater lumbar ROM in the early part of the movement (0-25%). Compared to the other 2 groups, the LBP-HIGH group had greater maximum lumbar ROM during PUO, and the differences in lumbar ROM occurred in the 1st 1/2 of the movement (0-50%). The amount of lumbar ROM early in FWB and PUO is positively related to

mODI scores. The data suggest that as the amount of lumbar ROM used increases, particularly early in the movement, the greater the LBP-related disability.

INTRODUCTION

Falls are responsible for reduction of functional independency, institutionalization, fear of falling and loss of confidence in older adults [1]. Previous studies demonstrated that older faller adults have lower strength, an increased energy cost of walking and changes on gait biomechanical, such as an increased gait kinematics variability than older non-faller adults [2-4]. However, to the authors' knowledge the identification of the best physical and gait performance parameter to discriminate older fallers and non-fallers still unknown.

Thus, the current study aimed to identify the best physical (lower limb maximum strength) and gait performance (metabolic and biomechanical) parameter to discriminate older fallers and non-fallers. Also, a second objective of this study was to identify the cut-point of the best physical and/or gait performance parameter to discriminate older fallers and non-fallers.

METHODS

Thirty-seven older female adults participated of this study (age 67.8 ± 7.1 yr). The subjects were separated into two groups: older fallers (n = 15) and non-fallers (n = 22) based on having fallen or not in the period of 1 year before the evaluation.

The volunteers visited the laboratory on two separate occasions within 24-72 hours. On the first day of data collection the preferred treadmill walking speeds (PTWS), and the hip, knee and ankle maximal isometric voluntary joint torques were measured. During the second day of data collection, the volunteers were familiarized with treadmill walking at PTWS for 10 min and then the energy expenditure during seated rest was measured via indirect calorimetry. Next the cost of walking at PTWS was measured followed by kinematic assessment of gait.

Kinematic gait parameters, cost of walking, and joint voluntary torques were assessed by: a motion analysis system with seven infrared cameras (Vicon Motus, Oxford, UK®) and an 8-channel, telemetered biological data system (Noraxon®, Phoenix, USA); a metabolic measurement system (Quark PFT, Cosmed®, Rome, ITA); and an isokinetic dynamometer (Biodex®, New York, USA).

For the kinematic gait parameters, 39 markers were fixed on the head, trunk, upper and lower limbs, according to the manufacturer's Plugin Gait Full Body model. The kinematic parameters were recorded at a sample frequency of 100 Hz. Also, heel contact and toe-off were detected by two footswitches (Noraxon®, Phoenix, USA), composed of four sensors attached on both feet at the heel, first and fifth metatarsals, and toe, which were synchronized with the motion analysis system.

The algorithm C4.5 of learning machines was used for the data analysis. Table 1 summarizes the variables used in the categorization.

Class
Faller
Non-faller

RESULTS AND DISCUSSION

The stance time variability was capable of distinguishing groups of elderly fallers and non-fallers. The accuracy achieved was 97.30%, correctly classifying 36 of 37 samples. Observing the model generated by C4.5, a decision tree was composed of a single node represented by stance time variability, with a discriminant value for the class of older fallers and non-fallers (Figure 1). In this case, the decision tree can be expressed as a single decision rule as follows: *if* (stance time variability ≤ 0.101917); *then* (class = non-faller); and *else* (class = faller).
Figure 1: Decision tree using full dataset.

The most novel aspect of this study was that it demonstrated that the best parameter to discriminate older fallers and non-fallers was the stance time variability with 93% of sensitivity, 100% of specificity and the cut-point of 0.1 seconds. Our findings corroborate with Bruijn et al. (2011)[5] and Toebes et al. (2012)[1] findings which demonstrated an association between step time variability and risk of falls.

The stance is the gait phase that requires more strength, balance and motor control during walking. During the initial stance phase, muscles are activated to maintain joint stability while the ground reaction forces are absorbed [6]. Also, during the final stance phase, while the hip and trunk muscles are activated to maintain balance, the plantar flexors are recruited to accelerate the center of mass to perform the next step [6]. Thus, once older adult fallers would have lower strength and poorer balance than older adults non-fallers the gait variability may be increased by this physical limitations.

CONCLUSIONS

The current study provides new knowledge of the best physical and gait biomechanics parameters to discriminate older fallers and non-fallers. According to our findings, the best gait biomechanical parameter to identify older fallers and non-fallers was the stance time variability (sensitivity of 93% and sensitivity of 100%) and the cut-point found was a variability of 0.1 seconds between the strides.

Role of the Paretic and Nonparetic Limbs to Arrest Forward Momentum Following a Perturbation

[1] Nicholas K. Reimold, [1,2] Keith E. Gordon and [1] Katherine M. Martinez

email: k-martinez@northwestern.edu

INTRODUCTION

Stroke survivors often have deficits in gait, balance and postural stability and are at higher risk for falls [1]. Clinically, ambulatory stroke survivors tend to initiate voluntary steps with their paretic leg. In contrast, when stepping is induced by a perturbation, individual less than three months post stroke show a preference to initiate stepping with their nonparetic leg [2]. However, the probability that ambulatory chronic stroke survivors will initiate stepping with their paretic leg in response to a perturbation will increase if the limb is passively unloaded [3]. The purpose of this study was to investigate the ability of community dwelling stroke survivors to use their paretic and nonparetic limbs to control their forward momentum following a significant postural perturbation. Specifically, our goal was to quantify the braking inpulse created during the first step after the perturbation. We hypothesized that the braking impulse created when subjects stepped first with their paretic limb would be significantly less than the braking impulse generated by their nonparetic limb and would often be inadequate to stop their forward momentum within a single step.

METHODS

Six individuals post stroke participated in the study. All subjects ambulated independently in the community (mean age 51.5 yrs, 4 males, 4 right side weak, 1-26 years post stroke). Subjects were tested without their ankle-foot orthosis and/or assistive devices.

We measured trunk and lower limb kinematics and ground reaction forces as subjects performed multiple trials in which they were instructed to respond naturally to the perturbation they would receive. Each trial began with subjects standing quietly with their feet shoulder width apart. Three initial standing conditions were included in which the distribution of the subjects body weight between their two feet was manipulated by providing visual feedback to the subjects about their weight distribution. The three conditions were weight equally distributed, more weight (70%) on the paretic limb, and more weight (70%) on the nonparetic limb. Once subjects achieved and held the target weight distribution for 250-1000 msec they would receive an anterior-directed waist pull perturbation. The perturbations were created by dropping a weight equal to 10% of their body weight connected by a cable attached to the front of a belt worn by the subject. Ten perturbation trials were conducted at the three different weight distribution conditions, and 6 additional catch trials at 2% BW were randomly applied. Rest breaks were given after 18 trials and as needed.

For each trial we first identified which limb subjects stepped with and calculated the number of recovery steps required after the perturbation. We also calculated the anterior-posterior impulse during the period from heel strike of the first step until heel strike of the second step after the perturbation. We estimated forward velocity at heel contact of the first step using the trunk markers. Finally we calculated change in forward momentum during the first step using the two previous values.

RESULTS AND DISCUSSION

All subjects stepped in all of the 10% body weight perturbation. In 83.6% of the trials subjects stepped their nonparetic limb and 16.4% of the trials with their paretic leg. Two subjects made their first response step exclusively with the nonparetic limb.

Across the body weight distribution conditions no significant differences in the anterior-posterior impulse ($F_{(2, .044)}=3$, p=0.13) or change in momentum ($F_{(2, 485.3)}=1.25$, p=0.54) were observed. Thus, the conditions were combined to increase the number of trials that could be used to compare the first step response between the limbs.

Making a first response step with the paretic or nonparetic limb did not result in a significant difference between the total number of steps taken in response to the perturbation or effect the forward velocity at the first heel strike after the perturbation. While there was a trend for individuals to display a smaller braking impulse (-0.21 Ns/kg vs -0.37 Ns/kg), smaller change in forward momentum (-29.68 $kg\frac{m}{s}$ vs -52.11 $kg\frac{m}{s}$), and shorter duration (.56s vs .79s) when the first response step was made with the paretic limb vs the nonparetic limb these trends were not significant (z=-1.83, p=0.068). The lack of significance is most likely due to small number of steps with both legs. These results suggest that during the first response step after a perturbation subjects post stroke were better able to decrease their forward momentum when using their non-paretic leg.

Change Forward Momentum
A-P Impulse

CONCLUSIONS

After a forward perturbation, there appears to be a difference between the ability of the paretic and non-paretic limb to produce the braking impulse required to reduce one's forward momentum. In the current study even when the paretic limb was initially unloaded when the perturbation occurred subjects almost always shifted their weight and took their first response step with their nonparetic limb. While this may delay an individual's time to respond to a perturbation, their overall ability to arrest their forward momentum may be improved because of the much greater ability of the nonparetic limb to generate a braking impulse. Task specific perturbation-induced step training with the paretic leg may strengthen the ability to generate a braking impulse with this leg and allow individuals post-stroke the option to slow their forward momentum with either leg.

INTRODUCTION

Astronauts experience a microgravity environment during spaceflight, which results in a central reinterpretation of both vestibular and body axial-loading information by the sensorimotor system. Subjects in bed rest studies lie at 6° head-down in strict bed rest to simulate the fluid shift and gravity-unloading of the microgravity environment. However, bed rest subjects still sense gravity in the vestibular organs. Therefore, bed rest isolates the axial-unloading component, thus allowing the direct study of its effects.

The Tandem Walk is a standard sensorimotor test of dynamic postural stability [1]. In a previous abstract [2], we compared performance on a Tandem Walk test between bed rest control subjects, and short- and long-duration astronauts both before and after flight/bed rest using a composite index of performance, called the Tandem Walk Parameter (TWP), which takes into account speed, accuracy, and balance control. This new study extends the previous data set to include bed rest subjects who performed exercise countermeasures. The purpose of this study was to compare performance during the Tandem Walk test between bed rest subjects (with and without exercise), short-duration (Space Shuttle) crewmembers, and long-duration International Space Station (ISS) crewmembers at various time points during their recovery from bed rest or spaceflight.

METHODS

All subjects provided written informed consent before participating in this study, which was approved in advance by the NASA Lyndon B. Johnson Space Center Institutional Review Board.

This study is part of a larger protocol that uses a suite of physiologic tests and functional tasks to relate physiologic changes to changes in functional performance of mission-critical tasks immediately after flight/bed rest. Subjects groups included: (a) 10 bed rest controls, all of whom completed 70 days of 6° head-down strict bed rest with no exercise countermeasure; (b) 17 bed rest exercisers, all of whom completed the same bed rest but with exercise countermeasures; (c) 6 short-duration crewmembers who completed Space Shuttle missions (12.9 ± 1.5 d) with in-flight exercise countermeasures, and (d) 13 long-duration crewmembers who completed missions aboard the ISS (151.6 ± 17.1 d) with in-flight exercise countermeasures. Data collection sessions occurred twice within a 2-month or 2-week time period before flight or bed rest, respectively (Pre), and four times after flight/bed rest: on the day of landing or end of bed rest (Post+0d), one day post (Post+1d), six days post (Post+6d) and a final session 10 days (bed rest) or 30 days (flight) post (Post+10/30). Due to logistical limitations, data could not be collected from long-duration crewmembers on landing day.

In the Tandem Walk test, the subjects walked in a heel-to-toe fashion at a self-selected speed for 10-12 steps with their arms crossed on their chests and their eyes closed. A spotter walked next to the subject to ensure safety and to monitor the step count. Three Tandem Walk trials were performed per session.

Torso and head linear accelerations (relative to their respective local coordinate systems) were recorded at 50 Hz using triaxial inertial measurement units (Xsens, North America Inc., Culver City, CA). During the analysis, the start and end of the trials were manually selected by inspection of a plot of the vertical head acceleration to get the total trial time. The gravitational acceleration was removed from the Z-component of the torso acceleration. The root-mean-square (RMS) of the resultant linear torso accelerations (TorsoAccR) over the trial was then computed. Video of the trials was reviewed to determine the percentage of heel-to-toe ("correct") steps during the task. The TWP was then computed for each session as follows:

$$TWP = ln\left(1 + \frac{PctCorrectSteps}{TotalTime * RMS(TorsoAccR)}\right)$$

The log transformation was used to prevent extreme values from dominating the data analysis. Larger values of TWP reflect better overall performance.

A separate analysis revealed no significant difference between the two Pre sessions, so their data were pooled in the subsequent analysis. A linear mixed model with TWP as outcome and random subject effects was used to estimate group-by-session means and test for pre-post differences between groups for each post session. P-value thresholds for reporting significance were calculated using the Hochberg multiple-comparison procedure [3] to control the family-wise Type I error rate to 0.05.

RESULTS AND DISCUSSION

All groups exhibited lower TWP values (i.e., increased instability) during Tandem Walk immediately after flight/bed rest (Figure 1). Thus, axial-unloading alone – as is the case in bed rest – resulted in decreased Tandem Walk performance immediately after flight/bed rest.

The multiple-comparison analysis of the pre- to postflight/bed rest difference estimates showed that the *change* in TWP for the bed-rest exercise subjects was: (a) significantly less than that of the bed rest controls for Post+0d and Post+1d, (b) significantly less than the long-duration flight group

for Post+1d, and (c) significantly more than the short-duration flight group for Post+6d. Thus changes in TWP in the bed rest exercise group were similar to short-duration astronauts for Post+0d and Post+1d, but similar to the long-duration astronauts at Post+6d. Therefore, exercise countermeasures helped mitigate some of the decrement in TWP after bed rest (exercise vs. control). However, additional balance and/or coordination training during flight/bed rest may be required to maintain TWP at Pre levels on Post+0d.
Figure 1: Tandem Walk Parameter (± 2SE)

CONCLUSIONS

Exercise countermeasures during space flight or bed rest helped mitigate some of the decrements in tandem walk performance immediately after flight/bed rest. But performance deficits remained, thus suggesting an additional sensorimotor countermeasure may be necessary to maintain tandem walk performance on Post+0d at preflight/bed rest levels.

USING THE FEASIBLE BALANCE REGION TO ESTIMATE THE STRENGTH REQUIREMENTS OF ONE LEG BALANCE:
EFFECTS OF AGE AND DIABETIC PERIPHERAL NEUROPATHY

Payam Mirshams Shahshahani and James A. Ashton-Miller
University of Michigan-Ann Arbor, email: mirshams@umich.edu

INTRODUCTION

In the clinic, balance is often assessed by testing the ability to stand on one leg. An inability to balance for 5 seconds is associated with an increased risk of injurious falls [1]. Prior efforts to assess postural stability have considered the human as a simple inverted pendulum under the control of an ankle torque and then have considered the state space containing center of mass position and velocity [2]. A knowledge gap is how hip torque affects balance, given the importance of hip and ankle strategies [3]. So we considered a double inverted pendulum model of one leg balance via hip and ankle torques and movements. If the ankle and hip each have a displacement and velocity state, then one can hypothesize a "Feasible Balance Region" (**FBR**) that is the volume within which the states have to remain in order to balance during the balance test. We thought it might be instructive to use this approach to study the quasi-static strength requirements for balancing on one leg.

METHODS

In this planar double inverted pendulum frontal plane model the lower link represents the stance leg with hinge joints at each end representing the ankle and hip. The upper link represented the rest of the body. For simplicity, the foot was assumed fastened to the floor. The link dimensions and masses for a mid-sized male (1.78 m, 81.4 Kgf) were taken from [3]. The torso was assumed rigid, the contra-lateral leg perpendicular to the pelvis, and the arms crossed. The state of the model is then determined with two angles and their angular velocities: the angle that the leg link makes with the vertical (θ_1) and the abduction angle of the ipsilateral hip (θ_2) (**Figure 1**). Angular accelerations and velocities were assumed negligible.
Figure 1: Model of one-legged-balance

The torques (**Figure 1c**) for holding a quasi-static posture are:

$$T_1(\theta_1, \theta_2) = -(m_1 l + m_2 h)g \sin \theta_1 + m_2 gr \cos(\alpha + \theta_1 + \theta_2) \quad (1)$$

$$T_2(\theta_1, \theta_2) = m_2 gr \cos(\alpha + \theta_1 + \theta_2) \quad (2)$$

$$T_{1min} \leq T_1 \leq T_{1max} \quad (3)$$

$$T_{2min} \leq T_2 \leq T_{2max} \quad (4)$$

where T_{1min} and T_{1max} are the maximum ankle inversion and eversion torques, respectively; and T_{2min} and T_{2max} are the maximum hip ABduction and ADduction torques. θ_1 and θ_2 are also constrained by the physiological ranges of motion for the ankle and hip joints. We can combine equations (1) and (2) with the ranges defined in (3) and (4) to find all the combinations of θ_1 and θ_2 that are achievable by a person for quasi-static balance. We called this region the FBR. The area of the FBR was then calculated (in deg^2) for three different populations: healthy young (**HY**) and healthy old (**HO**) subjects, and patients with diabetic peripheral neuropathy (**PN**). Values for maximum torque capacities and ranges of motion for each group were taken from the literature [5-7]. We used a dynamometer to measure the force-length characteristics of the maximum isometric hip torques over the ROM (**Figure 2**) [5]. We scaled the data for PN with respect to HO in [5] to obtain HY, HO, and PN values [7].
Figure 2. Estimated force-length characteristics on hip abduction torque in a healthy YM. (**Red**) The hip abduction torque when center of mass is centered over the ankle. (**Blue**)

RESULTS
Figure 3. The calculated FBR for HY (green+yellow+red), HO (yellow+red) and PN (red)
Figure 4. Effect of hip and ankle impairment on the FBR. No impairment (green+yellow+red), 25% impairment (yellow+red), 75% impairment (red)

For the males the calculated FBR area for the HY (222 deg^2) was x1.3-times larger than HO (177 deg^2); this was 3.8 times larger than PN (58 deg^2). For females, the corresponding results were 218, 146 and 104 deg^2 respectively (**Figure 3**). When ankle and hip strengths were impaired by 25% and 75%, the FBR area was slightly more sensitive to ankle strength impairment (164 and 48 deg^2) than hip strength impairment (211 and 69 deg^2) (**Figure 4**). The hip abduction torques required to stand on one leg without pelvic tilt ($\theta_2 = 0$, **Figure 2**) were 50%, 56%, 65%, and 80% of maximum hip abduction torques for HY males and females, HO males and females, respectively.

DISCUSSION

These results are the first to quantify the FBR and demonstrate how impairments in ankle and hip strength narrow and shorten the FBR, respectively, to make the balance task more difficult. If a state reaches a boundary of the FBR, T_1 or T_2 must have saturated, so any perturbation of the state beyond the boundary will result in instability. The reduction in FBR area with age correlates well with the decline in unipedal stance times [8]. The limitations of the analysis are (1) its quasistatic nature, (2) constant maximum ankle isometric torques, and (3) simplification to two body segments. The truncated FBR near the asterisk in Figure 3 likely resulted from weaker-than-normal male PN data.

Stride Time Variability and Fall Risk in Persons with Multiple Sclerosis

Yaejin Moon, D. A. Wajda, R. W. Motl, J. J. Sosnoff

Department of Kinesiology and Community Health, University of Illinois at Urbana-Champaign
email: ymoon9@illinois.edu

INTRODUCTION

Multiple sclerosis (MS) is one of the most prevalent chronic disability neurological diseases in young adults and results in conduction delays along neuronal pathways commonly resulting in impairments in gait [1]. There is evidence that gait variability measures may be more sensitive to subtle abnormalities in gait compared to average gait parameters in MS [2]. However, the clinical importance of higher gait variability in MS is not clear.

One potentially important interpretation of gait variability is as a possible indicator of fall risk for people with MS (PwMS) [2]. This investigation examined the relationship between the magnitude and structure of stride-time variability in a 6-minute walking test (6MW) and physiological fall risk in PwMS compared to age-matched healthy controls. It was predicted that 1) stride-time variability will be positively associated with fall risk and 2) the association will be stronger in the MS group.

METHODS

17 PwMS (F=11, M=6, age=62.8+/-7.4years) and 17 healthy age matched controls (F=12, M=5, age=62.8+/-5.9 years) participated. For the MS group, seven (41%) walked without assistive devices, six (35.3%) used a cane and four (23.5%) utilized a walker during the 6MW. Ten of the MS participants (58.8%) had relapse remitting MS, while four (23.5%) had secondary progressive, and three (17.6%) had primary progressive. None of the control group participants used an assistive device during the 6MW.

Fall risk was measured utilizing the short form of the Physiological Profile Assessment (PPA) [3]. The PPA involves a series of five tests including assessments of vision, proprioception, quadriceps force, reaction time and postural sway on a compliant surface. The outcome of each test was combined to generate an overall fall risk score [3]. Higher values indicate greater fall risk.

All participants performed the 6MW test in a 21 m hallway. Stride-time was assessed with use of Xsens MTx inertial measurement units (Xsens Technologies B.V., the Netherlands) attached to the participants' shanks. Shank angular velocity parallel to the mediolateral axis was obtained at sampling frequency of 150HZ. The stride-to-stride time interval was defined as the time between consecutive heel strikes of the same foot. It was determined using a custom MATLAB script (The MathWorks, Natick, MA) (See Figure 1) [4]. All analyses utilized the first 140 strides of the 6-minute walk based on the minimum number of strides within the sample.

Stride time data series was characterized with average stride time (AVG_{ST}) and with variability calculated by coefficient of variation ($CV_{ST} = SD_{ST} / AVG_{ST}$)

All statistical analyses were performed using SPSS (V19.0, Chicago, IL). To examine group differences of outcomes, independent t-tests were conducted for normally distributed measurements while the Mann-Whitney U test was conducted for non-normally distributed measurements. Due to the small sample size, Spearman rank order correlations were used to test the association between fall risk and stride-time parameters in each group respectively. The difference between the correlation coefficients was tested by Steiger's Z-test. All analyses used two-sided tests with an alpha of 0.05.
Figure 1: Schematic of shank angular velocity gait events and stride interval.

RESULTS AND DISCUSSION

Analysis of group differences of demographics revealed that there was no difference in age and gender composition between groups (P's>0.05). Self-reported disability of the MS group had median EDSS score of 6.0 (IQR 4.75 to 6.0). Also fall risk score was significantly higher in the MS group (Mean: 1.4+/-1.5) than in the control group (Mean: 0.1+/-0.7) ($p<0.01$).

Effect of group on stride time metrics: Stride time parameters as a function of group are presented in Table 1. The MS group exhibited greater average and variability of stride-time.

Table 1: Effect of group on stride-time metrics

Variables	MS	Control	P-value
AVG_{ST} (sec)	1.16 (1.07-1.32)	0.95 (0.88- 0.98)	<0.01
CV_{ST} (%)	3.43 (2.91-7.07)	1.67 (1.37- 2.21)	<0.01

Note: Median (IQR)

Correlation between stride time metrics and fall risk: AVG_{ST} was not correlated with fall risk in either group (*p's*>0.05). There was a strong positive correlation between CV_{ST} and fall risk in both groups (MS: $\rho=0.71$, $p<0.01$; Control: $\rho=0.67$, $p<0.01$) (Figure 2). The association was not different between groups (*p's*>0.05).

There are several potential mechanisms underlying the association between increased stride-time variability and fall risk. First, impaired reaction time, proprioception, and lower limb muscle strength might be a mediator of the relationship given that those are related to increased temporal gait variability [5] and have been attribute to falls in MS [6]. Also, considering a more variable gait is believed to be less energetically efficient, fatigue (a fall risk factor) could be another possible mediator [7]. Lastly, it has been suggested that increased gait variability reflects breakdown of the automatic gait rhythm system. Less rhythmic gait is believed to require greater attentional demand which has been related to increased fall risk in MS [6].

Also, although PwMS had higher gait variability and fall risk than the controls, the strong association between the factors might be driven by aging than MS related pathology.
Figure 2: Correlation between CV of stride-time and fall risk as a function of group

CONCLUSIONS

The current investigation demonstrates the amount of stride-time variability (but not average stride-time) is strongly related to physiological fall risk both in PwMS and the controls. The mechanisms underlying the association remain to be elucidated. A major limitation of the study is the small sample size with relatively high level of neurological impairment in the MS group. Also it may limit generalizability of the result that most of the controls had minimum risk of fall. It is possible that variability in other gait parameters may yield distinct results given that other parameters imply different aspects of gait impairment Future work examining whether gait variability is predictive of future falls in PwMS is warranted.

INTRODUCTION

Balance refers to the ability to move the center of mass (COM) in a safe and controlled manner. The Functional Reach Test (FRT) is commonly used to assess balance in both clinical and research settings. Though the reach distance is believed to be an indicator of COM and center of pressure (COP) excursions, there are conflicting reports across studies [1, 2]. The correlation of reach distance with COM excursion has been found to be dependent on the biomechanical strategy. Hip strategy (HS) is characterized by ankle plantarflexion and greater than 15º of hip flexion; ankle strategy (AS) is characterized by less than 15º of hip flexion, with or without some ankle dorsiflexion [3]. To the best of our knowledge, the relation between COP excursion and strategy has not been reported.

It may be argued that the reach distance can be driven or limited by different biomechanical factors in HS and AS. Sagittal plane hip and ankle moments are potential variables that can influence the choice of strategy. However, it is currently not known whether moments differ between strategies and whether they are associated with the reach distance.

Thus, the purpose of this study was first, to compare the biomechanics of hip and ankle strategy **within subjects during the FRT**. Secondly, the relations between reach distance and COP COM excursions, and hip and ankle moments were tested.

METHODS

Eight (5 females) healthy young individuals participated. Participants stood with their arms relaxed by the sides. A yardstick was placed parallel to the floor at the level of the acromion. They were instructed to reach forward as far as possible without taking a step and without raising their heels off the floor. 1-3 trials each were collected with 2 different instructions – do not bend the hip (AS) and bend the hip (HS) (Figure 1).

A full body marker set was used to define and track the following segments - foot, shank, thigh, pelvis, trunk, brachium, forearm, hand and head. Two AMTI force plates (Model #OR6-6-1, Watertown, MA) and an 11 camera motion capture system (Qualisys, Gothenburg, Sweden) were used to collect ground reaction forces and segment co-ordinates. Subsequently joint angles and moments, and whole-body COM and COP excursions were computed using Visual 3D (C-Motion, Inc., Germantown, MD) and Matlab (The Mathworks, Natick, MA). Reach distance was quantified as the distance between one marker on the distal heel and one on the 3rd metacarpal head at the point of maximum reach. Reach distance and excursions were normalized to body height.
Figure 1

Statistics

Given the small sample size, non-parametric tests (related samples Wilcoxon Signed Ranks Tests and Spearman correlation coefficient) were used. The following outcome variables were compared between HS and AS – reach distance, COM excursion, COP excursion, peak hip extensor moment, peak ankle plantarflexor moment. PASW Statistics 18 (IBM Corporation, NY, USA) was used for statistical analysis and the significance was set at alpha=0.05. The following correlations were tested for each strategy separately –

    a. Reach distance – COM excursion
    b. Reach distance – COP excursion
    c. Reach distance – peak hip extensor moment
    d. Reach distance – peak ankle plantarflexor moment

RESULTS AND DISCUSSION

When compared to the ankle strategy, reach distance and peak hip extensor moment were significantly greater in the hip strategy. There was no significant difference between strategies for any of the other variables (Table 1). Only the correlation between reach distance and peak hip extensor moment in the ankle strategy (rho=0.714, p=0.047) was significant.

Contrary to Liao and Lin [3], no significant correlation between reach distance and COM excursion was found in either strategy. Given that the reach distance is achieved by a combination of movements at multiple joints along the kinetic chain, the relation between COM or COP excursion and reach distance must be interpreted with caution. Reach distance may be driven by strength and/or flexibility at multiple joints and not necessarily by balance.

Given the difference in reach distance and peak hip moments between HS and AS, we hypothesized that the distance may be correlated with hip moment in the HS and ankle moment in the AS. However, this was not found to be true and other explanations must be considered in future research. Reach distance may be influenced by moment measures that incorporate duration (like impulse) rather than peak moments. It may also be driven by other joints or segments – large movements at the trunk and shoulder can have a considerable influence.

The findings of this study may be limited by the small sample size. Further, it must be acknowledged that conflicts across studies may be a reflection of differences in the exact instructions given to participants and differences in the methods used to compute and normalize each variable.

CONCLUSIONS

The use of reach distance during a FRT as a direct indicator of balance must be done with caution, and the biomechanical strategy employed by each individual must be taken into consideration. Also, future research should rule out strength and flexibility limitations before attributing decreased reach distance to poor balance.

ERROR AUGMENTATION FEEDBACK FOR DYNAMIC LATERAL WEIGHT SHIFTING

Kevin O'Brien and James Schmiedeler

The University of Notre Dame, South Bend, IN, USA

email:kobrie23@nd.edu, web: http://ame-robotics.nd.edu/LAB/Biomechanics/WeHab.php

Introduction

Regaining motor coordination is an important aspect of rehabilitation following stroke, and balance performance in particular is crucial to prevent injuries from falls. Previous work has shown that the type of visual feedback provided can influence balance performance [3]. Additionally, in arm reaching tasks, augmenting the visual feedback position error has been shown to promote faster learning of new reaching tasks [5]. The effects of such biofeedback in mobility and balance tasks, however, are not entirely known [6]. The current study investigates use of error augmentation in a lateral weight shifting task.

As a relatively inexpensive means by which to provide biofeedback in rehabilitation activities, low-cost gaming peripherals have potential for both clinical and home use. The Nintendo Wii Balance Board has been shown to perform comparably to more sophisticated force plates in terms of balance assessment based on center of pressure (CoP) data [1, 2]. The WeHab software [3] was developed to display visual feedback based on CoP data from the balance board and was extended in this work to include error augmentation capability.

Methods

Eight subjects each completed nine, three minute lateral weight shifting tasks with a period of rest midway through the test. All subjects gave their informed consent prior to the study, and this research received approval from the appropriate Institutional Review Board. Using the WeHab software, the tasks involved subjects laterally shifting their CoPs to lie within target regions presented as shaded rectangular areas, as in [3].

In previous error augmentation studies, the error was calculated relative to a straight line between the starting point and the target [5]. While the ideal path of the CoP may also be a straight line, the CoP exhibits a non-minimum phase (NMP) behavior in lateral weight shifting [4], so calculating the error is non-trivial. To account for this, shift data from a previous study were averaged to find an idealized CoP path as a function of the time after a target was presented.

The error was found by comparing the true CoP position to the time-dependent, ideal CoP positing in real time. A gain was then applied to the calculated error, and the CoP position displayed as feedback was the true CoP position with the augmented error added to it. To test the effect of this feedback, a perceived weakness was introduced which increased the force necessary to shift the displayed CoP in either direction relative to the center of the balance board.
FIGURE 1. Representative result for a single task. Data points represent time-to-target from all 8 subjects for shifts from center outward tasks. An exponential fit is shown for trials with simulated weakness.

The error feedback gain was applied for the entire task, having one of three values: no gain (in which the true CoP was displayed), low gain (33% error gain), and high gain (67% error gain). The gain increases the sensitivity of the CoP to movement when the subject shifts faster than the ideal trajectory, but decreases the sensitivity when the subjects shifts slower than the ideal trajectory. After subjects successfully shifted to 10 targets, an artificial weakness was applied for the next 15 weight shifts, making the targets more difficult to reach

by altering the CoP position. The three weakness conditions were no weakness, low weakness (44% reduction), and high weakness (63% reduction). Each subject experienced the nine possible combinations of gain and weakness in a different order to mitigate the covariance between tasks.
FIGURE 2. Learning amount
FIGURE 3. Learning rate

From the "No Weakness" tasks, a subject-specific average time-to-target for each gain value was determined. This time was used as a reference to normalize the time-to-target for the "Low" and "High Weakness" tasks. An exponential curve was then fit to the normalized time-to-target data (see Figure 1) to analyze both the rate and

extent of weakness learning for each gain, similar to [5].

$$t_x = A * e^{B*x},$$

where t_x is the approximate time-to-target for each target, x is the target number, A is the amount of learning (change in time-to-target for each task, Figure 2), and B is the rate of learning (time constant associated with each task, Figure 3).

Results and Discussion

Although the results are not statistically significant due to the high variability and small sample size, both the gain and weakness values affected the time to completion for each target. The learning response to each level of weakness also appears to follow an exponential curve (Figure 1). For "High Weakness" cases, the amount of learning increased, and the rate of learning also improved. Meanwhile, for "Low Weakness" cases, the level of weakness was too low to produce clear trends as results were fairly similar regardless of gain.

The results suggest trends that conform with previous learning and rehabilitation studies. The sensitivity to movement appears to help the subjects recognize changes in perceived weakness. This suggests that it may be appropriate to scale gain values according to the level of balance disability.

Conclusions

This study examined the effects that augmenting biofeedback error sensitivity has on a subject's ability to learn a simulated level of weakness in a lateral weight shifting task. The increased sensitivity provided a stronger feedback signal to the subject that appeared to offer greater benefits at higher levels of simulated weakness. Nonetheless, increasing the gain can make controlling the perceived CoP more difficult and destabilize the balance feedback system. Gain sensitivity in balance rehabilitation activities may require tuning to the impairment level of the patient.

ROLE OF MULTI-SENSORY INTEGRATION RELEVANT FOR BALANCE IN SLIP RECOVERY

Caitlin O'Connell, April Chambers, Arash Mahboobin, Rakié Cham

University of Pittsburgh, Pittsburgh, PA, USA
email: caitlino@pitt.edu, web: http://www.engineeringx.pitt.edu/hmbl/

INTRODUCTION

Falls are a leading cause of injury and death, particularly in the elderly, with over one-third of elderly adults experiencing a fall each year [1]. Stepping reactions are important for recovering and maintaining balance after gait perturbations such as slips and trips [2]. The purpose of this study is to determine if balance, specifically sensory integration abilities, play a role in stepping reactions to slips. It is predicted that deterioration in sensory integration abilities is related to delayed stepping reactions.

METHODS

Thirty-six subjects were recruited for participation in this balance and gait study and classified into two age groups: young (N=17, 8 females, age = 24.0 ± 3.2 years) and old (N=19, 9 females, age = 55.9 ± 4.6 years). Written informed consent approved by the University of Pittsburgh Institutional Review Board was obtained prior to participation. Exclusion criteria included orthopedic, neurological, pulmonary and cardiovascular abnormalities clinically hindering normal balance and gait.

For gait testing, participants walked along a vinyl tile pathway wearing a safety harness. Full body motion (120 Hz) and bilateral ground reaction forces (1080 Hz) were collected. EMG data were recorded from the trailing (swing) leg on the vastus lateralis (VL). Data was collected using a 8-channel Noraxon Telemyo EMG system sampled at 1080 Hz with a hardware bandpass filter (10-500 Hz).

Participants were instructed to walk at a comfortable self-selected pace. Several baseline (dry) trials were collected to ensure correct foot placement and consistency in gait. Then without participant's knowledge, a glycerol contaminant was placed on leading leg force platform. One trial, the unexpected slip (US), was collected with contaminant present. For the US, the start of the slip was defined as heel strike of the leading (slipping) leg. Slip severity is quantified by the peak slip severity (PSV) measured at the heel marker attached on the slipping foot shortly after heel strike onto the contaminated floor [3]. Slip hazardousness was classified into two categories: hazardous (PSV ≥1 m/s) and non-hazardous (PSV <1 m/s) [3].

EMG data was rectified and normalized using the average maximum value of the baseline gait cycles. EMG was not filtered to prevent smoothing of sudden onset of muscle activations. A custom algorithm was used to determine reactive muscle activation of the trailing leg [4]. Activation was calculated as the time when difference between slip and dry EMG signals exceeded 2 standard deviations of the difference during quiet period of gait. Only the VL was considered here due to its main contribution to a stepping reaction.

Standing balance testing consisted of sensory organization tests (SOT) using an Equitest posture platform (Neurocom, Inc). This platform is capable of providing rotations of the floor and/or the visual scene to allow sway-referencing of vision and/or proprioception [5]. Prior to testing, subjects donned a harness and instructed whether to keep eyes open or closed before beginning each trial. The SOT protocol consisted of six trials that were 20 seconds long, repeated twice (see Table 1 for trial descriptions). Only the second trial of each type was considered. The outcome variable of interested the mean velocity of anteroposterior (AP) sway.

The statistical analyses consisted of a regression model (α= 0.05) to determine the effect of age and sway mean velocity, as well as their interaction, on

the activation of the VL after slip. The log transformation of the mean velocity was used in the statistical model in order to normalize the data. Analysis was conducted within each SOT trial type and hazardousness of slip.

Table 1: SOT trial descriptions including eye, vision and proprioception conditions.

Trial	Eyes	Vision	Proprioception
1	Open	Fixed	Fixed
2	Closed	--	Fixed
3	Open	Sway	Fixed
4	Open	Fixed	Sway
5	Closed	--	Sway
6	Open	Sway	Sway

RESULTS AND DISCUSSION

Mean sway velocity was significantly related to VL activation of hazardous slips for SOT condition 4 only. SOT condition 4 provides accurate visual information but unreliable proprioception. Thus, proprioception may be more important than vision in sensing a slip and triggering a stepping recovery response.

An increase in COP sway representing less balance stability correlated to faster muscle activations after slip (Figure 1). This is contrary to the hypothesis that poor balance will be associated with a delayed stepping reaction. A possible explanation for this trend is that individuals with poor balance are more cautious during gait, specifically when they encounter a perturbation such as a slip. Thus, they may interrupt swing phase of the trailing gait more quickly after slipping faster to prevent loss of stability. Alternatively, poor balance may correlate to more severe slips that require a faster reaction to recover balance [6]. The lack of relationship between muscle activation and balance for non-hazardous slips further supports this theory.

Interestingly, there was no age effect on VL activation, nor was there an interaction between age and sway mean velocity for SOT condition 4. This could be explained by the relative fitness and age of the subjects in the older group. The subjects did not have any comorbidities that typically affect balance performance and fall risk in the elderly.
Figure 1: Relationship between reactive activation of the vastus lateralis muscle during hazardous slips and mean velocity of anteroposterior center of pressure sway during SOT condition 4.

CONCLUSIONS

The goal of this study was to determine the role that balance plays in slip recovery. The results suggest that proper integration of proprioception information is important in regaining balance after hazardous slips and that individuals with compromised balance may react more cautiously, and thus faster, to slips than those with normal balance.

LOW BACK FATIGUE INFLUENCES POSTURAL VARIABILITY

Michael W. Olson and Shelby Kemp

Southern Illinois University, Carbondale, IL, USA

INTRODUCTION

Human bipedal stance requires proprioceptive input from the external environment and successful neuromuscular and musculoskeletal responses to maintain an upright posture. The somatosensory system receives visual, tactile, auditory, and vestibular information which is transmitted to the central nervous system (CNS) for processing. The correct spatiotemporal neural responses (amplitude and firing rates) and the corresponding muscle forces generated must be specific to the constraints of the environmental parameters experienced by the system. Modification of intrinsic factors that influence the neuromuscular responses significantly alter the response of the system to the external environment [1,2]. Fatigue of the trunk extensor muscles, primarily the lumbar paraspinal (LP) muscles, is reported to significantly reduce system stability when external perturbations are applied during stance [3]. Similarly, the muscles surrounding the ankle joints assist in maintaining the postural control of the system. The position and velocity changes of the movements are modified as fatigue is induced, however, the variability of these variables, based upon the standard deviation measures, needs to be researched further to identify how the motor control strategy of the system is being influenced.

Determine how neuromuscular fatigue of the paraspinal muscles influences postural control of the system assists in studying motor control strategies. Therefore, it is hypothesized that the variability of the movement and variability of the EMG signals from the postural muscles will provide insight into the motor control strategy modifications of the system.

METHODS

Eighteen healthy individuals (7 men, 11 women) (74.3 ±16.8 kg, 1.71 ± 0.12 m, 22.6 ± 4.5 yrs) participated in this study. Static stance was performed for 30 s prior to and after the fatigue protocol. Participants were instructed to focus on a target (5cm x 5cm) on a wall (placed 3.5m from the participants), while standing with feet shoulder width apart.

Fatigue protocol: Participants were seated in a chair with the lower extremities fixed at the pelvis and thighs. The trunk was positioned 30 deg in flexion from erect posture. A harness system was secured to the trunk at the T6 level and attached through a tethered line to an isokinetic dynamometer (resistance). Three 8 s ramped maximal voluntary isometric contractions (MVIC) in trunk extension were performed to determine each participant's maximal torque output. Participants maintained isometric back extension at 50% of their predetermined voluntary maximum for up to 10 min.

Equipment: A multi-camera system (120 Hz collection rate) was used to track markers positioned bilaterally on acromion processes, posterior superior iliac spines (PSIS), anterior superior iliac spines (ASIS), greater trochanters, lateral femoral epicondyles, lateral malleoli, calcanei, and 5th metatarsopharengeal joints. Additionally, single markers were position on the skin over the T6 and S1 vertebrae. It was assumed that an ankle strategy was used by all participants, thus the body sway was calculated as the T6 marker about the left malleolus. From the kinematics data, variability of postural sway in the anteroposterior (AP) and mediolateral (ML) directions could be evaluated. Variability of the sway and sway velocities were analyzed. EMG (band-pass 20-500 Hz, CMRR ratio < 100 dB, input impedance < 10 MΩ, 1200 Hz collection rate) data were collected bilaterally from thoracic (LTP/RTP) and lumbar (LLP/RLP) paraspinal muscle groups along with soleus (LSol/RSol) and tibialis anterior

LTA/RTA) muscle groups using stainless steel electrodes (20 mm center to center distance). EMG data were analyzed for signal variability differences.

A low-pass Butterworth filter set at 10 Hz was used to reduce the kinematics data. The EMG data were full-wave rectified and then a low-pass Butterworth filter set at 10 Hz was used to smooth the data. Variability measures were determined as the standard deviation of respective position sway and sway velocity calculations.

A one way ANOVA was used to analyze the dependent variables of sway variability and sway velocity variability in the AP and ML directions, and EMG activity variability from trunk and leg muscles between pre and post fatigue conditions over 30 s periods. Alpha was set at 0.05.

RESULTS AND DISCUSSION

AP sway variability did not change (p > 0.05), but the AP sway velocity variability was significantly greater after fatigue ($F_{1,215}$ = 2.771, p < 0.02, Table 1). ML sway variability was significantly greater after fatigue ($F_{1,215}$ = 4.915, p < 0.03, Table 1) while ML sway velocity variability was not modified (p > 0.05).

The RLP EMG variability decreased significantly ($F_{1,215}$ = 5.98, p < 0.02, Table 2) as did the LSol EMG variability ($F_{1,215}$ = 4.621, p < 0.04, Table 2). No other muscle activities were modified (p > 0.05).

CONCLUSIONS

It was hypothesized that variability measures from kinematics and EMG variables would explain modifications in motor control strategies. The mean values of sway and sway velocity did not differ from pre to post-fatigue stances, but the variability in AP sway velocity and ML sway provided additional information regarding how the system was controlled. Muscle activity variability was either decreased or did not change, indicting the proprioceptive components, which determine the parameters of movement for balance, may have been modified to induce modifications in sway variables.

INTRODUCTION

To avoid falling while walking, individuals must be able to recover from unexpected perturbations. Sudden loss of the support surface can cause serious injury if one cannot create a rapid posture response in order to maintain balance. Previous work reported that the rapid response while stepping down into a hole was to extend the perturbed limb to avoid limb collapse and a fall [1]. Moreover, the muscle activity of the perturbed ankle was reported to show a high response for both the ankle plantar-flexor and the dorsi-flexor [2]. Not only is the posture response of the perturbed limb vital to avoid falls, but the trialing limb adaption also plays an important role in successful fall recovery. In this study, a drop-away floor tile was created to investigate the mechanisms of postural control and adaptation of the perturbed limb (PL) and the unperturbed limb (UPL) during unexpected loss of the support surface. We hypothesized that the drop-away floor would result in a rapid recovery process by increasing the maximum toe clearance (MTC, maximal distance between toes and ground during the swing phase), joint angles, and co-contraction indices (CCIs) of the perturbed and unperturbed limbs.

METHODS

Ten young, healthy adult subjects (5 males, 5 females) with a mean age of 24.3±5.0 years participated in this gait study. A 13 camera Vicon MX40 motion analysis system (Denver, CO) was used to collect motion data at 150 Hz and analyze gait parameters. A Noraxon electromyography system (Scottsdale, AZ) recorded muscle activity at 1500 Hz. A Hokuyo scanning laser rangefinder (Osaka, Japan) was used to create a speedometer displayed on a television screen at each end of the walkway to encourage subjects to walk at their preferred speed. The drop-away flooring was randomly activated to create an unexpected loss of ground support by dropping the walkway surface (8 cm). Kinematic parameters including MTC, joint angles (hip, knee, and ankle), and ankle and knee CCIs of the PL and UPL were recorded and analyzed during and after the drop-away perturbation. Muscle CCIs at the ankle and knee were examined during the stance and swing phases from the ratio of the antagonist/agonist muscles (tibialis anterior/lateral gastrocnemius; vastus lateralis/medial hamstring). CCIs were integrated to calculate the area under the CCI curve [3]:

$$CCI = \int_{start}^{stop} \frac{LowerEMG}{HigherEMG} \times (LowerEMG + HigherEMG)$$

One-way ANOVA, within subject (control v drop perturbation), was performed to test the difference of mean values on each dependent variable. JMP software (SAS Institute, Cary, NC) was used for all statistical analyses, and effects were considered significant at $p < 0.05$.

RESULTS AND DISCUSSION

MTC, joint angles, and CCI results are shown in Table 1. During drop-away perturbations, the PL was in stance phase and UPL was in swing phase. During fall recovery, the PL was in swing phase and UPL was in stance phase. MTC of the PL and UPL increased during the swing phase of the perturbation in order for subjects to avoid tripping over the edge of the hole after stepping into it. Ankle, knee, and hip joint angles of the PL during stance phase were significantly smaller than during normal gait. Ankle and knee CCIs of the PL during stance phase were significantly greater than during normal gait. The

PL creates the rapid response by extending all joints and increasing ankle and knee CCIs (stiffness) to compensate for the unexpected lower support surface and to prevent joint buckling. Ankle, knee, and hip joint angles of the UPL (swing phase) during the drop-away perturbation were significantly larger than those joint angles during the swing phase of normal gait. The results indicate that large joint angles are gait adaptations of the UPL to create higher limb swing in order to avoid unknown hazards. Ankle CCIs of the UPL during the swing phase were significantly greater than ankle CCIs during normal gait.

Table 1: Variable means ± standard deviations and statistical significances during normal and perturbed gait.

During fall recovery, ankle, knee, and hip joint angles of the PL during the swing phase were significantly larger than those joint angles during the swing phase of normal gait. Ankle and knee CCIs of the PL during the swing phase were significantly greater than those CCIs during normal gait. The PL during fall recovery tended to flex more and had higher ankle and knee CCIs than during normal gait in order for subjects to lift their limbs and generate a higher MTC to step out of the dropped floor. Only the knee joint angle of the UPL (stance phase) during fall recovery was significantly larger than knee joint angle during the stance phase of normal gait. The larger knee flexion of the UPL occurred during the beginning of fall recovery since the UPL was on the floor but the PL was about to create a toe-off from the hole. Ankle and knee CCIs of the UPL during fall recovery were significantly greater than the CCIs during normal gait. The UPL after perturbation increased joints stiffness to maintain stability while the PL stepped out of the dropped floor.

CONCLUSIONS

As hypothesized, MTC increased to recover from an unexpected drop-away perturbation. Knee angle (UPL, stance), ankle, knee, and hip angles (PL, swing), and ankle and knee CCIs (UPL, PL) increased during fall recovery of this perturbation indicating the importance of the knee joint when developing rehabilitation strategies for fall preventions. Future work is planned to compare these results to older adults with and without a history of falls in efforts to develop interventions to train fall avoidance and recovery ability.

DYNAMIC STABILITY DURING SINGLE STANCE IN MULTIPLE SCLEROSIS PATIENTS

[1,2]Alyson Reinholdt, [2]Sunny Ranu, [2]Jessie M. Huisinga

INTRODUCTION

Persons with multiple sclerosis (PwMS) are at a higher risk of falling than healthy persons, and 50% of all falls reported in PwMS have occurred during locomotion [1]. Static postural control is defined by the body's ability to maintain the center of mass (COM) within the base of support (BoS). Due to the dynamic-corrective nature of gait and one's ability to regulate COM motion, it is necessary to assess a person's step-to-step balance control to define their dynamic postural control during walking. To do this, Hof et. al [2] developed a measure of dynamic balance called 'margin of stability' (MoS) which is derived from the extrapolated COM. The extrapolated COM applies the necessity of maintaining the COM within the BOS to dynamic postural control through the addition of a linear velocity component to the COM [2]. The MoS is then able to characterize the discrepancy between the extrapolated COM and the BoS. Although MoS provides postural control information during walking which is advantageous over conventional static measures since most falls happen during walking, little research has been done to understand MoS in PwMS even though they are at high risk for falls [2]. The purpose of this study was to determine if there is a difference in MoS between healthy adults and PwMS with difference levels of disease severity. We hypothesized that healthy adults would have a greater MoS than PwMS regardless of their disease severity.

METHODS

Thirty-nine PwMS and 19 age-matched healthy controls (HC) participated (Table 1). Exclusion criteria for PwMS were an EDSS score greater than 5.5 or inability to walk 25 feet without an assistive mobility aide. To assess general walking disability, three timed 25-foot walk (25FTW) tests were performed and averaged for each subject. For the purposes of collecting kinematic data, reflective markers on the toe, heel, MTP, calcaneus, bilateral ASIS, and sacrum were used in this analysis to calculate MoS. Kinematic data were collected at 60 Hz using a 6-camera motion capture system (Eagle System; Motion Analysis Corporation, Santa Rosa, CA); ground reaction forces were collected at 600 Hz using a force platform (AMTI 1000; Advanced Mechanical Technology Inc., Watertown, MA). All data were analyzed using Matlab (MathWorks, Inc., Natick, MA). MoS was calculated only during single support by methods previously described by Hof et. al [2].

Five successful overground trials were collected for each foot. Because only single support data were used, MoS was only calculated in the anteroposterior (AP) direction. For analysis, PwMS were separated by 25FTW time into two groups: Mild (25FTW≤5.0 sec) and Moderate (25FTW>5.0 sec). A 1-way ANOVA with a between-subject design was performed using three groups: HC, Mild PwMS, and Moderate PwMS. Tukey's post-hoc comparison between groups was also performed. Significance was found when $p < 0.05$.

RESULTS AND DISCUSSION

Mean MoS for each group is listed in Table 2. There was a significant main effect of group ($F=43.76$, $p<.001$) on mean MoS. HC and Mild PwMS had a significantly greater mean MoS than Moderate PwMS ($p<.001$), but there was no significant difference between HC and Mild PwMS. This data in part supports our hypothesis that the MoS of healthy controls would be greater than that of PwMS. Not surprisingly, patients with a lower MoS (Moderate PwMS) also had a significantly slower 25FTW time compared to both HC and Mild

PwMS groups (p<0.001), whereas there was no significant difference between 25FTW times of HC and Mild PwMS (p=0.846) (Table 2). Previous studies have observed that an increased velocity allows the body's COM to be more quickly positioned above a stable BoS and to more effectively transition into the next step, decreasing fall risk and increasing balance [3, 4]. However, with the destabilizing effects of a decreased COM velocity combined with the known motor and muscular deficits in PwMS, the system becomes more unstable. This is evident in the finding of decreased MoS of Moderate PwMS compared to Mild PwMS and HC. It is important to make note of the lack of significant difference in outcome measures between HC and Mild PwMS. Our results show that dynamic stability of PwMS with a 25FTW time less than 5 seconds is no different from that of HC.

Table 2: Average 25-Foot Walk (25FTW) times and Margin of Stability (MoS) for each group.

	25FTW (sec)	MoS
Mild PwMS (n=24)	4.29±0.44	0.275±0.0384
Moderate PwMS (n=21)	6.33±1.50	0.194±0.0332
Healthy Controls (n=19)	4.38±0.44	0.269±0.0461

Velocity of the COM, leg length, and BoS are all used to calculate MoS. In PwMS, decreasing the distance between the COM and the leading limb heel strike during gait, i.e. shorter stride lengths, results in a smaller joint moment about the ankle and hip [5]. When people have an increased fear of falling, they are more likely to walk more slowly [6], decreasing their COM velocity. When walking slowly, strides are shortened, and BOS during double support is shortened which decreases MoS in the AP direction. However, subjects who walk more quickly take longer strides and therefore have a longer BoS which results in an increased MoS.

This may indicate that HC, who are at no risk for falls, and Mild PwMS, who are at a smaller risk for falls than Moderate PwMS, do not fear falling and can therefore have the confidence to walk more quickly [6]. In this study, MoS was only calculated in the AP direction. For future studies, MoS should be investigated during single stance and double stance to determine dynamic stability in both the AP and ML directions during walking.

CONCLUSIONS

Using MoS, a quantitative measure of dynamic stability during walking, we found that mild PwMS (faster 25FTW) and HC had a significantly greater MoS than moderate PwMS (slower 25FTW). However, no difference was found between PwMS with a faster 25FTW time and HC. By investigating dynamic stability, we hope to learn more about the factors that contribute to loss of balance in PwMS and understand which of those factors have the greatest impact on fall risk.

COP PARAMETERS FOR ACL REPAIRED INDIVIDUALS DURING STAIR NEGOTIATION

[1] Elizabeth Rullestad, [2] Michelle Hall and [1] Jason Gillette

[1] Iowa State University, Ames, IA, USA
[2] The University of Melbourne, Melbourne, Australia

INTRODUCTION

Almost 50% of individuals who have undergone anterior cruciate ligament reconstruction (ACLR) display symptoms of knee osteoarthritis within 10-20 years [1]. One proposed mechanism for the development of early onset knee osteoarthritis is reduced postural control in the knee joint. Short-term decreases in reach distance for the star excursion balance test and in jump distance for the single leg hop have been shown during post-ACLR assessment [2]. In the long-term, post-ACLR knee joints have demonstrated reduced postural stability and increased energy dissipation for knee varus and knee internal/external rotation motions [3].

Stair negotiation is a common activity of daily living. During stair ascent, the individual must have knee strength control to lift the weight of the body against gravity. During stair descent, the individual must have knee balance control to lower the weight of the body without falling forward and downward. Center of pressure (COP) velocities may be used to assess overall body postural control by measuring the rate at which body weight is shifting. Time-to-boundary (TTB) may also be used to assess postural control by estimating the time in which a postural adjustment is necessary before the COP leaves the base of support [4].

The purpose of this study was to compare COP velocity and TTB values between: 1) healthy controls, 2) non-injured legs of ACLR individuals, and 3) injured legs of ACLR individuals. It was hypothesized that the ACLR legs would demonstrate higher COP velocities and lower TTB.

METHODS

Seventeen ACLR individuals (7 males, 10 females; age 26 ± 6 yr; height 1.73 ± 0.14 m; mass 73 ± 16 kg) and 17 healthy controls (7 males, 10 females; age 26 ± 4 yr; height 1.70 ± 0.12 m; mass 68 ± 12 kg) participated in this study. Individuals performed three trials each of stair ascent and descent with a right and left leg lead. A three-step staircase was utilized for stair ascent and descent (step height 18.5 cm, tread depth 29.5 cm). Portable AMTI force platforms measured ground reaction forces on the lowest two steps of the staircase. An eight-camera Vicon Nexus motion analysis system was used to track retro-reflective markers placed on the feet.

COP velocities in the anterior-posterior (AP) and medial-lateral directions were calculated using the first central difference method. TTB values were calculated using COP positions, velocities, and accelerations in the AP and ML directions. The base of support for TTB calculations was determined using video marker data and foot anthropometrics. COP velocities and TTB values were calculated during the single stance phase of steps one and two for stair ascent and descent. Mean COP velocities and minimum TTB values were used for statistical comparisons. COP parameters were calculated using a custom-written Matlab code.

Univariate analysis of variance (ANOVA) was performed to test the effect of 'leg' on mean AP COP velocity, mean ML COP velocity, minimum AP TTB, and minimum ML TTB values. When a significant main effect was found, post-hoc Tukey tests were performed to compare control legs vs. non-injured legs and control vs. ACLR legs. Post-hoc paired t-tests were used to compare significant COP parameters for non-injured vs. ACLR legs. As secondary analyses, paired t-tests were used to test stair ascent vs. stair descent and step one vs. step two. The level of significance for all statistical tests was set to $p < 0.05$.

RESULTS AND DISCUSSION

There was significant main effect of 'leg' for mean AP COP velocity during stair descent ($p = 0.035$). Post-hoc comparisons further indicated that the mean AP COP velocity for the ACLR leg was significantly higher than the control leg for the first step of stair descent (Table 1, $p = 0.030$). There were no other significant main effects of 'leg' for other COP parameters ($p = 0.079$ and higher).

Secondary comparisons revealed that mean AP COP velocity (22.5 ± 6.0 cm/s vs. 15.4 ± 4.2 cm/s, $p < 0.01$) and ML COP velocity (8.1 ± 3.0 cm/s vs. 4.7 ± 1.1 cm/s, $p < 0.01$) were significantly higher during stair descent as compared to stair ascent. In addition, minimum AP TTB (0.13 ± 0.02 vs. 0.30 ± 0.06 s, $p < 0.01$) and ML TTB (0.21 ± 0.04 vs. 0.25 ± 0.04 s, $p < 0.001$) were significantly lower during stair descent. When comparing steps, minimum AP TTB values were significantly lower during step two of stair ascent (0.19 ± 0.04 vs. 0.41 ± 0.10 s, $p < 0.001$) and during step one of stair descent (0.12 ± 0.03 vs. 0.14 ± 0.03, $p = 0.01$).

CONCLUSIONS

The purpose of the study was to test COP parameters between an ACL reconstruction group and a healthy control group during stair negotiation. Our hypothesis that ACLR legs would have higher mean COP velocities was supported for one variable, while our hypothesis that ACLR legs would have lower minimum TTB values was not supported. Mean AP COP velocity was significantly higher for the ACLR leg than the control leg for step one of stair descent.

In general, COP parameters were not significantly changed in the ACLR leg. Postural stability measures that target the knee joint may be more sensitive than overall body measures. Higher mean AP COP velocity in the ACLR leg during the first step of stair descent is potentially of concern since the repaired ACL acts to restrict anterior translation of the tibia. In terms of assessment, stair descent was the more challenging movement with significantly higher COP velocities and lower TTB values. Testing multiple steps is suggested, with step one of stair descent and step two of stair ascent resulting in significantly higher AP TTB values.

BALANCE CONTROL DURING COMMON REHABILITATION EXERCISES IN OBESE FEMALES

Email: bhsingh@csufresno.edu

INTRODUCTION

Obese individuals have difficulties performing basic rehabilitation exercises due to balance problems, an important issue in addition to adipose tissue restriction [1, 2]. The association between obesity and balance deficits has been observed under certain conditions, but no research has been presented about the link between obesity and balance during execution of simple commonly performed exercises like squat and lunge. The purpose of this study was to analyze the balance of adult obese females while performing squat and lunge activities, as measured by center of pressure (CoP) area and root mean square velocity (RMS-V). It is hypothesized that obese females will have poorer balance control than their normal weight counterparts; and that as the difficulty of the exercises increase, the balance control deficits will be more apparent.

METHODS

Ten obese (BMI > 30 kg/m^2) female subjects age 37.4±3.7 years, BMI 39.2±3.7 kg/m^2 and ten normal weight (BMI<23 kg/m^2), age matched females, BMI 21.6±2.3 kg/m^2, volunteered for the study. Infrared marker triads were applied to the lower limbs, pelvis, and trunk to generate an anatomical model using three dimensional motion analysis system (Optotrak, NDI) (Fig 1).

Figure 1: Shows the skeletal model of an obese subject during squat exercise (left), placement of markers (center) and lunge exercise (right).

Testing session included: Quiet standing with eyes open for 30 seconds(s) on the force plate (Kistler). Squatting down, feet shoulder width apart on one force plate, holding for 3s at 3 different knee angles: 60, 70, and 80 degrees. Lunging at 3 different distances, holding for 3s at 1, 1.1 and 1.2 times subject's tibial length with one foot on each force plate (Fig 1). Sway area was defined as area of ellipse (cm^2) enclosing 95% of COP points over 3 seconds and RMS-V of sway as mean of anterior-posterior (AP) and medial-lateral (ML) peak velocities over 3 seconds.

DATA ANALYSIS

Visual 3-D (C-Motion) was used to analyze data. The 30 second standing data were analyzed, and seconds 2-5 were used to mimic the squat and lunge data collected (3s). A group (obese vs normal weight) by level of difficulty ANOVA was used to find differences in CoP area and RMS velocity across three levels of difficulty for the squat and lunge. Pearson correlation coefficient was calculated to find relationships between BMI and balance measures. SPSS 21.0 was used for analysis with p-value < 0.05 considered as significant.

RESULTS AND DISCUSSION

For standing, there was a significant difference for RMS-V between obese (1.7±0.3 cm/s) and normal weight females (1.41±0.19 cm/s) (p=0.011), but not for CoP area; 3.92±1.90 cm/s^2 for obese and 3.63±1.90 cm/s^2 for normal weight females (p=0.070). For squatting, changing the depth of the squat exercise (60, 70, and 80 degrees) did not result in a change in CoP area (p=0.401) or RMS-V (p=0.057). There was also no significant difference between obese and normal weight females for CoP area (p=0.120) or for RMS-V (p=0.212) (Table 1).

The analysis on squatting determined that the depth of the squat did not significantly alter the sway data, indicating that squat depth changes do not necessarily influence balance control significantly. There was also no significant difference in sway area or velocity between the obese and normal weight groups. There was a medium Cohen's effect size found for CoP area (0.73) and for RMS-V (0.53), indicating that there may be a trend for obese individuals to have increased sway than normal weight females.

The correlation coefficient for BMI and CoP area for squat 60, 70 and 80 degree levels was 0.13, 0.16 and 0.21 respectively. Similar trends were seen for RMS-V with correlation coefficient values of 0.17, 0.22 and 0.43 for the three squat levels. This is likely due to maintenance of the subject's center of gravity over the base of support during the activity, which minimizes challenges to balance control.

For lunge, altering the step distance for lunging did not result in any change in CoP area (p=0.297) or RMS-V (p=0.412). There was, however, a significant difference between obese and normal weight females for CoP area (p<0.001) and for RMS-V (p=0.005). The lunge had greater sway area as compared to standing as well as squat activities (p<0.001). Strong correlations were seen between BMI and CoP area (0.65, 0.77 and 0.70) and between BMI and RMS-V (0.45, 0.69 and 0.60).

Contrary to the squat, the base of support during a lunge is altered with the staggered step [2]. With increased adiposity, the subject's center of gravity is displaced, and when an increased demand is imposed by altering base of support, the subjects present with decreased balance control. Previous research on walking biomechanics has demonstrated that obese individuals require a wider base of support to maintain balance during gait [3]. Given this information, clinicians may want to consider the benefits versus concerns prior to prescribing lunging exercises to obese individuals.

CONCLUSIONS

The lunge activity was more challenging for obese females than squatting and standing, as shown by greater CoP sway area and RMS velocity. The results could be attributed to the greater base of support and more effort needed to stabilize the mediolateral shift of the trunk in obese females during lunging. There were no differences in the three squat depths, indicating that squat may be a better exercise choice for obese individuals, especially with fall risk. To conclude, identifying the underlying balance issues in obese individuals may help to better tailor exercise programs for this patient population, which could increase performance and decrease the risk for loss of balance, falls, and injury.

INTRODUCTION

Gait termination (GT) is a destabilizing transitional task that requires a shift from a dynamic state of motion to a static position [3]. GT can either be in response to unanticipated or anticipated stopping. While deficits in gait and gait initiation have been reported in individuals with essential tremor (ET), there is an absence in information regarding GT in those with ET, making it difficult for clinicians to design interventions to improve the ability to terminate gait quickly and efficiently.

ET is one of the most prevalent neurological disorders and yet when it comes to gait dysfunction there appears to be a void. Although, gait abnormality in ET has been documented as milder than that seen in patients with Parkinson's disease and cerebellar ataxia, it does seem to have functional consequences [1]. Recently, investigations of cerebellar dysfunction have supported the manifestation of motor disturbances in ET [1]. These investigations have shown that there is increased gait variability, increased dysfunction during tandem gait and difficulty initiating gait in ET.

However, to date no studies have been performed to analyze and compare planned and unplanned gait termination strategies in ET. In light of the movement control problems reported for patients with ET, the purpose of the study was to examine the lower extremity control strategies, specifically braking and propulsive ground reaction forces, dynamic postural stability and spatiotemporal characteristics during planned (feedforward) and unplanned (feedback) GT.

METHODS

Seventeen individuals with ET (mean ± SD age: 67.4 ± 9.1 years, mean height: 173.2 ± 3.3 cm, mean body mass: 95.3 ± 19.4 kg) participated in this study. Subjects using a self-selected walking speed, traversed an 8 meter walkway with three force plates (360 Hz; Bertec Corporation, Columbus, Ohio) mounted flush with the walking surface. Kinematic data, time-synchronized to the kinetic collection, were collected using an 8 camera Optical Capture System (120 Hz, Vicon Nexus, Vicon, Oxford, UK).

Subjects completed five planned and unplanned gait termination trials, with normal gait trials randomly mixed in to prevent anticipation of stopping for unplanned trials. This investigation utilized a two-step termination paradigm. Braking and propulsive forces under the lead and trail limb were calculated using the peak ground reaction forces from two force plates. Peak propulsive and braking forces were normalized to the subject's mass. Dynamic postural stability index (DPSI) was calculated from ground reaction force data [3] during a 1-sec interval starting from onset of heel strike on the second force plate (by the trail limb). Additionally, spatiotemporal variables of gait, step length (SL), step velocity (SV) and step time (ST) were measured on the lead limb (terminating limb of GT) as well as the average velocity prior to the terminating step.

Ground reaction forces during the braking and propulsive phases of gait termination were analyzed using a paired sample t-test. Additionally, a paired sample t-test was used to compare the mean differences in spatiotemporal variables, gait velocity and DPSI (and component indices) between conditions (Planned vs Unplanned) with $\alpha=0.05$.

RESULTS AND DISCUSSION

Braking forces were significantly greater during unplanned GT compared to planned GT (217.74 N/kg ± 67.9 vs 157.11 N/kg ± 49.5, $p<.05$). **(Figure 1)**. There were no statistical differences in propulsive forces. The analysis revealed there were no differences in DPSI scores between the planned and unplanned condition. However, further analysis revealed significantly higher value in the component indices during unplanned GT; specifically in the AP (81.5 ± 40.8 vs 32.3 ± 9.7, $p<.001$) and ML (177.6 ± 69.1 vs 90.6 ± 25.8, $p<.001$) directions. Results of the spatiotemporal variables of the lead limb in GT are found in **Table 1**.
Figure 1: Propulsive and braking forces with standard deviation during planned and unplanned gait termination. (*Denotes significant value $p < .05$)

The current investigation found during unplanned GT performance was characterized by a mild decrease in the propulsive force of the penultimate limb and statistical increase in the braking force of the termination limb. Research has shown that the ability to produce sufficient anterior–posterior ground reaction forces is crucial for stopping efficiently and safely.

It has been shown during tandem gait an increased number of mis-steps and variability during tandem gait is a risk factor for future falls [2]. Gait dysfunction during tandem gait is an apparent issue

in ET [1]. In the current investigation, postural stability scores in ET, specifically in the APSI and MLSI directions, suggested less stability during unplanned GT. The results of the current investigation, in combination with previous literature in tandem gait, suggest ET have impaired postural stability. This investigation indicated less stability during unplanned GT as compared to planned GT and thus more likely to become unstable when forced to terminate gait abruptly and could lead to higher incidence of falls.

The results of the current investigation converge with previous findings, that during unplanned GT, the control strategy is modulated so that the terminal limb would attenuate the forward velocity. This is evidence by the increased step length and velocity in the unplanned condition and the increased time in the planned condition of GT. The lack of statistically difference between the gait speeds prior to the terminal/lead step in planned and unplanned GT may imply that there is an inability to voluntarily adapt gait velocity in preparation for gait termination.

CONCLUSIONS

GT involves a rapid deceleration of the body's forward momentum and requires a complex interaction of the neuromuscular system, it is possible to challenge both the feedforward and feedback neuromuscular control. Inconsequence, we were able to ascertain that patients with ET utilized alternative biomechanical control strategies during planned and unplanned gait termination.

INTRODUCTION

Total hip arthroplasty (THA) is a common reconstructive surgery, with approximately 332,000 performed in 2010 and anticipated to reach over 500,000 each year by 2030 [1,2]. Functional deficits still remain after surgery, and are linked to weak hip abductor and knee extensor muscles and compensatory movement strategies developed in the late stages of osteoarthritis [3].

Hip abductor performance can be measured by assessing stability through examining the orientation of the pelvis during single limb stance for 30 seconds [4]. Clinical inference from the single limb stance test may be enhanced by the addition of quantitative postural measures. Trendelenburg angles are important measures in understanding the contribution of hip abductor strength to pelvic stability, but they are difficult to measure. Common measurements of pelvic posture use goniometers [5], which may not be sensitive to detect subtle, yet significant changes [6].

The purpose of this investigation was to assess the validity of using still-frames taken from video recordings to measure Trendelenburg postural angles. We validated these measurements to a criterion standard (motion capture system), and hypothesized that the video-based method would provide an accurate and reliable tool that can be easily incorporated into the clinic to examine contribution of hip abductors to pelvic stability.

METHODS

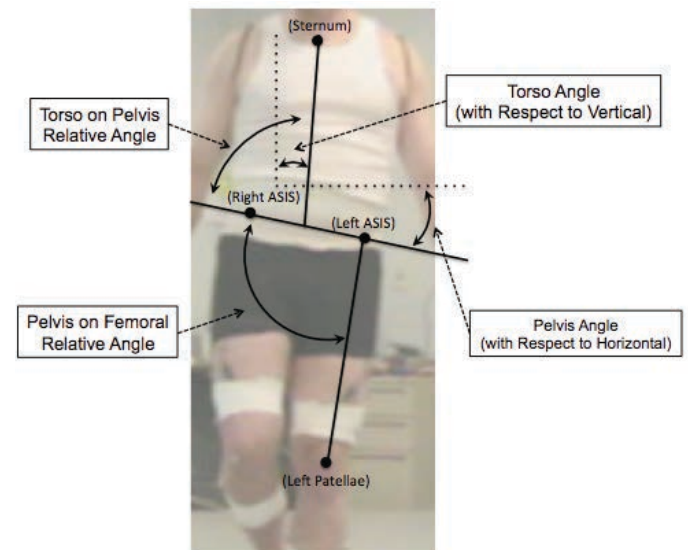
Eight patients (3 males, 8 females) diagnosed with end stage hip osteoarthritis before total hip replacement performed a single limb stance on their involved limb. Patients were instructed to balance on one leg for 30 seconds or until they lost balance. Each patient was instrumented with reflective markers on bilateral anterior superior iliac spine (ASIS), patellae, and sternum (Fig. 1). Video (30 Hz) from directly in front of the patient and Vicon motion data (100 Hz) were recorded simultaneously during the entire single limb stance task.


Figure 1: Single-limb stance with absolute and relative angles from reflective marker locations.

Three time points during the task, in which the patient was not visually unstable, were used for comparison between the video and motion capture methods: within the first 10 seconds of initial foot clearance, midtrial, and within the last 10 seconds. A still frame image was taken from the video at each time point of interest, and synchronized with the Vicon recording.

Two absolute angles (torso with respect to vertical, pelvis with respect to horizontal) and two relative angles (torso on pelvis, pelvis on femoral) were calculated at each time point. Still frame images were imported into NIH ImageJ software and the marker coordinates were used to generate angles of

interest. Motion capture coordinates of the reflective markers were used directly for the angle calculations. Differences between the methods (video-based, Vicon) were used to calculate error. 95% limits of agreement were calculated, and visual trends in the agreement were assessed using Bland-Altman plots.

RESULTS and DISCUSSION

Errors in the video-based measurement were smaller in the absolute angles than the relative joint angles (Table 1). All angles except for the torso, were smallest within the first 10 seconds of the trial. Mean error of the video-based method versus the Vicon criterion ranged from 0.1 to 2.5 deg. The smallest error was 0.1 deg (torso angle during last 10 sec) and the largest mean error was 2.5 deg (pelvis on femoral angle during mid trial). Bland-Altman plots demonstrated that errors were uniformly distributed across all angles in all angles except for pelvis on femoral (Fig. 2). The error of the pelvis on femoral angle increased as mean angle increased above 75 degrees, which is associated with the large mean errors in this variable.

Table 1: Measurements error (degrees) for each time point. Mean error [95% limits of agreement].

Angle	First 10 Sec	Mid Trial	Last 10 Sec
Pelvis	-0.2 [-5.7,6.1]	-0.3 [-4.7,5.3]	0.5 [-4.6,3.6]
Torso	0.2 [-3.6.3.3]	1.0 [-7.8,5.8]	0.1 [-7.1,6.9]
Torso on Pelvis	-0.7 [-7.0,8.4]	-1.7 [-7.7,11.0]	-1.6 [-6.9,10.2]
Pelvis on Femoral	-2.3 [-4.2,8.8]	-2.5, [-4.8,9.9]	-2.4 [-5.2,10.0]

The results demonstrate that using video-based still frames to estimate the Trendelenburg angles is a potentially viable method for clinical use. The error limits associated with the angles used in this investigation were centered around zero, and were consistent among time points.

Trendelenburg angles are important measures to understand hip abductor strength, but they are difficult to measure. A goniometer measure is challenging to implement and can affect patient behavior. It is impossible to measure torso on pelvis and pelvis on femoral angles at one time point using
Figure 2: Bland-Altman plot of torso and pelvis on femoral angle.

a goniometer. The video-based method will measure all Trendelenburg angles at the same time point.

The video-based method is easily implemented into a lab or clinic to measure Trendelenburg posture (difficult to quantify). For example, a smartphone, positioned on a tri-pod, can record a 30-sec one-limb stance and still frame images can be processed through NIH ImageJ software and Excel.

CONCLUSIONS

The video-based method was a good estimate of relative and absolute angles of a patient during a single limb stance. This method is easily and inexpensively implemented into the clinic and can help to reduce diagnostic errors associated with clinical observation.

EFFECTS OF A COMBINED INVERSION AND PLANTARFLEXION SURFACE ON KNEE AND HIP KINEMATICS DURING LANDING

INTRODUCTION

Landing from a jump is an activity commonly associated with many team sports including basketball, volleyball, and soccer. During the landing, assorted motions at the knee and hip have been associated with increased risk of anterior cruciate ligament (ACL) injury (1, 6). While many ACL injuries are non-contact, sports such as soccer and basketball often require jumping with other people in the vicinity and may result in landing on another competitors foot, providing an altered landing surface.

This altered landing surface often manifests into a lateral ankle sprain as a result of excessive inversion and plantarflexion during landing (4). As a result, it is likely that the knee and hip joints are subsequently affected by this altered position. Most research has not examined the affects of the altered landing surface on the knee and hip joints and how it may further predispose athletes to certain knee and hip injuries such as ACL injuries.

ACL injuries during landing often occur due to increased knee abduction motion (7), hip adduction (6), and reduced hip and knee flexion (1, 3). These joint angles may change as a result of the altered landing surface during jumping, which may further predispose these athletes to ACL injury risk during their landings. Therefore the purpose of this investigation was to examine the effects of landing on a combined inversion and plantarflexion surface on knee and hip kinematics during a drop landing.

METHODS

Twelve healthy recreational athletes (age: 24.4 ±4.2 years, height: 1.74 ±0.09 m, mass: 71.4 ±11.6 kg), ten males and two females, participated in this study. Participants did not have a history of major lower extremity injury and had not suffered a lateral ankle sprain within 6 months prior to testing. Subjects performed drop landings from a height of 30cm. Five successful trials were performed in three testing conditions (landing surfaces): a flat surface, a 25° inversion surface, and a 25° inversion and plantarflexion (combined) surface. The landing platform consisted of a movable top surface that was held by one ball-and-sock joint and two releasable ball-and-socket joints, allowing for the tilting of inversion only or a combination inversion and plantarflexion on contact (2). The landing trials were performed with the right leg (perturbed) landing on the modified surfaces while the left leg (non-perturbed) always on a flat surface.

A 9-camera motion analysis system (240 Hz, Vicon Motion Analysis Inc., Oxford, UK) was used to obtain 3D kinematic data during the trials. Anatomical and tracking markers were placed on the pelvis, thighs, shanks, and feet of both legs. Pilot data had shown that landing on the combined surface without practice frequently led to loss of balance after landing, therefore for safety reasons, surface conditions were not randomized. The kinematic data were computed using the Visual3D biomechanics analysis suite (4.0, C-Motion, Inc., Germantown, MD). The right-hand rule was used to establish the conventions of 3D kinematics. Marker trajectories were filtered with a zero-lag fourth order low-pass Butterworth filter at 12 Hz. A 2 x 3 (leg x surface condition) repeated measures analysis of variance (ANOVA) was used to examine the effects of the legs and surface conditions on hip and knee kinematics (SPSS 22.0, SPSS Inc., Chicago, IL). Post hoc comparisons with Bonferroni adjustments were performed using a pairwise t-test ($p < 0.05$).

RESULTS AND DISCUSSION

Significant interactions were seen in peak knee flexion ($p < 0.001$), knee flexion ROM ($p < 0.001$), peak hip flexion ($p < 0.001$) and abduction

(p<0.001), and hip flexion (p=0.001) and abduction ROM (p<0.001). A significant main effect for leg was seen in the peak hip flexion (F=16.765, p=0.002). In addition, a main surface effect was seen for knee abduction ROM (F=8.381, p=0.007), peak hip abduction (F=62.382, p<0.001), and hip abduction ROM (F=72.826, p<0.001). Post-hoc comparisons showed that peak knee and hip flexion was significantly lower and peak knee abduction was significantly higher in the perturbed leg on the combined surface compared to the flat and inverted surfaces (p<0.05, Table 1). Hip abduction ROM was significantly higher in perturbed leg compared to the non-perturbed leg in the inverted condition (p=0.024). On the combined surface, the perturbed leg compared to the non-perturbed leg showed decreased knee flexion ROM, peak knee flexion, hip flexion ROM, and peak hip flexion and increased knee abduction ROM, peak knee abduction, and hip abduction ROM and (Table 1, p<0.05).

Increases in knee abduction have been frequently suggested to place athletes at risk for ACL injury (5, 7). Results from this research suggest that landing on the combined surface may increase the risk of ACL injury due to the increased knee abduction seen in the perturbed limb. This result occurred during double-leg landing with the perturbed leg making contact first. But it is important to note that single-leg landing has been shown to further increase the knee abduction and therefore increase the risk of ACL injury (7). It is common for athletes in competition situations such as basketball, soccer, and volleyball to often land on a single limb which may increase the risk factor during landing on a combined surface. Additionally, our results

showed that the perturbed limb landed with a more extended knee, which decreases the ability of the hamstrings to prevent anterior tibial translation and increases ACL injury risk (3). It has also been suggested that hip adduction increases knee abduction. However landing on the tilting surfaces induced hip abduction, which may have been a protective mechanism to limit the amount of knee abduction experienced by the knees during landing.

CONCLUSION

Kinematic differences of the knee and hip between the flat and inverted conditions were few and small. However, when adding the plantarflexion to the inversion tilt, there were many more significant differences which may predispose athletes to ACL injuries during their landings. The increased hip abduction may be a protective mechanism designed to limit the knee abduction occurring during the inverted and plantarflexed landing.

EFFECTS OF DIFFERENT PERTURBATION LEVELS DURING FALL RISK ASSESSMENT FOR OLDER ADULTS AT HIGHER FALL RISK

Srikant Vallabhajosula, Jane Freund, Victoria Flood, Lucas Boyd, Mary Cameron Hamilton, Stephen P. Bailey

Department of Physical Therapy Education
Elon University, Elon, NC, USA
email: svallabhajosula@elon.edu, web: www.elon.edu/dpte

INTRODUCTION

A fall is defined as an event which results in a person coming to rest inadvertently on the ground or floor or other lower level. According to the World Health Organization, each year an estimated 424,000 individuals die from falls globally. Particularly, falls are a serious concern among the aging population with one in three adults aged 65 or above experiencing a fall every year [1]. In 2009, more than 2.4 million older adults had to visit emergency room for nonfatal fall-related injuries [2]. These falls cause both morbidity and mortality, resulting in multiple injuries and increased medical costs (estimated to become $54.9 billion by 2020) [3]. Hence it is critical to identify assessments and mechanisms that increase this risk of falls to design effective fall-prevention programs.

Assessments for risk of falls include examining the motor control strategies when an individual is given an external perturbation. While the use of systems like the Biodex Balance System SD that can provide an external perturbation in a clinical setting is increasing, little evidence exists on the amount and kind of perturbation needed to effectively and quantitatively assess risk of fall. The purpose of the current study is to examine fall risk assessment among older adults using two different conditions of perturbation (LESS and MORE) on the Biodex Balance System SD (Biodex Medical Systems, Shirley, NY). We hypothesized those older adults who are classified to be at higher fall risk will perform poorly than those who are classified to be at lesser fall risk under both the perturbation conditions but the performance will be more similar under the MORE perturbed condition.

METHODS

Twenty two older adults, including 15 females and 7 males were categorized into two groups based upon American Geriatrics Society guidelines for fall risk assessment; lesser fall risk, n=11, mean age 72 ±4.84 years and higher fall risk, n=11, mean age of 75 ±6.86 years.

The Biodex Balance system SD was used for fall risk assessment. The Biodex Balance System SD uses a circular force platform that is free to tilt in the anterior–posterior and medial–lateral directions simultaneously. It is possible to control the degree of perturbation from levels 12 to 1 with a higher level indicating more stable platform. In the current study two levels (conditions) were used: level 8 (LESS perturbation) and level 2 (MORE perturbation). Under each condition, participants performed one standing practice trial followed by two test trials for 30s each. Sufficient rest as desired by the participants was given between the trials and between the conditions. The order of the conditions was randomized among the participants. The force platform records center of pressure data during standing trials. However no visual feedback of the center of pressure was given while the participants tried to maintain their balance on the unstable platform. The recorded center of pressure data was used to calculate several center of pressure based dependent variables such as range, path length, mean velocity, root mean square displacement in medio-lateral and antero-posterior directions. Total path length and elliptical sway area were also calculated. All the calculations were made using customized Matlab scripts. For statistical analysis, independent samples t-tests and Receiver Operating Characteristics (ROC) curve analysis were performed for both the conditions separately as the main purpose of the study was to see the difference

between the groups during each condition. An average of both the test trials was used for statistical analysis.

RESULTS AND DISCUSSION

While all the participants could complete the LESS perturbation condition, 5 participants in the higher fall risk group and 1 participant in the lesser fall risk group could not complete the MORE perturbation condition.

For the LESS perturbation condition, older adults at higher fall risk displayed significantly greater medio-lateral range ($P = 0.044$), antero-posterior range ($P = 0.024$) and antero-posterior root mean square displacement ($P = 0.027$; Table 1). When perturbed MORE, older adults at higher fall risk who completed the task displayed significantly greater antero-posterior root mean square displacement ($P = 0.043$) and a trend towards greater elliptical sway area ($P = 0.057$; Table 1). These results suggest that among those who completed the tasks, older adults at higher fall risk performed poorly during both the conditions compared to those who were at lesser fall risk. More differences were seen when perturbed to a lesser extent as older adults at lesser fall risk group could perform this task better compared to the older adults at higher fall risk. However when perturbed more, perhaps participants in both the groups who could complete the task found it similarly challenging.

ROC curve analysis for the LESS perturbation condition showed that the area under the curve ranged from 0.69 to 0.79 for all the dependent variables. Similarly, ROC curve analysis for the MORE perturbation condition showed that the area under the curve ranged from 0.61 to 0.76 for all the

dependent variables. Results from the ROC curve analysis echo those of the independent samples t-test with a greater area under the curve seen for the LESS perturbation condition compared to the MORE perturbation condition suggesting that the LESS perturbation condition was better at differentiating the two groups.

CONCLUSIONS

Greater percentage of older adults at higher fall risk seemed to be unable to complete a more challenging perturbation task compared to those at lesser fall risk. This could be due to insufficient input from sensory systems to maintain balance when the force platform tilted more. Perturbing to a lesser extent also seemed to be beneficial to differentiate those at higher and lesser fall risk. Results of the current study suggest that older adults who were categorized as at higher fall risk could be further sub-divided during clinical examination into two groups – those who cannot perform the MORE perturbation task and those who can but perform poorly on the LESS perturbation task compared to older adults at lesser fall risk. Greater sample size is required to warrant these findings.

THE INFLUENCE OF LOCOMOTOR TRAINING ON DYNAMIC BALANCE AND ITS RELATION TO INCREASED WALKING SPEED IN POST-STROKE HEMIPARETIC SUBJECTS

Arian Vistamehr[1], Steven A. Kautz[2, 3], Mark G. Bowden[2, 3] and Richard R. Neptune[1]

INTRODUCTION

Slow walking speed and lack of balance control are common impairments post-stroke. Thus, rehabilitation interventions often target improved gait coordination and overall mobility. One intervention that has received much attention is locomotor training, which consists of walking on a treadmill with partial body-weight support [1] and manual assistance from trainers. While numerous studies have reported improved walking speed in subjects post-stroke (e.g., [1-2]), the effect of locomotor training on dynamic balance during walking is unclear.

To maintain dynamic balance, whole-body angular momentum (H) needs to be controlled through proper foot placement and generation of appropriate ground-reaction-forces (GRFs) (e.g., [3]). Thus, poor regulation of H during walking results in higher magnitudes of H, which may indicate a decreased ability to recover balance. However, no study has assessed if locomotor training improves dynamic balance through improved regulation of H. In addition, it is not clear if clinically meaningful increases in walking speed after locomotor training are correlated with improved dynamic balance.

The goal of this study was to assess the influence of a 12-week locomotor training program [2] on dynamic balance in post-stroke subjects during steady-state walking and determine if clinically meaningful improvements in walking speed are associated with improved balance control.

METHODS

Previously collected kinematic and GRF data [2] from 20 post-stroke subjects with hemiparesis (11 left hemiparesis; age: 56 ± 11.7 years) pre- and post-therapy were analyzed. Subjects participated in a 12-week locomotor training program described previously [2]. Three-dimensional kinematics and GRFs were collected within one week of therapy initiation and completion. Subjects walked on a split-belt instrumented treadmill at their self-selected (SS) and fastest-comfortable (FC) walking speeds pre-therapy. During post-therapy data collection, each subject walked at a speed matched to their pre-therapy SS and FC speeds. In addition, SS and FC speeds were determined post-therapy to allow the determination of speed increases from pre- to post-therapy. Kinematic data from ten healthy subjects [4] were used to provide a basis for comparison.

Dynamic balance was assessed using the peak-to-peak range of H in the frontal and sagittal planes as described by Vistamehr et al [4]. The range of H between pre-therapy walking at SS (and FC) speed and post-therapy walking at a speed matched to their pre-therapy SS (and FC) speed were compared for each subject using a paired t-test ($p < 0.05$). In addition, those with clinically meaningful improvements in walking speed (> 0.16 m/s, [5]) were identified as responders and Pearson's correlation analyses were performed to identify relationships between changes in SS walking speed and changes in the range of H walking at fixed speeds pre- and post-therapy. If significant correlations were found, to further understand the mechanisms used for maintaining balance and improving walking speed, GRF peaks and impulses (i.e., time integral of GRFs) were calculated during early (0-50%) and late (51-100%) stance. Also, foot placement was calculated as the vector from the

body center-of-mass to the center-of-pressure. Pearson's correlation analyses were performed between the range of H in each plane and GRFs (peaks and impulses) as well as foot placement.

RESULTS AND DISCUSSION

For the group as a whole, locomotor training did not improve dynamic balance as measured by changes in whole-body angular momentum. The range of H decreased (improved) in only 25% of the subjects and became worse (increased) in 35% of the subjects. The remaining subjects did not have a consistent response, with each subject improving, becoming worse or showing no change in the different planes and walking conditions (Fig. 1 and Table 1). Compared to the healthy control subjects, the range of frontal-plane H was higher in the hemiparetic subjects both pre- and post-therapy, suggesting poorer mediolateral balance control post stroke (Fig. 1). In the sagittal plane, the range of H was generally higher during the nonparetic leg stance than during the paretic leg stance (Fig. 1). This was mainly due to the longer duration of the nonparetic leg stance.

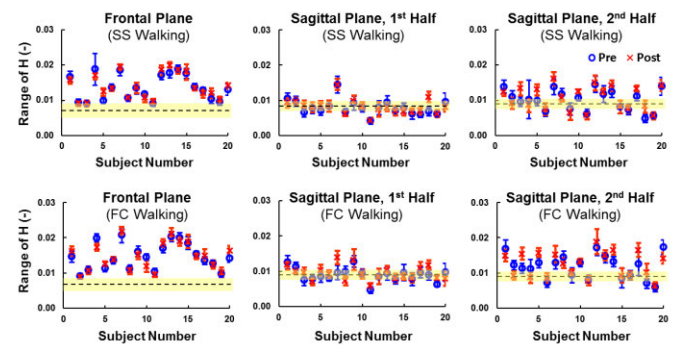
For those subjects who achieved a clinically meaningful improvement in their SS walking speed (n = 11), changes in walking speed were correlated with improved dynamic balance in the frontal plane (r = -0.48, approaching significance at P = 0.09) and sagittal plane during the first half of the paretic gait cycle (r = -0.55, P = 0.05). Also, changes in the FC walking speed were correlated with changes in the range of H in the sagittal plane during the first (r = -0.86, P < 0.001) and second (r = -0.63, P = 0.02) halves of the paretic gait cycle. Further, the improved dynamic balance was correlated with changes in foot placement and generation of GRFs. Specifically, better balance control was associated with a mediolateral paretic foot placement closer to midline, longer anterior nonparetic steps, higher braking GRF peaks and impulses, higher (lower) propulsive GRF peaks and impulses from the paretic (nonparetic) leg, and higher vertical GRF impulses from both legs in the late stance. These relationships highlight the importance of foot placement and appropriate GRF generation to balance control and may assist clinicians with designing effective locomotor therapies that target these biomechanical variables.


Figure 1: Normalized, mean (± SD) range of H for each hemiparetic subject pre- and post-therapy. The range of H in the sagittal plane is shown during the 1st (paretic leg stance) and 2nd (nonparetic leg stance) halves of the gait cycle. The dashed line indicates the group average range of H (shaded region, ± SD) for the healthy control subjects.

Table 1: Significant changes (p<0.05) in the range of angular momentum (H) between pre- and post-therapy are shown for each subject. Significant decreases in the range of H are shown with '✓' and significant increases are shown with 'x'. '1st' and '2nd' represent the 1st (paretic leg stance) and 2nd (nonparetic leg stance) halves of the gait cycle.

POSTURAL STABILITY DURING STAIR NEGOTIATION WHILE CARRYING ASYMMETRIC LOADS

Junsig Wang and Jason Gillette

Iowa State University, Ames, IA, USA

INTRODUCTION

Individuals often carry items in one hand instead of both hands during activities of daily living. Asymmetric load carriage is expected to produce a lateral shift of the center of mass. A laterally displaced center of mass during unilateral load carriage results in a challenge to postural stability during walking. Furthermore, asymmetrical load carriage during stair negotiation results in even higher demands on postural stability.

Previous studies have investigated how load carriage affects the biomechanics of human movement as a function of load magnitude and asymmetry. However, no studies exist that evaluate postural stability of asymmetric load carriage during stair negotiation. Therefore, the purpose of this study was to assess postural stability when carrying symmetric vs. asymmetric loads during stair ascent and stair descent. We hypothesized that: 1) postural stability would be decreased during unilateral load carriage as compared to bilateral load carriage, and 2) postural stability would be decreased during stair descent as compared to stair ascent.

METHODS

Twenty-five young healthy adults (13 males, 12 females; age 24.0 ± 4.2 yr; height 171.3 ± 7.7 cm; mass 68.7 ± 13.3 kg) participated in this research. A three-step staircase (step height 18.5 cm, tread depth 29.5 cm) with force platforms on the two lowest steps was used for stair negotiation. The participants were asked to carry three types of loads: no load, 20% body weight (BW) load on one side of the body, and 20% BW load split between both sides of the body. Two hand-held bags were filled with sealed bags of lead shot to match the two loaded conditions.

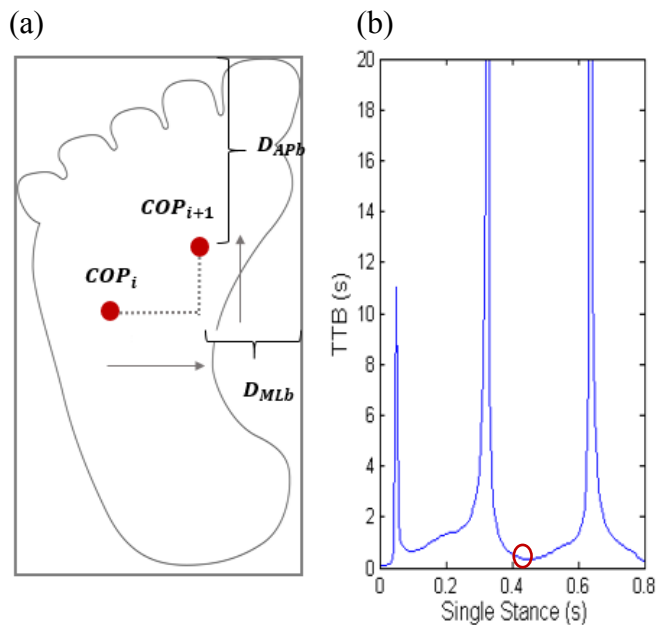
An eight-camera Vicon motion analysis system was used to collect three-dimensional kinematic data at a sampling rate of 160 Hz. Five retro-reflective markers were placed on toe, mid-foot, heel, medial malleoli, and lateral malleoli. Force platform data were sampled at 1600 Hz. Kinetic and kinematic data were synchronized using Vicon Nexus.

Center of pressure (COP) based parameters were calculated using custom-made Matlab code. COP velocities were calculated utilizing the first central difference method. Rectangular boundaries of the base of support were modeled from marker data and foot anthropometrics. Anterior-Posterior (AP) and Medial-Lateral (ML) COP position and velocity were then used to estimate Time-to-Boundary (TTB, Figure 1). TTB is the estimated time it takes the COP to reach the boundary of foot [1]. The dependent variables included mean COP AP and ML velocities and minimum AP and ML TTB values during single-leg stance.

Two independent variables were tested: loading conditions (no load, 20% BW bilateral load, 20% BW unilateral load) and stair negotiation (ascent vs. descent). Repeated measures ANOVA with two within factors (3×2) was performed to test the effects of loading conditions and stair negotiation. Holm-Bonferroni post-hoc tests were performed when appropriate. The level of statistical significance for all tests was set at $p < 0.05$.

RESULTS

For mean AP COP velocity, there were significant main effects of load condition ($p = 0.05$) and stair ascent vs. descent ($p < 0.01$, Table 1). Mean AP COP velocity was significantly higher during stair descent as compared to stair ascent, but post-hoc analysis did not detect any significant differences between load conditions ($p \geq 0.11$). For mean ML COP velocity, there was a significant main effect of stair ascent vs. descent ($p < 0.01$). Mean COP ML velocity was significantly higher during stair descent as compared to stair ascent (Table 1).

(a)   (b)


$$TTB_{(i)} = D_{b(i)}/COP_{Vel(i)}$$
D_b = displacement from COP to AP or ML boundary
COPvel = AP or ML COP velocity
i = each data point (1/160s interval)

Figure 1 Illustration of (a) TTB calculation and (b) the minimum TTB value (in ML direction)

For minimum ML TTB, there were significant main effects of stair ascent vs. descent (p < 0.01) and the interaction between stair ascent vs. descent and load condition (p = 0.01). Minimum ML TTB was significantly lower for stair descent as compared to stair ascent (Table 1). Exploring the interaction effects, minimum ML TTB was significantly lower for stair descent as compared to stair ascent when carrying no load, 20% BW bilateral load, and 20% BW unilateral load. For minimum AP TTB, there were no significant main effects.

DISCUSSION AND CONCLUSIONS

We investigated the effect of different methods for carrying loads on postural stability during stair negotiation in healthy young adults. Our first hypothesis that postural stability would be decreased during unilateral load carriage as compared to bilateral load carriage was not supported. Our second hypothesis that postural stability would be decreased during stair descent as compared to stair ascent was supported for three variables. More specifically, mean AP COP velocity was increased, mean ML COP velocity was increased, and minimum ML TTB was decreased during stair descent.

COP-based parameters measure challenges in postural stability. Specifically, minimum TTB estimates the lowest margin of safety before a postural adjustment is necessary [2-3]. These parameters indicated that stair descent results in decreased postural stability compared to stair ascent, particularly in the ML direction. However, load carriage did not significantly affect these measures of postural stability. Challenges associated with load carriage may be better assessed with musculoskeletal models that estimate structural loading.

INTRODUCTION

Lower back pain in the military population has been associated with injuries that result from heavy load carriage during training and operational tasks [1]. As a result, load carriage limits and configuration recommendations have been studied and established based on energy expenditure and situational awareness [2,3]. However, the interaction between load magnitude and distribution on lumbar spine (LS) posture has not been described in detail.

METHODS

A group of 12 active-duty Marines (age 24.42±5.48 years, BMI 24.69±2.53 kg/m^2, time of service: 57.21±44.72 months) were scanned using a 0.6T MRI scanner (Upright MRI scanner, Fonar Corporation, Melville, NY, USA). This scanner allows for images to be acquired while subjects are standing. The lumbar spine of each Marine was scanned while standing unloaded and loaded with 6 different configurations: carrying 22, 33 and 45 kg, with the load distributed 50% anteriorly and 50% posteriorly and 20%-80%, respectively. The order of the scans was randomized.

The imaging protocol consisted of a 3-plane localizer and sagittal T2 weighted images (TR = 1974msec, TE= 160sec, FOV =32cm, 224x224 acquisition matrix, 4.5-mm slice thickness, no gap, scan duration 3min) were acquired. Images were used to create a 3D representation of the endplates of each vertebra (L1-S1) by placing seed points on the four corners of each vertebra and posterior elements landmarks using Osirix (Pixmeo, Geneva, Switzerland). Custom software was then used to measure the overall angle of the LS with respect to the horizontal, overall LS lordosis, superior LS lordosis (Sup L1 to Inf L3), inferior LS lordosis

(Sup L4 to Inf S1), and intervertebral angles (L1-S1) [4].

All variables were compared using two-way (load × configuration) repeated measures ANOVA and *post hoc* Sidak tests to identify significant differences and interactions among these factors (α=0.05). All data in plots are reported as means ± standard deviation.

RESULTS AND DISCUSSION

A significant interaction (p<0.05) between load magnitude and distribution was found, meaning that the effect of load on LS posture is distribution dependent. Moreover, loads carried in the 20%-80% configuration induced (p<0.05) postural changes through 33kg, while those carried in the 50%-50% configuration did not have an effect on LS posture.

Increased trunk flexion (p<0.05) was found when load was carried in the 20%-80% configuration. However, no differences in lumbar flexion were measured between 33kg and 45kg (Fig. 1, solid bars).
Figure 1: Results for angle with respect to the horizontal. Thick dashed line indicates average value when standing without external load; thin dashed lines indicate one standard deviation. Clear bars: 50-50% load distribution; solid bars: 20%-80% load distribution. Horizontal bars represent statistical significance (p<0.05).

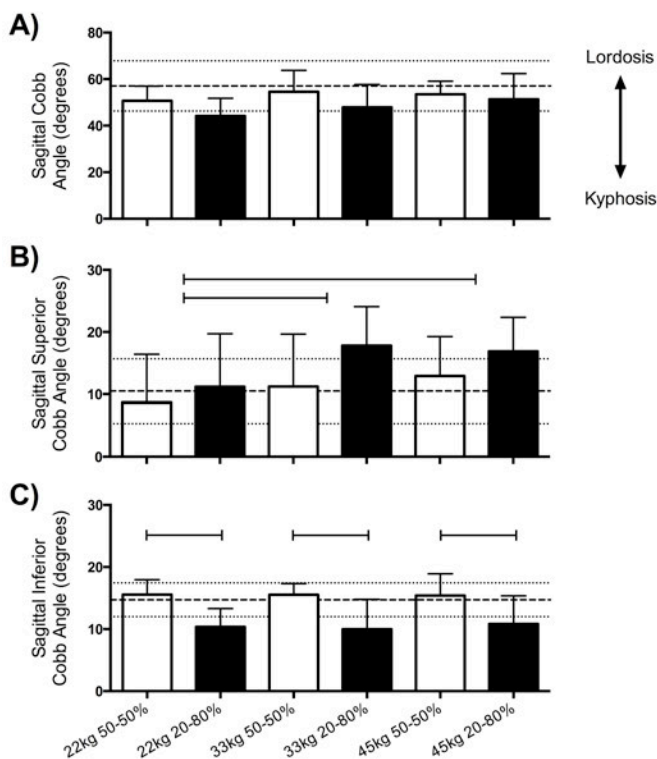
Significant (p<0.05) main effects of both load magnitude and configuration on whole LS lordosis were found. However, *post hoc* tests revealed no differences between load magnitudes (Fig. 2A). Furthermore, superior and inferior LS lordoses were measured to identify regional postural response to load magnitude and distribution. A main effect of load magnitude was found (p<0.05) on the superior LS. Overall, superior LS became more lordotic as load magnitude increased from between 22kg to 33kg, while no difference was detected 33kg and 45kg (Fig. 2B). Contrastingly, a main effect of load configuration was detected (p<0.05) on the inferior LS; furthermore, when load was carried in the 20%-80% configuration the inferior LS became straighter (~5°) regardless of load magnitude (Fig. 2C).


Figure 2: Results for A) whole, B) superior and C) inferior LS lordosis. Thick dashed line indicates average value when standing without external load; thin dashed lines indicate one standard deviation. Clear bars: 50-50% load distribution; solid bars: 20%-80% load distribution. Horizontal bars represent statistical significance (p<0.05).

CONCLUSIONS

Load carriage in the 50%-50% configuration did not induce changes in LS flexion or lordosis. These data suggest that the LS posture while carrying load equally distributed anteriorly and posteriorly is similar to that while standing without external load. Future work is needed to establish if this may have a positive or negative effect on LS health or operational efficiency.

In this study, we have shown that as load magnitude increases the LS flexes forward when load is carried in the 20%-80% configuration. Additionally, we observed opposing lordosis postures in the superior and inferior LS. The superior LS becomes progressively more lordotic as load magnitude increases, potentially to maintain an upright head position. Surprisingly, we found that the inferior LS became less lordotic regardless of load magnitude.

It has been previously hypothesized that LS postural changes during load carriage are aimed at maintaining the center of mass of the system. Interestingly, global LS postural differences were not found when Marines carried 33kg and 45 kg in the 20%-80% configuration. This may suggest a plateau effect of load induced postural changes with a posterior load-carriage bias. Importantly, lumbar spine postural changes were not observed when loads were balanced anterior to posterior.

THE EFFECT OF POSTERIOR FOOT PLACEMENTS ON
SIT-TO-STAND KINETICS, ENERGETICS AND MUSCLE ACTIVITY

Eric Pitman, Zachary A. Sievert, Kevin C. Fontenot, Jessica A. Mutchler & Joshua T. Weinhandl

Old Dominion University, Norfolk, Virginia, USA
Email: epitman@odu.edu

INTRODUCTION

The Sit-to Stand (STS) is an activity of daily living (ADL) frequently performed by all people [1]. The ability to accomplish this task is essential to perform other ADLs such as walking and stair climbing [2]. It has been shown that people with movement difficulties will alter their initial seated position to make this task easier [3]. There are a variety of different strategies to make this task easier based off the specific pathology; but, the common goal of the movement change is to reduce dynamic instability of the center of mass (COM).

A common strategy change for the STS is positioning the feet posteriorly by increasing flexion at the knee joint. This reduces the displacement of the COM to the base of support while increasing the joint moment of force at the knee while decreasing it at the hip. [3] However, it is unclear the accumulative effect of the moment of force at each joint in foot positions with varied knee joint angles. Therefore, the purpose of this study was to determine the effects of altered foot positions on joint angular impulse and work, as well as integrated surface electromyography (iEMG) of the dominant lower limb.

METHODS

Ten healthy, recreationally active participants (70.1 ± 8.70 kg, 1.66 ± 0.07 m, 18-30 years) volunteered to perform STS on a force plate. Prior to data collection, participants were informed of study procedures and provided written informed consent in accordance with institutional guidelines. Single reflective markers were placed on specific anatomical landmarks [4] and a static standing calibration trial (neutral position) was collected. Participants were asked to complete five STS with in three foot placements. The knee joint angle was positioned at 90^0, 100^0 and 110^0 measured by a goniometer. Three-dimensional marker coordinate data were collected at 200 Hz using an eight-camera Vicon motion analysis system. Synchronously, three-dimensional force data and surface EMG of 8 lower extremity muscles were collected at 2000Hz using a Bertec force plate and Delsys trigno sensors, respectively. The lower extremity muscles include: Tibialis Anterior, Soleus, Gastrocnemius, Rectus Femoris, Vastus Lateralis, Vastus Medialis, Biceps Femoris and Medial Hamstrings.

Raw three-dimensional marker coordinate and GRF data were low-pass filtered using a fourth-order, zero lag, recursive Butterworth filter with cutoff frequencies of 12 Hz and 50 Hz, respectively. The raw EMG data was pre-amplified and high-pass filtered using fourth-order, zero lag, recursive Butterworth filter with a cutoff frequency of 10Hz to remove artifact from movement. The signal was then full-wave rectified. The full-wave rectified signal was low pass filtered with a cutoff frequency of 5 Hz to create a linear envelope and normalized to the MVICs of the individual muscles. The linear envelope was then integrated over duration the rising phase.

A kinematic model comprised of the dominant side pelvis, thighs, shanks, and feet segments was created from the standing calibration trial [4]. Sagittal plane ankle, knee, and hip angles were calculated using a joint coordinate system approach [5]. From here, inverse dynamics was applied to calculate joint moment of force and secondary calculations were made for joint work and angular impulse. [6]

Separate one-way ANOVAs were conducted for each dependent variable with foot positions as the independent variable. Multiple comparisons were performed with the Bonferroni correction method between foot positions and individual kinetic, energetic and EMG dependent variables. Significance was set a priori at $p < 0.05$.

RESULTS AND DISCUSSION

Seven significant differences were found in the dependent variables. The result of a posterior shift of feet ultimately changed the linkages between the ankle, knee and hip joints. As the knee joint flexion angle increased, significant increases in joint work occurred in the ankle and knee with a subsequent significant decrease in the hip. This is indicative that the distribution of joint work for the STS will increase the energetic demand of the knee extensors and ankle plantar flexors while decreasing the demand of the hip extensors. As the feet

shift back, the base of support is now closer to the COM. This may explain why the hip joint experienced a decrease in work since there is a smaller range of motion which requires less time to move the COM over the base of support. As for the ankle joint, it is possible that shifting the feet back increased the initial dorsiflexion angle resulting in the increased range of motion resulting in increased work. As the knee joint increases flexion, there is a greater range of motion to be achieved thus resulting in increased knee joint work. However, the knee joint angular impulse did not follow this pattern entirely.

To clarify joint loading, angular impulse was determined at the ankle knee and hip joints. As the knees flexed from $90\text{-}100^0$ and then from $100\text{-}110^0$ there were significant increases in ankle angular impulse with subsequent significant decreases in hip angular impulse. As for the knee, there was a mild decrease from $90\text{-}100^0$ and then a slight increase from $100\text{-}110^0$. It is possible that the knee joint angular impulse remained constant due to the influence of trunk flexion. Increased trunk flexion will decrease the moment of force about the knee joint. Increasing trunk flexion is a strategy commonly used in those with quadriceps weakness to reduce the force at the knee. [7] The ankle joint experienced increased angular impulse in the negative direction suggesting that its primary role is absorbing force due to increased ankle dorsiflexion.

For iEMG, as the feet were shifted posteriorly, the only significant difference occurred in the biceps femoris and medial hamstring in the $90\text{-}100^0$ condition. This is likely the result of the significant decrease in hip joint work and angular impulse. Although not significant, there was an increase in activity in the Soleus and Gastrocnemius with a subsequent decrease in the Tibialis Anterior as the feet shifted back.

The activity of the Vastus Lateralis, Vastus Medialis, and Rectus Femoris followed a similar pattern of the knee joint angular impulse. This may also be explained by the role trunk flexion.

CONCLUSIONS

This study investigated the role of shifting the feet posteriorly from a 90^0 knee bend to 110^0 in the STS on the accumulative lower body joint energetics and kinetics along with iEMG. The decrease in joint angular impulse at the hip and increase at the ankle shows similarity with the results of the distribution of joint work. The knee joint work increased accordingly with an increase in knee joint angle; however, this was not the case for knee joint angular impulse. Future work should measure trunk kinematics since the extensor moment arm can be decreased with increased trunk flexion. There were few significant outcomes from iEMG of the lower extremity muscles, revealing the total muscle activity does not necessarily correspond with the total energy and loading contributions. Future research should evaluate the effect of foot position on the ability to improve STS performance in those individuals with movement difficulties.

INTRODUCTION

Falls are the third leading cause of unintentional death in homes and communities in the United States, causing 27,800 fatalities in 2012 [1]. The ability to maintain proper postural control is an essential part of activities of daily living (ADLs). However, recent types of alternative footwear may be placing the body's postural control system at an increased risk for perturbations to equilibrium and subsequent falls. The purpose of this study was to examine the effects of three forms of alternative footwear (thong style flip-flops (FF), clog style Crocs® (CC), and Vibram® Five-Fingers (MIN)) on postural control.

METHODS

Eighteen healthy male adults (age: 22.9±2.88 years; height: 179±6.0 cm; mass: 81.3±8.8 kg) with no history of neuro-musculoskeletal disorders participated in this study. Static balance measures were recorded using the six conditions of the Neurocom® sensory organization test (SOT) [eyes open (EO), eyes closed (EC), eyes open with sway referenced vision (EOSRV), eyes open with sway referenced support, (EOSRP), eyes closed with sway referenced support (ECSRP), and eyes open with sway referenced vision and support (EOSRVP). Surface electromyography (EMG) signals were recorded from the right leg musculature: tibialis anterior (TA), and medial gastrocnemius (MG). The EMG signals were recorded using silver/silver chloride monopolar surface electrodes. The ground electrode was placed on the tibial plateau. The EMG was recorded using Noraxon® MyoResearch software (Noraxon U.S.A.

Inc. Scottsdale, AZ.). Raw EMG data were collected at 1,500 Hz, Band-pass filtered (20-250Hz) and rectified prior to analysis. Post acclimatization, participants performed isometric MVC of plantar flexion and dorsiflexion, preceding and after a one-mile self-controlled walk on a treadmill. Muscle Co-contraction index (CCI) (operationally defined as the simultaneous activation of two muscles) was calculated based on the ratio of the EMG activity of antagonist/agonist muscle pairs of the lower leg (TA/MG) using the following equation [2],

$$(EMGS/EMGL) \times (LowerEMG + HigherEMG)$$

where EMGS was the level of activity in the less active muscle, and EMGL was the level of activity in the more active muscle. This ratio was multiplied by the sum of the activity found in the two muscles. This method has been used because it provides an estimate of the relative activation of the pair of muscles as well as the magnitude of the co-contraction. Results were analyzed in SPSS with a predetermined alpha level of 0.05 using a 2 x 3 [2 time measures (pre, post) x three footwear types (FF, CC, MIN)] repeated measures analysis of variance (ANOVA) for each of the SOT conditions. Pairwise comparisons with a Bonferroni correction were used to identify post-hoc differences if interaction or main effect significance were found. If at any point during analysis there was a violation of Mauchly's test of sphericity, a Greenhouse-Geisser correction was used to determine significance.

RESULTS

There is evidence of a significant interaction between footwear and time for CCI in the EOSRVP condition $(F(1.607, 27.322) = 3.684, p = 0.047)$ (Figure 2). Moreover, plotting of the results suggests a potential reverse interaction, follow-up analyses using simple effects were conducted in an attempt to understand the nature of this interaction. Analyses showed that following the one mile walk, the MIN showed significantly greater CCI than the FF $(F(2,16) = 7.002), p = 0.007)$ (Figure 3).
Figure 1: Co-contraction index before the one-mile walk. * represents a significant interaction, error bars represent standard error.
Figure 2: Co-contraction index following the one-mile walk. * represents a significant interaction, error bars represent standard error.
Figure 3: Plotted footwear by time interactionobserved in the EOSRVP condition. * represents simple effect significance.

DISCUSSION

Previous literature has suggested that when proprioceptive feedback at the ankle becomes less reliable due to age related effects, there is an adoption of a new co-contraction strategy for maintaining postural stability [3]. This study adds to this notion, and suggests that different footwear characteristics could potentially cause a fatigueing effect, and decline in proprioception at the ankle joint after a one-mile walk. This potential fatigue and shift in strategy may be explained in part by the increase in CCI observed currently, and may be exacerbated when other sensory information is also unreliable. This stiffening of the ankle joint, as opposed to relying on multiple sensory sources, may pose more of a threat to the individual's ability to stay stable, and subsequently lead to greater risk of a loss of balance and fall.

A BIOMECHANICAL MODEL TO PERSONALIZE AFO FOOTPLATES TO PROMOTE NATURAL SHANK KINEMATICS WITH LIMITED DORSIFLEXION

Elisa S. Arch, Bretta L. Fylstra, and Travis R. Pollen

University of Delaware, Newark, DE, USA
email: schranke@udel.edu, web: http://www.udel.edu/chs/facultystaff/arch.html

INTRODUCTION

A primary purpose of gait is to move the body forward in space. During the stance phase, the kinematics of the shank are critical for achieving sufficient, yet controlled, forward progression [1]. Shank kinematics are a function of ankle angle and foot-to-floor motion [2]. Thus, individuals with limited dorsiflexion range of motion (ROM) often have impaired shank kinematics. Owen developed an algorithm for tuning ankle-foot orthosis (AFO) and footwear alignment to achieve typical shank-to-vertical angle during midstance in an effort to promote forward progression during gait [1]. However, via this technique the ankle is locked in a static position, regardless of if the individual has some dorsiflexion ROM, and forward progression is achieved as the thigh and proximal segments progress over the shank-foot system [1].

As an alternative, AFOs with footplate toe rockers may be able to promote natural shank kinematics by replacing the impaired dorsiflexion with foot-to-floor motion. This approach will still utilize the individual's available dorsiflexion ROM and then engage the toe rocker when maximum dorsiflexion is reached, continuing to enable forward progression as the foot rocks over the ground. Algorithms by Owen include the use of rockers incorporated into the shoes, but proposed rockers are primarily designed for use during late stance with AFOs that inhibit all dorsiflexion [1]. Other studies have explored the influence of various rocker designs on pressure distribution or gait variables [3]; however to our knowledge, no study has proposed a quantitative model to personalize the toe rocker based on an individual's dorsiflexion limitation. The purpose of this study was to develop a biomechanical model to guide AFO footplate toe

rocker personalization to promote typical shank kinematics for individuals with limited dorsiflexion.

METHODS

A biomechanical model was developed to predict ankle joint center (AJC) and knee joint center (KJC) sagittal plane trajectories, which together determine shank kinematics, based on subject anthropometrics and footplate toe rocker design (start location and radius of curvature) (Eq 1-5; Fig. 1). The model predicts AJC and KJC trajectories from the time when the dorsiflexion ROM limit would be reached in typical gait until the end of stance.

$$AJC_y = Hsin\theta + (D+R\theta) - (D+L)cos\theta \qquad (1)$$
$$AJC_z = Hcos\theta + (D+L)sin\theta \qquad (2)$$
$$\text{where } L = 2*Rsin(\theta/2) \qquad (3)$$
$$KJC_y = AJC_y + Ssin(\theta+\alpha) \qquad (4)$$
$$KJC_z = AJC_z + Scos(\theta+\alpha) \qquad (5)$$
Figure 1: Schematic of shank kinematics with a personalized AFO footplate model.

Using this model, the toe rocker design that enabled the most typical shank kinematics was determined for three limited dorsiflexion ROM conditions (0°, 5°, 10° motion). For each condition, the toe rocker

start location (*D*) was set to the typical location of the center of pressure when the ankle angle reached its limit. Average typical, adult anthropometrics from our lab's database were used to determine ankle height (*H*) and shank length (*S*). Dorsiflexion angle (*α*) was held constant at its ROM limit (0˚, 5˚ or 10˚) until late stance, when it was allowed to decrease back to 0°. The progression angle (*θ)* was input to move the shank-foot system through a typical excursion. Then, AJC and KJC trajectories were calculated and compared to typical AJC and KJC trajectories for an average, comfortable walking speed (0.8 statures/second) [2]. The toe rocker radius of curvature (*R*) was iteratively adjusted until the model-predicted AJC and KJC trajectories best mimicked typical trajectories.

RESULTS AND DISCUSSION

The model identified toe rocker designs that are predicted to enable nearly typical shank kinematics for each of the three limited dorsiflexion ROM conditions (Fig. 2). The toe rocker start location was set to approximately 43%, 17% and 10% foot length and the radius of curvature was set to approximately 33%, 61% and 69% foot length for the 0˚, 5˚ and 10˚ dorsiflexion conditions, respectively.

Future studies will experimentally evaluate model predictions. Furthermore, while this model suggests that personalized AFO footplates can help preserve natural shank kinematics, it is not yet known how replacing ankle motion with foot-to-floor motion will influence the kinetics and energetics of gait.

CONCLUSIONS

This study successfully developed a model to predict how to personalized AFO footplate toe rockers to promote natural shank kinematics for individuals with varying dorsiflexion ROM limitations. Ultimately, we aim to implement this model to rapidly and effectively personalize AFO footplates to improve gait function for individuals with limited ankle ROM. Combining personalized AFO footplates with AFO bending stiffness [4], which can control the rotational velocity of the shank during available dorsiflexion for individuals who also have plantar flexor weakness, may provide meaningful enhancements in the gait function and mobility for individuals with ankle joint impairments.

INTRODUCTION

Femoral neck fractures are commonly repaired using percutaneous cannulated lag screws. Unfortunately these fractures are still associated with high rates of complications including osteonecrosis of the femoral head (15-45%), nonunion (10-30%) and iatrogenic subtrochanteric fractures (ISF, 2-4%) [1, 2]. Minimal gaps and good stability are essential to reduce the incidence of osteonecrosis and nonunion [1]. Little is known about the etiology of ISFs other than they typically occur through the lowest screw hole and lower hole placement seems to increase this risk [3]. We postulated that the stress risers caused by lag screw heads impinging on the lateral cortex could lead to ISF. We also hypothesized that these high local stresses could cause a settling effect that would lead to looseness at the fracture surface. The present study investigates the use of two novel tapered screw systems in an attempt to spread the load over a larger area to reduce the stress riser effect and minimize settling of the screw head.

METHODS

Two types of tapered screws were designed based on the geometry of traditional lag screws, the head of the screw being replaced with a conical taper (Fig. 1). One screw had a long, shallow taper (long tapered screw) while the other had a short, steep taper (short tapered screw). These screws were used to create two novel screw systems, both using three screws arranged in an upside-down triangle configuration [4]. One system used long tapered screws at all three positions (3 Long System) while the second system used two short tapered screws at the two superior positions and one long tapered screw at the inferior position (1 Short 1 Long System). These systems were compared to the current standard using three traditional lag screws (3 Lag System). All screws, including traditional lag screws, were custom manufactured from 316L stainless steel. Ten synthetic, fourth generation Sawbones® femur models were used to test the screws.

Figure 1: The three types of screws in this study are the traditional lag screw (top), long tapered screw (middle) and short tapered screw (bottom).

Each femur was cut 15.5 cm distal to the lesser trochanter and potted in PMMA. Three 5.0 mm holes were drilled in identical locations from the lateral proximal cortex in an upside-down triangle configuration with each hole oriented through the femoral neck. Femurs used for testing tapered screws were reamed using custom reamers with the same angle as the taper on the screws. Femoral necks were cut uniformly using an industrial band saw. Screws were tightened to achieve uniform pretension, which involved each screw type being tightened to a different torque due to unique head geometry. Femurs were loaded at the femoral head using a computer-directed algorithm that consisted of 1) a linear ramp from 20 to 750 N and back, 2) 500 sinusoidal cycles between 188 and 1875 N and 3) a linear ramp from 20 to 750 N and back. Load displacement data were recorded for steps 1) and 3) to evaluate pre and post-cyclic loading stiffness and post-cyclic loading permanent displacement of the femoral head.

Finite element analysis (FEA) mimicking mechanical testing was performed using a femur model with geometry identical to that of the synthetic femurs to predict stiffness values and strain distributions in the proximal femur [5]. Addition of the abductor muscles at the greater trochanter has been shown to yield more accurate FEA results than a joint load alone, so FEA including abductors was performed as a supplement [6].

RESULTS AND DISCUSSION

Results of mechanical tests are shown (Table 1, Fig. 2, Fig. 3). There was no difference in permanent displacement of the femoral head in any system.

Table 1: Results for FEA. Percentages are relative to the 3 Lag System.

FEA: joint force only		
	3 Long	**2 Short 1 Long**
Stiffness	-10.4%	5.4%
Strain at inferior hole	-9.1%	-4.2%
FEA: joint force + abductors		
	3 Long	**2 Short 1 Long**
Stiffness	-10.3%	2.9%
Strain at inferior hole	-5.3%	-2.9%
Stiffness (N/mm)

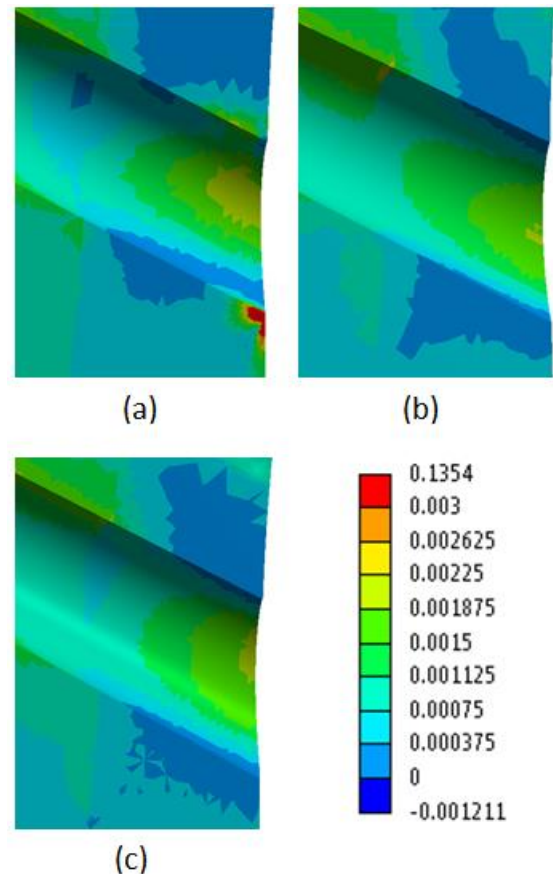
Figure 2: Bar graph showing stiffness following cyclic loading. Standard deviation whiskers and p-values are shown.


Figure 3: FEA showing a coronal section of first principal strain at the inferior hole in the a) 3 Lag, b) 3 Long and c) 2 Short 1 Long Systems.

FEA showed that the tapered screw systems eliminate the strain riser caused by the impinging traditional lag screw head and decrease strains at the sides of this hole, which may reduce the incidence of ISF. However, they also decrease the stiffness of the repaired femur which may increase the rates of the more common complications of osteonecrosis and nonunion. Therefore neither of these systems can be recommended to replace the current method using three traditional lag screws.

INTRODUCTION

Manual wheelchair users with spinal cord injuries (SCI) rely heavily on their upper extremities for independence in their home and community. Wheelchair propulsion along with wheelchair transfers have been linked to upper extremity pain and injury [1]. In addition, wheelchair propulsion has been shown to be generally inefficient with a reported gross mechanical efficiency around 10-12% [2]. Startup is an important aspect of wheelchair propulsion, yet little is known about how to optimize the first strokes to achieve the highest possible efficiency. The average wheelchair user spends more time during the day starting and stopping their wheelchair than in constant propulsion motion [3]. The purpose of this study was to better understand the relationship between terminal velocity and aspects of startup propulsion technique such as pushrim start and release angles, time spent on the pushrim and force variables. Terminal velocity is defined as the highest velocity attained by a person during any one wheelchair stroke.

METHODS

Subjects

Twenty nine subjects were recruited to participate in the study and all signed informed consent forms. The inclusion criteria for the study were: between the ages of 18 and 65, has a neurological impairment secondary to a spinal cord injury, the injury occurring after the age of 18, at least one year post injury, use a manual wheelchair as a primary means of mobility (over 40 hours per week) and the wheelchair has wheels with a 24 or 26 inch diameter. Exclusion criteria for the study were: women of childbearing age who are pregnant, having a history of fractures or dislocations in the arms including the shoulder, wrist and elbow, experience arm pain that interfered with propulsion and a wheelchair without quick release wheels.

Biomechanics Measurement

Kinetic data were collected using a SmartWheel® (Out-Front, Mesa, AZ), an instrumented hand rim that measures three dimensional forces and moments. The SmartWheel® was placed on the non-dominant side of the wheelchair and a dummy wheel of identical size and tread to maintain symmetry was placed on the dominant side. Kinetic data were collected at 240 Hz and filtered with an 8th order Butterworth low-pass filter, zero lag, and 20 Hz cutoff frequency. Data were down sampled to 120 Hz to align with kinematic data, which were collected at 120 Hz using a 20-camera VICON motion-capture system (Vicon Peak, Lake Forest, CA) surrounding a Figure-8 course. Reflective markers were placed on the center hub of the SmartWheel and on various boney landmarks on the head, trunk and arms to create a coordinate system with respect to the global reference frame.

Experimental Protocol

Participants used their personal wheelchairs to propel over level ground in a figure eight pattern (Figure 1). Each participant started at the center of the figure eight and was instructed to propel around a cone set at 9m from the center. Once back in the center they were told to come to a dead stop before propelling to the opposite cone. Participants propelled for one minute at a maximum self-selected speed while data were collected.

Data Analysis

Data was analyzed using Matlab (Mathworks Inc., Natwick, MA,USA). Strokes were identified using a custom Matlab program. The wheelchair stroke was separated into two phases, push and recovery using the forces and moments about the hub as indicators of when the hand was on and off of the pushrim. The first five strokes performed after every dead stop during the one minute trial were analyzed.

Start and release contact angles were calculated for each of the five strokes as well as time spent on and off of the pushrim. Contact angles were measured from the horizontal, with 90 degrees being at the top dead center of the wheel. Additionally, for each push phase peak mechanical effective force (MEF) and total force were calculated. Lastly, peak velocity was calculated during each propulsion

cycle. IBM SPSS version 21 was used for all statistical analysis. Pearson correlation was used to look at the relationship between terminal velocity and the other propulsion variables.
Figure 1. Figure eight course used in the study

RESULTS AND DISCUSSION

Twenty-five subjects, 17 males and 5 females, participated in this study. Their average age, weight, and duration of injury were 36 ± 10 years, 75.9 ± 20.9 kg and 12.9 ± 8.3 years, respectively. The levels of spinal cord injury ranged from C5 to L4.

For the first stroke, less time spent on the pushrim, greater total force, and a greater percentage of force directed tangentially to the pushrim (MEF) was significantly related to higher peak velocities (Table 1). However, for strokes two through four, more time spent on the pushrim and greater total force (strokes 2 and 4) was significantly related to higher peak velocities. For the second startup stroke, more time in the recovery phase was also significantly related to higher terminal velocity. For stroke two, persons who released the pushrim closer to top dead center achieved higher terminal velocities. Applying more force over a shorter period of time (e.g. impulse) and higher mechanical effective force was significantly related to velocity for the first push stroke only. Greater overall force and longer push times appeared to be important to achieving higher velocities for the remainder of startup (strokes 2-4) while total force seemed to be the only factor linked to higher velocity for stroke 5 (steady-state propulsion). Thus if a person needs to get up to speed as quickly as possible (e.g. to cross a busy intersection or to race across a basketball court), he or she should try to minimize the time spent on the push rim for the first stroke, but increase their time on the pushrim during the strokes that follow. Spending more time on the pushrim allows for more time to impart force which facilitates higher velocities. This strategy may also lessen the impact of loading on the upper limbs [1].

RUNNING-SPECIFIC PROSTHESIS MODELING EFFECTS ON JOINT MOMENTS DURING OVERGROUND RUNNING

email: bbaum@regis.edu

INTRODUCTION

Gait analyses for individuals using running-specific prostheses (RSPs) are often performed by placing tracking markers arbitrarily on the RSP to define joint and segment positions. RSP marker placement affects foot model definitions and can alter lower extremity joint kinetic estimations. Running studies investigating RSPs have estimated the prosthetic limb "ankle" joint to be at the same relative position as the intact limb's ankle joint [1] or the most acute point on the prosthesis curvature [1-3]. Using only one marker on the RSP may oversimplify keel motion and modeling RSPs as single rigid objects may not be appropriate since these devices can flex throughout their length. Using multiple markers to create multisegmented RSP models is challenging since definitive joint axes may not exist and anthropometric assumptions may induce critical errors. Considering an RSP as a unified deformable segment can accurately estimate the total power of below-knee prosthetic components [4], but this method is limited to stance phase calculations and cannot provide kinetic estimations within the RSP. The aim of this study was to investigate the effect of RSP marker placement on peak lower extremity joint moments during overground running. We hypothesized that marker placement on RSPs would not affect peak knee and hip joint moment estimations, but the RSP "ankle" definition would affect the peak prosthetic "ankle" moments.

METHODS

Eight male subjects with unilateral transtibial amputation volunteered to run around a 100m long track at 3.5m/s. Prior to running, reflective markers were placed on standard lower extremity anatomical positions for gait analysis. Eight markers were then fixed on the prosthetic keels (Figure 1), including the most proximal ("head") and distal ("toe") points of the keel along with the point of most acute curvature. Markers were placed laterally and medially at the base of the most proximal linear segment of each prosthesis. Three markers were evenly distributed on the lateral keels between the most acute point and the RSP toe. Prosthesis subsegments were considered rigid and defined via the keel markers. Body segment anthropometric and inertial properties were estimated with regression equations [5]. RSP inertial properties were measured [6] and RSP subsegment inertial properties were then estimated [7]. A 10-camera motion capture system (Vicon, Centennial, CO) captured marker positional data at 200Hz while 10 forceplates (Kistler, Amherst, NY) embedded in the track collected ground reaction forces at 1000Hz.

Four RSP foot models were defined by different marker combinations (Fig. 1). Model effects on joint moment outputs were compared for each subject. Joint moments were calculated using standard inverse dynamics equations with Visual3D software (C-Motion, Germantown, MD). The resultant "ankle," knee, and hip joint peak moments were compared across models. A one-way repeated measures ANOVA was used to test for peak moment differences between models with $\alpha=0.05$.

RESULTS

Sagittal plane joint moment profiles are presented in Fig. 2. Model differences were evident between Models 1, 2, and 3 for peak ankle plantarflexion moments ($P\leq0.006$). No differences were observed between models for stance phase peak knee and hip
Figure 1: Marker placements and model definitions for running-specific prostheses. Filled dots represent markers used to define each model.

extension moments. For peak swing phase knee flexion and hip extension moments, Models 1, 2, and 3 significantly differed from each other ($P \leq 0.027$). No significant differences existed between any of the models for any peak varus or valgus moments during stance or swing phase. Models 1 and 3 significantly differed for stance phase peak knee external rotation moments ($P=0.001$) and swing phase knee internal rotation moments ($P=0.009$). In both cases, these variables differed on average by only 0.003 Nm/kg.

DISCUSSION AND CONCLUSIONS

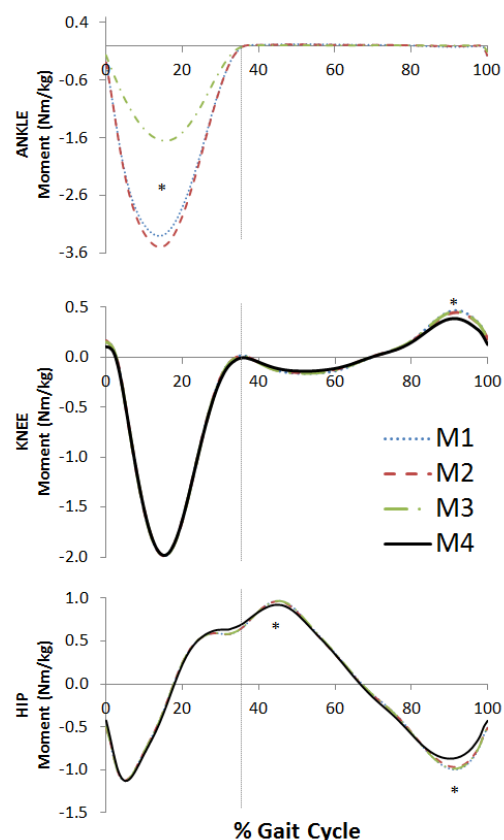
These data partially support and partially reject the hypothesis that the number of markers and their placement on the keel of RSPs do not significantly affect the residual limb joint moment estimations. With the exception of the peak knee external rotation moment, stance phase moments at the knee and hip joints were not affected by marker placement and modeling of the prosthetic foot. As expected, the RSP "ankle" joint plantarflexion moments during running stance were sensitive to the marker placement and definition of the ankle joint in the prosthetic limb. Marker placement on RSP keels has little effect on knee and hip joint moments, especially during stance phase. "Ankle"


Figure 2: Sagittal plane ankle, knee, and hip joint moment results for each model (M1-M4). Dorsiflexion and flexion moments are positive. * indicates significant model differences for the peak.

plantarflexion moments, however, can differ substantially based on marker placement. For consistency and flexibility in modeling, we recommend placing markers according to prosthesis architecture rather than intact limb architecture.

INTRODUCTION

Traditional ankle-foot orthoses (AFOs) often fail to restore normal ankle function because they lack the ability to actively modulate motion control during gait and cannot produce propulsion torque and power. A test bed of a portable, powered ankle-foot orthosis (PPAFO) has been developed to explore the issues and challenges related to creating mobile actively-powered orthotic devices [1].

In this study, we used the PPAFO test bed to further understand the functional needs and constraints of an active ankle assist device in a population of persons with gait impairment and Multiple Sclerosis (MS). The major disease process of MS is characterized by demyelination lesions of the white matter of the brain stem, cerebellum, and spinal cord [2] resulting in lower limb weakness leading to gait impairment [3]. Passive AFOs are often used clinically to assist with foot drop due to lower limb weakness in persons with MS, but have shown mixed results when analyzed in a research setting [4, 5]. An active AFO that can provide bidirectional powered assistance (dorsiflexor and plantarflexor torque) could be beneficial to persons with MS by helping to overcome their gait impairment.

METHODS

The study included 15 participants with a neurologist-confirmed diagnosis of MS and daily use of a prescribed custom passive AFO for gait assistance (11 Female/4 Males, age: 54.3 ± 5.3 years, Expanded Disability Status Score (EDSS): 5.2 ± 1.1). Approval for the study was granted by the Institutional Review Board and participants gave informed consent.

First, a clinical examination of disability was performed to establish EDSS score. Participants completed three standard 6-minute walk (6MW) tests that were performed over-ground in a hallway with four 90-degree turns. One 6MW was completed per footwear condition: *shoes*, *AFO*, and *PPAFO*. The PPAFO was worn on the affected limb (i.e. the same side as their AFO) with a normal walking shoe on the contralateral limb. Participants first wore the PPAFO for an adaptation period (>10 min) where their gait pattern was programmed into the PPAFO controller. The *shoes* condition 6MW was always completed first as a baseline. The remaining two conditions (*AFO* and *PPAFO*) were randomized between subjects with 10-minute periods of recovery between walks.

Multiple parameters of interest were collected during each 6MW. Spatiotemporal parameters of gait were measured as the participant passed over a 29 ft gait mat (GAITRite, Sparta, NJ) with each lap ($\geq$ 4 passes). Average values of *stride length*, *stride width*, and *stride velocity* for each participant were calculated. The total *6MW distance* traveled was recorded with a measuring wheel. Oxygen consumption (VO_2) was measured breath-by-breath using a commercially available portable metabolic unit (K4b2 Cosmed, Italy). VO_2 (mL/kg/min) was measured as 30-second averages for 1 minute before the 6MW (resting VO_2) and over the entire 6MW. Net steady-state VO_2 was computed from average VO_2 values of the final 3 minutes of the 6 MW and subtracting average resting VO_2. The *O_2 cost of walking* was then computed by dividing net steady-state VO_2 by walking speed during the 6MW [6].

Since multiple variables (*stride length*, *width*, *velocity, 6MW distance, O_2 cost*) were examined,

repeated-measures MANOVA tests* (SPSS Inc., Chicago, IL) were used to compare parameters across **footwear** conditions (shoes, AFO, and PPAFO) and between EDSS **groups** ($\alpha = 0.05$). Follow-up univariate ANOVAs were performed on significant variables. Post-hoc examination of data suggested distinct differences due severity of disability; therefore participants were binned into two groups based on EDSS (moderate: ≤ 5.5; severe: ≥ 6.0). *Accounting for *6MW distance* and *O_2 cost* data missing for one participant.

RESULTS AND DISCUSSION

The MANOVA tests found significant main and interaction effects for all variables ($p < 0.05$, Fig. 1). Significant main effects for **footwear** and **group** were found for *stride length*, *stride velocity*, and *6MW distance*. Only **group** was significantly different for *O_2 cost of walking*. Significant interactions of **group** × **footwear** were found for *stride length,* and *stride width*.

Follow-up univariate ANOVAs indicated that PPAFO use resulted in shorter *stride length*, slower *stride velocity*, and a shorter *6MW distance* than a custom AFO, especially in the moderate group compared to the severe group. The moderate group also widened their *stride width* in response to the PPAFO, whereas the severe group showed no change based on footwear. Also in agreement with previous research, regardless of footwear, the moderate group had longer and faster strides, and longer *6MW distances* than the severe group [7, 8]. The *O_2 cost of walking* was greater for the severe group than the moderate group, and footwear did not result in a significant change in the metabolic cost of walking.

CONCLUSIONS

These results indicate that within this study design, the participants did not overcome their gait impairment while using the PPAFO. Yet, the PPAFO did not negatively impact *O_2 cost of walking*. The hypothesized impact of the PPAFO providing gait assistance was not realized in this study and could be due to any number of factors, such as a need for more training and experience walking with the PPAFO, fatigue, or a need for improved device design.

Disability **group** differences were significant for all parameters except *stride width*.

A STRENGTHENING PROGRAM DESIGNED TO MINIMIZE KNEE LOADS IN WOMEN WITH KNEE OSTEOARTHRITIS: A PROOF-OF-PRINCIPLE STUDY

INTRODUCTION

Exercise prescription is the cornerstone to knee osteoarthritis (OA) management. Physical exercise reduces symptoms and comorbidity while improving function in people with knee OA [1,2]. While strengthening exercise is often prescribed, the type of strength training for knee OA is still unknown.

The knee adduction moment (KAM) represents the ratio of medial (versus lateral) loading in the knee [3] and predicts knee OA progression [4]. Studies suggest that strengthening exercise does not change the KAM in people with knee OA [5,6]. It is probable, however, that using the KAM as a guide to identify appropriate exercise a priori for people with knee OA could reduce load exposure with strengthening exercise while aiming to improve clinical outcomes.

The purpose of this study was to test whether a 12- week strengthening program designed to minimize the KAM could improve symptoms, mobility, and strength in women with symptomatic knee OA. The secondary objective was to evaluate KAM and muscle amplitudes during static squat and lunge exercises from the program as well as peak KAM from gait.

METHODS

Participant eligibility was based on clinical criteria for knee OA from the American College of Rheumatology (ACR) [7]. Participants completed a lower extremity strengthening program designed to minimize the KAM for people with knee OA. Participants were asked to attend a supervised exercise class 3 times per week for 12 weeks. The program focused on lower extremity strengthening and hip mobility using a variety of squats and lunges. Following a warm-up of large range body movements against gravity, weight-bearing isometric exercises emphasizing quadriceps strengthening were used. To balance the targeted focus on the quadriceps, exercises to engage the hamstrings and ankle plantarflexors were incorporated. Exercise modifications were available from the instructor.

All baseline and follow-up, measures reflected the most symptomatic knee. Self-reported symptoms and physical function were recorded using the Knee injury and Osteoarthritis Outcome Score (KOOS). Mobility was captured using the Six-Minute Walk Test (6MWT; distance covered in metres), the 30-second chair stand test (30-s CST; number of chair stands), and a stair ascent and descent task (timed in seconds). Lower extremity strength was captured during maximum voluntary isometric contractions (MVICs) of the knee extensors and knee flexors performed on a dynamometer (Biodex Medical Systems, Inc., Shirley, NY, USA) at 65 degrees of knee flexion. Values were normalized to body mass and expressed as Nm/kg.

The KAMs and muscle activations during static squats, static lunges, and gait were calculated from motion and force data. All kinematic, kinetic, and electromyography (EMG) data were time synchronized. Motion was captured using a 9-camera motion capture system collected at 100 Hz (Optotrak Certus, Northern Digital Inc., Waterloo, ON). Kinetic data were collected using a floor embedded force plate (OR6-7, AMTI, Watertown, MA) at 1000 Hz. KAM data were expressed relative to body mass (Nm/kg). EMG from the biceps femoris (BF), semitendinosus (S), rectus femoris (RF), vastus lateralis (VL), and the vastus medialis (VM) muscles were collected using a Desktop Telemyo DTS (Noraxon, Scottsdale, AZ). All EMG data had bias removed, were full-wave rectified, and linear enveloped using a 2nd order low-pass zero-lag Butterworth filter with a cutoff of 6 Hz. EMG data were normalized to %MVIC obtained from peak activation during the dynamometer MVICs.

For these motion analyses, squats included a legs-together squat (feet pointed forward and

shoulder-width apart) and a wide-legged squat (feet outside shoulder-width and externally rotated). For lunges, both the leading leg (front bent leg) and trailing leg (back straightened leg with the foot externally rotated on the floor) were examined. Squat and lunge trial data were extracted as a 3-second window of the static portion of the trial. An average of the two best trials were used. The peak KAM during each of the four best gait trials were extracted and ensemble averaged.

Paired t-tests evaluated group changes between baseline and follow-up of self-reported outcomes, mobility, and strength with an adjustment for multiple comparisons made with a Bonferroni correction (p<0.005). Five separate one-factor repeated measures analysis of variance (ANOVA) were conducted to evaluate differences in EMG amplitudes between five muscles and four exercises.

RESULTS AND DISCUSSION

Forty-five women with clinical knee OA (mean age 60.3 ± 6.5 years) enrolled. Six dropouts were recorded. One participant was lost to co-intervention. Therefore data from 38 women were analyzed at follow-up. KAM and EMG data were analyzed for 36 participants due to equipment issues. Mean attendance was 2.6 classes per week.

Improvements were demonstrated in all 5 subscales of the KOOS, ranging from 16.0-42.5% (p<0.001). Participants improved from 535.2 to 573.0 metres covered on the 6MWT (p<0.001). Participants also improved on the 30-s CST but this difference was not significant after adjusting for multiple comparisons (p>0.005). Stair ascent and descent time did not change. Participants improved strength in the knee extensors (1.8 to 1.9 Nm/kg; p=0.004). No significant change occurred between baseline and follow-up in knee flexor strength (p>0.005). KAMs during the four exercises tested were lower than that of normal gait (p<0.001). Muscle activations from the exercises are displayed in Figure 1. Amplitudes ranged from 7.3-31.0 %MVIC across all exercises. There was a main effect of the intervention on the semitendinosus and rectus femoris muscles with decreased activation following the intervention for both muscles [$F_{(1.0, 506.3)}$ = 4.30, p=0.046; $F_{(1.0, 471.0)}$ = 4.51, p=0.041 respectively]. For all three quadriceps muscles, the squat exercises generated higher amplitudes than the lunge exercises (p≤0.009).
Figure 1: Muscle activations normalized to %MVIC for the four static exercises. Significant main effects are denoted with an asterisk (*).

These data show promise for the design of a strengthening program minimizing medial knee loads in women with knee OA. Our finding that KAM was unchanged after the intervention is consistent with the literature [4]. Although we did not expect KAM to change, we showed that utilizing KAM to guide exercise prescription can result in an improvements in clinical outcomes. Second, we demonstrated that achieving muscle amplitudes lower than those cited in the literature to elicit strength gains can improve isometric strength in women with knee OA.

CONCLUSIONS

This study showed that a strengthening program designed to minimize the KAM resulted in improvements in self-reported outcomes, mobility, and strength while appropriately activating lower limb musculature in women with knee OA.

A PILOT PROGRAM TO DETERMINE INTRAMUSCULAR FAT PERCENTAGE IN THE QUADRICEPS AND HAMSTRINGS MUSCLES IN WOMEN WITH KNEE OSTEOARTHRITIS

INTRODUCTION

Thigh muscle weakness is a trademark feature in knee osteoarthritis (OA). People with knee OA have demonstrated greater declines in thigh lean muscle mass beyond that typically seen with healthy aging [1]. Given that declines in thigh lean mass alone cannot directly explain OA-related declines in strength, muscle composition must also be considered.

Magnetic resonance imaging (MRI) is a useful tool for visualizing muscle. In the elderly, MRI scans of the lower limb were used to calculate muscle quality, or strength per unit of lean muscle mass. With aging, a loss of lean muscle mass is often accompanied with a concomitant increase in fatty infiltrates in the muscle belly. This issue is exemplified with obese elderly individuals who, despite having greater absolute lean muscle mass, demonstrated poor performance on dynamometer strength tests and mobility on the six-minute walk test [2]. With knee OA, fat in the muscle may play a role in the loss of physical function.

Manual and semi-automated image segmentation methods exist for examining tissue composition from MRI scans. However, there are two major limitations: 1) it is time consuming; and 2) pixel intensity thresholding is often subjectively chosen by the user, with little standardization between participants. Therefore, the primary aim of this study was to create a pilot program for calculating intramuscular fat percentage in the quadriceps and hamstrings muscle groups from MRI scans of the thigh from the most symptomatic knee in older women with knee OA. The secondary purpose was to determine a protocol for objectively choosing a pixel intensity threshold from the MRI image to complete image segmentation.

METHODS

Images of the thigh were used from a previous study explained in detail elsewhere [3]. Briefly, all participants had radiographic and symptomatic knee OA as defined by the American College of Rheumatology [4]. A fixed-flexion, weight-bearing knee radiograph was acquired of each participant's most symptomatic knee [5]. Next, MRI scans were acquired of the thigh of the same knee using a GE Discovery MR750 3.0T scanner (WATER:AX PD IDEAL, axial plane, 512x512, 75 slices, 280 display of vie, 3mm slice thickness, slice gap 0, TE=31.512 ms, TR=2000 ms, echo train length = 6, bandwidth = 195.3 kHz, 1 NEX, scan time = 7.25 minutes). The most proximal slice was acquired at the 70% site (distance from the knee joint space to the lesser trochanter) and moved 180 mm distally. Post-processing Surface Coil Intensity Correction (SCIC) was used to improve image intensity homogeneity.

Gold Standard: All images were analyzed for intermuscular and intramuscular fat volumes using SliceOmatic 5.0 software by a single rater (MD) using traditional semi-automated segmentation techniques. Intermuscular fat refers to all fat within the fascial lining of the thigh exterior to the muscle and intramuscular fat is all fat present within a muscle belly. Percentage intramuscular and percentage intermuscular fat were calculated for each the quadriceps and hamstrings muscle groups from these volumes.

Pilot Program: The pilot program was created in Matlab (Mathworks, Inc., Natick, MA). Pilot data were compiled from 2 participants using the first 50 proximal slices from their scans (Participant 1 was 71 years and 98.4 kg; participant 2 was 66 years and 75.8 kg). For each slice, a histogram of the pixel intensities from the thigh region was created (Fig 1).

Next, a Lorentzian curve was fit to the muscle intensity spike (first peak of the histogram; Fig 1) and the fat intensity spike (second peak of the histogram; Fig 1). The peaks from each of these curves were extracted and thresholds between each

peak were normalized to 100% to create a new curve (0% as the peak of the muscle spike and 100% as the peak of the fat spike). At each percentage of this normalized curve, fat was separated from each muscle group using the corresponding threshold. A total percentage of fat from each muscle group was calculated creating 100 threshold cutoffs for each muscle group.
Figure 1: A histogram (right) created from the thigh slice (left).

Percentage fat in the muscle was calculated by a single rater (EB) and compared to the 'gold standard'. Pearson correlation coefficients and intraclass correlation coefficients were computed for each calculated percentage. Bland-Altman plots were created using the best cutoff for each the quadriceps and hamstrings muscle groups to analyze agreement.

RESULTS AND DISCUSSION

For the quadriceps, Pearson correlation coefficients showed good to excellent agreement across all cutoffs, ranging from 0.77-0.89. The peak ICC value was 0.86 and occurred at the 35% mark of the normalized curve. For the hamstrings, both Pearson correlation coefficients and intraclass correlation coefficients demonstrated low to moderate agreement: Pearson coefficients ranged from 0.31-0.85 and a peak ICC value of 0.85 occurring at 24% of the normalized curve.

A Bland-Altman plot for both muscle groups is displayed in Figure 2. Bland-Altman plots show that the pilot program has a mean difference comparable to output from the SliceOmatic program, with an average mean difference of 0.1% and 0.3% for the quadriceps and hamstrings, respectively. However, estimates for the quadriceps were less variable than hamstrings (±1.96 SD represents approximately 4% error between programs for the quadriceps and 10% for the hamstrings). These plots suggest that the ability of the pilot program to estimate percent
Figure 2: A Bland-Altman plot showing agreement between the pilot program and traditional MRI scan segmentation using SliceOmatic for percentage of intramuscular fat in the quadriceps (black circles) and hamstrings (red triangles) muscle groups. The dotted lines show the mean of the program differences for quadriceps (black) and hamstrings (red). Similarly, the solid lines show ±1.96 SD of the mean difference.

is better for the quadriceps muscle group compared to the hamstrings muscle group. Differences in estimates for each muscle group may be explained by the increased overall adiposity in the hamstrings group compared to the quadriceps group in these 2 participants. The increased proportion of adipose tissue in this region may make it harder to distinguish borders between muscle and fat, and therefore muscle group estimates are more variable between slices.

CONCLUSIONS

A pilot semi-automated program was created that objectively quantified percentage of fatty infiltration of muscle from axial MRI scans. This program chooses threshold cutoffs based on a pixel intensity histogram. The program showed good to excellent agreement with traditionally segmented data for the quadriceps muscle group, but not the hamstrings. Further piloting and testing is required.

INTRODUCTION

An ankle foot orthosis (AFO) is commonly prescribed to improve walking ability in individuals with lower limb neurological and/or muscular impairments. For example, the Intrepid Dynamic Exoskeletal Orthosis (IDEO), a custom carbon fiber passive-dynamic AFO, has been prescribed to over 600 service members to meet their need to perform a wide range of functional activities [1]. Many factors, to include mechanical properties such as stiffness and alignment angle have the potential to influence an individual's walking ability [2,3] and the demand placed on the muscles of the limb.

To aid in the prescription and design of AFOs, gait biomechanical analysis is used to investigate the effects of various AFO mechanical parameters and the associated patient costs and benefits. For example, AFO sagittal plane alignment can impact patient shock absorption capabilities and energetic cost during gait [4,5]. Associated with these adaptations are muscle activity responses, of which quantitative analyses are limited.. Therefore, the purpose of this study was to determine the effects AFO alignment had on muscle activity accompanying biomechanical changes.

METHODS

Nine male subjects with limited unilateral ankle range of motion and plantar flexor weakness due to limb injury participated in the study. Each subject was fit with a custom IDEO in which the neutral alignment was based on the recommendation and experience of the prosthetist/orthotist and the patient's available pain-free ankle range of motion. A 3° wedge placed between the posterior strut and foot plate (Fig. 1) was used to test three distinct alignment conditions: no wedge (Neutral), 3° dorsiflexion (DF), and a 3° plantarflexion (PF) angle.

Fig. 1: IDEO in dorsiflexed condition (left) and plantarflexed condition (right). A 3° wedge between the strut and footplate changed alignment angle.

Subjects walked at a standardized velocity over level ground while marker (120 Hz, Motion Analysis Corp.) and ground reaction force data (1200Hz, AMTI, Inc.) were recorded. Surface electromyography (EMG) was collected (1200 Hz, Motion Laboratory Systems, Inc.) from the soleus, medial gastrocnemius, tibilias anterior, vastus medialis (VM) and rectus femoris (RF). Sagittal plane knee angles and moments were calculated and time normalized to 100% of the gait cycle for five strides; peak values were averaged across the strides. EMG data were demeaned, high pass filtered (20 Hz), low pass filtered (400 Hz) and smoothed using a root mean square calculation with a 50 ms window. The processed signal was normalized to 100% of the gait cycle. The gait cycle was divided into six phases [6] and the integrated EMG value for each phase was averaged for five strides (MatLAB, The Mathworks, Inc).

Normality was assessed with a Shapiro-Wilk test (SPSS, IBM Corp., $p > 0.05$). A repeated measures

ANOVA (p<0.05) identified significant main effects. Least Significant Difference post-hoc comparisons determined significance between conditions.

RESULTS AND DISCUSSION

A 3° change in the AFO sagittal plane alignment significantly affected muscle activity as well as kinetics and kinematics during 10-30% of the gait cycle (early single leg support). EMG activity of the VM and RF in the DF alignment was 76.5% (p=0.046) and 55.8% (p=0.045) greater, respectively compared to the PF alignment (Fig. 2). Muscle activity differences for the other muscles did not reach significance between conditions.

Consistent with the increase in quadriceps muscle activity, the DF alignment increased the internal knee extensor moment (KEM) by 61.9% compared to the PF alignment (p<0.001). Compared to the Neutral alignment, KEM increased by 21.1% (p=0.002) and decreased by 25.2% (p<0.001) in the DF and PF alignments, respectively (Fig. 2). Maximum knee flexion angle increased by 7.9% (p=0.019) and 13.3% (p=0.010) in the DF alignment compared to the Neutral and PF alignments, respectively (Fig 2). Subjective patient experience was in agreement with the reduced KEM and knee flexion angles and associated decrease in quadriceps muscle activity in the PF alignment. Preference for alignment conditions showed 7/9 subjects preferring PF over DF and Neutral alignments.

In other patient populations, however, potential benefits resulting from a DF alignment have been highlighted [4]. For post-stroke patients, a DF alignment also increased the KEM and knee flexion angle but beneficially increased shock absorption capability [4], suggesting that specific alignments may serve patient groups differently.

A limitation of this study was the non-standardized neutral alignment position used to accommodate patient specific clinical needs. This limits the generalizability of a precise prescription metric for optimal alignment, but the results of this study indicate that erring on the side of a PF alignment may better serve this patient population.
Fig. 2: Mean (SD bars) maximum values at 10-30% of the gait cycle. Horizontal bars indicate significant differences between conditions.

In conclusion, these results highlight the importance of proper alignment in the design and prescription of AFOs. Device alignment angle can be modified to influence joint moments and the demand placed on proximal muscles.

CLINICAL MEASUREMENTS WITH A DEVICE TO ENABLE WEIGHTBEARING CT IN A HORIZONTAL GANTRY

Bradley C. Campbell[1], Stephen F. Conti, MD; Mark Carl Miller, PhD[1,2]
[1]The University of Pittsburgh, Pittsburgh, PA, USA
[2]Allegheny General Hospital, Pittsburgh, PA USA
Email: brc57@pitt.edu

INTRODUCTION

Weightbearing imaging can be the most appropriate method for diagnosis of many orthopaedic pathologies[1]. Certain deformities, like hallux valgus, are altered by the application of loading and the change in geometry can affect clinical decision-making[2]. Vertical devices for imaging have been developed but are costly and not readily available. Therefore, we designed and developed a computed tomographic imaging system compatible foot and ankle-loading device to be retrofitted to horizontal entry, donut gantry devices. The current goal is to demonstrate the method for device validation and illustrate the change caused by weight-bearing in hallux valgus.
Figure 1: Device for simulated weightbearing in a CT scan. The springs (grey struts) apply a pedal load

which in turn is limited by the darker grey bolts.

Figure 2: Device in use for a CT scan.

METHODS

The main function of the device is to apply a load to a patient's foot during a CT scan in order to simulate full weightbearing. The device should also allow for variation of the pressure distribution between the heel and forefoot.

The device is comprised of a platen with a spring-loaded pedal and a seat at an adjustable distance from the device.(Figures 1, 2) The pedal mechanism abuts polyester-based elastomer rings which function as springs positioned between two plates: one plate is fixed and one is capable of planar movement guided by slots. The deflection of the springs provides a measurable load on the foot and ankle. Calibration of the elastomeric springs is shown in Figure 3. The maximum load is chosen by adjusting two bolts that limit the spring deflection. The patient's foot pushes on the top, moveable plate until it compresses the springs and the top plate is stopped from further movement by the bolts.
Figure 3 Force-deflection curve for loading of the CT device.

The pedal and adjustable seat are constructed from 3/4-inch thick Delrin and fastened with nylon hardware. Both the pedal and seat are easily detached for portability.

The intent of the device is for use with foot imaging during computed tomography. As a first validation of the device, standing full weightbearing plane film radiographs will be compared with horizontally captured CT scans utilizing the device. Full weightbearing radiographs were taken in the anteroposterior plane at 15°. CT scans, loaded and unloaded, were taken employing the device with the GE Lightspeed scanner with a slice thickness of 1mm. The image was reconstructed and projected onto the anteroposterior plane.

RESULTS AND DISCUSSION

The hallux valgus angles, the angle between the first phalanx and metatarsal[3], were compared between a normal patient in a standing radiograph and weightbearing CT scan. The HV angle in the radiograph was 7° while the HV angle in the CT scan was 6°. Weightbearing and non-weightbearing CT scans were also compared in an HV patient. In the non-WB CT, the HV angle scan was 28.8° and, in the WB CT scan, the HV angle was 36.6°.

CONCLUSIONS

The initial tests show that the HV angles in the standing radiograph and in the CT image created while using the device in a normal patient are almost identical. The difference observed for the HV patient demonstrates that the device effects a change due to load application. Further data collection to obtain a sample size more generalizable to the population and to validate simulated full weightbearing equivalence to full weightbearing is underway.

INTRODUCTION

Individuals with paraplegia rank walking as a high priority to improve their quality of life [1]. The ability to perform and control the standing up and sitting down movements is important before walking. These movements can be facilitated with different technologies such as functional neuromuscular stimulation (FNS), powered lower extremity orthoses commonly known as exoskeletons, or hybrid neuroprostheses (HNP). FNS produces strong muscle contractions to coordinate limb movement but lacks stability. Exoskeletons can support an upright user and coordinates limb movements but requires large power consumption. A HNP coordinates muscle contractions generated by FNS with the support and stability of an exoskeleton to create the desired movement. Stand-to-sit (STS) requires eccentric contractions or lengthening of the active quadriceps muscles, which can be difficult to achieve with FNS. STS maneuvers performed with FNS alone result in high knee angular velocities, large impact forces when making initial contact with the chair, high accelerations, and an excessive amount of force placed on the upper extremities [2]. This study evaluates two different hydraulic mechanisms for a hybrid neuroprosthesis to control stand-to-sit maneuvers in participants with spinal cord injury who are using FNS.

METHODS

The first hydraulic approach being evaluated to control the STS maneuver after spinal cord injury is a hip-knee coupling mechanism that locks, unlocks, or couples the movement of the ipsilateral hip and knee joints. Hydraulic fluid is transferred between cylinders at the hip and knee joints such that hip flexion extends the hip cylinder rod and results in the knee cylinder rod retracting to cause knee flexion via a mechanical transmission. Fluid can also flow between the blind side of the knee cylinder and blind side of the hip cylinder during movement for synchronized joint extension. By coupling the ipsilateral hip and knee joints, subjects with paraplegia should be able to control the speed of their hip angle flexion using a walker and their upper extremities, thus controlling the rate of knee angle flexion.

The second approach is a knee damping mechanism that locks, unlocks, or damps the movement of the knee joint. A proportional valve in the hydraulic circuit directs the fluid flow between the rod and blind sides of the knee cylinder. The knee joint will be locked when the proportional valve is fully closed. However, a damping force will be created at the knee when the proportional valve is partially open. By damping the knee joint, subjects with paraplegia would have a slower knee angular velocity that better controls knee flexion during STS.

The hydraulic mechanisms are bilaterally affixed to the uprights of the exoskeleton as a part of the HNP device. Subjects with paraplegia perform the STS transition using one of the hydraulic mechanisms at a time. Motion capture data are recorded to determine kinematic variables such as joint angles, while a load instrumented walker (AMTI, Inc., Watertown, MA, USA) measures upper extremity

forces. A chair instrumented with a force plate on the seat (AMTI, Inc., Watertown, MA, USA) measures the impact forces and moments when making contact with the seating surface. Measures such as upper extremity effort, knee angular velocity, and impact force are being compared between the two hydraulic mechanisms and between the mechanisms and only using FNS.

RESULTS AND DISCUSSION

The mechanisms have undergone bench testing to ensure safety before clinical evaluation in able-bodied volunteers and subjects with paraplegia. A consistent 1:1 coupling ratio is created with the hip-knee coupling mechanism, where one degree of hip flexion results in one degree of knee flexion. 1:1 hip-knee angle relationships are similar to that seen in able-bodied STS maneuvers and show promise for controlling the STS for subjects with paraplegia [2]. The damping mechanism was used in a preliminary experiment to determine the feasibility in controlling the STS, and it resulted in an impact force at least half of that found in a previous study when only FNS was used to perform the STS. Both mechanisms are undergoing further testing during STS maneuvers for subjects with paraplegia from spinal cord injury to determine the effectiveness of the mechanisms in controlling the STS transition.

SPINAL CURVATURE AND SHOULDER KINEMATICS DURING WHEELCHAIR PROPULSION: EVALUATING THE IMPACT OF SPINAL CORD INJURY LEVEL

Beth A. Cloud, Kristin D. Zhao, Arin M. Ellingson, and Kai-Nan An

Mayo Clinic, Rochester, MN, USA
email: zhao.kristin@mayo.edu (KD Zhao)

INTRODUCTION
Upper limb pathology is common in individuals who use manual wheelchairs (MWC). Shoulder pain in particular has been reported at rates of up to 70%[1]. To better understand the mechanism of how pain and dysfunction develop, upper limb kinematics have been evaluated during MWC-based activities. However, little is understood about spinal posture and movement during MWC-based activities. Due to reported interactions between posture and shoulder movement [2], postural parameters may contribute to the development of pain and dysfunction and may be a means by which upper limb motion can be influenced.

The overall goal of our research is to quantify the relationship between spine and shoulder movement and determine the influence, if any, spinal curvature has on shoulder kinematics. The purpose of this work was to **(1)** quantify spinal curvature, trunk motion, and shoulder kinematics across the propulsion cycle in MWC users with spinal cord injury (SCI); and **(2)** evaluate differences between high and low SCI level groups.

METHODS
MWC users with SCI (n=13, 10 male: sex proportion comparable to the SCI population) were recruited and provided written informed consent to participate. All participants had been using a wheelchair as their primary mode of mobility for at least one year.

Spinal curvature was captured at 60 Hz with a fiber optic sensor system (ShapeTape, Measurand). The ShapeTape was placed in a flexible sleeve and placed over spinous processes from the first sacral (S1) to seventh cervical (C7) vertebra. The ShapeTape was anchored over S1 but was otherwise free to move with contour changes of the spine. Spinal curvature was defined as regions of lordosis (concave posteriorly) and kyphosis (concave anteriorly) of the thoracolumbar spine as previously described [3]. Spinal curvature was quantified as the angle created between the normal lines to the curve at the endpoints of each curvature region.

Shoulder and thorax motion were captured at 120 Hz with electromagnetic sensors (Liberty, Polhemus) placed on the thorax at the sternum, scapula at the acromion, and humerus via thermoplastic cuff. The thorax, scapula, and humerus segments were defined according to ISB standards [4]. Motion was quantified with Euler sequences and included thoracic (relative to global, ZX'Y"), humerothoracic (YX'Y"), scapulothoracic (YX'Z"), and glenohumeral (ZX'Y").

Participants propelled in their personal MWC on a custom set of stationary rollers at a self-selected speed. Minimum and maximum values were identified from an averaged propulsion cycle (based on two trials) for all outcome variables (lordosis, kyphosis, thoracic flexion/extension, 3 humero-thoracic rotations, 3 scapulothoracic rotations, 3 glenohumeral rotations). Range of motion across the propulsion cycle was determined from the minimum and maximum values.

Minimum, maximum, and range of motion values were compared between individuals with high levels of SCI (T9 and above) and individuals with low SCI (T10 and below) using a Wilcoxon Rank Sum test (α= 0.05).

RESULTS AND DISCUSSION
In the high injury group (n=7, 7 male), SCI level ranged from C6/7 to T5, mean age was 36.9 (SD: 9.8) years and years using MWC was 13.8 (12.0). In the low injury group (n=6, 3 male), SCI level ranged from T10 to L1, mean age was 48.8 (5.3) years and years using MWC was 16.6 (8.8).

The low injury group had a significantly higher maximum lordosis (26.8±15.8° v. 8.1±9.2°) and

range of lordosis (12.4±9.1° v. 4.5±4.6°) as well as minimum and maximum kyphosis (42.4±5.4° v. 53.2±6.3° & 50.0±4.6° v. 62.6±6.3°) than the high injury group (Figure 1). There are trends for the low injury group to have less flexion at maximum trunk angle (-1.6±7.2° v. -9.6±10.5°) and a larger minimum lordosis (14.4±13.0° v. 3.6±5.4°).

Differences in shoulder kinematic parameters did not reach significance. However, the low injury group trended toward having a larger range of glenohumeral axial rotation (20.8±4.2° v. 15.9±4.1°) and humerothoracic plane of elevation (87.3±23.2° v. 68.0±7.0°), as well as a larger maximal humerothoracic internal rotation (78.5±8.0° v. 63.6±15.8°, Figure 1).

CONCLUSIONS
Based on our results, individuals with low levels of SCI have greater maximum and range of thoracolumbar lordosis and lower minimum and maximum kyphosis than individuals with high levels of SCI. This occurs with possible differences in thoracic sagittal plane motion, humerothoracic motion and range of glenohumeral axial rotation. Therefore, spinal posture may be influencing the overall motion of the humerus relative to the thorax with various strategies occurring at the glenohumeral and scapulothoracic joints to obtain this effect. Additionally, thoracic motion alone may not be sufficient to describe trunk movement - measures of lordosis and kyphosis are necessary. Though differences were seen between groups with different injury levels, the differences could also be attributed to differences in sex or age, as these characteristics differed between the groups. This work represents an intermediate in understanding the relationship between spine and shoulder motion during propulsion. Additional data collections and analyses are ongoing.

IDENTIFICATION OF FINGER FORCES OVER RANGES OF MOTIONS: A COMPARISON BETWEEN HEALTHY AND REDUCED HAND FUNCTIONALITY PARTICIPANTS

Introduction

Diagnosing the amount of hand function lost due to injury, arthritis, or nerve damage is currently task-based and subjective to the clinician [1, 2]. Recently, work has modeled the differences in kinematic finger space between hands with and without reduced functionality due to arthritis [3]. This model includes the full range of motions for each finger; however, the forces that each finger can produce at each posture are not included.

Both motion and forces associated with each finger posture are necessary to generate a comprehensive hand model for clinical use. Such a model will result in a tool for clinicians to easily compare changes in hand function and finger strength pre- and post- rehabilitation, treatment or surgical intervention.

Thus, to achieve this comprehensive model, the forces that can be applied over various finger postures must first be quantified and compared. The goal of this work was to map forces associated with the index finger at different positions and orientations within the kinematic fingertip workspace of participants with and without reduced hand functionality.

Methods

Twelve participants (average age 26.5 years, SD 5.99 years) without any reported injury or arthritis, termed "Healthy", and fifteen participants (average age 73.5, SD 4.81 years) with doctor diagnosed arthritis, termed "Arthritic", were included in this study.

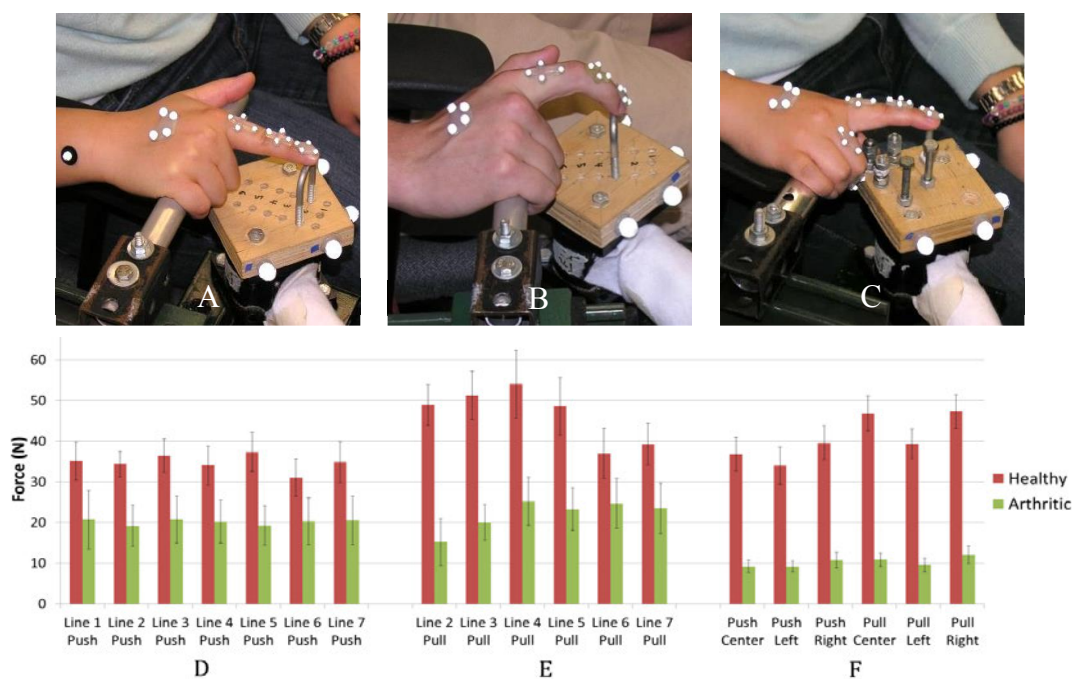
The maximum forces of the index finger were measured in two tests. In-plane forces (no adduction


Figure 1: Healthy and Arthritic data. Experimental setup and force data for in-plane push (A, D),
in plane pull (B, E) and out-of-plane (C, F) motions with standard error of the mean. For in-plane motions,
the U-shaped device was moved in toward the participant resulting in 7 different positions (line 1-7).

or abduction of the finger) measured differences by using a "U-shaped" metal bracket placed in seven positions along a line, each a half inch apart. This set-up was developed to measure the maximum forces related to changes of finger flexion. Each participant was asked to press down on the bracket with their maximum load (Figure 1A) then pull the bracket with maximum load for each position (Figure 1B). During data collection participants were asked to continually grip a cylindrical handle to isolate the finger forces and to maintain a consistent orientation of the wrist.

Out-of-plane maximum finger forces were measured at each of six positions to determine force differences related to abduction/adduction. Three of the positions were at maximum extension and the other three positions were at moderate flexion of the interphalangeal joints (Figure 1C).

Results/Discussion

Using a two-way ANOVA, several differences were identified in the finger forces. Overall, the forces of Arthritic participants were less than those of Healthy participants ($p < 0.001$). Neither the Healthy or Arthritic groups showed differences in the forces perpendicular to the palm (push) with varying amounts of finger flexion or extension, $p = 0.967$ (Figure 1D). While there was no statistical significance, there was a visible trend showing maximum applicable force for the pull motions at position 4 (Figure 1D). Both push and pull forces varied with respect to abduction/adduction. In both Healthy and Arthritic groups, maximum forces were lower with abduction (left) and increased with adduction (right). While not statistically significant ($p = 0.077$), this is should be investigated with a larger sample size (Figure 1F).

Models overlaying these force data with the kinematic space were also successfully developed. Figure 2 shows the kinematic fingertip workspace for a single participant with the measured force directions and magnitudes represented by the vectors projected onto the sagittal plane of finger flexion. The color scale represents the sum of possible ways to reach that position with the finger

tip, with red indicating the most possibilities. The forces pointing towards the top left represent the push motions and the forces pointing towards the bottom left represent the pull motions.

Subject specific modeling that includes both force generation and kinematics will allow for clinical comparisons pre-/post interventions. With the combination of motions and forces, these models will be robust tools for clinical assessment of the hand and fingers.
Figure 2: Sagittal plane view of kinematic finger space for the index finger of a healthy participant with overlaid force vectors. The displacements of the workspace and force vector origins were measured from the center of the wrist with the vertical axis normal to the palm.

COMPARISON OF TIBIA STRAIN BETWEEN SIMULATED EXOSKELETON-ASSISTED GAIT AND NORMAL GAIT

[1] Ying Fang, [2] Nathan Smith, [1] Joshua E. Johnson, [1] Karen L. Troy

INTRODUCTION

Spinal cord injury (SCI) is associated with rapid bone loss, which can be attributed to the reduction in mechanical strains that are generated through gait and other activities. Recently, the development of exoskeletons such as the Ekso (Ekso Bionics, Richmond, CA), ReWalk (Marlborough, MA) and others has made walking possible among individuals with complete paralysis. Dissimilar to natural walking, where motion is driven by muscle force, the joint torque needed to initiate exoskeleton-assisted gait generally comes from an external actuator that produces a strap force on the mid-thigh and shank. Weight-bearing gait training using exoskeletons may potentially improve bone health through bone adaptation, depending on the strain the bone undergoes during gait. On the other hand, exoskeleton users with SCI are at higher risk of fracture due to their weaker bones. Bone strain occurring during exoskeleton-assisted gait is a critical factor for evaluating both the potential therapeutic benefit, and also patient safety during this task. Here, we compared tibial strain magnitude and distribution between simulated exoskeleton-assisted gait and normal gait at heel strike (HS), midstance, and toe off (TO).

METHODS

Musculoskeletal model

A generic 12-segment, 23-degree of freedom, 54 muscle musculoskeletal model (Gait2354 Model), originally developed by Delp et al. [1] was used and scaled to a subject with height of 1.8 m and mass of 72.6 kg using OpenSim (3.2, SimTK, Standford, CA, USA).

Previously reported experimental gait data of the subject, which were initially collected by John et al. [2], were applied to the scaled model. Inverse kinematics and dynamics were performed to identify net joint moment and joint reaction forces. Next, individual muscle forces were calculated via the "Computed Muscle Control (CMC)" tool, and joint contact forces were calculated.

Muscle insertion location and muscle force vectors at HS, midstance, and TO were calculated based on muscle properties provided by OpenSim. All vectors were transformed to the tibia coordinate system.

Finite element model

A finite element (FE) model of a right tibia was generated from the Living Human Digital Library (LHDL) database. Bone was assigned inhomogeneous linear-elastic material properties based on apparent density [3]. As described below, normal and exoskeleton-assisted gait were simulated, and distal nodes of the tibia were constrained for both conditions (Figure 1).
Figure 1: Boundary conditions applied to the right tibia FE models. Left: normal condition with muscle forces and joint contact forces; Right: exoskeleton-assisted condition with strap force and joint reaction forces.

For normal gait, knee contact force vectors and muscle force vectors derived from the musculoskeletal model were applied to the FE model. Knee joint contact forces were applied such that 63% of the total force acted on the medial tibial compartment and 37% on the lateral [4]. Muscle

forces were applied as surface traction with appropriate vector directions. Included muscles were long head of biceps femoris (BFL), short head of biceps femoris (BFS), gracilis, sartorius, rectus femoris, vastus, soleus, tibialis anterior (TA), and tibialis posterior.

For exoskeleton-assisted gait, it was assumed that muscles exerted zero force and the net joint moments resulting from the inverse dynamics calculations were generated via the strap at the tibia. The strap force was modeled as pressure normal to the tibia and located at 22% of the tibia length. The strap area and location were estimated using photographs and measurements of an Ekso suit. The strap force magnitude was set such that the net external moment generated at the knee was the same for exoskeleton-assisted gait and normal gait. Knee reaction force was assumed to be the net joint reaction force at the knee calculated via inverse dynamics.

Von Mises stress and equivalent strain was calculated within the entire tibia and in a 1.5 cm transverse region of interest located 3.5 cm proximal to the distal end. Variables were considered at HS, midstance, and TO.

RESULTS AND DISCUSSION

Peak Von Mises stress within the entire tibia in exoskeleton-assisted gait was 18, 71, 2.5 MPa, which was smaller than 139, 96, 176 MPa in normal gait at HS, midstance, and TO, respectively. The stress distribution was different between conditions; high stress regions were identified medially during normal gait, but posteriorlaterally during exoskeleton-assisted gait. A qualitative comparison of stress distributions at midstance is shown in Figure 2.
Figure 2: Posteriorlateral view of a right tibia FE model illustrating Von Mises stress (MPa) at midstance for normal and exoskeleton-assisted condition.
Figure 3: Mean Von Mises stress and mean equivalent strain of the region of interest at HS, midstance, and TO for normal and exoskeleton-assisted gait.

The summed magnitude of forces applied to both models were highest at midstance. It is interesting to note that tibia strain and stress were the lowest for normal gait, and highest for exoskeleton-assisted gait at this time point (Figure 3). This suggests muscles may play an important role in redistributing and decreasing bone stress. Once the muscles are dysfunctional, the protective mechanism disappears.

To validate the simulation, we compared normal gait ankle reaction forces from FE model to those calculated from OpenSim. The error was 58%, 19%, 35% at HS, midstance, and TO, respectively. The larger errors at HS and TO may be attributed to the neglect of segment inertia and acceleration, as we used quasi-static methods in current study. In addition, the net joint moment was assumed to be the same at the knee for both conditions. The FE and gait models were generic and derived from able-bodied subjects. Despite these limitations, the data suggest that tibial stresses and strains during exoskeleton gait are dissimilar to normal gait. Our long term goal is to improve these models with CT-based FE models from individuals with SCI and real exoskeleton-assisted walking data as input.

CONCLUSIONS

The strain distribution and magnitude in the tibia were different for exoskeleton-assisted gait and normal gait. Future study is warranted to determine the degree to which these calculations, which were performed based on able-bodied gait data, are corroborated with experimental data in individuals with SCI.

PREDICTING INERTIAL PROPERTIES FOR INDIVIDUALS WITH TRANSTIBIAL AMPUTATION

INTRODUCTION

Compared to the intact limb, the mass of the prosthetic side of a transtibial amputee (TTA) is consistently 30-40% less, the center of mass location is 25-35% closer to the knee joint, and the moment of inertia is 50-60% less about a transverse axis through the knee joint [1]. Inverse dynamics requires knowledge of the inertial properties of each segment in the model. Although previous research [2] has suggested that changing the inertial properties of a segment by as much as 5% has little to no effect on joint moment magnitudes, Smith et al. [1] recently reported that the reduced inertia of a below-knee prosthesis significantly influences the joint moment magnitudes of swing.

The only method currently available to researchers for estimating prosthesis inertia involves directly measuring the inertial properties of the prosthesis itself. This method measures inertial properties of the prosthesis via oscillation and reaction board techniques [1]. This process is time consuming; it takes as much as 30 minutes to complete these measurements. The purpose of this study was to develop predictions of prosthesis inertial properties based on direct measures obtained from the prosthetic limb. A secondary purpose was to determine the effects of these predictions on joint moment estimates during walking.

METHODS

This study was divided into two phases. The first phase focused on developing an inertial model to predict prosthetic side inertial properties (n=11 TTAs). The second phase assessed the validity of the developed inertial model using an inverse dynamics analysis of walking (n=5; different TTAs). IRB approval and written informed consent were obtained prior to data collections.

In phase one, total body mass and height were measured while participants wore their prostheses. Prosthesis inertia properties were then measured directly. Prosthesis mass (with and without shoe), center of mass location (COM), and moment of inertia about a medial-lateral axis through the prosthesis center of mass were determined using a standard scale, reaction board, and oscillation techniques, respectively [1]. The combined inertial properties of the residual limb and prosthesis were then distributed into a prosthetic shank and foot based on proportions of mass between these two segments for a dismantled prosthesis. The mass, COM, and radius of gyration (ROG) were determined for the shank (including the residual limb) and foot segments of the prosthetic leg. Inertial property estimates of the intact shank and foot were estimated using de Leva [3].

In phase two, participants walked at 1.5 m·s^{-1} along a 10 m walkway with embedded force plates. Inertial properties of their prostheses were measured as previously described above. Ground reaction forces (2000 Hz) and motion data (100 Hz) were collected. Using a three segment inverse dynamics model, joint moments at the hip, knee, and ankle were computed with three different inertial models: (1) INTACT − prosthetic leg inertia properties were assumed to match those predicted for the intact leg estimated using de Leva, (2) DIRECT - our direct measures using an oscillation and reaction board technique, and (3) PREDICTED - using the mean percentages from the DIRECT model to estimate the mass of the shank (as a percentage of body mass), COM location (as a percentage of segment length), and ROG about the COM (as a percentage of segment length). ROG was subsequently used to predict the moment of inertia using $I = m \cdot k^2$. A single factor MANOVA was preformed to identify significant differences between the three inertial

models and between peak joint moments during swing (α=.05).

RESULTS

Inertial properties of the prosthetic shank and foot obtained from DIRECT measures and used in the PREDICTED model are shown in Table 1. COM and ROG of the foot were based on data from de Leva as a starting point for our predictive model given that the inertial properties of the foot are minimal in comparison to those of the shank. Inertial properties of the prosthetic shank were significantly different between the INTACT and DIRECT models and between the INTACT and PREDICTED models (Table 2). No statistically significant differences in inertial properties were found between the DIRECT and PREDICTED models of the shank. Mass of the foot was significantly greater using INTACT compared with DIRECT and PREDICTED models.

Table 1. Estimates of inertial properties for prosthetic shank and foot for PREDICTED model based on DIRECT measures (n = 11).

	Mass (%body mass)	COM (% segment length)	ROG (% segment length)
Shank	3.3	20.9	17.2
Foot	1.3	[a]44.15m 40.14f	27.9m 24.5f

Note: [a] Estimates based on de Leva were gender specific (M: male, f: female) ; prosthesis inertia values were not.

Moment magnitudes were not significantly different at the ankle regardless of inertia model. Peak joint moments at the knee and hip during swing were significantly smaller for the DIRECT and PREDICTED models compared with the INTACT model (Table 2). There were no significant differences in moment magnitudes between DIRECT and PREDICTED models (Figure 1).

DISCUSSION AND CONCLUSIONS

In phase one, we developed predictions for inertial properties of the prosthetic limb based on direct measures from 11 TTAs (see Table 1). In phase two, inverse dynamics analyses illustrated that our predictions did not result in significantly different joint moments at the knee and hip compared with direct measures. Thus, our predictions for segment mass, COM location, and ROG should be used by other researchers where direct measurements of prosthesis inertia are unavailable.

INTRODUCTION

In the design and control of assistive devices for human locomotion, rigid connections between devices and their users are commonly assumed and often do not exist. Yet, the mechanics of these interfaces can constrain device assistance [e.g., 1].

For example, amputees wear prosthetic sockets, which capture bone, muscle and soft tissue of the residual (i.e., amputated) limb and transmit linear and angular loads to the outside of limb. Using radiographic techniques, displacement of the residual tibia and femur inside the sockets of transtibial and transfemoral amputees have been identified decades ago, respectively [2, 3]. Despite these known phenomena and advances in radiography [e.g., 4], large knowledge gaps exist.

Displacement per unit load (i.e., stiffness) in functionally-relevant weight-bearing conditions, stiffness about both linear and angular axes, and the influence of socket technologies are unknown. The purpose of this study was to develop and test a technique to fill these gaps regarding the socket-limb interface of transfemoral amputees. These outcomes are needed to provide quantitative rationale for prescription and engineering of prostheses as well as insights into the underlying mechanisms contributing to abnormal gait mechanics, chronic pain and joint disorders of amputees [for review, see 5].

METHODS

A transfemoral amputee (female, 75.6 kg, 1.64 m, 49 yrs. age and 35 yrs. post-amputation, osteosarcoma etiology) provided informed consent. Residual limb length was 69% of the sound limb. The subject was positioned in front of a digital radiographic system (Phillips, Inc.), including a vertical digital detector and suspended X-ray tube carrier—capable of imaging a 43 cm by 36 cm window encompassing the residual limb and socket (Fig. 1). The subject wore a custom prosthetic assembly including a flat rigid foot, pylon and 6-axis load cell (AMTI, Inc.) (Fig. 1). Two test sockets (ischial containment and subischial) were fabricated based on a cast of the subject's limb by a licensed prosthetist. These sockets are common clinical options and vary in trim-line height (Fig. 2).

For each socket, a total of eight static radiographic images were captured. Images during unloaded, loaded with body weight in a neutral standing posture, and loaded with medial and lateral as well as anterior and posterior foot placements were taken from corresponding frontal and sagittal-plane views. For loaded conditions, the subject received visual feedback of a corresponding load cell signal (i.e., axial force for loaded in a neutral position, frontal-plane moment for medial/lateral foot placements, and sagittal-plane moment for anterior/posterior placements). She was asked to maintain a maximum constant isometric load for a total of eight seconds.

Multiple pairs of landmarks from the digitized radiographs (Fig. 1) were used to determine changes in axial and angular positions of the socket relative to the residual femur. Stiffness was computed as the change in average force or moment divided by changes in angle or linear position for given unloaded/loaded conditions. Stiffness was computed for repeated pairs of digitized landmarks.

RESULTS AND DISCUSSION

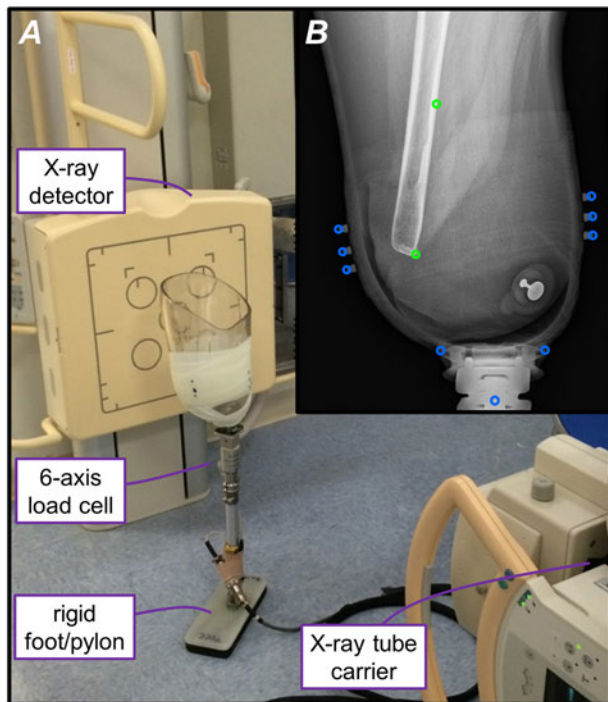
Socket design, loading plane, and foot placement (i.e., loading direction) were all shown to influence the interface stiffness (Fig. 2). Across conditions, the ischial containment socket was found to increase stiffness over the subischial socket. A ~3 fold


Figure 1: Experimental setup, subject not shown (A); and example radiograph with digitized bone and prostheses landmarks (B).

increase in the axial stiffness, as well as the rotational stiffness in the lateral and posterior foot placement conditions, were observed. Greater than 10 fold increases of rotational stiffness were found in the other conditions. Thus, these trends support the use of ischial containment to increase interface stiffness.

The ischial containment socket has the highest trim-lines on the lateral and posterior aspects of the socket. These geometries correspond with the largest rotational stiffness and largest increases in stiffness relative to the subischial socket occurring with the foot loaded in medial (2100 Nm/rad) and anterior (2000 Nm/rad) positions. In these respective conditions, external abduction and extension moments result in the highest, most proximal, locations of the socket engaging the limb. These data highlight the importance of trim-line geometry and socket height in influencing interface stiffness.

In the subischial socket, the highest trim-lines were also on the lateral and posterior aspects of the socket. Yet, opposite trends were observed with the largest rotational stiffness occurring in lateral and posterior foot positions (Fig. 2). These data suggest that when a bony prominence such as the ischium cannot be engaged, interface stiffness becomes more dependent on the underlying tissue makeup of the limb, as well as contraction level of residual limb muscle associated with weight-bearing.

CONCLUSIONS

Even in transfemoral sockets with ischial containment, the interface should not be considered rigid. As a reference, the sagittal-plane stiffness of conventional prosthetic feet (~1300 Nm/rad, [6]) are similar to the largest interface stiffness, and higher than the smallest stiffness measured. Thus, irrespective of socket type, the interface likely influences the dynamics of locomotion. These characterizations are increasingly relevant, as biomimetic control approaches of emerging robotic devices seek to emulate able-bodied joint mechanics, and do not account for the mechanics of the interface.

ASSISTIVE ANKLE POWER PROMPTS MUSCULAR COMPENSATIONS DURING GAIT

Emily S. Gardinier, Wyatt Felt, Jeffrey Wensman, C. David Remy and Deanna H. Gates

University of Michigan, Ann Arbor, MI, USA
email: egardin@umich.edu, web: http://rehab-biomech-lab.kines.umich.edu/

INTRODUCTION

Muscular compensations by both intact and residual limbs have been described for individuals walking with passive elastic ankle prostheses [1, 2]. These devices can only supply about half the power normally provided by the plantarflexors in the intact human ankle. A commercially-available, powered ankle-foot prosthesis that supplies plantarflexor power with each step has shown promise in improving walking economy and normalizing ankle kinematics and kinetics [3, 4]. However, the neuromuscular adaptations that drive these changes are not yet understood. Characterizing these adaptations will help clarify the mechanisms by which powered devices improve walking economy and may inform future device design. Therefore, the purpose of this study was to characterize the muscular compensations exhibited in response to walking with various amounts of prosthetic ankle power.

METHODS

Two (2) males with trans-tibial amputation were fitted with the powered ankle prosthesis (BiOM T2 Ankle System, BiOM, Inc., Bedford, MA) by a manufacturer-certified prosthestist. Subjects were experienced prosthesis-users (44 and 15 yrs post-amputation; ages 59, 24 yrs old; BMI: 28.9, 26.9 kg/m^2, respectively). Testing consisted of treadmill walking at five ankle power settings in random order: prosthetist-chosen, 0%, 25%, 75% and 100% power (0P, 25P, 75P, 100P). Metabolic cost of transport was measured using a portable gas analyzer. Surface electromyography (EMG) was recorded from gluteus medius (GM), vastus lateralis (VL), rectus femoris (RF), medial/lateral hamstring (MH/LH), medial/lateral gastrocnemius (MG/LG) and tibialis anterior (TA) bilaterally where possible. Treadmill belt speed was set based on leg length

(1.16, 1.23 m/s). The first power setting condition was preceded by a 10-minute accommodation period and subsequent accommodation periods were five minutes each. After accommodation, a 3-minute sample of expired air and a 30-second sample of EMG were acquired. Cost of transport was energy expenditure normalized to bodyweight and distance traveled. After visual inspection of raw EMG signals, linear envelopes were generated by full-wave rectifying and applying a low-pass filter (6 Hz). The resultant envelopes were normalized to peak EMG from the prosthetist-chosen settings. Muscle EMG magnitude variables included peak amplitude (pkEMG) and the integral of muscle activity per gait cycle (iEMG). Muscle co-contraction was assessed for 2 muscle pairs: VL-LH and MG-TA. Co-contraction indices equaled the agonist iEMG divided by antagonist iEMG. For analysis, the gait cycle was divided into discrete phases as outlined by Seyedali et al. [5] (for VL-LH: early mid-stance and late swing, for MG-TA: early stance, late stance and early swing).

RESULTS AND DISCUSSION

Metabolic cost of transport tended to decrease with increasing levels of ankle power (means in J/Nm; 0P = 0.396; 25P = 0.427; 75P = 0.375; 100P = 3.57). For the intact limb, the maximum prosthetic ankle power (100P) was associated with large, consistent decreases in EMGpk and iEMG in muscles of the intact limb, particularly the hamstrings, quadriceps and gluteus medius muscles (Table 1). Increased prosthetic ankle power was associated with inconsistent changes in muscle co-contraction indices (Figure 1). In general, the muscles of the intact limb were less active when additional ankle power was supplied (Figure 2). The largest decreases in muscle activity were seen for the intact limb, which suggests that much of the energetic gains provided by the powered ankle

prosthesis are accomplished by reducing demand on intact limb muscles crossing the hip and knee.
Figure 1. With increased power, co-contraction for residual limb VL-LH increased in early mid-stance and decreased in late swing (means ± SE). Residual EMG unavailable for S02 at 0P and 100P.

For the residual limb, modest-sized decreases in pkEMG and iEMG occurred for hamstrings (Table 1). Changes in other residual limb muscles were small and inconsistent in direction. Persons using passive elastic ankle-foot prostheses walk with greater residual limb hamstring and hip flexor activity [1, 2]. The addition of ankle power in the present study appeared to decrease compensatory hamstring activity. For the residual limb, VL-LH co-contraction was greater than for the intact limb and tended to increase in early stance with increasing ankle power (Figure 1). Co-contraction on the prosthetic side may indicate a limb stiffening strategy adopted to increase stability early in stance.

Figure 2. Peak EMG decreased for intact limb muscles of both subjects with increasing power (means ± SE).

CONCLUSIONS

Data from the two individuals tested in the present study suggest that reductions in energy cost of walking with a powered ankle prosthesis may stem from decreased muscular effort of the intact limb. Additionally, residual limb hamstring muscle compensations appear to decrease when using a powered ankle. Further work with more subjects will clarify the mechanisms by which ankle power can reduce energy expenditure during gait.

METABOLIC COST CHANGES WITH THE AMOUNT OF PROSTHETIC ANKLE POWER PROVIDED

Audra Davidson, Wyatt Felt, Jeffrey Wensman, Emily S. Gardinier, C. David Remy, Deanna H. Gates

The University of Michigan, Ann Arbor, MI, USA
email: gatesd@umich.edu, web: http://rehab-biomech-lab.kines.umich.edu/

INTRODUCTION

The ankle plantarflexors produce roughly 80% of the mechanical power required for normal gait [1], yet current passive elastic prostheses only produce an eighth of this power [2]. Likely due to this deficit, people with transtibial amputation have a 10-30% greater metabolic cost for walking than non-amputees [3]. Active ankle prostheses that are able to accommodate for the functionally absent plantarflexors have improved metabolic cost during walking [4]. However, it is unclear whether directly matching the power of the intact limb would alleviate this plantarflexor deficit, as higher power outputs might be needed to counteract sub-optimal power delivery of the prosthesis. Therefore, the purpose of this study is to determine how incremental adjustments in prosthetic ankle power affect the metabolic cost of walking.

METHODS

Two males with transtibial amputation (ages 59, 24 yrs; BMI 28.9, 26.9 kg/m^2) were fitted with the BiOM T2 powered ankle prosthesis (BiOM, Inc. Bedford, MA) by a certified prosthetist. Subjects walked on a treadmill while the power supplied to the prosthesis was varied. Metabolic costs were measured using a portable gas analyzer (K4b^2, Cosmed, Rome, Italy). Treadmill speed was determined by subject leg length and remained consistent across conditions.

Each participant was given 10 minutes to accommodate to treadmill walking prior to testing. Subjects were tested at five ankle power setting conditions in random order: prosthetist-chosen (PC), 0%, 25%, 50%, 75% and 100% power. Participants were given five minutes to acclimate to each power setting, after which a 3-minute sample of expired air was acquired during steady-state oxygen consumption.

In order to determine if changes in metabolic costs were a result of a true metabolic change rather than normal variability, the minimal detectable change (MDC) value for metabolic cost of transport (COT) was determined. This was acquired by collecting steady-state oxygen consumption data on nine healthy subjects (age 23 ± 3 years, 56% male) during treadmill walking. Oxygen consumption was collected for three bouts of walking interrupted by three bouts of seated rest to obtain within-session variability of COT. Testing was performed on two separate days to determine between-session variability. Intraclass correlation statistics were performed on COT within a session and on the average COT between days. The MDC was calculated using the intraclass correlation coefficient [5] and compared to the changes exhibited in the subjects with amputation.

RESULTS AND DISCUSSION

The within-session MDC value determined for cost of transport was 0.016 J/N.m (Table 1). The between-day ICC was 0.878, and the MDC was 0.0543 J/Nm.

Table 1. Reliability of Cost of Transport (COT) Values for COT are given as mean (standard deviation) across nine healthy subjects for each of three bouts of treadmill walking over two days.

	COT (J/Nm)			ICC	MDC
	Bout 1	**Bout 2**	**Bout 3**		
Day 1	0.350 (0.077)	0.347 (0.063)	0.331 (0.065)	0.991	0.017
Day 2	0.346 (0.046)	0.350 (0.047)	0.349 (0.050)	0.987	0.015

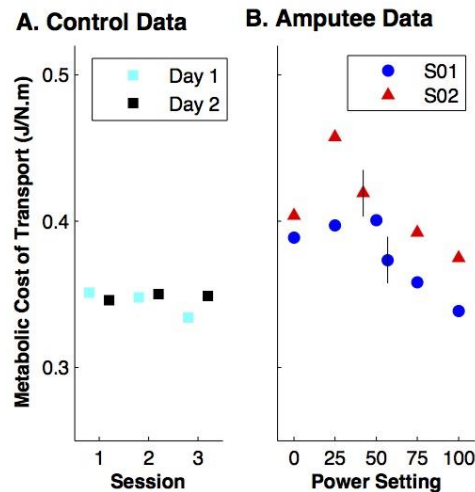
For subjects with amputation, the COT tended to decrease as ankle power increased (Fig. 1). There were no measurable differences in COT in comparison to 0% power for S01, as this was measured on a separate day (Table 2). COT was measurably diminished at 75% and 100% power for S01, whereas no detectable differences in COT were exhibited in the lower power levels or between 100% and higher power levels. The COT difference between PC (57%) power and 0% power was -0.013 J/N.m, falling below the between-day MDC value.


Figure 1: (A) Average COT for healthy subjects over two days over three sessions of walking and (B) COT during three minutes of steady state walking for two subjects with a solid line representing ± MDC (0.016 J/Nm) on PC power.

Subject S02 demonstrated measurable changes in COT between all power settings except for 75% to 0% power. COT was higher for PC (42%) power when compared to 0% power, and for 25% compared to 0% power (0.027 J/N.m and 0.0650 J/N.m respectively). All other pairings demonstrated measureable decreases in COT (Table 2).

For both subjects, increasing the power supplied by the prosthetic beyond PC power yielded decreases in cost of transport greater than the MDC (Table 1).

Prosthetist-selected power settings were chosen in an effort to match the ankle work done by the intact limb. These data suggest that higher ankle work of the prosthesis may further reduce the metabolic cost of walking. It is possible that the power output of the prosthesis is not only compensating for the loss of plantarflexor power, but also reducing muscular compensations at the hip flexors of the residual limb [6]. Additionally, accommodating for any inefficiencies in power delivery of the device may lead to the necessity of power increases greater than that of the intact ankle. This inefficiency would lead to the dissipation of energy needed to aid powered ground push-off, thereby requiring increased power supply.

CONCLUSIONS

Increased power delivered by the ankle prosthesis was sufficient to reduce COT by measurable amounts. Future directions for this work include an examination of these parameters with a larger sample size. Characterizing the effects of the timing of power delivery on metabolic costs as well as changes in muscular activity will further clarify the mechanisms of these metabolic cost savings.

Developing a Robotic Elbow Joint Controlled by EMG Stimulus

Louis Christensen, Julia Jenks, Cody Johnson, and Craig M. Goehler

Department of Mechanical Engineering, Valparaiso University, Valparaiso, IN, USA
email: craig.goehler@valpo.edu

INTRODUCTION

Prosthetics allow users to regain mobility in limbs that were lost due to trauma or birth defect. Due to the variety of patient needs and capabilities, prosthetics can be categorized as aesthetic, functional, or robotic. Aesthetic prosthetics recreate the limb with little to no functionality while functional prosthetics allow users to regain basic movements, such as grasping objects, by implementing simple systems like pulleys and hooks. Robotic prosthetics provide finer control with a broader range of motion in tasks but can be difficult to use. Although the field of prosthetics has made vast improvements in terms of replicating natural movement, people still stray away from these advancements because they are difficult to use, expensive, or do not have aesthetic appeal.

The goal of this design study was to independently create an elbow joint prototype with an emphasis on simplicity and affordability. The resulting design uses a battery powered worm drive and an EMG control system. This paper describes the process for the joint design along with completed electronic schematics and part drawings for the completed design.

METHODS

To begin the joint design, literary review was conducted to determine a baseline for this design. One design used pneumatics to simulate muscle contractions; however, this design was bulky, inaccurate, and overdesigned for lifting in a typical prosthesis [1]. This led the design towards a more mechatronic approach.

Useful designs were found for a high thrust helical motor joint design [2] and an elbow rehabilitation device [3]. The helical motor design was a lighter, more compact design that provided the torque necessary for an elbow joint, but the cost for a helical motor was too great to be practical for this study. The elbow rehabilitation design contained an alternative to the helical motor that was similarly compact and significantly reduced the cost involved for the prosthetic. This ultimately led to a final design which implements a worm gear drive to provide thrust for the joint movement.

For the control system, EMG signal processing was found to be the simplest solution that allowed the user the most natural control for the joint. EMG processing circuits have already been developed to convert the muscle stimulus into a usable signal for control [4]. These designs were reconfigured to reduce cost, which resulted in a signal processing system that can be calibrated for the user in real time.

RESULTS AND DISCUSSION

Figure 1 displays the SolidWorks model of the elbow joint. The elbow was built around the motor, gear, and worm. These design parameters keep the product relatively small and allow for future modular construction. The forearm allows for any number of end effectors to be attached, such as a hook, a false hand, or even a robotic alternative. The prosthetic can be attached by fitting a tube into the brackets on the elbow, above the motor. This tube could be clamped onto a static surface, or onto a socket for use on a person. Plastic covers, shown in orange, enclose the worm drive to ensure the user does not contact the high-speed motor. Finally, each part is designed to be simple to machine. This reduces the build time and the cost.
Figure 1: 3D Rendering of the Elbow Joint

The simplicity in the design stemmed from some aspects of human kinematics being ignored. The normal range of motion for a human elbow is 145 degrees, but this design can move up to 180 degrees. This can be accounted for in the control program where a limit of motion is imposed from feedback with a potentiometer. Another aspect that is overlooked is the carrying angle of the elbow. Normally, this is between 5 and 15 degrees, but in this elbow it is 0. This simplified the design because it allowed the device to be symmetric about a middle plane.

The electrical system was similarly designed with a focus on simplicity. The EMG processing circuit, shown in Figure 2, provides a DC analog voltage that can relate to muscle flexion. By rectifying and then envelope filtering the output of the EMG amplifier, the system utilizes a simple method to create a signal usable by a microcontroller.
Figure 2: EMG Processing Circuit

The control system then interprets EMG signal from the triceps and biceps to move a set point that the motor will follow. To provide an inexpensive method of elbow feedback, a potentiometer is connected to the elbow joint. By combining position feedback and EMG inputs, the user can move the mechanical elbow up and down by tensing and relaxing muscles in their arm that would have originally been used to move the anatomical elbow.

CONCLUSIONS

The scope of this project can extend to multiple fields. Outside of prostheses, the joint could be implemented as part of a robotic arm for high torque operations. The EMG processing could eventually stem into the fields of virtual reality for finer control by users. For prosthetics, creation of end effectors would be the next step, as a wide variety of end effectors adds functionality to the elbow. These can range from a simple hook to a fully controllable hand. Experiments could also be performed to create calibration curves in order to design a more universal design rather than the current custom calibrated system. Finally, the design could be adapted for mass production by improving the construction techniques for the elbow.

MECHANICAL ENERGY DIFFERENCES IN ARM-CONSTRAINED HUMAN ROLLING

Mahdi Hassan, Linh Q. Vu and Nils A. Hakansson

Wichita State University, Wichita, KS, USA
email: nils.hakansson@wichita.edu, web: http://www.wichita.edu/thisis/home/?u=bme

INTRODUCTION

Rolling is a complicated movement that requires the coordinated motion of the entire body. The ability to roll, most commonly executed as turning in bed, is a milestone in human development [1] and is one of the most fundamental activities of daily living. However, the underlying mechanisms, i.e., the neuromuscular coordination and muscular strength requirements, necessary to roll, remain unknown.

Healthy individuals use a wide range of movement patterns when they roll from the supine to side-lying position. The motion of the upper extremities is a primary source of the variability in the movement patterns [2]. A reduction in rolling variability could facilitate a biomechanical analysis and improve our understanding of rolling. Therefore, the goal of the study was to determine whether constraining the arms would alter biomechanical measures associated with rolling. To this end, the objective of this study was to determine whether crossing the arms over the chest changed the energy demands of rolling from the supine to side-lying position.

METHODS

All subjects gave informed consent to participate in the study that was approved by the Wichita State University Human Subjects Review Board. Experimental kinematic data were collected from ten college-aged subjects (male to female ratio 6:4) with no limitations to their ability to roll.

An 8-camera video motion capture system (Motion Analysis Corp., Santa Rosa, CA) recorded (50 Hz) the positions of 32 retro-reflective markers that were used to define the foot, shank, thigh, pelvis, trunk, upper and lower arms, and head segments for each subject for both a standing static pose and the rolling motion.
Figure 1: Musculoskeletal model of rolling for the arms crossed (upper figure) and arms uncrossed conditions.

For the rolling trials, subjects laid on a firm surface in the supine position and rolled to their right into a side-lying position. Subjects performed two types of rolling movements: i) arms crossed over the chest and ii) arms uncrossed and free to move naturally. Five trials were collected for each type of rolling and for each subject, resulting in 100 trials total.

Marker position data were imported into OpenSim (v3.2) [3] to calculate the centers of mass (COM), linear ($!$), and angular velocities ($"$) of the body segments. The parameters of a full body musculoskeletal model consisting of 20 segments and 37 degrees-of-freedom were adjusted to best fit the experimentally measured subject mass and markers positions (Figure 1). The resultant kinematics were low-pass filtered at 4Hz and then analyzed to determine the COM and linear and angular velocities of each body segment.

The potential and kinetic energy of the body segments were calculated to determine the

mechanical energy. The potential (E_p) and kinetic (E_k) energy were calculated as:

$$Ep = mgh$$

$$Ek = \frac{1}{2}mv^2 + \frac{1}{2}I\omega^2$$

where m is the mass of body segment, g is the gravitational constant, h is the height of the segment COM, v is the velocity of the segment COM, I is the mass moment of inertia of the segments, and ι is the angular velocity of the segment. Total energy (E_{tot}) was calculated by summing all positive increments in E_p and E_k [4].

A two-factor repeated measures ANOVA (# = 0.05) was performed to identify differences in E_{tot} between the two rolling conditions. The two factors were rolling condition at 2 levels and trials at 5 levels.

RESULTS AND DISCUSSION

The mechanical energy averaged across subjects for rolling with the arms crossed and uncrossed was 60.1 ± 12.1J and 72.6 ± 13.8J, respectively. For nine of the ten subjects, the mechanical energy averaged across the five trials was lower for rolling with the arms crossed than with the arms uncrossed (Figure 2). The statistical analysis indicated that there was a significant difference ($p = 0.007$) between the E_{tot} measures for rolling with the arms crossed and uncrossed. There were no identified differences in E_{tot} associated with the trials or the interaction between trials and rolling conditions. The potential energy component comprised the majority of E_{tot} for arms crossed (90%) and uncrossed (87%) rolling.

Based on the results, crossing the arms over the chest changed the energy demands of rolling from the supine to side-lying position. The result that rolling with the arms crossed is associated with less mechanical energy than rolling with the arms uncrossed was not unexpected. Potential energy increases were the primary contributor to E_{tot} for both rolling conditions. Motion of the arms increases both potential and kinetic energy as they are raised and maneuvered to either assist or not

interfere with rolling. However, the motion of the lower extremities was not examined in this study and could have contributed to the observed differences in the E_{tot} measures.
Figure 2: Mean mechanical energy for rolling with the arms crossed and uncrossed. Error bars represent ± 1 standard deviation.

CONCLUSIONS

Rolling is a complicated motor task for which there exist many movement patterns. This study is one of the first to quantify biomechanical measures of human rolling and the first to examine the effects of constraining the arms on generated mechanical energy. The result that crossing the arms over the chest changed the energy demands of rolling could have implications for future biomechanical studies and clinical settings.

VARIABILITY IN TORSO KINEMATICS IN ARM-CONSTRAINED HUMAN ROLLING

Linh Q. Vu, Mahdi Hassan and Nils A. Hakansson

Wichita State University, Wichita, KS, USA
email: nils.hakansson@wichita.edu, web: http://www.wichita.edu/thisis/home/?u=bme

INTRODUCTION

Decubitus ulcers (DU), also known as bedsores, are injuries to the skin and underlying tissues. Estimates indicate that 1 to 3 million people develop a DU in the United States each year and at a cost of over one billion dollars per year [1].

Human rolling, most commonly executed as turning in bed, is one of the most fundamental activities of daily living. Rolling in bed serves to improve comfort, circulation, sleep quality, and reduce the risk of DU. Rolling is a complicated movement that requires the coordinated motion of the entire body [2, 3]. Previous research on human rolling has been dependent on observing the rolling motion with constraints to decrease due to the variable nature human rolling [3]. Based on the observations of the aforementioned studies [2, 3], we hypothesized that applying constraints to the rolling motion, for example arms crossed over the chest, would not change the fundamental rolling movement patterns of the torso. Therefore, the objective of this study was to determine whether constraining the upper extremities would alter shoulder and pelvis kinematics when rolling from the supine to side-lying position.

METHODS

All subjects gave informed consent to participate in the study that was approved by the Wichita State University Human Subjects Review Board. Experimental kinematic data were collected from twelve college-aged subjects with no limitations to their ability to roll.

An 8-camera video motion capture system (Motion Analysis Corp., Santa Rosa, CA) recorded (50 Hz) the positions of retro-reflective markers adhered to the left and right acromion of the shoulders and anterior superior iliac spine (ASIS) of the torso of each subject as they rolled from the supine to side-lying position. Subjects performed two types of rolling movements: i) arms crossed over the chest and ii) arms uncrossed and free to move naturally. All subjects rolled to their right. Five trials were collected for each type of rolling and for each subject, resulting in 120 trials total.

Shoulder and pelvis angles were defined as the angle formed by the vector from the right to left shoulder markers and by the vector from right to left pelvis markers with respect to the horizontal plane, respectively. The angular velocities of the shoulders and pelvis were determined through numerical differentiation (central difference method) of the angle data.

Initiation and cessation of the rolling motion was based on the shoulder and pelvis angular velocities. Initiation of the roll was defined as the earlier occurrence of the last peak before the shoulder or pelvis angular velocity increased monotonically towards its peak velocity. The cessation of the motion was defined by the latter of the shoulder or pelvis angular velocities to reach zero after achieving its peak velocity. All trials were normalized as a percentage of the rolling motion (supine to side-lying) based on the identified initiation and cessation times.

One-factor repeated-measures ANOVA tests were performed to examine the effect of crossing the arms had on the segment that initiated and ended the roll (shoulder or pelvis), the peak shoulder and pelvis angular velocities, the percentage of roll at which the peak velocities occurred, and the duration of the roll. For each test, the independent variable was rolling condition at two levels (arms crossed and uncrossed).

RESULTS AND DISCUSSION

Rolling with arms crossed did not significantly affect the segment that initiated the roll (p = 0.667), the segment that concluded the roll (p = 0.331), or the timing of peak shoulder and pelvis angular velocities. The rolling condition effects did significantly affect the peak shoulder (p = 0.001) and pelvis (p = 0.004) angular velocities, and the duration of the roll (p = 0.044). In the arms crossed condition, subjects had increased roll completion times by a mean difference of .167 seconds. Across the 60 trials for each rolling condition, the percentage of rolls in which the pelvis or the shoulder started and ended the roll were similar (Table 1).

Table 2: Percent of trials in which the shoulders and pelvis initiated or terminated the motion for the two rolling conditions for the 120 trials.

Sequence order	Rolling Restraint	Segment	Occurrence (%)
Start of roll	Arms crossed	Shoulder	75%
		Pelvis	23.3%
		Both	1.7%
	Arms uncrossed	Shoulder	70%
		Pelvis	26.70%
		Both	3.30%
End of roll	Arms crossed	Shoulder	45%
		Pelvis	40%
		Both	15%
	Arms uncrossed	Shoulder	43.30%
		Pelvis	48.30%
		Both	8.40%

The focus of this study was on torso kinematics because the torso largely controls how the rolling motion is executed. An important finding was that there was no significant change in whether the shoulder or pelvis initiated the roll or whether shoulder or pelvis concluded the roll, when rolling with the arms crossed and uncrossed. These findings are consistent with those presented by Richter et al. [2] who reported that the most common rolling movement initiation involved shoulder movement first. Another important finding was that peak shoulder and pelvis angular velocities

varied as a result of different rolling conditions. However, the time in the roll at which these peaks were observed did not vary. beacause the occurrence of peak velocity for both the shoulder and peak velocities across conditions was not significantly different, it was inferred that the integrity of the roll was kept and the timing of the rolling motion was similar. The third important finding was that people execute the rolling motion slower when crossing the arms, as compared to arms uncrossed. The increased pelvis and shoulder velocity in arms uncrossed may be due to a momentum increase from the usage of the arms. The extension of the arms could have generated more torque by shifting the center of mass away from the axis of rotation during rolling.

CONCLUSION

Rolling is a fundamental and complicated task. By having subjects roll with their arms crossed, it increased the speed of the roll, yet produced no identifiable difference in their fundamental rolling movement. This finding is very useful because the folding of arms will remove any momentum that can be generated and still keep the integrity of the roll. Studies made using the arms crossed constraint may be more inclusive as persons with physical or neurological limitations may not have use of their arms to assist in the roll. The study provides more information regarding the biomechanics of human rolling that may be useful in the creation of solutions for those persons who cannot roll independently.

Human-Exoskeleton Hybrid Model to Produce Stable Gait through Inter-limb Coordination

Duanyi Wei, Ioannis Poulakakis, Jill S. Higginson

University of Delaware, Newark, DE, USA
email: higginso@udel.edu

INTRODUCTION

Robotic gait training has been studied and tested in research labs and clinical settings [1]–[3], and it has shown mixed success in improving the functional ambulation in post-stroke individuals [4,5]. The current state-of-the-art in rehabilitation robots is to encourage subjects' participation in tracking desired trajectories obtained from healthy subjects, by providing feedback about the performance error [5]. As human locomotion is composed by movements of both sides, it clearly involves well-organized inter-limb coordination. But current rehabilitation robots fail to include this cooperative mechanism of locomotion. To address the dynamic interaction between human and exoskeleton, a model is needed to capture key aspects of human locomotion and provide the infrastructure for evaluating different coordination strategies.

Current musculoskeletal models are insufficient to address gait stability over time [6], thus are of limited value when it comes to predicting the interaction between human and exoskeleton. Low-dimensional human-inspired biped models [7]–[9], on the other hand, have proven capable of producing salient human-like gait features and providing tractable measures to ensure gait stability and robustness. The objective of this study is to construct a low-dimensional model to represent the asymmetric, hybrid human-exoskeleton locomotion. We then use this model to propose a control strategy for the robotic limb that accounts for the contralateral human limb dynamics, and test the hypothesis that the proposed control framework can achieve stable gait.

METHODS

Model: To characterize the dynamical asymmetry between the side wearing exoskeleton and the unaffected
Figure 1: Model of human (red) and robotic (black) limbs.

limb, a hybrid, low-dimension, sagittal-plane model of Fig. 1 is proposed. We adopt the prismatic-leg model in [7] as the representation for "human limb". Such models have proven successful in capturing key gait features [7,8]. The exoskeleton is represented as a two-link structure. The torso mass is condensed to a point mass at the hip. The human side is actuated by the hip and the robotic actuators are located at contralateral hip and knee joints. To avoid confounding internal interactions, it is assumed that the robot drives the affected human side and behaves as human limb during stance (Fig. 2).

Dynamics: Due to the lateral asymmetry of the model, the cyclicity of gait over a complete stride composed by a left and right step is monitored. Each step consists of swing phase (SW), impact, double stance (DS) and liftoff. Rather than presenting detailed derivations, we highlight the modifications with respect to impact dynamics. The derivation of impact dynamics follows the impact hypotheses and procedure as in [9], except that we enforce the post-impact stance leg to be fixed to the ground in order for the system to enter double stance, which permits the influence of external forces at the stance leg end during impact. See [7]-[9] for more details.

Limb Coordination: Coordinated locomotion is achieved by enforcing output functions that prescribe the motion of the robot relative to the human, to zero. Specifically during robot swing phase, we want to coordinate hip and knee angles according to motions of the human side. We construct output functions that embed the constraints of controlled variables: $h(q) := [q_3, q_4]^T - h_d(\theta)$ where h_d specifies the desired evolution of hip and knee angles, which can be parametrized by polynomials of self-selected order. By choosing θ to be the angle of the human limb (q_2), the movements of the robot hip and knee are coordinated with the states of the human side upon zeroing the outputs. To fulfill the objective, we adopted input-output linearization to compute the torque necessary to maintain the output at zero [9].

Gait Stability: The notion of stability in this work assures that nominal walking motion can be recovered when the system is perturbed. A Poincaré map [10] is defined as a mapping from the starting states to the states when the model returns to the same instance
Figure 2: Snapshots of the model over one full gait cycle

after a full cycle. Our model is initialized at the instant of human limb push-off. A periodic gait *exists* if the corresponding initial states can be repeated after the return to the human push-off in the next step. The stability of this gait is further guaranteed by ensuring the eigenvalues of the linearized Poincaré map have magnitude less than 1 [10].
Figure 3: Phase portrait of the system if hip angle (q_3) is perturbed by 2º(10%)away from its initial value. The blue trajectory indicates nominal walking motion.
Figure 4: GRF profile of stable gait over three consecutive steps. The step starts after human limb push-off. The vertical lines separate swing and double support phases. All forces are normalized by body weight.

RESULTS AND DISCUSSION
Fig. 3 shows the stability of the obtained gait cycle (magnitude of eigenvalues<1) after perturbation. The hybrid model eventually returns to its nominal walking

motion (blue) over time. Despite apparent asymmetry in the limbs, the introduction of coordinated exoskeleton motion with respect to human makes the system tolerant to external disturbances. This is due to the fact that exoskeleton can respond to changes in the human gait. In addition, despite the internal complexity of the actual system, this generic hybrid model demonstrates close resemblance in gait kinematics and GRF profile (Fig. 3) to human.

CONCLUSIONS AND OUTLOOK
This work proposed a control framework of enforcing inter-limb coordination. The results have shown the success of such coordination strategy in stabilizing the gait cycle in the presence of moderate disturbances. So far the controller only engages during the swing phase. Future work will identify a control strategy to coordinate the two sides during stance phase. Currently, we are also seeking means to integrate the controller with gait data from human locomotion and implement the control framework to human walking with the assistance of an exoskeleton device. This has potential applications in promoting limb coordination and gait stability for post-stroke subjects.

WRIST COMPRESSIVE FORCES AFFECT THE MEDIAN NERVE RESPONSE TO WHEELCHAIR PROPULSION AND OTHER MARKERS FOR CARPAL TUNNEL SYNDROME IN PEOPLE WITH PARAPLEGIA

INTRODUCTION

Wheelchair users with paraplegia rely on their arms to perform most activities of daily living, and thus carry a high risk of developing repetitive strain injuries. One common injury in this population is carpal tunnel syndrome (CTS) [1], a compressive neuropathy in the wrist. One CTS risk factor is the repetitive application of external forces to the wrist, especially during movement [1]. Indeed, propulsive handrim kinetics and wrist kinematics are linked to CTS [2,3]; however, joint forces have not been examined in this context. The purpose of this paper was to investigate how propulsive wrist joint forces relate to markers for CTS in a sample of wheelchair users with paraplegia. Higher compressive wrist forces were hypothesized to correlate with subjective symptoms, physical examination findings, and ultrasound markers for CTS.

METHODS

Wheelchair users with non-progressive paraplegia were recruited through research registries and flyers. They were included if they were 18-65 years old; were injured for at least a year and after age 15; spoke English; had no unhealed upper limb fracture or dislocation, upper limb dysthetic pain, or cardiopulmonary problems; had a quick-release axle; and were not pregnant. Participants provided informed consent prior to the study, which was approved by the appropriate Ethical Committees.

Participants completed demographic and CTS symptom questionnaires [4], were weighed on a scale, and underwent a physical examination of the median nerve (PEMN). This scale is comprised of five clinical tests for median nerve health: Phalen's test, Tinel's sign, thenar muscle atrophy and weakness, and pin-prick along median nerve distribution. Each is scored 0 (no sign), 1 (equivocal), or 2 (sign present). Bilateral scores are summed for a maximum of 20. Quantitative ultrasound (QUS) measurements of the median nerve were taken before and after the propulsion activity; this technique has high reliability when obtaining serial images [5]. A cross-sectional image of the nerve was obtained at the inlet of the carpal tunnel – the level of the pisiform bone – in the non-dominant hand (Fig. 1). A higher cross-sectional area (CSA) indicates a larger nerve proximal to the carpal tunnel, and thus possible entrapment. A MATLAB algorithm utilizes boundary trace to determine CSA of the nerve on the image, while blinding the user to subject and image time point.

Figure 1. *Cross-sectional ultrasound image of the median nerve (MN) at the pisiform bone (arrows).*

Participants propelled down a 15-meter runway over tile and carpet at self-selected and targeted (1.5 meters/second) speeds, then around a figure-8 course at maximum speed (five trials per condition). A 20-camera VICON system captured the runway volume. Participants were equipped with reflective

markers on the acromion, trunk, medial and lateral epicondyles, ulnar and radial styloids, and 3rd metacarpal-phalangeal joint; 8 reference markers were added to the upper- and lower-arm. A SmartWheel, which detects handrim kinetics, was attached to the chair. The SmartWheel and markers were placed on the non-dominant side. Kinematic data were collected at 60 Hz and filtered using a 4th order zero-phase low-pass Butterworth filter with 7 Hz cutoff. Kinetic data were collected at 240 Hz and filtered using an 8th order zero-phase low-pass Butterworth filter with a 20 Hz cutoff, then down-sampled to 60 Hz to match kinematics. Trials were split into start-up (first 3 strokes) and steady-state (all other strokes). All steady-state strokes per trial, and all trials per condition were averaged. Propulsion during the targeted and self-selected conditions was analyzed for the present study (no figure-8 trials). An inverse dynamics model was created to transform handrim kinetics from the SmartWheel to the wrist local coordinate system, which was defined as recommended by the International Society of Biomechanics [6]. Compressive forces are those acting along the long axis of the hand, directed proximally.

Significance was set to α=.05. Kinetics from the four conditions were correlated (p<.05) and thus averaged to minimize Type 1 error. Body-weight can influence propulsive forces; thus, compressive forces were weight-normalized [2]. Three multiple linear-regression models were built with age, weight, and normalized compressive force as predictors. Outcomes included PEMN and CTS symptom questionnaire scores, and post-propulsion CSA. Baseline CSA was a covariate when post-propulsion CSA was an outcome, which tests how changes in CSA relate to age, weight, and force.

RESULTS AND DISCUSSION

Twenty-three wheelchair users with paraplegia were recruited yet data from 18 were analyzed; 3 did not meet inclusion criteria and 2 had kinematic data that could not be analyzed. Participants were 35.3±10.4 years old with 13.3±8.9 years since injury and weighed 75.5±20.8 kilograms. There were 13 males and 5 females; 14 were white, 3 were black, and 1 was multiracial.

Subjects who propelled with higher compressive forces reported more CTS symptoms (R^2=.370, p<.05) and PEMN findings (R^2=.272, p<.05). Greater post-propulsion increases in median nerve CSA were also observed in those who propelled with higher compressive forces (R^2=.195, p<.10). The wheelchair handrim rests along the palm, approximate to the carpal tunnel. Prolonged exposure to force at this location may cause entrapment of the nerve or cumulative trauma; both of which may cause nerve damage that manifests as pain, weakness, or other symptoms. Although the relationship only trended toward significance (p<.10), a medium/large effect was observed. A larger sample size would likely yield significance.

CONCLUSIONS

CTS symptoms and physical examination findings were greater in those who propelled with higher compressive wrist forces. Using higher forces also amplified the median nerve response to propulsion. It is possible reducing the amount of upper limb force during this activity can delay or prevent the onset of CTS in this population.

WEEKLY CHANGES IN VASTUS LATERALIS VOLUME AFTER ACL INJURY

[1]Kevin Yoh, and [1]Benjamin W. Infantolino
[1]Penn State - Berks, Reading, PA, USA
email: bwi100@psu.edu

INTRODUCTION

Anterior cruciate ligament (ACL) injuries are one of the most prevalent injuries in athletics, affecting females at a much greater rate than males. The musculature around the knee is affected in several ways, but the most negative effects occur in the vastii muscle group, and more specifically the vastus lateralis [1]. Muscle volume is indicative of the power a muscle can produce and therefore knowing muscle volume at different points in the process (post injury, reconstruction surgery, and rehabilitation to full participation) can provide insight into how the muscle   is effected by injury, surgery, and rehabilitation.   Additionally, thigh circumference is used clinically to track muscle volume changes and there is no consensus if this is accurate. Therefore, the purpose of this study was to quantify vastus lateralis volume post ACL injury and throughout the reconstruction surgery and rehabilitation process and to compare volume changes to changes in thigh circumference.

METHODS

The participant was a 20 year old female Division III soccer athlete whose mass was 59kg, and height was 1.63m. Informed consent was obtained in accordance with The Pennsylvania State University Institutional Review Board. The athlete suffered a non-contact ACL injury during a game. The ACL was reconstructed using a bone-patellar-bone autograft approximately 3 weeks post-injury. Weekly measures of vastus lateralis volume (estimated using B-mode ultrasound; EchoBlaster 128, Telemed, Lithuania) and thigh circumference commenced 4 days post injury following the procedures detailed in Infantolino et al. [2]. Briefly, a system of wire guides was placed on the thigh to break up the vastus lateralis on the ultrasound image (Figures 1 and 2).

Figure 1. System of wires on subject's leg.
Figure 2. Ultrasound images illustrating one full cross-section of the vastus lateralis. Yellow outlines show the outline of the muscle. The dark vertical artifacts are the wires

The cross-sectional area of the vastus lateralis was measured every 2 cm.   Two sequential cross-sectional areas and the distance between the areas was used to calculate the volume of the segment. Segment volumes were added to reach total muscle volume.   A schedule of weekly measures was adhered to as closely as possible with 3, week-long academic breaks being the only interruptions in the schedule. Measures were discontinued once the athlete was cleared by her physician to participate in soccer again (8 months post-injury). The athlete participated in a full season of Division III soccer once cleared for full participation. Muscle volume and thigh circumference correlation was assessed using a Pearson's correlation test.

RESULTS AND DISCUSSION

The results of the Pearson's correlation test indicated a correlation between muscle volume and thigh circumference measures ($p < 0.05$). Figure 3

illustrates muscle volume throughout time. Important points of change in the volume occur at:

- Week 3 – the measurement after ACL reconstruction (volume probably influenced by swelling post surgery).

- Week 5 – volumes illustrate how much volume decreased 2 weeks after surgery (36% from week 1).

- Week 15 – subject stopped attending physical therapy after 30 sessions.

- Week 19 – subject returned to physical therapy.
Figure 3. Vasuts Lateralis volume throughout time.

CONCLUSIONS

The results of the correlation indicate that thigh circumference is an accurate method for assessing vastus lateralis volume changes during rehabilitation following ACL reconstruction. This is clinically important as thigh circumference measurements are used to track muscle hypertrophy during rehabilitation and are much quicker measurements than measuring muscle volume. Another important finding was how quickly atrophy ensued following discontinuation of rehabilitation. In this study the subject stopped attending regular physical therapy sessions during the winter break. During this time her vastus lateralis volume decreased by nearly 18%. This demonstrates that consistent rehabilitation is critical to maintaining muscle hypertrophy gains.

Some limitations exist in this study with the largest limitation being sample size. Since the injury, operation, and rehabilitation were not unique there is no reason to believe that these results would not be seen on other individuals. However, without additional subjects it is difficult to categorically state that these findings would generalize to other individuals. Another limitation would be the focus on the vastus lateralis muscle. Given that previous literature has shown decreases in the other quadriceps muscles there is no reason to suspect that these findings would not apply to the other quadriceps.

Clinically, these results indicate that thigh circumference can be used to estimate vastus lateralis muscle volume changes. Muscle volume is an indicator of the power a muscle can produce and therefore can be used during rehabilitation as an independent measure of muscle power production ability. Finally, these results also demonstrate the need for continuous rehabilitation (even months post-op) to continue increasing vastus lateralis muscle volume.

email: jahanian@uwm.edu

INTRODUCTION

Wheelchairs are the primary mobility device for individuals having difficulty with ambulatory activities [1]. In the U.S. it is estimated that 3.3 million people used a wheelchair in 2010 [2], of which 90% used manual wheelchairs (MWs) [3]. However, MWs often lead to reduced independent function and quality of life [4]. Furthermore, shoulder pain and injuries are commonly associated with MW propulsion [5]. Geared manual wheelchairs (GMWs) may be a promising alternative that reduces the biomechanical demands of the shoulder needed for MW propulsion while maximizing function. However, there is limited scientific evidence supporting the benefits of GMW mobility.

The purpose of this study is to compare the glenohumeral (GH) joint dynamics and shoulder flexors electromyography (EMG) during geared and standard MW propulsion. It is hypothesized that using GMWs will decrease glenohumeral joint range of motion and shoulder muscle activity.

METHODS

Six able-bodied individuals, 4 females and 2 males, ages 18-30, were recruited for this study. This study was approved by the University of Wisconsin-Milwaukee Institutional Review Board (IRB). An acclimation period (30 minutes) was provided to the participants to familiarize themselves with wheelchair propulsion techniques. Subjects were instrumented with 27 reflective markers on the upper body and surface electrodes on the anterior deltoid and pectoralis major muscles. Maximum voluntary contractions (MVCs) were performed against manual resistance for the targeted muscles [6]. Subjects were asked to propel both standard and geared MWs on a level, carpeted floor, to simulate the home environment. A Breezy MW (Sunrise Medical LLC.) was used with both its standard wheels and Easy Push (IntelliWheels, Inc.) geared wheels (gear ratio of 1:1.6). Motion analysis data was collected using a 14 camera, three-dimensional (3-D) Vicon T-series motion capture system (120 Hz). A custom inverse dynamics model was used to calculate the 3-D upper extremity (UE) joint dynamics [7]. Delsys Trigno wireless surface electrodes were used to record EMG data (2040 Hz) All recorded EMG signals were rectified and their root mean square (RMS) were normalized by their associated MVC. Normalized EMG was used to determine onset, offset [8], peak time, peak EMG and integrated EMG during a wheelchair stroke cycle using Matlab (The Mathworks, Inc.) software. Statistical analyses were completed with IBM SPSS software using a paired samples t-test ($p = 0.05$ significance level).

RESULTS AND DISCUSSION

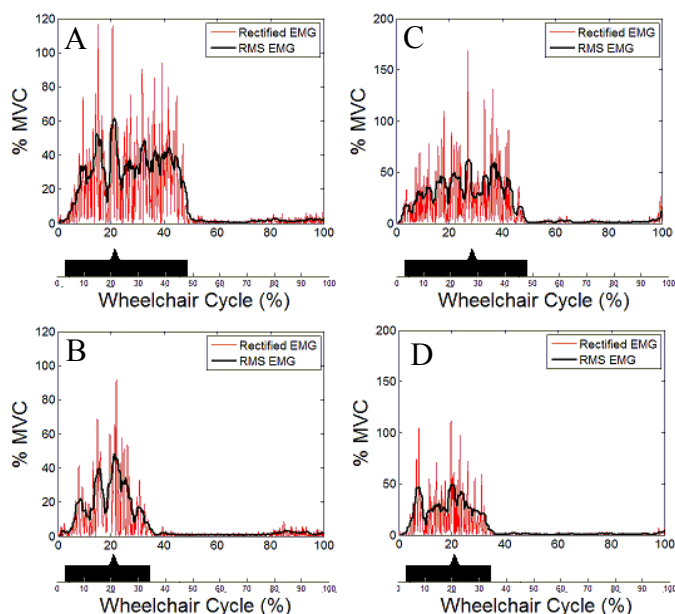
EMG onset and offset, burst duration, peak time, peak EMG and integrated EMG were calculated for three trials of the wheelchair stroke cycle for five subjects. The results of a representative subject are shown in Figure 1. Peak EMG of pectoralis and anterior deltoid decreased by an average of 7% and 8% during GMW propulsion, but they were not statistically significant. Pectoralis burst duration throughout one stroke cycle decreased by 24% (p=0.038) with geared wheels, and integrated EMG for pectoralis and anterior deltoid decreased by 36% and 21%, respectively, but was not statistically significant. When normalized by the distance travelled per stroke cycle, both burst duration and integrated EMG were not significantly different between the two wheel types.


Figure 1: Anterior deltoid and pectoralis major muscle activity during wheelchair propulsion. (A) pectoralis: standard wheel, (B) pectoralis: geared wheel, (C) anterior deltoid: standard wheel, and (D) anterior deltoid: geared wheel.

Glenohumeral joint kinematics of five subjects were not significantly different between geared wheels and standard wheels and SWs. Glenohumeral joint angle mean ranges of motion in the sagittal, coronal and transverse plane are presented (Table 1).

CONCLUSIONS

Preliminary results of this study demonstrate trends between wheel types and showed benefits for GMW mobility based on muscle activity. Reducing peak EMG may be advantageous for wheelchair users during demanding tasks such as propulsion on carpeted floor. Howarth and colleagues [9] reported similar results for using GMWs during ramp ascent. Reduction in muscle energy (integrated EMG) may result in less resultant joint force in the shoulder [8]

which may potentially prevent associated UE pathologies. Further investigation is underway with a larger population of able-bodied persons and persons with spinal cord injury. The results from this study will help us determine the types of mobility tasks and populations of users for which GMWs are beneficial. Ultimately, this work will lead to new multi-geared wheel designs for manual wheelchairs.

EFFECT OF PROSTHETIC FOOT DAMPING ON ANKLE PUSH-OFF WORK IN LATE STANCE

[1] Li Jin, [2,3] Peter G. Adamczyk, [1] Michelle Roland, [1] Michael E. Hahn

[1] University of Oregon, Eugene, OR, USA
[2] Intelligent Prosthetic Systems, LLC, and [3] University of Michigan, Ann Arbor, MI, USA
email: ljin@uoregon.edu, web: bssc.uoregon.edu

INTRODUCTION

Lower limb amputation poses many challenges and can lead to secondary impairments such as knee osteoarthritis (OA) in the intact limb. It has been reported that intact limb the 1st peak of knee external adduction moment (EAM) is related to the prosthetic limb push-off work [1]. Different prosthetic foot properties such as stiffness and energy storage and return are related to ankle-foot system push-off work during late stance phase. Little is known regarding the effect of prosthesis damping on the energy return in late stance phase. We hypothesized that use of an energy return foot would increase the ankle push-off work compared to a foot with significant damping.

METHODS

Eight healthy subjects (23 ± 1.9 years, 167.5 ± 7.6 cm, 65.5 ± 10.0 kg) walked wearing a prosthesis simulator boot with two kinds of prosthetic feet (Figure 1): the energy return foot (ERF) and the damping foot (DF). Each foot had three stiffness variations (high, medium and low stiffness), all matched in stiffness, mass and ground contact geometry.

Figure 1: The energy return foot (left) and the damping foot (right).

Subjects walked along a 10 m walkway over four in-ground force plates, using each foot (ERF, DF) in each stiffness condition (high, medium and low), at three walking speeds (self-selected fast, normal and slow). We recorded body motion and ground reaction forces and performed standard inverse dynamics analysis. We also computed prosthetic ankle power according to a deformable-body model, as the sum of rotational and translational power at the distal shank [1, 2]. It was expressed as:

$$P_{ankle} = M_{ankle}\omega_{shank} + F_{ankle}v_{shank}$$

where P_{ankle} is the power, M_{ankle} and F_{ankle} are the ankle joint moment and joint reaction force, ω_{shank} and v_{shank} are the angular and translational velocities of the distal shank [1]. Prosthetic foot-ankle push-off work was calculated as the positive integral of power during late stance phase (~50-60% of gait cycle) [1, 2]. Parameters were normalized to body mass (Figure 2).
Figure 2: Prosthetic foot-ankle power during gait cycle in high stiffness condition (DF & ERF) at self-selected slow walking speed.

Statistical analysis was performed using a 3-way ANOVA (foot*speed*stiffness) in SPSS (V22.0, IBM, Armonk, NY). Bonferroni procedure was used to reduce pairwise comparisons.

RESULTS AND DISCUSSION

Main effects of foot, speed and stiffness on the prosthetic foot-ankle push-off work were all significant, while the interaction effect between them was not significant. For pairwise comparisons, the energy return foot significantly increased the ankle push-off work compared with the damping foot ($p = 0.001$). Within three different stiffness comparisons, prosthetic ankle push-off work was significantly larger in low stiffness condition than the medium and high stiffness condition ($p = 0.001$); medium stiffness was also larger than the high stiffness condition ($p = 0.01$) (Figure 3). Comparing across walking speeds, fast walking resulted in significantly larger ankle push-off work compared with slow walking ($p = 0.004$).
Figure 3: Prosthetic foot-ankle push-off work with high, medium and low stiffness feet. Work was significantly different among stiffness conditions.

CONCLUSIONS

The results of the study support the hypothesis. The damping effect of the prosthetic foot significantly reduced foot-ankle push-off work in the late stance phase of gait, compared with the energy return foot. There was a trend that positive peak ankle power value is higher by wearing the energy return foot (Figure 2). This is due to the damping effect of foam or rubber cushions in prosthetic systems dissipates some of the energy in the mid stance phase (30-50% of gait cycle) (Figure 2). The damping foot also appears to absorb energy over a longer period of time. All of these contribute to the reduced energy return observed in this study.

Different stiffness levels also play an important role in affecting prosthetic foot-ankle push-off work. The lower stiffness condition led to higher ankle push-off work. When the loading force remains the same, a higher stiffness would result in lower deflection, which subsequently reduces energy storage and resultant energy return [3]. Increased walking speed will result in higher ground reaction force impulse, thus leading to increased foot-ankle system push-off work. Future research should explore the changes of walking speed on the prosthetic foot-ankle energy storage and return efficiency, to better generalize new developments for clinical application.

INTRODUCTION

In activities of daily living (ADL), postural control plays a significant role for people with neurological impairments. Jeka et al. [1] have shown that light touch (contact force less than 1N) of fingers on fixed surfaces contributes to postural control during quiet standing and walking. By virtue of this additional sensory information from skin stretch feedback, people with neurological impairments may reduce their body sway in ADL, which can ultimately lead to improved quality of life.

In recent years, Verite et al. developed a sensory augmentation system for postural control while quiet standing [2]. However, this system is not portable because this system requires force plate and fixed structure of actuators, which in turn limit the usability of device in daily living and have less availability in ADL. Therefore, portability was one of the main concerns in our study. The objectives of this study are to i) design a portable sensory augmentation system for postural control, and ii) estimate the feasibility of our system in postural control application.

METHODS

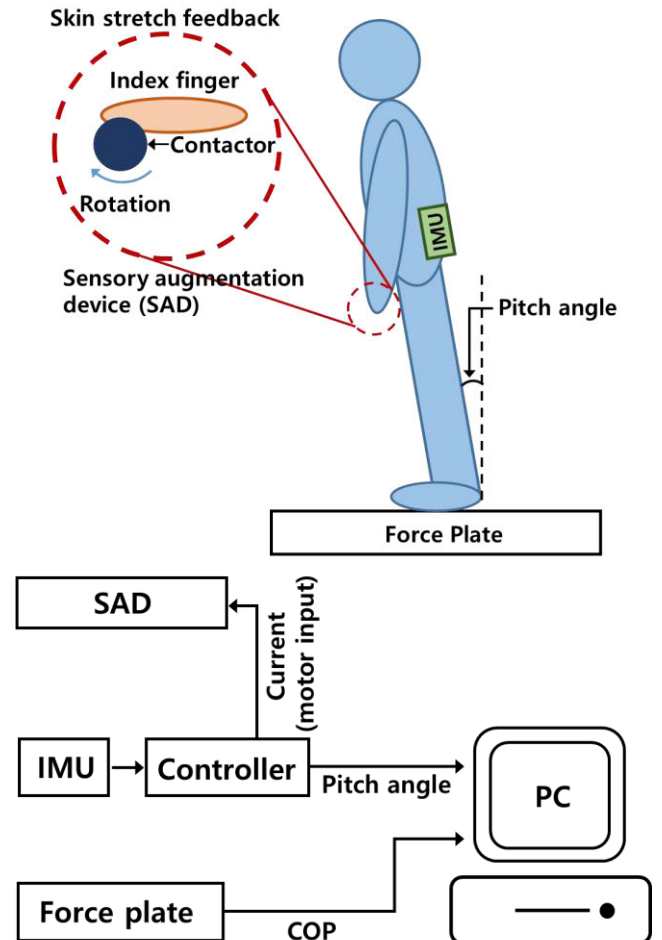
Fig. 1 shows a schematic diagram of our sensory augmentation system and Fig. 2 shows a fabricated system. Using the gradient descent algorithm [3], the pitch angle in subject's anterior-posterior direction is calculated from the data of inertia measurement unit (IMU) (MPU-9150, InvenSense Inc., San Jose, CA) which is attached at the center of mass (COM) of a subject. Contactor's angular velocity is defined to be proportional to angular deviation of pitch angle from a reference angle. A reference angle is defined as a pitch angle when a subject is standing upright. When a subject tilts forward, the contactor rotates in clockwise direction and vice versa. The contactor is operated by a DC motor (Faulhaber, Germany). An embedded control


Figure 1: Schematic diagram of sensory augmentation system.

unit (myRIO, National Instruments, Austin, TX) takes the pitch angle of a subject from the IMU as an input, calculates the desired angular velocity, and controls the DC motor so that the contactor will maintain the desired angular velocity. A PID feedback control and an encoder were used to robustly maintain angular velocity of the contactor to a desired value.

The skin stretch is triggered at the index fingertip pad since the distribution of mechanoreceptors sensitive to skin stretch on the hand is concentrated
Figure 2: Fabricated sensory augmentation system.

at the index fingertip pad [4]. The DC motor is mounted at the housing of sensory augmentation device (SAD) where subject's index finger is inserted. Several contactors and housings with different size were fabricated using the 3D printer (Replicator 2X, Makerbot, Brooklyn, NY) to accommodate various finger sizes of subjects.

Besides the portable system of SAD and IMU, a force plate (OR6, AMTI, Watertown, MA) and a data acquisition system (DAQ) (USB-6002, National Instruments, Austin, TX) with a PC were prepared to collect center of pressure (COP) and pitch angle data. These data will be used to evaluate the efficacy of the SAD system. The IMU, embedded control unit, and a motor driver are enclosed in a waist belt so that subjects can easily wear the system (Fig. 2). Sampling rates of SAD, IMU and DAQ system were 2kHz, 500Hz, and 1kHz, respectively.

RESULTS AND DISCUSSION
Fig. 3 shows the relationship between contactor's angular velocity and pitch angle. As expected, contactor's angular velocity tracked the desired
Figure 3: Relationship between contactor's angular velocity and pitch angle of subject.

angular velocity determined by body postural sway (pitch angle). Note that the reference angle was set to 90°.

CONCLUSIONS AND FUTURE WORK
A sensory augmentation system for postural control rehabilitation was developed using skin stretch feedback. This portable system consists of SAD, embedded control unit, motor driver, and IMU. To test the efficacy of the system, a force plate and DAQ was additionally used. By virtue of this device, subjects would receive skin stretch feedback, which may contribute to the reduction of body sway. Currently, only pitch angle was used to determine the motor velocity input. However, time derivative of pitch angle can also be used. Furthermore, battery should be used as a power source for portability. These studies will be included in future work. The efficacy of SAD system will be evaluated by examining the effect of augmented sensation at the fingertip due to SAD on quiet standing balance for various sensory modalities

IMPROVING THE MOBILITY AND POSTURAL BALANCE OF INDIVIDUALS WITH MULTIPLE SCLEROSIS

[1] Brenda L. Davies, [1] David J. Arpin, [1] Min Liu, [1] Heidi Reelfs, [2] Kathleen G. Volkman, [1] Brad Corr, [3] Kathleen Healey, [3] Rana Zabad, and [1] Max J. Kurz

INTRODUCTION

Multiple sclerosis (MS) is a demyelinating disease that affects about 570,000 individuals in the United States [1]. These individuals are often faced with muscular impairments that have devastating effects on their mobility and standing postural balance. Traditionally, clinicians have discouraged individuals with MS from participating in exercise programs or intensive physical therapy because it was thought that these types of activities would exacerbate the MS symptoms [2]. However, this notion has been challenged by numerous studies that have shown that exercise and physical therapy does not aggravate the symptoms and can result in postural balance and mobility improvements [3-5]. Outcomes from our recent investigation have shown that an intensive neuro-physical therapy can result in substantial improvements in the mobility and postural balance of individuals with MS [4]. Our protocol was different from prior clinical trials in that it was performed twice-a-day, five days a week. This immersive therapeutic protocol was directed at igniting beneficial neuroplastic changes through a massed practice paradigm that constantly challenged the patient's movements. Exemplar individualized challenging exercises included standing on foam with feet close together and eyes closed, walking sideways on a treadmill, or walking overground while stepping over obstacles. Although the initial outcomes appeared to be quite successful, it is currently unknown if the clinically relevant changes were related to the therapeutic dosage or the novel therapeutic paradigm. The purpose of this study was to test the therapeutic outcomes of our prior study by comparing it with the mobility and postural balance outcomes for a cohort of individuals with MS who participated in an exercise based training protocol that was conducted at the same therapeutic dosage.

METHODS

Twenty-four adults with relapsing-remitting or secondary progressive MS participated in this investigation (Mean Age: 53.5 ± 1.8 years). The subjects were assigned to either the Therapeutic Challenge Group (TCG) or the Exercise Group (EG). All subjects completed a battery of biomechanical testing before and after the 6-weeks of training. Postural control was measured based on the composite score from the Sensory Organization Test (SOT) (NeuroCom® International, Clackamas OR), where a higher score indicated a lower amount of postural sway. The preferred walking pace spatiotemporal kinematics were measured with a GAITRite® system (CIR Systems Inc., Sparta, NJ). Two walking trials were completed and averaged together for analyses.

Both groups completed their training five consecutive days each week, two times each day, over a 6-week period. The initial two weeks were completed on the UNMC campus under close supervision of a licensed physical therapist (HR, KGV, or BC). The TCG completed the same training that was conducted in our initial investigation [4]. For this group, each session consisted of 5 minutes of movements isolating the control of joints, 20 minutes of challenging postural balance training and 20 minutes of challenging gait training. The EG completed 15 minutes of strength/flexibility exercises, 15 minutes of postural balance exercises, and 15 minutes of treadmill walking. This group focused more on completing the assigned exercises rather than learning new

motor control strategies. After the initial two weeks of therapy, both groups completed the remaining four weeks of their training at home and were monitored though weekly phone contact from one of the treating therapists. Separate repeated measures ANOVAs (group x Pre/Post Assessment) were used to evaluate the differences in the treatment effects of the respective groups.

RESULTS AND DISCUSSION

For the SOT measures, we found a significant Pre/Post main effect, which indicated that all of the patients reduced their postural sway after the therapy ($p<0.001$; Fig. 1A). However, we did not find a significant group main effect or an interaction ($p>0.05$), indicating that the postural sway improvements were equivocal for the two treatment groups. We also found a significant Pre/Post main effect for walking speed ($p=0.007$; Fig. 1B), indicating that all of the patients walked faster after participating in the therapy. Yet, we did not find a significant group main effect or an interaction ($p>0.05$); indicating that the walking speed improvements were the same for the two groups. There additionally was a significant Pre/Post main effect for the step length ($p=0.001$; Fig. 1C), suggesting that all the patients improved their walking speed after therapy by using a longer step length. There was not a significant group main effect or interaction for the step length ($p>0.05$), once again indicating that there were no differences between the two treatment groups. Lastly, there were no significant differences for the step width or the cadences for both the main effects and interactions ($p>0.05$).

Our results show that a high dosage of physical therapy over a 6-week period can result in clinically relevant improvements in the mobility and postural balance of individuals with MS. On the other hand, our results also indicated that there were no differences for any of the outcome variables between the respective treatment groups. This suggests that the therapeutic gains in postural balance and mobility were more likely related to the high therapeutic dosage rather than the type of therapy implemented. Potentially, an intensive mass-practice of a motor task may be an important

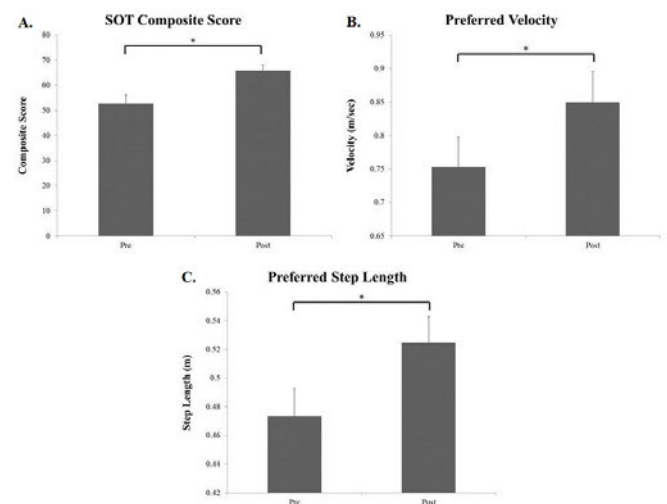
treatment parameter for promoting clinically relevant improvements in the mobility and posture of individuals with MS. The training conducted with the TCG was guided by the challenge point framework, which states that beneficial changes in motor learning can be augmented by altering the task difficulty. It is possible that there were no differences between the two treatment strategies because a high dosage of activity was sufficient for the patient to work above their challenge point. Alternatively, we suspect that having the patient perform the training at home may be the reason the TCG group did not perform better than the EG. Our rationale is that the patients in the TCG may have not known how to reliably exceed their challenge point without the therapist's daily guidance. Effectively, the TCG home training program may have been relatively similar to the home program of the EG.


Figure 1: A) SOT composite scores, B) velocity, and C) step length for both therapy groups combined before and after the 6-weeks of therapy.

Comparing Effects of Body Weight Supported Treadmill Training on Bone and Muscle Following Complete and Incomplete Spinal Cord Injury

[1] J.P. Loftus,[2] J. Kadlowec,[1&2] A. Singh

[1] Widener University, Chester, PA, USA

email: jploftus@mail.widener.edu

INTRODUCTION

The incidence of lower extremity fractures has been reported to be as high as 46% post SCI (spinal cord injury), as seen in [1-3]. Body weight-supported treadmill training (BWSTT) has been reported to restore muscle mass and prevent bone loss in SCI patients. While the beneficial effect of this therapy is known, the effect of this training paradigm on varying severity of SCI has not been investigated in a single study. The purpose of this study was to investigate the effects of BWSTT on the muscle mass and biomechanical properties of the bone in transected and contused rats.

METHODS

A. Group Set Up

In this experiment 32 female Sprague-Dawley rats were split up into five groups (Fig. 1). Animals in the training group received 8 weeks of BWSTT at 75% BWS and 7 cm/sec speed and 500 steps/day for 5 days/week using a robotic device (Robomedica Inc., CA) (Fig 2). At the end of nine weeks post injury, all animals were euthanized and the right tibia and soleus muscle were harvested. Muscle mass was measured and calculated against the total body weight. The tibial bone was subjected to a three point bending test.

B. 3-Point Bending Test

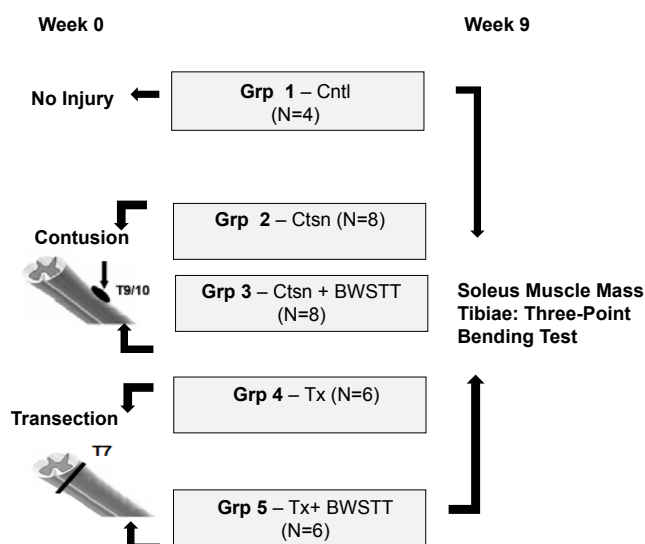
The tibiae were placed on the lateral surface on two rounded supporting bars with a distance of 20 mm (Fig. 3). A constant displacement rate of 5 mm/minute was applied at the medial surface of the diaphysis by lowering a third rounded bar until failure (shampo, FGS-100PVH/L, Itasca, Illinois) Ultimate failure load (lb) was calculated for each specimen.


Figure 1: Groups Details
Figure 2: Body Weight-Supported Treadmill Training apparatus.

Figure 3: 3-Point Bending Test

RESULTS
Figure 4: Percent Soleus Muscle Mass for each animal group. Asterisk indicates significant difference from control. Bracket with # indicate significant difference between groups (p<0.05).
Figure 5: Failure Loads in Tibiae Bone When Subjected to 3-Point Bending Tests .

CONCLUSIONS

BWSTT led to significant improvement in the soleus muscle mass when compared to no training in both contused and transected animals. However, no significant improvement in the biomechanical property of the tibial bone was observed in the BWSTT animals. We attribute this to the severity of contusion injury that results in non-weight supported locomotion in animals in response to injury and also to the 75% BWSTT. Lower body weight support might result in significant improvement in the biomechanical properties of the tibial bone. Future studies are needed to investigate the effects of BWS and bone strength in various SCI models.

DETERMINING THE SAGITTAL PLANE FUNCTION FOR A MODEL PROSTHETIC FOOT

Anne E. Martin[1], Jeremy D. Smith[2], Robert D. Gregg[1], and James P. Schmiedeler[3]

INTRODUCTION

While it is generally believed that the choice of prosthetic components affects amputee gait, systematically quantifying the effects of prosthetic design on amputee walking is difficult [1]. A simulation model capable of predicting human amputee gait could allow for quantitative, systematic investigations. Existing models of amputee gait are either too complex for a predictive study (e.g. [2]) or do not provide any validation that the models can accurately predict amputee walking (e.g. [3]). One successful strategy to limit the complexity of predictive models for healthy human gait is to model the function, not the form, of the foot and ankle complex using a rigid curved foot and revolute ankle joint [4]. The curved foot captures the control of the center of pressure location [5], and the ankle joint helps to capture the change in the whole-body center of mass (CoM) velocity during the step-to-step transition [6]. Without ankle joints, the model exhibits excessively short step durations and large joint angle oscillations [4], both of which are uncharacteristic of healthy human walking. Whether an ankle joint is likewise required to capture the function of a passive prosthetic foot in an analogous model of amputee walking is unclear. Similar to human feet, prosthetic feet help to control the center of pressure location [7], but since passive prostheses cannot generate net positive ankle work, it appears they provide far less control of the CoM velocity than intact ankle joints [2]. Thus, a model prosthetic ankle joint may not be required. Prosthetic feet can, however, store and subsequently release energy during certain parts of the step. If an amputee model without a prosthetic ankle joint is able to capture amputee gait, this may indicate that amputees do not use this energy transfer to help control the CoM velocity.

METHODS

A planar, five-link, asymmetric bipedal model was developed (Fig. 1) to investigate whether or not the prosthetic foot helps to control the CoM velocity. The amputated leg has a thigh and a combined shank/foot segment, i.e., no ankle joint. The contralateral/sound leg has a thigh, shank, and foot. Both feet are modeled as rigid circular arcs. Because the curved model foot captures some of the motion of the physical ankle, the model and physical ankle motions are not expected to match. The stance foot is assumed to roll without slip. Each stride consists of a finite-time amputated stance phase, an instantaneous transition between stance legs, a finite-time contralateral stance phase, and a second instantaneous transition. The model is controlled using the hybrid zero dynamics control method, which is capable of accurately predicting healthy human walking [4]. Gaits were designed by minimizing the error between the simulation and existing transtibial amputee walking data at the self-selected speed. The experimental data are from overground walking trials of five fully ambulatory amputees (4 male, average age of 44 ± 20 years, average years since amputation of 10 ± 14) wearing their prescribed prosthesis [8].

RESULTS AND DISCUSSION

The model reproduced the kinematics of amputee walking (Fig. 2). In all cases, walking speed error was less than 1%, step period error was less than 2%, and range of motion error was less than 3°, all of which were within the bounds of normal human variation. In particular, the result that the amputee model captured both step periods suggests that a
Figure 1: Schematic of the model. The contralateral leg has both knee and ankle joints, while the amputated leg has just a knee joint.
Figure 2: The hip and knee angles for both sides for one representative subject. The amputated stance phase goes from 0 to 48%, and the contralateral stance phase goes from 48% to 100%.

model prosthetic ankle joint may not be needed. The model accurately captured the shape of amputated-side hip motion, but predicted the peak extension of the contralateral hip to occur too early in the gait cycle (error of 15% of the stride). For the amputated-side knee, peak flexion and extension during swing both occurred approximately 5% later in the stride for the model. For the contralateral knee, peak extension during swing occurred approximately 4% later in the stride for the model, but peak flexion was accurately matched. The model was least accurate in capturing the motion of both knees during stance, with the most consistent issues being early peak knee flexion during the weight acceptance phase (errors between 1 and 16% of the stride) for both knees and early peak extension (error of 10% of stride) for the contralateral knee. This difficulty in accurately capturing the knee motion was not surprising because the model allowed for greater variability in stance knee motions compared to the hip motions while still achieving stable, periodic walking. None of the model joint angles exhibited the oscillations observed in the healthy human model when ankle joints were omitted [4]. Since the model was able to accurately match most of the kinematics of amputee walking, it can be concluded that a prosthetic ankle joint is not required in the model. This indicates that the function of the prosthetic foot can be entirely captured using just a curved model foot. Further, it suggests that the energy storage and return capabilities of prosthetic feet do not have a significant effect on the control of the CoM velocity.

CONCLUSIONS

A planar, five-link, asymmetric model is capable of matching the kinematics of transtibial amputee walking for amputees wearing a passive prosthesis. Since a model prosthetic ankle joint is not needed, it appears that the prosthetic foot helps to control the center of pressure location but has minimal influence in controlling the CoM velocity during the step-to-step transition. Using the validated model, an optimization capable of predicting transtibial amputee walking for amputees wearing a passive prosthesis is currently being developed. This predictive model will be used to systematically quantify the effects of prosthetic foot design on amputee gait.

HAND KINEMATICS BEFORE AND AFTER TENDON TRANSFER SURGERY IN HANSEN'S DISEASE PATIENT WITH ULNAR NERVE PALSY

[1] Jéssica de Abreu, Ana Paula Fontana[2] and [1] Luciano L. Menegaldo

[1] Biomedical Engineering Program, Federal University of Rio de Janeiro, Brazil
[2] Medicine School, Federal University of Rio de Janeiro, Brazil
email: jabreu@peb.ufrj.br

INTRODUCTION

Eradicated in many countries, Hansen's disease still presents a challenge for countries like India and Brazil, with 127.195 and 33.955 new cases in 2011, respectively. Patients often experience symptoms like loss of sensitivity, muscular atrophy, paresthesia, erythrocyanosis and nerve pain [1]. One of the most common movement disorders is the ulnar claw, characterized by metacarpophalangeal joints (MCP) hyperextension and interphalangeal joints hyperflexion of the fourth and fifth fingers, as shown in Figure 1.
Figure 1: Hansen's disease patient with ulnar claw.

Tendon transfer surgeries followed by rehabilitation therapy can restore hand movement and physiologic posture. The main objective is to improve hand prehension capability by reducing MCP hyperextension. Surgical techniques may vary, normally emulating lumbrical and interossei muscles action. The distal tendon of the long finger flexor superficialis is released, divided in four stripes, and attached to extensor hood, proximal phalanx, A1 pulleys or interossei tendons) [2].
Selection of the surgical technique, tendon tensioning and attachment site is a complex task [2]. Deformities resulting from incorrect surgery decisions, such as swam neck and intrinsic plus, are common. In this study, we provide a framework for kinematic evaluation of tendon transfer surgeries to correct ulnar claw in Hansen's disease patients.

Fifth finger kinematics of a patient with ulnar claw, before and after being submitted to Zancolli-lasso procedure, is shown. We hope the results can provide insight into the biomechanical behavior resulting from the surgical procedure, improving therapeutics and surgical parameters choice.

METHODS

A BTS motion capture system (Milan, Italy) with 8 200Hz infrared cameras was used to measure hand movements of 10 healthy subjects and one Hansen's disease patient with ulnar claw, before and after a Zancolli-lasso tendon transfer surgery. Patient was a 17 year old female teenager with hypermobile joints. Marker protocol includes 23 markers, as shown in Figure 2. Capture sequence includes static posture, flexion/extension and pinch in neutral wrist position and circa 30º forearm rotation. In this paper, subjects are instructed to start in hyperextension, execute pinch involving fingers around a pencil and return to hyperextension immediately after touching the object.

Figure 2: Hand marker protocol. Hand markers are 4 mm and wrist markers 8 mm diameter.

The hand kinematics model adopted in this work considers bones as rigid segments connected by pivot (1 degree of freedom - DoF), Cardan (2 DoF) or spherical joints (3 DoF) [3]. Marker tracks processing includes noise attenuation with a 6 Hz

Butterworth low-pass filter and gaps interpolation. Local reference systems are positioned in each joint according to ISB recommendations [4]. Relative angles between proximal and distal reference systems are estimated. Angle tracks processing includes removal of frames before and after effective movement, according to a trigger of 2.5% of joint angle range. Tracks are normalized and synchronized according to the longest track. Healthy subjects mean and standard deviation are estimated for each frame.

RESULTS AND DISCUSSION

Ulnar claw affects mostly the movement of fourth and fifth fingers, which usually presents the greater joint angle deviations [5]. Figures 3 and 4 show the comparison between patient fifth finger flexion angles during pinch, before and after surgery, referenced to the healthy subjects' average pattern.
Figure 3: Fifth finger MCP flexion angle during pinch movement.

MCP and distal interphalangeal (DIP) joint angles varies only slightly during pinch movement before the surgery, indicating fifth finger paresis. Figure 3 shows a post surgical MCP movement similar to normal pattern. In Figure 4 significant reduction of distal interphalangeal joint (DIP) hyperflexion can be observed. However, the patient possibly requires greater contact forces in order to detect pencil touching, causing DIP joints to extend slightly in the middle of the movement cycle.
Figure 4: Fifth finger DIP flexion angle during pinch movement.

CONCLUSIONS

A kinematic model of the hand was implemented and joint angles were estimated for a Hansen's disease patient with ulnar claw. Patient's movement was measured before and after a Zancolli-lasso tendon transfer surgery, and compared to the average kinematics of healthy subjects. Results might support qualitative analyses of tendon transfer surgeries outcomes. Further work includes developing methods to characterize pathological movement and quantify surgical improvement.

INTRODUCTION

The prevalence of knee osteoarthritis (OA) is roughly twice as high in the intact limb of lower limb amputees compared to non-amputees [1]. The reasons for this disparity are unknown. However, local mechanical loading is thought to be a major factor in the general OA disease process [2].

Our long-term goals are to better understand how amputee gait mechanics, fitness, and prostheses affect the loading of the intact limb, and if the loads accumulated throughout the day can be modified to mitigate their OA risk. As a first step in these directions, we compared joint loading during self-paced walking between the knee of the intact limb in amputees who have recently begun using their prosthesis, to knees of a non-amputee control group.

Most previous studies on amputee joint loading have assessed loading using peak values of joint moments such as the external knee adduction moment (KAM). Joint moments relate to OA etiology, but do not directly reflect joint contact forces, and can give a misleading picture of how contact forces differ between conditions or subjects [3]. We therefore expected that contact forces summarized using features other than the peak would be greater in amputees than in controls, while peak KAM would be similar between groups.

METHODS

Institutional approval was obtained and consent was granted from each participant. Motion capture and ground reaction force data were measured from 10 unilateral lower limb amputees (five transtibial, five transfemoral). All amputees were Service Members who had sustained traumatic limb injuries in Iraq, Afghanistan, and related military conflicts, and had been walking independently with their prosthesis for 2 months. Subjects walked overground at self-selected speed (mean 1.25 m/s) and step rate. Knee joint angles, forces, and moments were calculated in Visual3D and averaged over 5 strides. Control data collected elsewhere for 10 non-amputees walking at the same mean self-selected speed were referenced [3] and processed using the same methods.

Knee muscle forces were calculated (custom Matlab code) from the knee extension moment assuming no antagonism, and joint contact forces were then estimated using a frontal plane model to balance the internal and external loads on the joint [4].

Joint loading was quantified using the KAM, the resultant moment (KRM), the medial contact force (Fmed), and the total contact force (Fcon). Summary variables were peak, loading rate in early stance (LR), impulse, and per-unit-distance load (PUD). Forces and moments were scaled by bodyweight (BW) and BW*height (Ht). Results were compared between groups using t-tests ($p < 0.05$) and effect sizes ($d > 0.80$).

RESULTS AND DISCUSSION

Compared to controls, the intact limb's knee had:
- Greater KRM peak (5.73±1.63 vs. 4.37±1.11 %BW*Ht, $p = 0.036$, $d = 0.98$)
- Greater KRM impulse (1.89±0.41 vs. 1.43±0.25 %BW*ht*s, $p = 0.007$, $d = 1.36$)
- Greater Fmed impulse (0.71±0.12 vs. 0.60±0.10 BW*s, $p = 0.049$, $d = 0.93$)
- Greater Fcon impulse (1.03±0.16 vs. 0.82±0.08 BW*s, $p = 0.002$, $d = 1.65$)
- Greater Fcon peak (2.74±0.47 vs. 2.15±0.31 BW, $p = 0.042$, $d = 1.47$)

None of the KAM summary parameters, and none of the LR or PUD parameters, were significantly different between groups. The contact force results were robust to 95% of random perturbations to the knee joint model parameters and muscle force distributions, suggesting results were driven by the gait data rather than by modeling assumptions.

The results indicate that conclusions on knee joint loading between amputees and controls depend on (i) the variable chosen to represent loading, and (ii) how that variable is summarized for statistical analysis. For example, if the KAM were chosen, we would conclude no difference in joint loading between groups, regardless of how the KAM is summarized. The same conclusion would be reached for any loading variable summarized using LR or PUD. In contrast, KRM, Fmed, and Fcon all suggest loading is greater in the amputee intact limb's knee joint when summarized with impulse. This latter conclusion is perhaps the expected result if we (ostensibly) assume that knee OA risk in amputees is related to the intact limb's knee joint being mechanically overloaded.

CONCLUSIONS

The choice of how to quantify and summarize joint loading is an important one that can dictate the conclusions reached in a study. The KAM is clearly an important variable in knee OA, but may need to be combined with other gait variables to fully characterize the joint loading environment and risk for mechanics-driven joint degeneration.

INTRODUCTION

Advances in prosthetic technology and rehabilitation strategies have allowed ambulation to no longer be an extraordinary task for Service Members (SMs) with unilateral lower extremity amputation (ULEA). Despite locomotion advancements, the majority of research on this population focuses on straight, level-ground walking tasks, which insufficiently defines activities of daily living. Altered gait biomechanics and ambulation strategies while changing direction may contribute to the development of chronic secondary injuries such as osteoarthritis (OA) and low back pain [1].

The task of turning presents a potential challenge to those with ULEA due to increased residual limb pain or discomfort [2]. This pain may lead to gait alterations and decreased stability [3]. Published work has focused on what compensatory strategies are utilized by persons with ULEA as they turn. Limited information regarding turning strategy preference has been documented. Step turning and spin turning are the two main strategies used for 90° turns. Step turning involves a change in direction opposite to the stance limb. Spin turning involves a change in direction toward the same side as the stance limb where the stance limb can pivot or stay rooted throughout the turn [4]. Preliminary analysis of uninjured individuals suggests that the step turn strategy is most commonly selected [4].

This study presents preliminary data obtained as SMs followed laser-guided pathways that consisted of randomly generated transient tasks from a unique system (MITRE, USA). This method of moving freely about the lab space in a controlled manner is called freeform walking (FFW). The concept behind FFW is that participants will walk in a more realistic manner compared to a forced turning command. This FFW based evaluation allows for the preliminary analysis of how those with ULEA complete non-linear walking tasks, specifically 90° turns. We hypothesize that SMs with a ULEA will adjust turning strategies to favor the sound limb for turning. Therefore, step turns will maintain prominence when turning towards the prosthetic side and spin turns will be favored when turning towards the sound side.

METHODS

Institutional approval was granted by Walter Reed National Military Medical Center to enroll human subjects into this protocol; all subjects provided informed consent prior to participation. Three SMs with unilateral transtibial amputations (TT01, TT02, and TT03) and four uninjured SMs participated in this evaluation. Participants with amputations wore preferred prosthetic components and walked without use of other assistive devices. Motion capture data (Vicon, UK; AMTI, USA) were collected as SMs followed five different laser-guided paths conducted in a randomized order (Figure 1). Laser-guided path speed matched pre-determined self-selected walking pace of each SM.
Figure 1: Digital schematic – aerial view of the gait lab area (light green is available area, dark green is the lab perimeter buffer zone), force plate locations (yellow) and an example of laser guided paths (grey / black).

The total numbers of 90° turns were counted and turning strategy was noted for each change of direction.

RESULTS AND DISCUSSION

Results are reported as mean (STD). Control participants averaged a total of 87(2) left turns and 60(5) right turns. SMs with ULEA averaged 71(13) sound side turns and 77(12) prosthetic side turns. Consistent with literature regarding uninjured turning technique preference, all participants were more likely to use a step turn technique than a spin turn strategy when tasked with a 90° turn in a FFW environment [4] (Figure 2).
Figure 2: Average self-selected turning techniques of uninjured control group (Control (AVG)) and each SM with amputation (TT01, TT02, TT03).

When turning towards the sound side participants TT01 and TT03 carried out spin turns at a greater rate than the control group. This result indicates that they preferred to change direction while standing on their sound side. When turning towards the prosthetic side TT01 and TT02 implemented step turns at a greater rate than the control group. The greater frequency of step turns to the prosthetic side demonstrates a preference of turning with the

sound limb in stance. Regardless of direction, participant TT02 executed a higher percentage of step turns in comparison with the control subjects. This result may have occurred due to prosthetic fitting or pain associated with spin turns to either direction. This participant was the only SM with ULEA using a powered prosthetic device.

Within participant comparisons between sound and prosthetic side turns indicate that all SM with ULEA performed a step technique more often when turning towards the prosthetic side and utilized spin turns more frequently when turning to the sound side. These observations support the hypothesis that SMs with ULEA adjust their turning strategy to keep the sound limb in stance.

CONCLUSIONS

This observational analysis provides a preliminary comparison of freeform turning techniques used by SMs with and without ULEA. The collection of additional data and further analysis on turning method preference as well as temporospatial, kinematic and kinetic analyses will lead to a better definition of how those with ULEA complete common activities of daily living.

DESIGN AND 3D PRINTING OF A DYNAMIC WRIST SPLINT IN THE DART THROW MOTION PLANE

INTRODUCTION

Rehabilitation following a wrist fracture often includes exercising flexion-extension movements with a dynamic splint. Current studies show that these sagittal wrist movements are not representative of the natural daily wrist movements. We actually perform most of our daily functions, with our wrist moving on a Dart Throw Motion (DTM) plane, also defined as the plane between radial-extension and ulnar-flexion [1]. The DTM may be considered a more stable and controlled motion, since most motion occurs at the midcarpal joint with the proximal row of carpal bones remaining relatively immobile [2]. This might prove advantageous in rehabilitation following wrist fracture, where the ligaments are intact, since minimal pain is expected as a result of minimal bone movement in the proximity of the injured site. To date, no dynamic brace exists which facilitates wrist exercise in the DTM plane. Also, it has not been reported whether the DTM plane angle is similar for the dominant and non-dominant hand. If DTM is similar between hands then the DTM splint can be used for injuries of both dominant and non-dominant hands. Also, we would be able to calculate the individual natural DTM plane of the patient from the uninjured hand and design the splint characteristics according to the calculated plane. Our aims are therefore (1) To characterize the DTM plane in the wrist bilaterally during daily activities, and (2) to design and 3D print a subject-specific dynamic wrist splint that facilitates wrist exercise in the DTM plane.

METHODS

First, the DTM plane was calculated using a wrist electrogoniometer placed on both wrists (Fig. 1a) of healthy subjects (N=36; 28 females; age 30.5±12.8 years), performing twelve activities of daily living (ADL), e.g. using a hammer, opening a jar, pouring water from a bottle, throwing a ball, and answering the phone. The activities were performed once with the dominant hand and once with the non-dominant hand. The geometry of the splint was designed in Solidworks to fit to a 3D scan of the arm, wrist and hand (Fig. 1b). The brace design comprise of a proximal attachment to the arm and a distal accurate envelope of the palm. An axle with two wheels is attached to the proximal part. Two wires attach the proximal part with the medial-palmar and lateral-ventral aspects of the distal part: when the wrist extends, the medial wire is released and the lateral wire is strained towards the radius. When the wrist flexes, the lateral wire is released and the medial wire is strained towards the ulna. The splint was attached to the wrist using Velcro as two wires attached to two pulleys, situated on a joint axis, pull the hand to move in the desired calculated plane.

RESULTS AND DISCUSSION

As hypothesized, no significant difference was found between the DTM plane angles of the dominant and non-dominant hands, while performing daily activities. In several of the tasks, the angle of the plane of motion was negative DTM plane (radial-flexion to ulnar-extension). The most common ADLs occurred at a DTM plane angle of approximately 20° to 45°. The printed splint fitted the wrist of the subject, was easy to don and doff and constricted movement to the desired DTM plane. The design is adjustable for different DTM planes by calculating the lengths of the wires and the diameter of the two wheels. Hooks were inserted on each part to allow the addition of rubber bands for resistance training towards muscle strengthening.

CONCLUSSIONS

It has been hypothesized that activation of the wrist in the DTM plane following distal radius fracture will accelerate the recovery of the patient and enable him or her improved functionality. Our results show that the DTM angle can be determined from either the dominant or non-dominant wrists. The design of the patient-specific dynamic splint is the first step towards assessing whether DTM splinting is beneficial to the rehabilitation of individuals following distal radius fracture, compared to conventional treatment. The evaluation of the clinical benefits of this method, compared to conventional rehabilitation methods following wrist fracture, are a part of a PhD work, currently conducted by an occupational therapist (KCY).

INTRODUCTION

The scapula plays an important role in the overall function of the shoulder complex, however, accurate dynamic measurements of scapulothoracic (ST) kinematics have proven challenging to obtain. Surface markers fail to capture motion when the scapula translates beneath the skin. Other techniques are either invasive, expensive, or limited to static positions. One of the most widely used estimation approaches, the acromion marker cluster (AMC), is clinically feasible, however loses accuracy at extreme elevations and in pathological populations [1,2]. Improvements in accuracy have been seen from using an interpolated AMC calibration from two different positions [3], however, this validation study was performed on planar motions. An appropriate method for estimating ST kinematics during a cyclic activity such as upper extremity (UE) cycling exercise has yet to be validated. This study aimed to find the optimal method for measuring scapular kinematics during UE cycling. Given the repetitive and constrained nature of cycling, a multi-point calibration of the AMC seemed both promising and feasible. We hypothesized that a four-point AMC calibration would be more accurate in estimating scapular orientation during cycling than a single or double AMC approach.

METHODS

Thirteen healthy adults were recruited. Retroreflective 6mm cube markers were fixed on the trunk and humeri. Additional markers were placed on the cycle to calculate crank position. An acromion marker cluster consisting of three non-collinear cube markers were attached to the acromion process (AP) with the central marker flush to the AP. Subjects moved through eight static positions in 45° increments of the crank revolution. At each position, markers were placed on the trigonum spinae and the inferior angles of the scapulae. Positions of the markers were recorded at 60 Hz by a nine camera motion capture system and used to define coordinate systems for the trunk, scapula and humerus. Scapulothoracic and humerothoracic (HT) angles were calculated using a helical method and then decomposed into X, Y, Z components to avoid dependence on order of motion [4]. Crank angles were calculated from markers placed on the pedal shaft.

Scapulothoracic angles were calculated via three different methods. The first was the standard single AMC calibration which used the relationship between the AMC and the palpated scapula in the 0° position to create a calibration to estimate scapular orientation from the AMC at other cycle positions. The double calibration approach was similarly created from the 0° and 180° positions, and ST angles were calculated using a weighted average of the two calibrations based on the position of the crank angle. The multiple AMC method repeated the calibration process at three more points: 90°, 180° and 270°. The intermediate positions of 45°, 135°, 225°, and 315° were used to test the accuracy of the three approaches.

Palpation was used as the standard of accuracy for comparison [5]. Paired two-tailed t-tests were used to determine if the three methods were statistically different from palpation. Paired t-tests were run for each method and along each axis of motion for a total of twelve tests. No Bonferroni corrections were performed. Root mean square errors (RMSE) were calculated for each axis for each method.

RESULTS AND DISCUSSION

The root mean square error (RMSE) values of estimated ST angles ranged from 3.8° to 9.2° (Fig. 1). In general, the single AMC calibration produced the highest errors. The paired t-tests showed that the ST angles predicted by the single AMC calibration were significantly different from palpation along the internal/external rotation (Y) and anterior/posterior tilt (Z) axes. Additionally, the ST angles predicted by the double and multiple AMC calibrations were each significantly different from palpation about one axis. Means and standard deviations of the absolute differences between predicted and palpated angles are given in Table 1.
Figure 1: RMSE of ST Angles by Axis and Method

Statistical testing of the new methods demonstrated a marginal improvement upon the single AMC method. For functional application, the RMSE provided an estimate of error independent of directionality and offered a clinically meaningful evaluation of overall accuracy. This study's maximum RMSE under single AMC calibration was 9.2°, which is consistent with previously reported results [3]. For all three methods, the largest RMSE values were found around the X axis (upward rotation). As this is the axis about which

the scapula experienced the most movement, these errors appear to scale within the context of motion. The double and multiple AMC calibration methods both demonstrated improvements in error. The maximum RMSE for the dual AMC calibration was 8.5° and the multiple AMC calibration outperformed both other methods with a maximum RMSE at 6.2° and the smallest RMSEs for each axis. Increasing the number of calibration points notably reduced the errors from AMC estimations of scapulothoracic angles. While additional calibration points could potentially reduce the angle errors even further, the multiple AMC interpolation from four calibrations appears sufficient in both application feasibility and accuracy for UE cycling.

CONCLUSIONS

For cyclic activities such as upper extremity cycling, it appears that the addition of multiple calibration points facilitates the accuracy of scapulothoracic orientation estimates. Looking ahead, we intend to apply this approach to differentiate the scapulothoracic and glenohumeral contributions to shoulder motion during upper extremity cycling therapy in patients with spinal cord injury.

THE EFFECT OF ANKLE-FOOT ORTHOSIS ALIGNMENT ON ROLL-OVER SHAPE IN PATIENTS WITH LOWER LIMB RECONSTRUCTION

[1]Mitchell D. Ruble, [1,2]Elizabeth Russell Esposito, [1,2]Jason M. Wilken

[1] Center for the Intrepid, Department of Orthopaedics and Rehabilitation, Brooke Army Medical Center, JBSA, Ft. Sam Houston, TX, USA, [2]DoD-VA Extremity Trauma and Amputation Center of Excellence

INTRODUCTION

Injuries requiring limb reconstruction surgery often result in pain and plantar flexor weakness, for which ankle foot orthoses (AFOs) are commonly prescribed. The Intrepid Dynamic Exoskeletal Orthosis (IDEO) is a passive-dynamic AFO created to improve upon conventional AFO designs by utilizing energy storage and return [1]. However, an AFO may compromise how the foot rolls over the ground due to its semi-rigid footplate. Ankle-foot roll-over shape (ROS) is a biomechanical measure which characterizes how the center of pressure (COP) moves relative to the limb. The foot and shoe are viewed as a rocker with a single radius and the COP path relative to the limb is characterized from ipsilateral initial contact to contralateral initial contact [3]. Maintaining an optimal ROS is thought to increase the stability and efficiency of pathologic gait [3]. The ROS technique was initially developed to understand the relationship between device alignment and function [4]. Alignment has been shown to directly influence ROS in prosthetic devices, but its effect on ROS in AFOs is not well understood. The purpose of this study was to measure the effects of the sagittal plane alignment of the IDEO on ROS in patients with lower limb reconstructions.

METHODS

A total of nine male subjects with unilateral limb reconstruction (age 30±6, height 1.78±0.09 m, mass 87.2±9.7 kg) underwent gait analysis in a motion laboratory (marker data: 120 Hz, Motion Analysis Corp, analog data: 1200 Hz, AMTI, Inc.). Testing was performed with the IDEO aligned in 3 different conditions using a 3° wedge attached to the posterior strut (Fig 1): neutral (determined by orthotist based on pain-free range of motion), 3° more dorsiflexed, and 3° more plantarflexed.
Figure 1: The IDEO aligned in dorsiflexion (left) and plantarflexion (right) using a 3° wedge.

Each subject walked until their affected and unaffected limb each made full contact with a force plate 5 times. To determine ROS, the COP of the ground reaction force was calculated in Visual3D (C-Motion, Inc.), in the shank coordinate system. Ankle-foot ROS was initially calculated from contralateral heel strike to ipsilateral heel strike, then further cropped using only data from forward COP progression and normalized to height. A circle was fit to calculate the ROS radius. A 2-way repeated measures ANOVA (limb x alignment) was performed on the ROS radius values and ankle angle peaks. Paired t-test post-hoc analysis separated main effects ($p<0.05$).

RESULTS AND DISCUSSION

The 3° modifications in sagittal plane IDEO alignment significantly changed ankle alignment at the stance and swing phases throughout the gait cycle ($p\leq0.004$ for all comparisons). However, these 3° changes in the alignment from the neutral position did not influence ROS radius in patients with lower limb reconstruction ($p=0.455$) (Fig 2-3). They also did not affect the ROS of the sound limb ($p=0.800$). There were no significant interactions ($p=0.606$).

Affected Limb Roll-Over Shape
Figure 2: Mean ankle ROS.

Roll-Over Shape Radius
Figure 3: Mean and standard deviation ROS radius.

The mean radii for ROS in the IDEO were found to be consistent with prior studies; Hansen et al. [6] found a range of median ROS radii to be between 0.12-0.28 in healthy controls. Despite the semi-rigid structure of the IDEO, and its impact on ankle biomechanics during walking [6], it did not affect ROS. This may indicate the IDEO maintains an appropriate rocker shape. In addition, the lack of differences between limbs indicates that the limited ankle range of motion permitted by the IDEO [6] did not negatively influence the ability of the intact limb to maintain near-normative ROS radius.

Prior research has studied the effects of other interventions on ROS, such as modifying heel height to change the sagittal plane ankle angle [6]. Similar to the alignment changes about the ankle in the present study, changes to ankle angle by systematically altering heel height also did not change ROS radii from their baseline control levels. The 6-degree range of changes in sagittal plane IDEO alignment were chosen because they were expected to be within the range different orthotists may choose when fitting a patient. Alignment alterations significantly affect the vertical displacement and overall alignment of the ROS ($p<0.012$). The results of this study indicate that, within this 6-degree range, these modifications to alignment are not expected to negatively impact the rocker profile of the foot.

One limitation of this study is the lack of a no-IDEO condition, which would identify the acute effects of the IDEO on the rocker shape profile. Multiple subjects were unable to walk pain-free without the use of this assistive device and this condition was necessarily excluded from the study.

CONCLUSIONS

A 6-degree range of changes in the sagittal plane alignment of an AFO influenced the positions of the ROS relative to the leg, but not the radii in patients with lower limb reconstructions. ROS radii values were consistent with previously published literature from able-bodied individuals and did not differ from the unaffected limb. These results indicate that the ROS of the device effectively mimicked that of an intact limb during single limb stance.

BIOMECHANICAL ADAPTATIONS TO ANKLE-FOOT ORTHOSIS STIFFNESS DURING RUNNING

[1,2]Elizabeth Russell Esposito, [1,2]Harmony S. Choi, [1]Johnny G. Owens, [1,3]Ryan V. Blanck, [1,2]Jason M. Wilken

[1] Center for the Intrepid, Brooke Army Medical Center, JBSA, Ft. Sam Houston, TX, USA, [2] DoD-VA Extremity Trauma and Amputation Center of Excellence, [3] Hanger, Inc., Tacoma, WA, USA
E-mail: erussell.kin@gmail.com

INTRODUCTION

Limb trauma requiring reconstructive surgery commonly results in decreased performance of key functional activities such as walking and running. Ankle-foot orthoses (AFOs) are frequently prescribed to restore limb function by providing mechanical support. To address the desire of patients with injuries requiring lower limb reconstruction to return to running and other high-energy activities, a custom carbon-fiber, passive-dynamic orthosis, the Intrepid Dynamic Exoskeletal Orthosis (IDEO), was developed to improve upon previous AFO designs [1] and facilitate the return to high-energy, performance-based tasks [2]. The customizable nature of the IDEO allows certain features, such as its stiffness, to be tailored to meet the needs of the individual. This mechanical stiffness may also influence the stiffness or compliance of the lower extremity joints [3]. The purpose of this study was to determine the effect of AFO stiffness on lower extremity running biomechanics in individuals with lower limb reconstructions.

METHODS

Ten male subjects with traumatic, unilateral lower limb reconstruction underwent gait analysis (marker data: 120 Hz. Motion Analysis Corp, ground reaction force data: 1200 Hz, AMTI, Inc.) of the lower extremity during overground running at a self-selected speed. All patients were regular users of a custom IDEO (Fig. 1) whose stiffness characteristics were clinically prescribed by the prosthetist/orthotist based on the patient's available range of motion, activity level, body mass and load carriage requirements. Three struts were fabricated using a selective laser sintering technique [4]: 1. Nominal (clinically prescribed stiffness, mean: 832

± 182 Nmm), 2. Compliant (20% less stiff), and 3. Stiff (20% stiffer).

Figure. 1. The Intrepid Dynamic Exoskeletal Orthosis (IDEO) consists of a carbon fiber distal supra-malleolar ankle-foot orthosis, a proximal tibial cuff, and a removable, connective, posterior-mounted strut.

Five trials in which each the affected and unaffected limbs made full contact with one of the force platforms were analyzed. Lower extremity joint angles, moments and powers, and loading rates from the vertical ground reaction force were calculated. At the ankle and knee joints, mechanical work was calculated by integrating the joint power curves and joint stiffness was determined using a torsional spring model during the braking phase of stance. A 2-way repeated measures ANOVA (strut x limb) assessed statistical significance of the dependent measures. Paired t-tests separated main effects. Bonferroni-Holm corrections were used with main effects of strut or interactions ($p < 0.05$).

RESULTS AND DISCUSSION

There was a significant interaction ($p = 0.011$) such that the stiffness of the sound ankle remained unchanged across conditions while the affected ankle was, on average, 152.5% stiffer than the unaffected ($p < 0.001$) and increased joint stiffness with increasing strut stiffness ($p = 0.019$). Specifically, the stiffest strut resulted in an 18% increase in ankle joint stiffness compared to the compliant strut ($p = 0.001$) (Fig 2). Strut stiffness did

not affect temporal spatial measures, preferred running speeds, kinematics or any other kinetics.
Fig 2. Ankle and knee joint stiffness during the braking phase of stance for the affected (solid bars) and unaffected (dashed bars) limb. ǂ indicates significance between strut stiffness conditions and * indicates significance between groups.

Although the affected ankle was stiffer than the unaffected side, the knee of the affected limb was, on average, 123.2% more compliant (p=0.007), potentially in an effort to preserve total limb stiffness [3]. Positive and negative mechanical work were 212.0% and 64.2% greater, respectively, on the unaffected limb for the ankle (pos: p<0.001, neg: p=0.013) and 62.3% and 124.3% greater for the knee (pos: p=0.008, neg: p=0.003), respectively.

Limb stiffness is a fundamental component needed for optimal performance [5] and dynamic AFO stiffness can influence the amount of energy storage and return an individual experiences during gait. However, a 40% range in strut stiffness did not influence kinematic and most kinetic mechanics of running. Subjects either readily adapted to the different stiffness conditions or the 40% range of stiffnesses evaluated in this study was not broad enough to elicit significant changes in mechanics. The only exception was that the stiffer strut did

increase the stiffness of the affected biological ankle joint compared to the compliant strut. However, the increase in ankle stiffness did not affect mechanical work or decrease the knee stiffness, which would be expected if total leg stiffness were maintained [3].

CONCLUSIONS

Strut stiffness did not influence joint angles, moments, powers, or mechanical work during running in individuals with unilateral lower limb salvage. However, a stiffer AFO results in a stiffer ankle joint structure which may be particularly useful for patients with limited pain free ankle range of motion. The changes in joint stiffness were not associated with significant changes in mechanical work. It is unknown how these results translate to populations with other injuries and pathologies, but is likely that some adaptation occurs to different stiffnesses. Therefore, a range of stiffness may be clinically appropriate when prescribing ankle-foot orthoses for running activities, while a stiffer AFO may reduce the risk of mechanical failure during high-energy activities other than running.

INTRODUCTION

More than 50% of individuals with lower limb amputation fall at least once/year [1]. Therefore, understanding how these persons regulate walking from step-to-step is critical. In the sagittal plane, unimpaired people walking on treadmills control *speed* from stride-to-stride but not absolute position [2]. However, people are less stable in the mediolateral (M-L) direction [3,4] and it is unknown what control strategies both unimpaired and persons with amputation adopt in this direction. This study characterized the mediolateral step-to-step control strategies of individuals with unilateral transtibial amputation (TTA) and able bodied controls (AB) during un-perturbed and continuously-perturbed walking.

METHODS

Eight physically active traumatic TTAs and 13 ABs (age 22-40) participated. Each participant walked in a "CAREN" virtual environment and completed five, 3-minute trials each for each of 3 conditions: no perturbations (NOP), pseudorandom mediolateral visual field perturbations (VIS), or pseudorandom mediolateral treadmill platform perturbations (PLAT) [3].

For each step, for each trial, we computed absolute mediolateral *position* (z_B), *change* in z_B from the previous step (Δz_B) (i.e., "heading"), and step width (w) (Fig. 1). Mean standard deviations were calculated for z_B, Δz_B, and w. Detrended Fluctuation Analysis (DFA) quantified the level of statistical persistence (reflecting relatively weaker vs. stronger "control"; [2,5]) across steps for each stepping parameter. Lastly, for each stepping parameter, we quantified how deviations from the mean values (e.g., $w_n' = w_n - \bar{w}$, etc.) were directly corrected on the subsequent step (e.g., $\Delta w_n = w_{n+1} - w_n$, etc.). For each plot of the corrections vs. relative deviations, we

computed the slopes and strength of correlation (r^2) values. "Perfect" control of a particular stepping variable would result in a slope $\approx$ -1 with an $r^2 \approx 1$.

Figure 1: Key parameters for lateral step control: z_B is lateral deviation from some absolute position (e.g., center). Δz_B is change in lateral deviation from previous z_B. w is step width. Humans could control one or more of these three stepping variables while walking.
RESULTS AND DISCUSSION
Figure 2: Standard deviations and DFA α values for z_B, Δz_B, and w for AB (red) and TTA (black). Error bars represent a 95% confidence interval.

Standard deviation values for z_B, Δz_B, and w all significantly (p<0.001) increased when visual (VIS) and

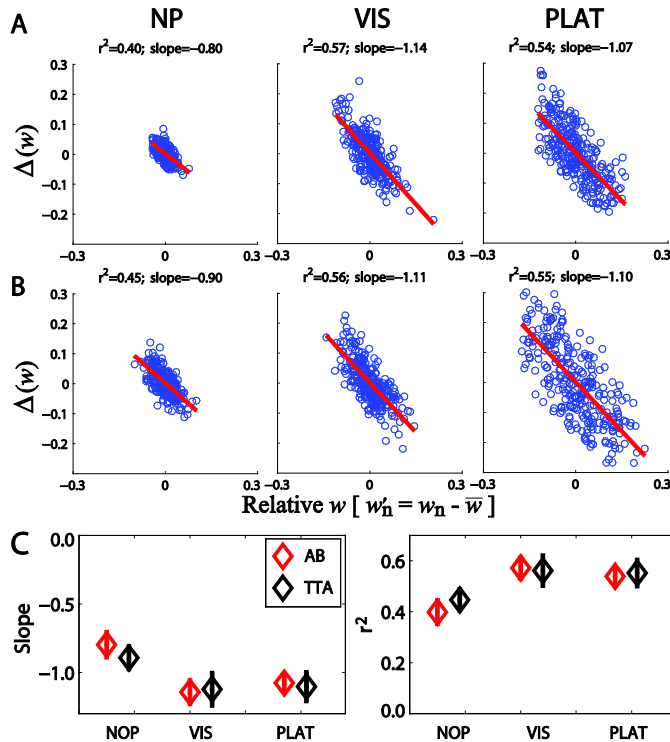
platform (PLAT) perturbations were introduced (Fig. 2A). Thus, these perturbations were highly effective in creating a destabilizing environment for both groups [3]. Differences between AB and TTA were only seen in variability of Δz_B and w during PLAT. This may be related to the biomechanical impairment created from the loss of limb.


Figure 3: Representative scatter plots of Relative w vs. $\Delta(w)$ for (**A**) AB and (**B**) TTA. **C**: Group means ($\pm 95\%$ CI) for linear regression line slopes and r^2 values for the fitted Relative w vs. $\Delta(w)$ plots.

During all 3 walking conditions, all subjects exhibited anti-persistence for Δz_B ($\alpha < 0.5$), statistically uncorrelated fluctuations ($\alpha \approx 0.5$) for w, and strong statistical persistence ($\alpha \gg 0.5$) for z_B (Fig. 2). PLAT perturbations significantly increased (p<0.001) the degree of anti-persistence (i.e., as reflected by sharp decreases in α) in all three variables.

Plots of Relative w vs $\Delta(w)$ (Fig. 3A-B) support the idea that subjects strongly controlled step width (i.e., slopes $\approx$ -1 with high r^2). Under VIC and PLAT perturbations, slopes became steeper with stronger correlations (Fig. 3C), indicating increased step-to-step

corrections. Thus, it appears both AB and TTA tightly control step width through rapid corrections of their step-to-step changes in foot placement and that control increased under perturbed environments.

Findings support the idea of strong prioritization of step width control to maintain lateral balance [4] with far less attention paid to lateral position control [6].

CONCLUSIONS

TTA adopted approximately the same control strategies as AB during both unperturbed and perturbed walking. Higher standard deviation values exhibited by TTA when physically perturbed (Fig. 2A; PLAT) likely indicate that the biomechanical impairments from the amputation make it more difficult for TTA to implement this control strategy. Therefore, when physically perturbed, TTA might have more difficulty adjusting their foot placements, which could lead them to become more unstable.

Pediatric Joint Dynamics during Manual Wheelchair Mobility

[1,3] Alyssa J. Schnorenberg, [1]Christine Aurit, [2]Joseph Krzak, [2]Adam Graf, [4]Sergey Tarima, [2]Lawerence C. Vogel, [2-4]Gerald F. Harris and [1-3]Brooke A. Slavens

INTRODUCTION

Ten percent of all spinal cord injuries (SCIs) are pediatric cases [1] with an estimated 1455 children admitted for SCI treatment to US hospitals each year [2].   Children with SCIs may achieve functional, home and community mobility through the use of manual wheelchairs (MWCs).   The repetitive use of MWCs, however, increases upper extremity (UE) loading demands, and commonly results in pain and injuries which reduce an individual's mobility and quality of life.   Studies have examined adult MWC users during mobility tasks including: level propulsion, ramp ascent, start and stop, and weight relief and found significantly different UE joint demands across tasks [3]. Although children are proportionately different than adults, with developing musculoskeletal systems, there is limited research on pediatric wheeled mobility. In order to prevent or slow the development of pain and pathology, a clear understanding of the UE joint dynamics during each mobility task is needed.   The purpose of this study is to quantify UE kinematics and kinetics of pediatric MWC mobility during three functional tasks: 1) propulsion, 2) starting from a static position, and 3) stopping from steady state propulsion.   We hypothesize that the UE joint dynamics during the start and stop tasks will be significantly greater than during propulsion.

METHODS

Fourteen pediatric MWC users, nine males and five females, with an average age of 13.7 ± 4.8 years, participated at Shriners Hospital for Children – Chicago. Subjects were diagnosed at least one year prior to the study; average time since injury was 5.3 ± 3.9 years. SCI levels ranged from C3 to T10.

A custom pediatric UE biomechanical model, using 27 reflective markers, defined the acromioclavicular glenohumeral (GH) and wrist, joints (three degrees-of-freedom – DOFs) as well as the sternoclavicular and elbow joints (two DOFs) [4].   Subjects propelled their MWCs along a 15 m level tile walkway using a self-selected speed and propulsion pattern. A 14-camera Vicon MX motion capture system and a SmartWheel system, simultaneously collected bilateral kinematic data at 120 Hz and dominant side kinetic data at the hand-handrim interface at 240 Hz, respectively. During the propulsion task subjects propelled their MWC across the room. Ten stroke cycles were analyzed. To remove acceleration and deceleration effects, the first two and last two strokes were excluded. For the start task subjects began at a static position in the center of the room and propelled to the far side. The first stroke was analyzed for each of three trials. For the stop task subjects propelled into the center of the room and stopped. The last stroke cycle of three trials was analyzed. Three-dimensional (3-D) joint dynamics were determined with the model, normalized to 100% stroke cycle, and processed at 1% increments.   Forces and moments were normalized to subject's body weight (% BW) and BW times height (% BWxH), respectively.

RESULTS AND DISCUSSION

Group mean joint forces, and moments (± one standard deviation) of the GH, elbow and wrist joints were characterized over the wheelchair stroke cycle. Mean peak forces and moments at the joints

were also computed (Table 1). A one-way ANOVA with linear mixed model analysis determined statistically significantly different biomechanical parameters among tasks (p<0.05).

We found many significantly different parameters across all joints among mobility tasks. All of the significant differences between the propulsion and start task indicate higher forces and moments during the start task. Most of the statistically different parameters were less during the stop task than the propulsion and start tasks, except for the superiorly directly forces for all joints, and the wrist and elbow joint extension moments, which were greater during stop. Functional tasks of start and stop should therefore be of high concern in regards to long-term joint health in children and adolescents.

In a study of adult MWC users with SCI, Morrow et al. reported only GH joint external rotation and extension moments to be greater than propulsion and found no differences among the tasks for GH joint forces. Our results may be attributed to musculoskeletal development and maturation. Research is currently in progress exploring biomechanical differences of task performance between children and adults.

CONCLUSIONS

The study successfully quantified 3-D UE joint dynamics during pediatric MWC mobility tasks. Results indicate that each of the mobility tasks require differing joint demands. Therefore, while propulsion is one aspect of MWC mobility, functional tasks, such as starting and stopping, should also be evaluated due to their importance in community and home mobility. Further investigation into other factors such as duration of load demands, SCI level, and time of MWC use is underway with a larger population. This knowledge may assist in improving training of functional tasks to reduce high joint demands that are causative of pain and pathology.

THE INFLUENCE OF SPEED AND GRADE ON WHEELCHAIR PROPULSION HAND PATTERN

[1]Jonathan S. Slowik, [2]Philip S. Requejo, [2]Sara J. Mulroy and [1]Richard R. Neptune

[1]The University of Texas at Austin, Austin, TX, USA
[2]Rancho Los Amigos National Rehabilitation Center, Downey, CA, USA

INTRODUCTION

The movement of the hand during manual wheelchair propulsion is closely linked with propulsion mechanics, so the hand pattern (i.e., full-cycle hand path) can provide insight into the user's propulsion technique [1]. However, previous hand pattern analyses have been limited by their reliance on subjective, qualitative characterization methods and/or focus on a single propulsion condition. Pattern characterization has typically involved raters classifying patterns as one of four pattern types (Fig. 1). However, these qualitative methods have difficulty identifying differences between patterns of the same type, and hybrid patterns lead to inconsistencies between raters [1]. In addition, while most hand pattern studies have focused on level propulsion at a self-selected speed, daily living activities can require an individual to propel their wheelchair during different conditions (e.g., at a higher speed or up a graded surface) that may place the upper extremity at a higher risk for injury.

Figure 1: The four hand pattern types: arcing (AR), single loop (SL), double loop (DL) and semi-circular (SC). The solid line denotes contact phase, while the dashed line denotes recovery phase. Also depicted is the handrim radius (r) and the contact angle (θ).

Therefore, the purpose of this study was to develop a set of objective, quantitative parameters to characterize hand patterns and determine the influence of propulsion speed and grade of incline on the patterns preferred by manual wheelchair users.

METHODS

Experimental kinematics and handrim forces were collected from 170 individuals with complete motor paraplegia on a stationary wheelchair ergometer during three conditions [e.g., 2]: level propulsion at self-selected speed (free), level propulsion at fastest comfortable speed (fast), and propulsion at an 8% grade at level self-selected speed (graded). Contact and recovery phase data for each cycle were time-normalized and averaged across cycles. Cadence, contact percentage (CP), and average (F_{avg}) and peak (F_{pk}) resultant handrim forces were also calculated and averaged across cycles. The hand pattern was defined as the path of the third metacarpophalangeal joint projected onto the handrim plane. Each pattern was also objectively characterized by two parameters, net radial thickness (NRT) and total radial thickness (TRT):

$$\text{NRT} = \frac{\sum_{i=1}^{nloops} A_i}{r\theta} \qquad (1)$$

$$\text{TRT} = \frac{\sum_{i=1}^{nloops} |A_i|}{r\theta} \qquad (2)$$

where $nloops$ is the number of loops, A_i is the signed area enclosed by the ith loop of the curve, r is the handrim radius, and θ is the contact angle. A set of basic thresholds were then used to ascertain the pattern type (e.g., Fig. 2). For comparison, a multiple rater system was also used to classify each pattern as one of four types (Fig. 1). To determine if propulsion condition affected the hand pattern, differences in the propulsion variables were assessed using a one-factor repeated measures ANOVA with three levels (α=0.05), followed by

paired t-tests with Bonferroni adjustment if a significant main effect was found.

RESULTS AND DISCUSSION

With pattern type thresholds set at TRT = 0.03m, NRT/TRT = -0.95 and NRT/TRT = +0.95, the objective pattern classification method and the subjective method produced the same results 90% of the time. All variables were found to have a significant propulsion condition main effect. The pairwise comparisons showed that compared to the free condition, the fast condition resulted in significantly higher NRT, TRT, θ, cadence, F_{avg} and F_{pk} and significantly lower CP (Table 1). Compared to the free condition, the graded condition resulted in significantly lower TRT and significantly higher NRT, θ, cadence, CP, F_{avg} and F_{pk}. Compared to the fast condition, the graded condition resulted in significantly lower TRT and significantly higher θ, CP, F_{avg} and F_{pk}.

Increased propulsion speed resulted in a shift away from under-rim hand patterns (e.g., SC), which may be due to the increased velocity of the arm. This would prolong the transition between shoulder flexion and extension at the beginning of the recovery phase and encourage use of a pattern that moves the hand above the handrim. Increased grade of incline resulted in patterns in which the hand remains near the handrim throughout the cycle (e.g., AR), likely because the increased contact percentage requires selection of a short and direct recovery handpath.

The results of the present study suggest that speed and grade significantly influence preferred hand patterns and related parameters. Task-specific constraints and upper extremity demand requirements likely preclude the existence of a single optimal hand pattern for all propulsion conditions.
Figure 2: Hand pattern parameter values across conditions. Regions are labeled with the objective pattern type classification. Propulsion condition is indicated as follows: free (●), fast (■) and graded (▲). Small symbols correspond to individuals, while large symbols correspond to across-subject mean values.

EVALUATING THE ASSUMPTION OF SYMMETRY IN MANUAL WHEELCHAIR PROPULSION

[1]Shelby L. Soltau, [1]Jonathan S. Slowik, [2]Philip S. Requejo, [2]Sara J. Mulroy and [1]Richard R. Neptune

[1]The University of Texas at Austin, Austin, TX, USA
[2]Rancho Los Amigos National Rehabilitation Center, Downey, CA, USA
Email: shelbysoltau@utexas.edu, web: http://www.me.utexas.edu/~neptune/

INTRODUCTION

Manual wheelchair propulsion is commonly assumed to be a symmetric task. The rationale is that asymmetry would make straight-line propulsion difficult due to the uncoupled nature of the wheels, and therefore experienced wheelchair users develop symmetrical propulsion mechanics over time [e.g., 1]. However, few studies have tested this assumption. The limited number of studies is partly due to the lack of instrumentation to measure bilateral kinetics. While instrumented wheels are available to measure handrim kinetics, many laboratories are equipped with only one instrumented wheel due to the high cost [3]. Thus, the switching of wheels and multiple trials are required for bilateral measurements.

Despite these challenges, a number of studies have examined side-to-side differences in propulsion mechanics. However, there is a lack of consensus as to whether asymmetry exists. Early studies have suggested that bilateral propulsion mechanics are symmetric [e.g., 1, 2], while more recent studies have suggested they are not [e.g., 3]. Part of the lack of consensus may be due to the limited number of subjects analyzed and conditions under which symmetry was investigated (e.g., at a single speed). Asymmetry may become more prevalent as the task demands increase such as at higher speeds or on a graded surface.

Therefore, the purpose of this study was to evaluate bilateral symmetry in manual wheelchair propulsion with a large number of subjects across different propulsion conditions (self-selected, fast and graded). These results have important implications for the experimental setups in future analyses of wheelchair propulsion mechanics.

METHODS

Data collected from 80 individuals with paraplegia who were free of shoulder pain and used a manual wheelchair at least 50% of the time for community mobility were analyzed (74 men; age: 37.0±9.9 yrs; time from injury: 9.0±6.6 yrs; height: 1.72±0.09 m; mass: 74.5±16.9 kg). Participants propelled a stationary wheelchair ergometer during three conditions [e.g., 4]: level propulsion at their self-selected speed (free), level propulsion at their fastest comfortable speed (fast), and propulsion on an 8% grade at their level self-selected speed (graded).

Subjects acclimated to each condition until they felt comfortable and a 10-second trial was recorded for each condition. Data was collected separately from both the dominant and non-dominant sides, with the side tested first being randomly selected. Handrim forces were collected using an instrumented handrim (SmartWheel, 200 Hz) along with 3D kinematic data (CODA, 100 Hz) from the wheel, trunk and ipsilateral upper extremity. Shoulder and elbow joint ranges of motion (ROMs), peak and average tangential and resultant forces, fraction effective force, cycle time, push percentage and push angle were calculated for each cycle and averaged across cycles for each subject during each condition.

Differences in quantities were compared using two-factor (condition, arm) repeated measures ANOVAs. The condition factor consisted of three levels (free, fast and graded) and the arm factor consisted of two levels (dominant and non-dominant). If an ANOVA had a significant interaction effect, pairwise comparisons were performed using paired t-tests with a Bonferroni adjustment for multiple comparisons. The unadjusted threshold for statistical significance for

all analyses was set at α=0.05. Condition main effects and pairwise differences between conditions were not reported.

RESULTS AND DISCUSSION

Elevation angle, shoulder rotation, and elbow flexion ROMs had significant side main effects (Table 1), with larger values in the dominant side. Elevation plane, shoulder rotation and forearm pronation ROMs as well as push angle had significant interaction effects. There were no other side main effects or interaction effects in any of the kinematic, kinetic or spatiotemporal measures. Pairwise comparisons revealed that elevation plane, shoulder rotation and forearm pronation ROM values as well as the push angle were significantly larger in the dominant side during the graded condition. There were no significant differences between sides for these variables during the free and fast conditions. All differences were below 5 degrees except for shoulder rotation ROM during the graded condition.

These results suggest that low levels of asymmetry exist in manual wheelchair propulsion, particularly during graded conditions when the upper extremity demand is high. However, the side-to-side differences were generally smaller than differences between conditions or between individuals. Thus, the clinical significance of these differences should be carefully considered.

In conclusion, the assumption of symmetry is likely reasonable when analyzing groups of subjects without secondary injury or pain in their upper extremities and the study conclusions are likely not to be influenced by these low levels of asymmetry.

INTRODUCTION

Lumbar multifidus (LM) is considered a key muscle group in spinal stability. Change in muscle quality, contractile properties, and reduced activation has been associated with low back pain (LBP). Reduced LM activation has been associated with higher number of predictors for patients requiring rehabilitative exercises [1]. Larger impairments in muscle quality are predictive of LBP, as well as being thought to play a role in recurrence. LM does not recover automatically and general exercise is ineffective in restoring its function [2]. Neuromuscular electrical stimulation (NMES) provides a method to improve activation of muscle, and thus reverse contractile and quality impairments [3]. However, it is currently unknown if NMES can selectively target LM due to anatomy of the lumbar region, nor if it can provide adequate therapeutic dosage of muscle activity to propagate change. Electrical signal interference of the NMES makes use of EMG in studying muscle activity with NMES difficult. Near infrared spectroscopy (NIR) identifies blood flow patterns associated with muscle contraction, does not have interference making it an option for the study of NMES on the LM. The aim of this study was to determine if 1) NMES activity can be isolated to the LM, and 2) a predictive relationship could be built using an EMG and NIR model, that could demonstrate therapeutic benefit through muscle overload.

METHODS

Ten healthy subjects performed 3 tasks of varying trunk extensor activation: Modified Sorensen, and Multifidus lift tests (MLT) with varying weights [4]. Simultaneous SEMG and continuous wave NIR were collected for LM, lumbar erector spinae (LES) and thoracic erector spinae (TES). Subjects then received NMES to the LM with NIR collected at LM, LES, and TES.

For NIR, light absorption changes of 730nm and 850 nm were converted to changes in oxygenated hemoglobin (HbO2) and deoxygenated hemoglobin (Hb) using the Beer-Lambert Law. A logarithmic ratio of absorption for the two wavelengths was used to create arbitrary units (AU) for HbO2 and Hb with resting values set to 0 AU.
Figure 1: Example of HbO2 changes of the LM, LES, and TES during administration of NMES to LM for a single subject.

ANOVA of mean LM, LES, and TES AU were performed to determine NMES' ability to isolate activation of LM.

EMG was heart rate stripped, RMS rectified (Tc=30ms) and normalized to the Modified-Sorensen (sMVIC). Pearson correlation was performed between EMG amplitude and NIR variables that were time synchronized during the

MLT lift tests. Results from the linear regression were used to predict a percentage of the sMVIC during NMES across 10 subjects. A paired t-test of the predicted percent sMVIC of the 1st and 5th NMES stimulations were performed to determine if NMES could provide adequate dosage to overload the LM to achieve therapeutic benefit.

RESULTS AND DISCUSSION

An example of HbO2 plot over time, during NMES elicited contraction (**Fig 1**). LM demonstrated significantly greater HbO2 levels (mean=1.15 AU ± 0.8) compared to the LES (mean=0.3 ±0.8) and the TES (mean=0.2 ±0.45), $F_{(1,39)}$=39.21, p<.001. This supports the ability of NMES to isolate contraction to the LM.

LM HbO2 vs LM EMG yielded the highest correlations (p< .05, r=.81). Plots of these variables demonstrated a linear best-fit line; therefore, HbO2 and EMG amplitude of the LM were entered into a linear regression to predict the percentage of sMVIC produced by NMES (**Fig. 2**).
Figure 2: Plot of LM HbO2 and EMG amplitude, with linear regression results (adjusted R^2).

Group average predicted percentage of the sMVIC produced by the NMES (**Fig.3**). Individual subjects produced as high as 100% of the sMVIC in the first trial and as low as 8% of the sMVIC by the 5th trial. There was a significant difference in percent sMVIC produced by the NMES from the 1st to 5th trial, p<.05, demonstrating the ability of NMES to produce progressing levels of fatigue in the LM.
Figure 3: NIR predicted average percentage of LM sMVIC produced by NMES.

CONCLUSIONS

The current study demonstrates that NMES can isolate LM activity to at least 43% of the activation that occurs during a Modified-Biering Sorensen maneuver. It also demonstrates the ability to cause progressive fatigue to the LM within 5 trials. The result suggests that this modality has the potential to cause muscle overloading fatigue with potential to provide a therapeutic effect. This makes NMES a theoretically useful adjunctive treatment in patients with LBP, especially those who have difficulty with voluntary recruitment of this muscle.

Overload of the muscle is required to reverse atrophy and gain muscle hypertrophy. This is not possible in the presence of impairments in muscle activation. NMES has been shown to be effective in reducing these activation impairments and aiding in muscle hypertrophy [3]. In patients with LBP, similar ability to preferentially activate LM to therapeutic levels may be beneficial in recovery of this muscle and reversing changes associated with low back pain.

OPTIMAL RUNNING PROSTHESES
FOR SPRINTERS WITH BILATERAL LEG AMPUTATIONS

[1]Paolo Taboga, [1]Owen N Beck, [1,2]Alena M Grabowski

email: paolo.taboga@colorado.edu

INTRODUCTION

To run and sprint, athletes with leg amputations use running-specific prostheses (RSPs), which are comprised of carbon-fiber and intended to replicate the spring-like sagittal plane actions of a biological ankle. RSPs store elastic energy in the first half of stance and release a large portion of this energy in the second half of stance. However, the compliance and passive nature of RSPs impairs the rapid application of vertical force on the ground [1], which is the primary determinant of maximum sprinting speed [2]. Additionally, at speeds ≥6 m/s, non-amputee runners progressively increase their normalized leg stiffness (K_{leg}) with speed, while sprinters with unilateral leg amputation maintain the same K_{leg} in their unaffected leg and decrease K_{leg} in their affected leg [1]. Thus, we hypothesized that stiffer RSPs would allow faster top sprinting speed compared to softer RSPs. Since K_{leg} is influenced by the change in total leg length, we hypothesized that increasing RSP height would permit faster top sprinting speed.

METHODS

Three male sprinters with bilateral transtibial amputations gave written informed consent to participate (Table 1). A certified prosthetist fit each athlete with three different models of RSPs. The recommended stiffness category was selected based on each manufacturer's suggestion and the recommended height was set at the maximum allowable height (Ht0) for each runner according to IPC rules [3]. If Ht0 could not be set due to RSP design and residual limb anatomy, the baseline height was set as close to Ht0 as possible.

Each sprinter performed three sprint trials at the recommended, +1, and -1 stiffness categories for each RSP model in a randomized order, while maintaining the baseline height. Then, the category that allowed the top running speed for each model was selected and height was changed (±2cm with respect to baseline height) to determine the effect on top sprinting speed.

Each set of sprint trials started at 3 m/s with speed incremented by 1 m/s until subjects approached their top speed. Then, smaller speed increments were employed until subjects reached their top speed, which was defined when subjects could not maintain their position on the treadmill for ten consecutive strides.

All trials were performed on a 3D force-measuring treadmill (Treadmetrix, USA) (1000Hz). We used a custom Matlab program (MathWorks, USA) to condition signals (30Hz low-pass Butterworth filter) and determine contact time (t_c), and peak vertical ground reaction forces ($vGRF_{peak}$). We calculated K_{leg} as:

$$K_{leg} = \frac{vGRF_{peak}}{\Delta L}\left(\frac{L_0}{BW}\right)$$

where L_0 is leg length, ΔL is leg length change during stance and BW is body weight [1].

We used a statistical linear mixed model to determine the effects of RSP model, stiffness, and height on top speed. Then, we used another linear mixed model to predict top speed based on $vGRF_{peak}$, t_c, and K_{leg}.

RESULTS AND DISCUSSION

The linear mixed model showed no significant effect of RSP model or stiffness category (p = 0.07 and p = 0.27, respectively), but an inverse relationship between prosthetic height and top speed (Fig. 1):

$$TopSpeed = 9.69 - 0.06 \times Ht$$
$$(r^2=0.54, p<0.001)$$

For every centimeter increase in prosthetic height, there was a 0.06 m/s decrease in top speed.
Figure 1: Top speed for each subject and condition relative to Ht. Dashed line is the regression line.

The second linear mixed model showed an inverse relationship between t_c and top speed, but no effect of vGRFpeak and K_{leg} (p=0.83 and p=0.81, respectively) (Fig 2):

$$Top\ Speed = 13.09 - 29.13 \times t_c$$
$$(r^2=0.15, p=0.02)$$

For every 0.01 s increase in t_c, there was a 0.29 m/s decrease in top speed.

LIMITATIONS

To date, three subjects with bilateral leg amputations participated in our study. We intend to recruit more subjects in order to improve our statistical power. Subject 1's starting height on RSP 1 was set at +10 cm compared to Ht0, due to his long residual limbs; the RSP height was then increased by 2 and 4 cm. Subject 3's starting height
Figure 2: Top speed as a function of contact time (tc). The dashed line is the regression line

on RSP 3 was set at -3 cm compared to Ht0 due to the dimensions of RSP 3 and the existing attachments on his running sockets; the height was then shortened by 2 and 4 cm.

CONCLUSIONS

Contrary to our initial hypothesis, we found that taller prostheses reduced top sprinting speed, while RSP model and prosthetic stiffness category had no significant effect. Across the different RSP configurations, sprinters with bilateral leg amputations achieved faster sprinting speeds by shortening contact time.

INTRODUCTION

To run and sprint, athletes with leg amputations use running-specific prostheses (RSPs), which are comprised of carbon-fiber and intended to replicate the spring-like sagittal plane actions of a biological ankle. RSPs store elastic energy in the first half of stance and release a large portion of this energy in the second half of stance. However, the compliance and passive nature of RSPs impairs the rapid application of vertical force on the ground [1], which is the primary determinant of maximum sprinting speed [2]. Additionally, at speeds ≥6 m/s, non-amputee runners progressively increase their normalized leg stiffness (K_{leg}) with speed, while sprinters with unilateral leg amputation maintain the same K_{leg} in their unaffected leg (UL) and decrease K_{leg} in their affected leg (AL) [1]. Thus, we hypothesized that stiffer RSPs would allow faster top sprinting speed compared to softer RSPs. Since K_{leg} is influenced by the change in total leg length, we also hypothesized that increasing RSP height would permit faster top sprinting speed.

METHODS

Three sprinters (2M, 1F) with unilateral transtibial amputations gave written informed consent to participate (Table 1). A certified prosthetist fit each athlete with three different models of RSPs. The recommended stiffness category was selected based on each manufacturer's suggestion and the height was adjusted based on the prosthetist's experience.

Each sprinter performed three sprint trials at the recommended, and ±1 stiffness categories for each RSP model in a randomized order, while maintaining the baseline height. Then, the category that allowed the top running speed for each model was selected and height was changed (±2cm with respect to baseline height) to determine the effect on top sprinting speed.

Each set of sprint trials started at 3 m/s with speed incremented by 1 m/s until subjects approached their top speed. Then, smaller speed increments were employed until subjects reached their top speed, which was defined when subjects could not maintain their position on the treadmill for ten consecutive strides.

All trials were performed on a high-speed 3D force-measuring treadmill (Treadmetrix, USA). We used a custom Matlab program (MathWorks, USA) to condition signals (30Hz low-pass Butterworth filter) and determine contact time (t_c), and peak vertical ground reaction forces ($vGRF_{peak}$) of UL and AL separately. We calculated K_{leg} as:

$$K_{leg} = \frac{vGRF_{peak}}{\Delta L}\left(\frac{L_0}{BW}\right)$$

where L_0 is leg length, ΔL is leg length change during stance and BW is body weight [1].

We used a statistical linear mixed model to determine the effects of RSP model, stiffness, and height on top speed. Then, we used another linear mixed model to predict top speed based on $vGRF_{peak}$, t_c, and K_{leg} of the UL and AL.

RESULTS AND DISCUSSION

While controlling for other variables, across all conditions, RSP 2 and RSP 3 elicited 8% (p=0.004) and 11% (p<0.001) faster speeds compared to RSP 1. For RSP 1, every increase in stiffness category reduced top sprinting speed by 5% (p=0.02) (Fig. 1), while every 1 cm increase in Ht elicited a 7% decrease in top sprinting speed (p<0.001). Stiffness category and Ht showed no statistically significant effect on top speed for RSP 2 and RSP 3.
Figure 1: Top speed for each subject and condition relative to Stiffness category. Solid lines are the regression lines for each RSP model.

The second linear mixed model showed that, while controlling for other variables, a 0.01 s increase in t_c for the AL or UL reduced top speed by 4% or 6% respectively ($p<0.001$) (Fig. 2a), 1 BW increase in $vGRF_{peak}$ for the AL or UL increased top speed by 7% or 6% respectively ($p<0.001$) (Fig. 2b), and a 1 unit increase in Kleg for the AL or UL, reduced top speed by 1% ($p<0.001$).

LIMITATIONS

To date, three subjects with unilateral leg amputations participated in our study. We intend to recruit more subjects to improve our statistical power. Subject 3's lowest attainable height on RSP 2 was -1 cm due to the dimensions of the RSP 2 and the length of her residual limb.

CONCLUSIONS

RSP 2 and RSP 3 allowed subjects to reach faster sprinting speeds compared to RSP 1. Stiffness and category showed a statistically significant effect only on RSP 1, with faster top speed achieved with a softer category and lower height. Faster top speeds are achieved, among all conditions, by shortening t_c, increasing $vGRF_{peak}$ and lowering Kleg.

Motor learning effects on variability in goal-directed upper limb movements using time warping analysis

[1] Sibylle B. Thies, [2] Alaa A. Ahmed and [1] Laurence P.J. Kenney

[1] The University of Salford, Manchester, UK
[2] University of Colorado at Boulder, Boulder, Colorado, USA
email: s.thies@salford.ac.uk

INTRODUCTION

We previously introduced a novel methodology, based on dynamic time warping, to calculate measures of timing and amplitude variability over entire movement trajectories [1]. Our methodology has the advantage that it separates out the two elements of trial-to-trial variability: temporal and amplitude variability. As a first demonstration of the method, we established a link between upper limb movement variability calculated using these measures and neurological impairment [1]. A subsequent study built on our approach and used it successfully to identify differences in trajectory variability when comparing stroke survivors with right and left hemisphere lesions to one another as well as to healthy controls [2]. However, while both studies showed that our new methodology identified increased trajectory variability in patients with stroke, compared with controls, the merits of the new methodology for characterizing upper limb movements in relation to motor learning have yet to be explored. Hence it is the objective of this study to determine whether temporal and amplitude variability can serve as metrics for motor learning.

METHODS

Ten young and twelve older adults performed repeated goal-directed reaching movements from a home circle to a target in the horizontal plane (Fig.1). A rehabilitation robot provided corresponding position data that was then assessed for trial-to-trial variability. Temporal variability (Warp Cost) was determined utilizing dynamic time-warping for curve registration since such an approach allows for assessment of signal variations in time. Amplitude variability was defined as the remaining RMS error between signals. Variability was investigated for repeated trials of three conditions 1) unperturbed reaching: 'Null', 2) immediately after onset of a force perturbation: 'Force 1', and 3) after prolonged exposure to the force perturbation: 'Force 2'. Effects of 'condition' and 'age group' were assessed with General Linear Mixed Effect Models (SPSS), and the accuracy with which variability measures classified subjects to belong to their respective group was determined. Finally, variability measures were compared to a commonly used metric of motor learning, Movement Error (deviation from a straight line), via calculation of Pearson's correlation coefficient.
Figure 1: Illustrations of the experimental design. A: Setup. B: Experimental Protocol. Shaded areas represent the trials used for data analysis. C: Schematic of perturbing forces on a forward reach (arrows are equally spaced in time).

RESULTS AND DISCUSSION

An established measure of motor-learning in goal-directed upper limb movements is Movement Error [3,4]. Movement Error typically increases with the onset of a novel perturbation force, and decreases as motor learning progresses with prolonged exposure to the force. In agreement with this we likewise found that for both, young and older adults, both

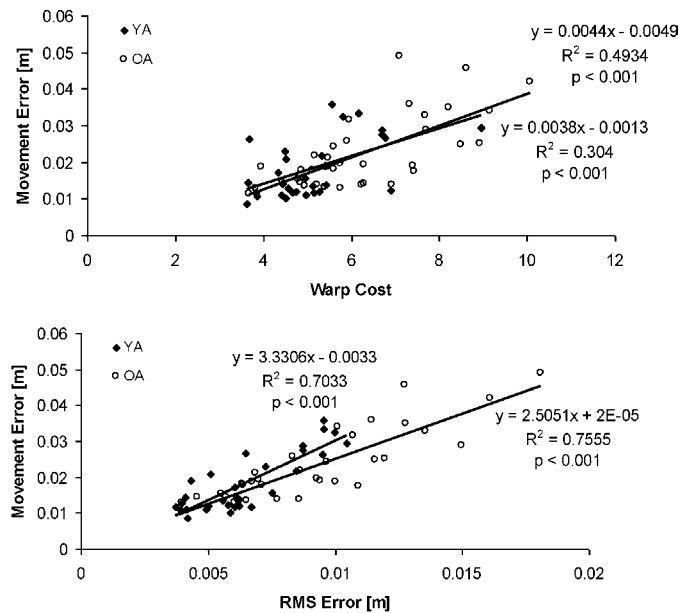
trial-to-trial variability measures increases with onset of a perturbation force and decreases over prolonged exposure to the force (p<0.01 for all pairwise comparisons) (Table 1). Moreover, both variability measures correlated positively with Movement Error (Fig. 3). Finally, older adults exhibited greater variability than young adults (p<0.01) (Table 1), and Warp Cost classified 80% of young adults and 66.7% of older adults correctly to be in their respective group, while RMS Error classified both, young and older adults with 100% accuracy to belong to their respective groups.


Figure 3: Correlations of Warp Cost (top) and RMS Error (bottom) versus Movement Error. YA: young adults; OA: older adults.

CONCLUSIONS

Considering the healthy test population and the simplicity of the task, a single goal-directed movement towards a target, it is encouraging that variability measures proved informative even though not many directional changes during task performance were required to complete the task successfully. Hence this study adds to the existing literature [1, 5, 6] on the sensitivity and use of movement variability measures for the assessment of upper limb performance.

This study used data from a motor-learning experiment to investigate the merit of temporal and amplitude variability as a proxy for conventional metrics of motor learning. While in this study trial-to-trial variability was computed from planar position data of an expensive rehabilitation robot, variability could equally be calculated from signal trajectories derived from an alternative, low cost device, such as an accelerometer restricted to move on a low friction planar surface between two targets. Hence we identified the potential for development of an inexpensive clinical assessment method for the upper limb.

MECHANICAL PROPERTIES OF DYNAMIC ELASTIC RESPONSE PROSTHETIC FEET

Christina M. Webber and Kenton R. Kaufman

Mayo Clinic, Rochester, MN, USA
email: kaufman.kenton@mayo.edu

INTRODUCTION

In comparison with basic prosthetic feet, dynamic elastic response (DER) prosthetic feet more closely mimic the native ankle joint, storing and returning energy throughout the gait cycle [1, 2]. This is particularly beneficial to amputee patients who lead active lives.

With countless prosthetic foot manufactures and models, it can be difficult to compare various options when prescribing a prosthetic foot. Both functional and mechanical testing of prosthetic feet provides important information to prosthetists and patients [2]. While many groups have studied the functional characteristics of DER feet, few have focused on the more objective testing of the mechanical properties that is not influenced by intersubject variability [1]. Therefore, the purpose of this study was to test the mechanical properties of DER feet in a standardized and repeatable manner. In particular, the stiffness and hysteresis of the heel and forefoot regions of commercially available DER feet was investigated.

METHODS

DER feet, coded as L5986 and L5987, from four different manufacturers (Table 1) were compared. All feet were 27 cm and recommended for a hypothetical male patient, described as high activity with a right side below-knee amputation, weighing 200 lbs. An MTS 858 Mini Bionix II servohydraulic test system (Eden Prairie, MN) was used to test each specimen in compression. Stiffness testing was conducted adhering to the Static Proof Test detailed in ISO Standard 10328 [3]. Testing was not conducted to failure.

Each foot was tested with the manufacturer-provided foot cover. A compressive load was applied to the foot at 100 N/s until the load reached 2240 N, per ISO 10328. The system was then completely unloaded at the same rate. Both the heel and forefoot regions of all feet were tested in three successive compression trials. During compression, the load and displacement were measured using a uniaxial load cell and linear variable differential transformer, respectively. Data were collected using Multipurpose TestWare software (MTS, Eden Prairie, MN) at 20 Hz. Heel and forefoot stiffness was observed as the slope of the load-displacement curve for each prosthetic foot. Hysteresis, the difference between the loading input energy and unloading energy, was calculated for the heel and forefoot testing of each DER foot.

RESULTS AND DISCUSSION

There were differences in stiffness for the heel (Fig. 1) and forefoot (Fig. 2) of all DER feet tested. During walking over level ground, a person will experience a peak ground reaction force of approximately 1.2 times body weight [4]. At this loading level, the heel and forefoot of feet A and B were stiffer than feet C and D. If that same patient was to run at a moderate pace, they would experience a peak ground reaction force of approximately 2.5 times body weight [4]. At this loading level, the stiffness was increased, and heel stiffness was greater than forefoot stiffness. The relative rank of stiffness for feet A and B changed for heel loading, but not for forefoot loading. A greater displacement was observed for all DER feet when loaded at the forefoot.

Hysteresis varied between samples under the different loading configurations (Fig. 3). Feet with higher stiffness had greater energy loss at both the heel and forefoot.
Figure 1: Representative load-displacement curves for heel loading and unloading of DER feet
Figure 2: Representative load-displacement curves for forefoot loading and unloading of DER feet
Figure 3: Average hysteresis of heel (solid) and forefoot (crosshatch) of DER feet ± SD

CONCLUSIONS

When used with the functional kinematic data already present in literature, the stiffness and hysteresis data for commercially available prosthetic feet can be used to guide prosthetic prescriptions of DER feet.

INTRODUCTION

The prosthetic socket is a critical component of the prosthesis and greatly impacts comfort, functional performance, and overall user satisfaction with a prosthesis. Therefore, every prosthetic socket is custom made for each amputee in order to create an intimate fit to maximize comfort and create a strong biomechanical connection. Critical parameters to control to achieve these goals are socket geometry/volume and the method of suspension. However, current clinical practices lack quantitative analysis of socket fit, leaving prosthetists with limited tools with which to determine whether appropriate socket fit has been achieved. Prosthetists are currently limited to using feedback from the amputee, visual inspection of movement and skin blanching, as well as previous experience. The socket fitting procedures would greatly benefit from a process to provide prosthetists with empirical data upon which they can base clinical decisions. A few studies have aimed at measuring socket fit and suspension using x-ray techniques[1,2,3] and optical techniques[4]. Although these techniques were able to measure movement between the socket and residual limb, the techniques themselves were not clinically practical because the data had to be collected at rest or during simulated phases of gait, required large expensive equipment, or required that parts of the socket be removed.

Elevated vacuum suspension creates sub-atmospheric pressure between the prosthetic socket and the interface material. Preliminary work suggests that monitoring the change in sub-atmospheric environment during volitional movement of the amputee can enable a clinically relevant method of assessing socket fit, specifically looking at movement between the limb and socket. The underlying principle stems from Boyle's Law which states that, assuming a closed system, pressure is inversely related to volume. Therefore, if there is a change in the vacuum pressure, it must be a result of a change in volume between the liner and socket wall, and there must be movement of the residual limb relative to the socket. The purpose of this work is to evaluate the correlation between vacuum pressure fluctuation and distal displacement and to determine the ability of these outcomes to assess socket fit.

METHODS

The testing protocol was divided into benchtop and subject based testing to evaluate the correlation and clinical relevance of vacuum pressure socket fit.

Benchtop Testing: The purpose of this test was to isolate socket fit as the experimental factor. Three different residual limb models were made from a hard plastic core surrounded by a layer of thermoplastic elastomeric material. These models were designed to all fit within a carbon fiber socket.

The amount of vertical displacement and amount of vacuum pressure fluctuation were evaluated for each residual limb model by suspending them across the linkages of a tension-compression machine. The machine was programmed to produce similar amounts of vertical tension and compression in a cyclic pattern for 12 seconds at a frequency of 1.25 Hz. Three different tension and compression values were used in the study, simulating a low, normal, and high force expected during gait. The different residual limb models were placed in the test socket and elevated vacuum suspension applied according to the specified treatment level. Five treatment levels for vacuum setting were used: vacuum set for 5, 9, 13, 16, or 20 inHg. Three repetitions at each treatment were performed. Simultaneous vacuum pressure data measured by the LimbLogic Vacuum System and displacement

data measured by the testing apparatus were collected.

Figure 1: The three models used to simulate socket fit conditions in the benchtop testing.

Subject Testing: Vacuum pressure data was collected from one transfemoral amputee during ambulation. For each trial, vacuum pressure and kinematic data was streamed from the LimbLogic Vacuum System (Ohio Willow Wood, Mt. Sterling, OH).

The ambulation task was repeated for a series of treatment conditions to assess changes in residual limb volume and changes in socket volume. To evaluate changes in residual limb volume, subject testing occurred on two different testing days approximately one month apart. To achieve changes in socket volume, two different sized sockets were made. The subject also wore prosthetic liners with different thicknesses in each of the sockets produce additional changes in fit. Verbal feedback from the patient was also recorded. This was recorded on both testing days as well as after one week of at-home use following the second data collection day.

RESULTS AND DISCUSSION

The benchtop testing demonstrated that the amount of displacement decreased as the vacuum pressure setting increased, consistent with preliminary data. Similarly, distinct trends in the data regarding socket fit were identified. Strong correlations exist between vacuum pressure fluctuation and the amount of vertical displacement, though correlation values and regression results were influenced by socket fit. Two of the models exhibited similar but slightly different results, while the third model resulted in drastically different data. This third result is not surprising due to the visible difference in socket fit when compared to the other two models.

The subject testing corroborated the benchtop testing. Even though the subject was able to comfortably don both sockets with each liner combination while in the clinic, and reported that each socket felt comfortable, differences were found to exist with the vacuum pressure data. Interestingly, after a week of at-home use, the subject reported that one of the sockets, which corresponded to the socket which had the most movement during the testing days, became uncomfortable after extended periods of use and was rejected. The subject testing also showed that differences in residual limb volume can impact movement of the prosthesis relative to the residual limb. Overall, the socket with the lowest amount of movement was found to be the most comfortable by the patient. Presumably this may be related to a reduction of adverse forces placed on the limb tissues and a superior mechanical connection with the artificial limb.

The technique used in this study to quantify socket mechanics represents a clinically relevant method because it can be supported using existing prosthetic hardware. The ability to assess socket fit can be a useful tool to clinicians to help make more informed decisions. Further research can help identify salient features or trends that can guide the clinical practice of fitting a prosthetic socket. Further work is needed to quantify socket fit in non-elevated vacuum suspension systems which have been shown to exhibit more movement at the socket interface[4,5].

DESIGN OF TWO LIGHTWEIGHT HIGH BANDWIDTH, TORQUE-CONTROLLED ANKLE EXOSKELETONS

Kirby Ann Witte and Steven H. Collins

Carnegie Mellon University, Pittsburgh, PA, USA
Email: kwitte@andrew.cmu.edu, web: http://biomechatronics.cit.cmu.edu

INTRODUCTION

Lower-limb exoskeletons have the potential to enhance rehabilitation [1], assist walking for people with gait impairments, reduce the metabolic cost of normal and load-bearing walking [2], improve stability and probe interesting questions about human locomotion. Designing effective lower-limb exoskeletons may be simplified by focusing on a single joint. During walking, the ankle produces larger peak torques and performs more positive work than either the hip or the knee [3], thereby making it an effective location for assistance.

The ankle joint experiences a wide range of velocities during walking, with plantarflexion occurring rapidly. It is therefore desirable to have high bandwidth and high torque capabilities to accurately produce a wide variety of torque profiles.

Many exoskeletons have been developed employing different approaches to design, actuation and control, but the most effective mechanical methods of assisting the ankle remain unclear. The process of developing and testing our devices has produced several guiding principles of exoskeleton design that may influence future exoskeleton development.

METHODS

We designed, built and tested two ankle exoskeletons, here called Alpha and Beta, for use with a tethered emulator system (Fig 1 A) described in detail in [5]. Both exoskeletons feature strong lightweight frames, comfortable three-point contact with the leg, series elastic elements for improved torque control [4], modularity, structural compliance in selected directions, and sensors for measuring torque, joint angle, and phase of gait.

Torque is controlled using a combination of proportional feedback, damping injection and iterative learning during walking tests. Series elasticity is provided by leaf springs in the Alpha design and a coil spring in the Beta design. Spring type strongly affected the overall exoskeleton envelopes.
Figure 1: Emulator system and exoskeletons. **A** The testbed comprised a powerful off-board motor and controller, a flexible transmission, and an ankle exoskeleton end-effector. **B** The Alpha design. Each exoskeleton contacted (1) the heel with a string, (2) the shin using a strap, and (3) the ground with a hinged plate embedded in the shoe. The Bowden cable conduit attached to (4) the shank frame, while the Bowden cable terminated at (5) the series spring. **C** The Beta design. In addition to (1-5), this device has (6) a titanium ankle lever made using direct-metal additive manufacturing and (7) a tubular carbon fiber Bowden cable support.

The Alpha device (Fig. 1B) was designed to provide compliance in selected directions. The Beta exoskeleton (Fig. 1C) was designed to reduce overall envelope. Benchtop tests quantified system-wide closed-loop torque bandwidth, and walking trials quantified torque tracking error while verifying that large torques could be comfortably applied. Both ankle exoskeletons interface with the foot under the heel, the shin below the knee, and the ground beneath the toe. The exoskeleton frames include rotational joints on either side of the ankle, with axes of rotation approximately collinear with that of the human joint (Fig. 1 B, C).

The exoskeletons were designed to provide greater peak torque, peak velocity and range of motion than observed at the ankle during unaided fast walking. The Alpha and Beta devices can deliver peak plantarflexion torques of 120 Nm and 150 Nm respectively. The Alpha and Beta devices both have a range of motion of 30° in plantarflexion to 20° in dorsiflexion.

We tested closed-loop torque control by commanding 50 Nm and 20 Nm linear chirps in desired torque while the exoskeletons were worn by human users.

RESULTS

The total mass of the Alpha and Beta exoskeletons were 0.835 and 0.875 kg, respectively. The gain-limited closed-loop torque bandwidths of the Alpha device with 20 Nm and 50 Nm peak torques were 21.1 Hz and 16.7 Hz, respectively. The phase-limited bandwidths for the Beta device, at a 30° phase margin, with 20 Nm and 50 Nm peak torques were 24.2 Hz and 17.7 Hz, respectively. In walking trials with the Alpha device, the peak average measured torque was 80 Nm. The maximum observed torque was 119 Nm. The root mean square (RMS) error for the entire trial was 1.7 ± 0.6 Nm, or 2.1% of peak torque, and the RMS error of the average stride was 0.2 Nm, or 0.3% of peak torque. With the Beta device, the peak average measured torque during walking was 87 Nm. The maximum observed torque was 121 Nm. The RMS error for the entire trial was 2.0 ± 0.5 Nm, or 2.4% of peak

torque, and the RMS error of the average stride was 0.3 Nm, or 0.4% of peak torque.

DISCUSSION

The measured bandwidth, peak torque capability, and mass of both exoskeletons compare favorably with existing devices and with human ankle musculature. In walking tests, we demonstrated robust, accurate torque tracking and the ability to transfer large dynamic loads comfortably to a variety of users. Our results demonstrate that these exoskeletons can be used to rapidly explore a wide range of control techniques and robotic assistance paradigms as the primary elements of versatile, high-performance testbeds.

The three point interface featured in both devices was comfortable and effective. Leaf springs and coil springs were effective series elastic elements. Leaf springs were lighter, but also less robust and more bulky than the coil spring. Strain gauges used in the Beta device were lighter, less expensive, and more effective than the load cell used in the Alpha exoskeleton. The reduced envelope of the Beta exoskeleton was achieved by an acceptable reduction in compliance. These results provide insights into desirable properties of lower-limb exoskeleton hardware, which may inform future designs.

SEVERITY OF FUNCTIONAL IMPAIRMENT INFLUENCES REACH KINEMATICS IN PEOPLE POST STROKE

[1,2]Clinton J. Wutzke, [2]Evan Chan, [2]Michelle Harris-Love

[1]Veterans Affairs Medical Center, Washington DC, USA
[2]National Rehabilitation Hospital, Washington DC, USA
email: clinton.wutzke@va.gov,   web:www.reachingrehab.org

INTRODUCTION

Although people post stroke with severe functional impairment have the greatest need for rehabilitation to attain a higher level of function, few studies have examined reaching movement patterns in this population [1,2]. Differences between levels of functional impairment in people post stroke may indicate a need to optimize rehabilitation paradigms.

The purpose of this study was to determine the influence of functional impairment on seated reaching in people post stroke. We hypothesized people post stroke with severe upper extremity functional impairment have slower movement patterns and greater between subject variability than people with mild functional reaching impairment.

METHODS

Twenty-eight people post stroke ($\bar{x}$ UEFM: 32.9$\pm$20.4, $\bar{x}$ age: 60.1$\pm$9.4 years; 19M/9F) participated in this study. Categorization of functional impairment (mild or severe) was determined by score on the Upper Extremity Fugl-Meyer (UEFM, range: 0-66).

Participants were seated in an adjustable chair with chest restraints to limit movement of the trunk. Subjects completed 20 forward reaches with the paretic arm. Trials were initiated from a common starting position. Participants reached forward to 80% of his/her maximal reach to two targets located on a flat, level table. Subjects were asked to reach forward and touch the target as quickly as possible following a visual go stimulus.

Movement of the paretic arm was tracked using an Optotrak (NDI, Waterloo, CAN) motion capture system with a marker placed on the ulnar styloid of the paretic arm. Temporal (response time, reaction time, movement time) and spatial (peak velocity, initial directional error, and end point error at peak velocity, movement units, path length) variables were calculated for the paretic arm using custom MatLab programs. Between subject variability was calculated as the coefficient of variation within each functional group (mild/severe). A one-way ANOVA (severity) was conducted with significance determined a priori at α=0.05.

RESULTS AND DISCUSSION

Fifteen participants ($\bar{x}$ UEFM: 16.0$\pm$7.9, 8M/7F) were identified as severely impaired and 13 participants ($\bar{x}$ UEFM: 52.3$\pm$9.7, 11M/2F) were categorized as mild functional impairment (p<0.001).

Temporal and spatial measures of reaching differed between people post stroke with severe and mild functional impairments. Temporal variables (response time, reaction time, and movement time) were greater for people with severe impairment compared to people with mild impairment (response time: F=10.8, p=0.003, Table 1; reaction time: F=22.3, p<0.001; movement time: F=5.2, p=0.031; Figure 1).

Anterior/posterior peak velocity was greater in people with mild impairment compared to people with severe impairment (F=18.1, p<0.001, Table 1). Deviation from ideal path at the start (initial error, F=10.6, p=0.003, Figure 1) and at peak velocity in relation to the target (end point error at peak velocity, F=14.6, p=0.001, Figure 2) of movement differed between functional groups.
Figure 1: Movement time of forward reach with the paretic arm in people post stroke with severe (blue) and mild (red) functional impairment.
Figure 2: Initial directional Error during forward reach of paretic arm of people post stroke with severe (blue) and mild (red) functional impairment.

Variability of movement units (quantity of oscillations in tangential velocity during reach) within functional groups was greater in the severe functional group compared to the mild functional group when reaching with the paretic arm (F=7.238, p=0.012, Table 1).
Figure 3: End point error at tangential peak velocity of paretic arm during reaching in people post stroke with severe (blue) and mild (red) functional impairment.

CONCLUSIONS

The results of this study suggest that functional impairment influences reaching movement patterns in people post stroke. People with severe functional impairment have longer duration of movement and increased error compared to people with mild functional impairment. Future studies to identify within subject variability may be beneficial to identify rehabilitation paradigms to improve reach function in people post stroke with severe impairment.

EFFECT OF CUSTOMIZED HAPTIC FEEDBACK ON
NAVIGATION CHRACTERISTICS AND PERFORMANCE

Han U. Yoon and Pilwon Hur

Department of Mechanical Engineering, Texas A&M University, College Station, TX, USA
email: {hanulyoon,pilwonhur}@tamu.edu, web: http://hurgroup.net

INTRODUCTION

Assistive technologies for driving and navigation have been engaged for the past two decades. However, the effectiveness of the outcome of assistive technologies using haptic devices is still debatable. Specifically, determining the level of haptic assistance, e.g., the magnitude and direction of haptic force, is a challenging problem [1]. For instance, an excessive assistance level may degrade user's performance and cause discomfort, whereas a lack of enough assistance may yield task failure.

Previous studies have shown possibilities to enhance human task-performance by adopting control characteristics [2] and to design a controller by mimicking human's driving style via inverse optimal control (IOC) [3]. In this study, subject's control strategy for given tasks was parameterized by IOC. Also, the obtained parameters will serve as metrics to customize haptic feedback for each subject by i) assigning a *coach* whose task-performing characteristics are the desired characteristics for the rest of the subjects, ii) defining a *spine* (guiding path) which guides subjects based on the coach's strategy, and iii) determining the level of assistance. Therefore, the objective of this study is to identify the effect of customized haptic guidance on subjects' task-performance and performing-characteristics.

METHODS

Sixteen healthy young adults (14 male and 2 female, age=20-35 yrs) participated in this study. Subjects were seated at 1.5m from a 105cm-by-81cm (width-by-height) screen as shown in Fig.1. The modified version of Novint Falcon (Novint Technologies, Albuquerque, NM) was used to provide 2D haptic interface [4]. All subjects gave informed consent prior to their participation and this research was proved by the University Institutional Review Board.
Figure 1: The experimental environment.

The experiment consisted of two separate sessions: the first session for obtaining the baseline data and the second session (one week apart) for identifying the effect of customized haptic feedback based on the baseline data. For both sessions, the subjects were asked to drive a virtual vehicle along four roads each of which had a difference radius of curvature and obstacles. The subjects were instructed to drive the vehicle as fast and safe as possible. Completion time, sampling time, task#, trial#, successes, fails, vehicle's positions and heading direction were recorded from the start line to the finish line. Each task was repeated 3 trials. The sequence of the tasks was randomized. Sampling frequency was 60Hz. This virtual task environment was developed by Unity3D (Unity Technologies, San Francisco, CA).

After the first session, the subjects' strategy for each task was analyzed. A cost function that each subject may have minimized during each task was assumed to be in the following form: $cost = \sum_{i=0}^{N} c_v v(i)^2 + c_\omega \omega(i)^2 + c_{d_o} d_o(i)^2 + c_{d_f} d_f(i)^2$ where v: linear velocity, ω: angular velocity, d_o: distance from the vehicle to road boundary on obstacle side, and d_f: distance from the vehicle to road boundary on obstacle-free side. As these four variables at each discrete time step $i \in [0,N]$ corresponded to the baseline data, positive coefficients, c_v, c_ω, c_{d_o}, and c_{d_f}, could be estimated by solving an IOC problem [2][3].

Subject's *performing-characteristics* vector q was defined from the estimated coefficients as $q = [c_v, c_\omega, c_{d_o}, c_{d_f}] \times 100 / (c_v + c_\omega + c_{d_o} + c_{d_f})$ where each element represents subject's efforts for *speed control*, *steering*

control, and *lane selections for routing and obstacle avoidance* as percent, respectively. By clustering the *q* vectors in $\mathbb{R}_+^4$ via k-means clustering algorithm, the subjects were classified into 3 groups. As a result, subjects in the same group have similar driving patterns. A subject whose task-completion time was fastest in each group was designated as a *coach* in each group. The *coach*'s baseline vehicle trajectory in the first session was used as a *spine* to guide the rest of subjects in the same group. The level of haptic guidance for each subject was determined proportional to L_1-norm distance from his/her to the *coach*'s performing-characteristics vector. The resulted guidance is called *customized haptic guidance* (CH). For the second session, CH was applied to assist the subjects. To compare the effect of CH to typical guiding method, another type of haptic guidance that enforced the vehicle to a road center (RH) was applied.

The following 3 parameters were investigated: i) summed average task-completion time, $\sum T_{avg}$, ii) summed standard deviation (std) of T_{avg}, denoted by $\sum T_{std}$, and iii) guided driving characteristics under three assistance modes, NA(no assist), CH, and RH. A repeated measures analysis of variance (rANOVA) was used to identify the effect of haptic guidance on subject's task-performance and performing-characteristics. Significance level was set to 0.05 (SPSS v21, Chicago, IL)

RESULTS AND DISCUSSION

Based on the baseline data during the first session, subjects were grouped into 3 groups (bold is a coach): {**s4**, s2, s5, s7, s8, s13, s14, s15}, {**s9**, s10, s16}, and {**s12**, s1, s3, s6, s11}. The coach data were excluded from statistical analysis since coach data were used as references. First, rANOVA found that $\sum T_{avg}$ was not significantly affected by haptic assistance. Some improvements of $\sum T_{avg}$ could only be observed in slower subjects, e.g., s10, s7, s16, as shown in Fig. 2.
Figure 2: $\sum T_{avg}$ with respect to NA, CH, and RH (From left to right, ordered by $\sum T_{avg}$ under NA).
Figure 3: The difference of $\sum T_{std}$ under CH and RH compared with NA.

Next, rANOVA on $\sum T_{std}$ showed tendency for reduction of $\sum T_{std}$ when haptic assistance was provided (F(2,24)=4.168, *p*=0.061, with mean of 3.929, 2.430, and 2.658 for NA, CH, and RH, respectively). The mean of variability of subjects' performance reduced the most when CH was provided. Figure 3 depicts the difference of $\sum T_{std}$ for CH and RH compared with NA. However, rANOVA on the guided driving characteristics, which was represented by L_1-norm distance from the coach under three assistance modes, showed no significant difference.

By direct data observation, several interesting aspects were found. From Table 1, both mean and std decreased in **s12** group for CH. For **s4** group, most subjects' performing-characteristics were already close enough to **s4** as the smallest mean for NA indicated. Hence, applying haptic feedback to **s4** group might work as disturbance. Increased mean in **s9** group might be caused due to small number of subject, but std was reduced under CH. For further statistical analysis on L_1-norm distance, more data will be collected. Also, task-difficulty will be elevated to investigate the broader range of subjects' performance.

Table 1: Mean(std) of subjects' L_1-norm distance from the group coach under three assistance modes.

	NA	CH	RH
s4 group	11.95(13.39)	31.34(45.00)	16.44(22.89)
s9 group	27.12(18.38)	67.49(7.53)	37.20(39.58)
s12 group	16.44(6.84)	6.67(3.80)	10.66(9.54)

Proportional Myoelectric Control of a Robotic Hip Exoskeleton

[1] Aaron J Young, [1] Bridget Cook and [1] Daniel Ferris

[1] The University of Michigan, MI, USA

email: aayoung@umich.edu, web: http://kines.umich.edu/lab/human-neuromechanics-laboratory

INTRODUCTION

Robotic lower limb exoskeletons have significant potential for providing gait assistance and rehabilitation to individuals with lower limb impairment and augmenting human locomotion capability. The objective of this study was to test a hip exoskeleton capable of supplying both flexion and extension torques using proportional EMG control from hip muscles and determine the resulting torque profile. The primary outcome measure was metabolic cost of walking using the powered exoskeleton. We hypothesized that a proportional EMG based controller on the robotic hip exoskeleton would reduce the metabolic cost of walking. We expected the exoskeleton would provide a biological torque profile given that the user can alter the torque based on their muscle recruitment.

METHODS

We designed a hip exoskeleton device to apply torques around the user's hip joint. The design was a modification of a previous exoskeleton frame from our lab [1]. Bidirectional pneumatic actuators (BIMBA) on each leg provided hip flexion and extension assistance. Load cells in line with the actuators measured output force. The exoskeleton attached to the user through straps around the thigh and waist. Only the sagittal plane was actuated but there was passive range of motion in the frontal plane. We placed electrogoniometers (Biometrics, Ltd.) on the exoskeleton to measure hip joint angle.

EMG electrodes on the rectus femoris (RF) and gluteus maximus provided the control signal. The controller used gluteus maximus EMG to activate hip extension assistance. Rectus femoris EMG activated hip flexion assistance. Rectus femoris is not an ideal muscle for hip flexion assistance because it is biarticular, but other hip flexion muscles (such as the illiopsoas and the sartorius) are hard to record with surface electromyography. To deal with this issue, the controller ignored the rectus femoris burst in early stance.

A single female subject (63.5 kg) wore the exoskeleton during walking at 1.0 m/s. University of Michigan Medical School Institutional Review Board approved the protocol. After fitting the device, she stood for 3 minutes while we measured oxygen consumption and carbon dioxide production using a metabolic analysis system (Max-II, AEI Technologies). The subject walked on a split-belt instrumented treadmill (Bertec) to measure ground reaction forces. The user acclimated to walking with the exoskeleton unpowered for 5 minutes before we collected metabolic data for 6 minutes. The user was given a short resting period before beginning an adjustment period to the powered exoskeleton. The controller applied flexion and extension torque proportional to the myoelectric activity from the control sites. We conducted 6 minutes of walking metabolic data under the powered condition. We calculated metabolic power using the equation from Brockway for each condition, and subtracted standing metabolic power to get net metabolic cost.

RESULTS AND DISCUSSION

When the exoskeleton was powered, the gluteus maximus was active in early stance and turned off by 10-15% of the gait cycle (Fig. 1). The proportional signal was typically between 50-60% of max power. The rectus femoris was active in late stance at a lower proportional signal of between 20-30% of max power, but for a longer part of the gait cycle. The RF was also active in early stance, but

was set to zero as this burst is associated with knee extension activity.
Figure 1: EMG control signals used for applying hip assistance. The hip extension signal (red) was proportionally controlled by the gluteus maximus. The hip flexion signal (blue) was proportionally controlled by the rectus femoris. Data shown are for one subject averaged across 1117 steps (both left and right side).

The exoskeleton device provided torque assistance about the hip that was a small percentage of normal biological torque (Fig. 2). Hip extension torque peaked between 10-20% of the gait cycle, and hip flexion torque peaked between 40-55% of the gait cycle. The average maximum extension torque per stride was 0.477 N*m/kg, and the average maximum flexion torque per stride was 0.280 N*m/kg.

The powered exoskeleton reduced metabolic cost by 9.3% compared to the unpowered condition. Average metabolic cost of walking with the unpowered exoskeleton was 184.2 W. Average metabolic cost of walking with the powered exoskeleton was 167.1 W.

CONCLUSIONS

The max torque generated by the exoskeleton was a relatively small amount of the normal biological torque, but provided a substantive decrease in metabolic cost of walking. The torque profile is roughly consistent to the biological torque profile during stance phase to those required at the hip. The peak extension torque was slightly delayed (due in part to the pneumatic actuation) from normal

walking but otherwise similar. The peak flexion torque typically occurs at 50% and is similar to what was observed in this experiment. The exoskeleton provided nearly zero torque during swing phase, and any torque provided was a result of passive mechanics – except during early swing in which a small amount of flexion torque was provided due to RF activity. EMG-based control may be an effective way to produce biological torque profiles at the hip to help reduce metabolic cost.
Figure 2: Torque generated by the hip exoskeleton (blue) normalized by body weight. Biological hip torque data from [2] is shown in red as we had not yet calculated inverse dynamics for the subject. Hip extension is positive and hip flexion is negative. Exoskeleton data shown are for one subject averaged across 1117 steps (both left and right side).

INTRODUCTION

Exoskeletons have been used for human performance restoration and enhancement for many years. Due to the dynamic nature of human locomotion, torque control is widely used in lower-limb exoskeleton assistance during stance phases of walking. In these systems, series-elastic actuators (SEA) are commonly used to provide low error torque tracking in the presence of unknown and changing human dynamics. Good torque tracking performance is important to the fidelity of gait-related biomechanical experiments and the effectiveness of clinical gait recovery training. Control of lower-limb exoskeletons is normally hierarchical, with high level controllers determining behavior-related desired torques and torque control lying at a lower level. Many low-level control methods have been proposed for existing exoskeleton systems. However, relatively little has been reported on the relative performance of different torque controllers on the same platform under practical walking conditions, making differentiation among candidate methods difficult. Moreover, the interactions between high- and low-level controllers are unknown. This study aimed to compare the torque-tracking performance of prominent torque controllers, under realistic experimental conditions, with multiple high-level controllers, in a single exoskeleton platform [1]. These results are expected to help guide the selection and tuning of lower-limb exoskeleton torque controllers for locomotion assistance, which will benefit gait-related biomechanics research and clinical training.

METHODS

The ankle exoskeleton testbed used in experiments consisted of an off-board geared electric motor with real-time driver, a flexible Bowden cable transmission with series compliance, and an exoskeleton that interfaced with the human body (Fig. 1). Motor input
Figure 1: Schematic and photo of the tethered ankle exoskeleton system. (A) Schematic of the system; (B) Photo of the exoskeleton worn by a human.

voltage was regulated by a motor driver running in velocity control mode, which provides smoother torque tracking in series elastic actuators. Desired motor velocity was commanded to a dedicated hardware motor controller for all torque controllers investigated. Nine torque controllers, including variations and combinations of classical feedback control, model-based control, adaptive control and iterative learning, were experimentally compared in this study. Each was tested separately with four high-level controllers that determined desired torque based on time, ankle angle, a neuromuscular model (NMM), or electromyography (EMG). Under each high- and low-level controller combination, the exoskeleton was tested with one subject who walked on a treadmill with 1.25 ms^{-1} for one hundred steady-state steps on a treadmill. The root mean squared torque errors were calculated for each stride (RMSE) and for an averaged stride (RMSE-A).

RESULTS AND DISCUSSION

The best torque tracking performance was observed with the combination of model-free, integration-free feedback control and iterative learning for all high-level controllers, both in real-time and for the average stride. In this study, this type of controller was represented by proportional control and damping injection compensated by iterative learning (PDa+LRN) as described below.
Figure 2: Overlapped trajectories of the desired and measured torques in time for all high level controllers with PDa+LRN

$$\dot{\theta}_{m,des}(i,n) = \underbrace{-K_p e_\tau(i,n)}_{\text{Proportional Control}} + \underbrace{-K_d \dot{\theta}_m(i,n)}_{\text{Damping Injection}}$$

$$\underbrace{\phantom{-K_p e_\tau(i,n) -K_d \dot{\theta}_m(i,n)}}_{\textbf{PDa}}$$

$$+ \underbrace{\dot{\theta}_{m,des}^{LRN}(i+D,n)}_{\text{Iterative Learning (\textbf{LRN})}}$$

In this equation, $\dot{\theta}_{m,des}$ is the desired motor velocity to be commanded, K_p is a proportional gain, e_τ is torque error, K_d is a damping gain, and $\dot{\theta}_m$ is measured motor velocity. $\dot{\theta}_{m,des}^{LRN}$ is the compensation from iterative learning, which is updated by

$$\dot{\theta}_{m,des}^{LRN}(i,n+1) = \dot{\theta}_{m,des}^{LRN}(i,n) - K_L e_\tau(i,n),$$

where i is the time index (number of control cycles elapsed) within this step, n is this step and $n+1$ is the next step, K_L is the iterative learning gain, and D is an estimate of the delay between commanding and achieving a change in motor position. Using this controller, the motor commands arose primarily from feedback control, with iterative learning compensating for consistent tracking errors. Part of the controller is labeled as 'damping injection' instead of 'derivative control' since motor velocity is used instead of the relative velocity between motor and ankle joint. This was to reduce noise while maintaining comparable control performance. The iterative learning part only acts in the next step based on the torque errors of the current one.

Table 1: Tracking errors with PDa+LRN torque control

	RMSE	$\%\tau_{max}$	RMSE-A	$\%\tau_{max}$
Time	0.57 ± 0.18 Nm	**1.3%**	0.10 Nm	**0.2%**
Angle	0.99 ± 0.23 Nm	2.5%	0.11 Nm	0.3%
NMM	0.93 ± 0.32 Nm	2.3%	0.12 Nm	0.3%
EMG	2.14 ± 0.77 Nm	5.9%	0.22 Nm	0.6%

Error values for PDa+LRN and their percentage of

the peak desired torque, τ_{max}, for the average step are given in Table 1. Overlapped desired and measured torque trajectories for one hundred steps with PDa+LRN are shown in Fig. 2. The high variations of torques for Angle- NMM- and EMG-based high level controllers are the result of step-to-step gait variation of the subject. Depending on high-level conditions, the real-time torque errors with this controller were 38%-84% lower than with PDa alone, and average-step torque errors were 91%-97% lower. This approach is effective since it is analogous to the classical proportional-integral-derivative control. The proportional term provides basic tracking; damping injection improves the system stability like derivative control; iterative learning, which is a step-wise integral control, eliminates steady-state errors in cyclic operations.

CONCLUSIONS

A systematic comparison of uni-directional Bowden cable driven exoskeleton torque controllers under walking conditions was conducted, demonstrating that proportional control with damping injection compensated by iterative learning had better torque tracking performance than any other methods tested in this study and in the literature. Implementation of this controller was straightforward, requiring sequential tuning of only four parameters. Our results suggest that this approach can be applied to multiple torque-controlled lower-limb exoskeletons used in cyclic processes like locomotion. The application of this controller in lower-limb robotic devices will improve the precision of interventions and allow better-controlled experiments.

LOWER BODY JOINT KINETICS IN STANDING BROAD, VERTICAL, AND SQUAT JUMPS

[1]Kaylin Bean, [1]J. Bryan Mann, and [1]Trent M. Guess

[1] University of Missouri, Columbia, MO USA
email: beank@health.missouri.edu, web: www.mizzoumotioncenter.com

INTRODUCTION

A major interest in athletics is increasing overall power output. A widely accepted way to determine overall athletic ability and power is the vertical jump test [1]. Much research has been conducted on overall jump power in order to determine possible strategies for training [1, 2], but little research has been conducted on the contributions made by the three leg joints (hip, knee, and ankle) and with multiple types of jumps. In order to produce the most powerful movement possible, all three leg joints must work maximally [3] and assessing the joint contributions in jumping power can help determine specific areas of concentration for strength and conditioning.

METHODS

With approval from the institution's human subjects review board, 20 female collegiate soccer players (Mean±standard deviation: 19.6±1.3 yrs; 166±7 cm; 60.4±8.1 kg) participated in the study. All subjects performed five trials for the standing broad jump, vertical jump, and squat jump. The subjects were encouraged to jump maximally and could use their arms as desired on the standing broad and vertical jumps. For the squat jump, the subjects were restricted to keeping their hands on their head to reduce arm contribution to the jump. The best jump by each subject was chosen for analysis; the best referring to the longest standing broad jump and the highest vertical and squat jumps. Before jumping, basic anthropometric data was collected and 16 reflective markers were placed on the lower body using the Plug-in Gait model.

All jumps were measured using an 8 camera VICON MX-T40S retro-reflective motion analysis system synchronized with two AMTI Optima force plates. The motion data was sampled at 100Hz, processed using Vicon Nexus 2.1 software, and filtered at 6Hz using a 4th order Butterworth filter.

The force plate data was sampled at 1000Hz. Joint moments for the ankle, knee, and hip were calculated using inverse dynamics. Data was analyzed from the point of maximum knee flexion (0%) to toe-off (100%), and total maximum power was determined during the propulsion phase (see Figures 1, 2, & 3). A summation of the total joint moments was calculated, and contributions of each joint to the jump were determined as percentages of the sum at the maximum power output during the propulsion phase [3]. Total support jump differences were determined using a repeated measures one-way ANOVA with post hoc t-tests to determine between jump difference. Jump-by-joint differences were determined using a repeated measures two-way 3x3 ANOVA with post hoc one-way ANOVAs to determine between jump differences.

RESULTS AND DISCUSSION

Mean total support power differed significantly between jumps ($F_{(2, 38)} = 28.326$, $p < 0.001$)) (Table 1). Post hoc tests revealed power during the vertical jump was 8.7 W/kg ($p < 0.001$) and 3.6 W/kg ($p = 0.045$) greater than during squat and broad jumps, respectively, and 5.1 W/kg ($p = 0.001$) greater during broad jump compared to squat jump. The difference in mean total joint power in the squat jump can be attributed to the restricted arm movement. The arms act as a driving force, increasing the tension applied to the three leg joints [4]. Thus focusing on the timing of the arm swing with muscle activation of the legs can help produce a greater power output.

There was a significant interaction effect of jump type and joint contribution of total power ($F_{(4, 38)} = 28.299$, $p < 0.001$). Post hoc tests revealed significant between jump differences at the ankle ($F_{(2,38)} = 14.014$, $p < 0.001$), knee ($F_{(2,38)} = 46.105$, $p < 0.001$), and hip ($F_{(2,38)} = 17.690$, $p < 0.001$) (Table 1). Power during broad jump was significantly

BIOMECHANICAL FACTORS ASSOCIATED WITH MEDIAL TIBIAL STRESS SYNDROME: A PROSPECTIVE STUDY

James Becker, Mimi Nakajima, Wilbur Wu

Center for Sport Training and Research,
Department of Kinesiology, California State University Long Beach, 90840
email: james.becker@csulb.edu

INTRODUCTION

Multiple epidemiological studies over the last thirty years have reported medial tibial stress syndrome (MTSS) as one of the most common overuse running injuries [1,2]. Despite the prevalence of this injury, its etiology is still not well understood. Hip muscle strength [3], passive range of motion [4], and running kinematics [5] have all been suggested as possible factors. While many of these studies have been prospective in nature [3,4,5] each study has focused on a single area such as range of motion, muscle strength, or kinematics, in isolation. It is likely that MTSS results from a combination of all these areas and thus, prospective studies combining all areas are needed.

In relation to foot movement in particular, excessive amounts or velocities of foot pronation are often cited as kinematic factors contributing to MTSS [7]. However, to date, there is conflicting reports in the literature regarding such this relationship. An alternative hypothesis suggests it is not the amount or velocity of pronation which is the issue, rather the time during stance phase over which the foot remains in a pronated position [1]. However, as it relates to MTSS, the idea of prolonged pronation has not yet been investigated.

Therefore, the purpose of this study was to compare flexibility, strength, and kinematics between runners who went on to develop MTSS and a healthy control group. It was hypothesized that compared to controls, the runners who developed MTSS would be weaker, would display limited ranges of motion during a clinical exam, and would have altered hip and foot kinematics during stance phase including higher peak hip adduction and internal rotation, similar amounts but longer durations of pronation, and a higher tibia varus angle at initial foot contact.

METHODS

These data are part of an ongoing prospective study on relationships between running mechanics, injury, and performance. To date, twenty five runners have participated (sex: 12 female, 13 male; age: 20.2 ± 1.1 years; weekly running mileage: 67.4 ± 18.7). Participants were all members of a collegiate cross country team. All participants underwent an orthopedic exam evaluating lower limb flexibility. Muscle strength for the hip abductors, internal and external rotators, and extensors was measured using a hand held dynamometer (MicroFET2, Hoggan Scientific, LLC). For each muscle group, participants performed three five-second contractions followed by five seconds of rest. Peak force on each trial was recorded and the final value used for each muscle group was the average of the three trials, normalized by body mass.

Participants then completed a three dimensional running gait analysis. Forty two reflective markers were attached to bony landmarks after which participants ran on a treadmill at self-selected speeds approximating their easy training pace. While body kinematics were recorded using a 12-camera motion capture system (Qualisys, Inc.) sampling at 200 Hz. Marker trajectories were exported to Visual 3D (C-Motion, Inc.) where the following specific kinematic variables were calculated: peak amount, velocity, and duration of rearfoot eversion, peak hip adduction and internal rotation, peak contralateral pelvic drop, and shank varus angle at the time of initial foot contact. All variables were calculated over stance phase only.

Runners were followed throughout the course of the cross country season. Diagnosis of MTSS occurred when the injury became severe enough to cause the runner to seek evaluation and treatment from a certified athletic trainer. To date, six participants have been diagnosed with MTSS, forming the injured (INJ) group. Injured participants were matched with a control group (CON) on the basis of sex, and weekly running mileage. Independent samples t-tests were used to compare differences in orthopedic exam measures, muscle strength, and kinematic variables between INJ and CON groups.

RESULTS AND DISCUSSION

There was no difference in running speed between the two groups (INJ: 3.5 ± 0.3 m/s; CON 3.4 ±0.5 m/s, p = .047). Compared to the CON group, the INJ group demonstrated tighter hip flexors and IT bands as indicated by lower scores on the Thomas and Ober's tests, reduced passive hip internal rotation range of motion (Table 1), and weaker hip abductors then the CON group (Table 2). While not significantly different, there was also trend towards weaker hip external rotors in the INJ group.

Table 1. Range of motion measurements. SLR: straight leg raise, DF: dorsiflexion range of motion.

ROM Measure (°)	INJ	CON	p
SLR	91.4	87.2	0.616
Thomas	4.2	13.1	0.034
Ober's	9.0	17.0	0.037
Hip IR	34.4	44.6	0.043
Hip ER	43.8	40.5	0.483
DF	12.4	10.2	0.473

Table 2. Hip muscle strength measures. Values are percentage body weight.

Strength Measure	INJ	CON	p
Hip ABD	96.2	124.9	0.036
Hip ER	76.2	75.1	0.926
HIP IR	81.2	90.8	0.350
HIP EXT	117.4	177.1	0.078

For the kinematics the only the differences between INJ and CON groups were in the amount (INJ: 9.2 ± 2.1°, CON: 5.5 ± 1.4°, p = .004) and duration of rearfoot eversion (INJ: 85.4 ± 5.1 % stance, CON: 68.6 ± 7.7 % stance, p = .001). Rearfoot eversion-inversion curves are shown in Figure 1.
Figure 1. Rear foot eversion-inversion curves for INJ (black) and CON (gray) groups.

CONCLUSIONS

These preliminary results suggest the etiology of MTSS is multifactorial with muscular strength, flexibility, and running kinematics all playing a role. For kinematics specifically, these results suggest distal kinematics may play a more prominent role than proximal kinematics, despite proximal strength deficits. However, since distal kinematics may be influenced by proximal muscle strength, the relative importance of proximal and distal factors as they relate to MTSS still needs to be clarified. The results agree with previous studies documenting increase amounts of rearfoot eversion in runners with MTSS [5]. However, the results also suggest the duration of rearfoot eversion is an important parameter, one which should be considered separately in future studies on this injury.

JOINT MOMENT DIFFERENCES IN DANCERS LANDING IN TURNEDOUT VERSE PARALLEL POSITIONS

Katherine Spitzley, Renae Jackson, Britte Nielsen, Karen Clippinger, and James Becker

California State University Long Beach, Long Beach, CA, USA
email: katespitzley@gmail.com

INTRODUCTION

Dancers incur up to 88% of injuries in their lower limbs, the majority in the hips and knees [3,5]. With 100% of retired dancers, 90% of professional dancers and 63% of student dancers reporting injuries at some point in their career, finding the cause for these injuries should be a priority in research [1]. Studies have shown that classical ballet and professional football are comparable in the amount of physical demand on the body. Yet, little research has been done to sufficiently account for that toll in the ballet world [2].

Knee pain in dancers has been attributed to the repetitive jumping motions which make up many of the most popular ballet movements [3]. Multitudes of studies have investigated the correlation between turnout, external rotation, and injury. These have merely collected static data using manual techniques such as goniometer and inclinometer readings. No research has been conducted to investigate the forces working within the joints during the movements being discussed.

This study will examine joint forces through the hip and knee during a common jumping movement in a turned out ballet position, and compare them to the joint forces through the hip and knee during a jumping motion with the legs in parallel position. This method will give insight into root biomechanical factors contributing to such prevalent hip and knee pain in dancers.

METHODS

Fourteen female college age dancers participated in this study (age: 20.2 ± 1.1 years; 16.1 ± 1.8 years of dance experience). All participants were healthy at the time of testing with no reported injuries.

Participants completed a 10 minute standardized warm up which included aerobic and lower body muscular work. Subjects then performed three sets of three maximal vertical jumps under two different conditions. For condition 1 participants were instructed to perform jumps with feet in turned out first position. For condition 2 participants were instructed to perform jumps with their feet in parallel position. The order of conditions was randomized.

Whole body kinematics were recorded using a 12-camera motion capture system (Qualisys) sampling at 200 Hz while ground reaction forces were recorded using two force plates (Bertec) sampling at 1000 Hz. Marker trajectories and force data were exported to Visual3D (C-Motion, Inc.) where joint moments at the hip, knee, and ankle were calculated. For each joint peak, moments in the sagittal, frontal, and transverse planes were identified. Moments were expressed as internal moments. Differences in moments between conditions were determined using paired t-tests.

RESULTS AND DISCUSSION

We observed notable differences in performance between the right and left legs of each dancer. As a result, the data represented here are based on analyzing each leg individually.

Hip extensor, knee external rotator, and ankle external rotator average curves are presented in Figure 1. Hip extensor moments were lower during mid-stance in the turned out position then in the parallel position, but they were not different early or late in stance phase. Knee extensor moments and ankle external rotator moments were higher throughout stance, suggesting higher torsion being applied to the knee in these conditions.

a.

b.

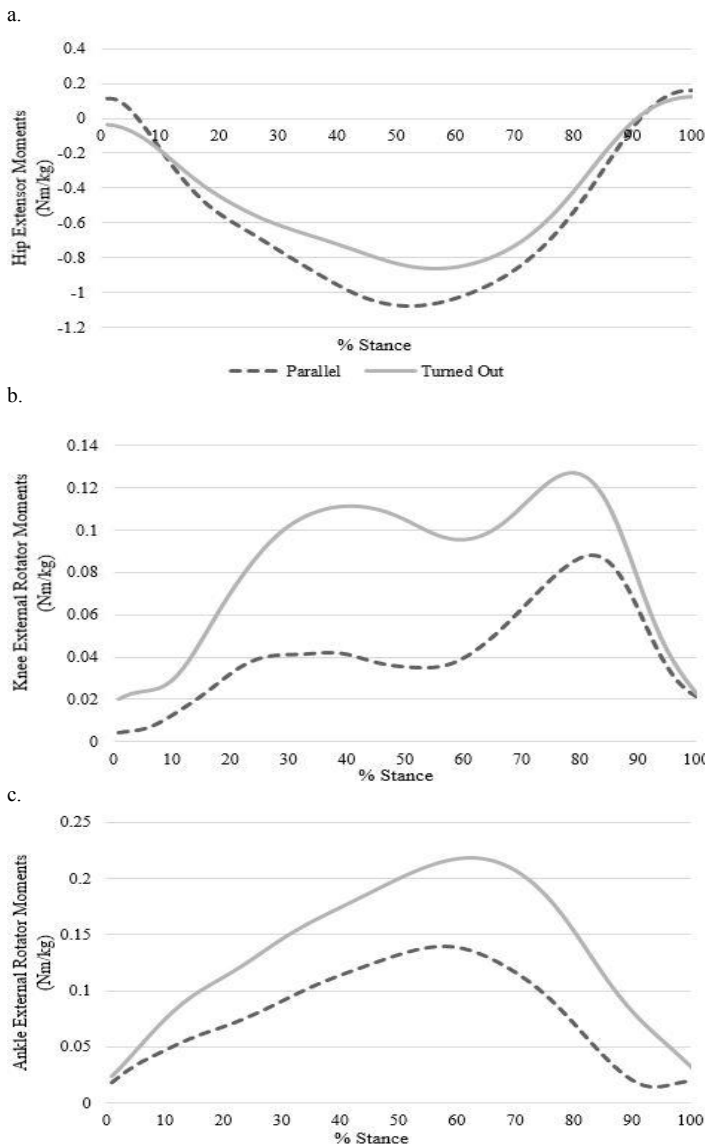
c.


Figure 1: Average moments throughout stance phase comparing parallel and turned out jumps.

Peak moments are shown in Table1. Peak hip extensor and external rotator moments were lower

in the turned out than parallel conditions, while peak knee and ankle external rotator moments were higher in the turned out than parallel condition.

CONCLUSIONS

As hypothesized, the knees and hips were subjected to higher moments when jumping in a turned out position. As the differences were primarily in the transverse plane, this suggests higher torsional loading being applied to the joints in a turned out position. Previous work has hypothesized that torsional forces could be one contributing factor to knee pain and injuries [4]. Knowing that dance specific movements such as turnout may increase joint loading can be useful for coaches and instructors. This information can aid them in appropriately planning the number of jumps in a given training session. Additionally, the distinction in force generation between extension and external rotation components required to maintain the specific aesthetic involved in turnout should be further examined.

TURNOUT GENERATION STRATEGIES AND RESULTING JOINT MOMENTS IN DANCERS

Renae Jackson, Kate Spitzley, Britte Nielson, Karen Clippenger, and James Becker
California State University of Long Beach, Long Beach, CA, USA
email: james.becker@csulb.edu

INTRODUCTION

Turnout is a fundamental component of proper ballet technique. Theoretically perfect turnout requires 90° of external rotation at the hip with the remainder of the limb in a neutral alignment [1]. However, numerous studies have indicated this theoretical ideal is rarely achieved, showing instead, that turnout is a result of summative contributions from the hip, knee, and ankle [1]. Therefore, the term total turnout (TTO) was created to include all of the joint contributions. It has been suggested that the hip contributes approximately 60% of the external rotation while the knee and ankle contribute roughly 40% of the external rotation [1].

Previous research on joint contributions to TTO has primarily been performed under static conditions or quasi dynamic conditions [1]. However, for a truly functional assessment, TTO and relative joint contributions should be measured throughout the entire range of dynamic movements. Therefore the purpose of this study was to characterize the strategies used by collegiate dancers for achieving turnout. Specifically, we examined what percentage of TTO is generated from the hip, knee, and ankle when dancers performed vertical jumps in turned out first position. Additionally, to assess consequences of turnout generation strategies, we examined the relationship between percent TTO which was generated at the hip and peak joint moments during the ground contact phase of the vertical jumps. We hypothesized that dancers with larger TTO contribution from the hip would have lower peak joint moments at the hip and knee than dancers with larger TTO contributions from the knee and foot/ankle.

METHODS

Thirteen female university dancers (Age: 20.2 ± 1.1 years; dance experience: 16.1 ± 1.8 years) participated in this study. After completing a standardized ten-minute warm-up, participants performed four vertical jumps for maximal height while maintaining turned out first position. Whole body kinematics were recorded using a 12 camera motion capture system (Qualisys AB) sampling at 200Hz while ground reaction forces were recorded by two force plates (Bertec) sampling at 1000Hz.

Marker trajectories were exported to Visual 3D (C-Motion, Inc.) where joint angles and moments at the hip, knee, and ankle were determined. TTO was calculated by summing the external rotation components of the hip, knee, and ankle [2]. At each instant across stance phase, the percent contribution of each joint to TTO was calculated by dividing that joints' external rotation by the TTO.

The percent of TTO originating from the hip was calculated as the average hip contribution to TTO across the ground contact phase of the jump. Linear regression was used to examine the relationship between percentage of TTO originating at the hip and peak joint moments in the sagittal, frontal, and transverse planes. Simply watching the dancers perform the movement during data collection revealed pronounced asymmetry in the amount of turnout on left and right sides. Therefore each limb was treated separately in the analysis.

RESULTS AND DISCUSSION

Across all thirteen dancers the average TTO was 41.3° (± 10.1°), of which 52.2% (± 16.7%) came from the hip. Of the 26 legs analyzed, only 5 achieved 60° of external rotation at the hip, as suggested by previous research [1]. Although many participants achieved the same amount of TTO, their strategies used to achieve it were very different. For example, Figure 1 shows data from two participants who achieved the same amount of TTO, however, participant 1 primarily uses the knee

to achieve turnout, whereas participant 2 predominantly uses the hip and ankle.
Figure 1: Example Turnout Generate Strategies from Two Dancers. Solid lines represent participant 1 and dashed lines represent participant 2. Black represents TTO achieved in degrees. Blue, green, and red lines represent % contribution to TTO from the hip, knee, and ankle, respectively.

The variation in strategies for generating turnout could be due to a variety of factors including: level of dancer, muscular strength or range of motion limitations, and anatomical variation among the participants. While there are numerous studies investigating how these factors influence turnout under static conditions, there is currently no literature examining how these factors influence turnout in dynamic scenarios. This should be a focal point of future research on dance instruction and dance medicine.

Regression results revealed no relationship between percent TTO generated at the hip and peak hip extensor, hip abductor, or knee adductor moments (Table 1). However, there was a significant relationship between percent TTO generated at the hip and peak hip external rotator and knee extensor moments (Table 1). The greater the hip contribution

to TTO, the higher the peak knee extensor moment and the lower the peak hip external rotator moment. These findings reveal the importance of considering joint contribution when assessing turnout, as different strategies may result in higher or lower loading which overtime could affect the likelihood of overuse injuries.

Table 1. Peak Hip and Knee Moments, R^2 values and p values. Moments are expressed as internal moments and are normalize by body mass.

Moment	Peak Value	R^2	p
Hip Flex.	-1.03 (± 0.33)	0.071	0.188
Hip. Abd.	-0.34 (± 0.18)	0.136	0.064
Hip Ext. Rot.	-0.21 (± 0.17)	0.152	0.048
Knee Ext.	1.62 (± 0.39)	0.199	0.022
Knee Add.	0.16 (± 0.09)	0.008	0.671

CONCLUSIONS

Turnout plays an important role in performance and injury evaluation, however, the results of the current study suggest dancers vary in both their degree of turnout and strategy used to achieve it. These results also suggest there is a relationship between turnout generation strategies and joint moments, although functional consequences, such as how they relate to injury risk, need to be examined further. Although a higher degree of turnout is sought for optimal ballet posture, the manner in which turnout is produced should be more importantly considered as it relates to increased joint loading. It may be interesting to examine if joint contribution to turnout is a skill that can be taught or if it is a characteristic that is pre-defined by an individual's anatomy. Future studies should examine professional dancers with a similar training background to more clearly define the relationship between joint moments and TTO contributions in dynamic scenarios.

KINEMATIC DIFFERENCES BETWEEN DROP JUMP, CUTTING, AND REBOUND LANDINGS

[1] Jim Becker [1] Jonaz Moreno Jaramillo

[1] California State University, Long Beach
email: jim.becker@csulb.edu, jonaz.morenojaramillo@student.csulb.edu

INTRODUCTION

It is well established that non-contact ACL injuries are one of the most common injuries among female basketball players [1]. Predominantly, the risk of non-contact ACL injuries are far greater in sports where athletes perform pivoting and jumping maneuvers [2]–[3].

A common method to estimate the potential an athlete has to obtaining a non-contact ACL injury is through analysis of lower body kinematics during the vertical drop jump (DJ). The DJ has been shown to highlight potential knee valgus on the initial contact , as well as on the second contact that prelude to greater risk of injury [2],[5]. Yet little research has been done comparing lower body kinematics of the DJ to common basketball movements.

The purpose of this study is to determine whether DJ kinematics compare to the basketball movements rebound and cut maneuver. This method will investigate the potential differences of the knee and hip angles between the DJ landings (DJ-1 DJ-2), rebound, and cut maneuver to investigate the potential of alternative methods in predicting ACL injury across athletes.

METHODS

A total of 7 division 1a female basketball players (mean age = 19.9 years), (mean height 178.3 cm), (mean weight 67.8 kg), participated in this study. All participants were healthy and had no prior record of ACL injuries.

.

Each Athlete performed 3 trials of drop jump, 4 reactive cutting maneuvers, and 3 rebounds. During the cutting maneuver motion, the player reacted to the movements of another participant to simulate a one-on-one scenario. Both rebound and cutting maneuver were intended to be as close to a game scenario as possible.

Kinematics were recorded using a 12-camera motion capture system (Qualisys) sampling at 200 Hz. Marker trajectories were exported to V3D (C-Motion, Inc.) where joint angles for the hip and knee were calculated.

Knee and hip angles from initial foot contact to max knee flexion were compared through DJ-1, DJ-2, rebound, and the cut maneuver. Differences in joint angles were determined using multiple 1-way ANOVAs with repeated measures. A bonferroni post-hoc was used to find differences between dependent measures.

RESULTS AND DISCUSSION

Results indicated a significant difference of ROM in each movement, for hip external/internal rotation, knee varus/valgus, flexion/extension, and internal/external rotation. Contact angles for hip internal/external rotation, knee varus/valgus, and flexion/extension were also significantly different among movements. Peak angles for hip internal/external rotation, knee internal/external rotation, and knee flexion again showed significant differences between the different movements. Mean angles and standard deviations are indicated in the Table 1.
Figure 1. Joint Kinematics throughout the four different movements

CONCLUSIONS

The results indicate that when compared to rebound and cutting maneuvers, the drop jump accurately represents knee varus/valgus and hip ab/adduction values of an individual. However, it was found that hip internal rotation was greater during a rebound and cutting maneuver. The larger ROM of hip internal rotation during these movements could lead greater chance ACL injury if knee valgus and hip abduction are occurring simultaneously. Therefore, it could be beneficial to test athletes not just on a drop jump but rather a combination of game like dynamic movements to better evaluate and assess an individual's risk to a non-contact ACL injury

THE RELATIONSHIP BETWEEN CENTER OF MASS EXCURSION AND ACL INJURY RISK VARIABLES IN THE STATIONARY SINGLE LEG HOP (STASH)

INTRODUCTION

The anterior cruciate ligament (ACL) provides static stability to the knee joint. Non-contact ACL injuries are common in female athletes and are theorized to result from poor neuromuscular control at the knee joint [1]. Variables that have been associated with poor knee joint neuromuscular control include reduced sagittal plane knee excursion and increased normalized vertical ground reaction force (vGRF) [2]. Frontal plane angular knee excursion has also been shown to be higher in females than in males during a single legged hop test [3]. This finding suggests that frontal plane angular knee excursion may play a role in the well-reported increased female injury risk.

The STAtionary Single Leg Hop (STASH) test is a novel and maximal effort task that can investigate the link between generalized neuromuscular control and neuromuscular control at the knee joint. In the STASH the athlete is required to perform three consecutive hops on one leg, jumping as high as possible while attempting to land in the same place after each hop. They are also required to maintain balance on the same leg after the third landing.

METHODS

Center of mass excursion (COM) is the net distance traveled by the COM during a time interval in the x-y plane (Fig. 1). Typically, the analogous center of pressure (COP) excursion measurement is used to assess postural control in static tasks. In a dynamic task, however, a total COM excursion value quantifies neuromuscular control because COP cannot be assessed whilst athletes are airborn.
Figure 1: Depiction of total COM excursion calculation

The purpose of this study was to determine the relationship between generalized neuromuscular control, measured as total body COM excursion, and the injury risk biomechanics including vGRF and knee excursion in the sagittal and frontal planes. Prior to testing, Institutional Review Board approval of the protocol was attained and informed consent was provided to all subjects. Eighteen athletes from a Division I university women's soccer team (18.94 ± 0.94 yrs, 1.68 ± 0.054 m, 63.68 ± 6.52 kg) with no current lower extremity injury were recorded performing the STASH using tri-axial Bertec 4060 force plates collecting at 1500Hz and a 10-camera Vicon MX-F40 motion capture system collecting at 300Hz. Each athlete performed two repetitions of the STASH on each leg.

49 retro-reflective markers were placed on each athlete using a modified plug-in-gait model. Pelvic markers were used to estimate the COM location, and total COM excursion was calculated for each trial by tracing the total distance traveled between the time points of peak knee flexion at initial takeoff and peak knee flexion on the third landing. Measurement via this method did not allow the elapsed time to obstruct the measurement, which would have been the case if the distances between starting point and COM were summed at each frame for the duration of the STASH.

Total knee sagittal plane excursion and total knee frontal plane excursion values were calculated by summing the angular excursion differences at each frame during the entire stance phase of each of the three landings. Vertical GRF was normalized by peak potential energy (bodyweight x jump height before landing) to account for force generation and force absorption [4], and the three vertical GRF values were averaged for each trial.

RESULTS and DISCUSSION

Moderate correlations driven by two clusters of data points were found between total center of mass (COM) excursion and total knee frontal plane angular excursion (avg.=59.37°±17.24; r=0.62; p=0.006) (Fig. 1), total sagittal plane knee excursion (avg.=265.39°±37.34; r=0.48; p=0.046) (Fig. 2), and normalized peak VGRF (avg.=21.58N/J±2.862; r=-0.44; p=0.065) (Fig. 3).
Figure 1: Scattergram of FP Angular Excursion
Figure 2: Scattergram of SP Angular Excursion
Figure 3: Scattergram of Norm. Avg. Peak vGRF

A limitation of this novel STASH test assessing knee biomechanics is that COM excursion may not have been the ideal way to assess generalized neuromuscular control because it did not take into account the direction of the COM deviation. Other means of assessing generalized neuromuscular control in a static task include COP 95% ellipse area, standard deviation in the anterior–posterior and medial–lateral directions, and root mean square velocity in the anterior–posterior and medial–lateral directions [5]. These measurements can be applied or adapted to the dynamic STASH test, and their relation to knee joint neuromuscular control can be investigated. Further corroboration of the link between generalized neuromuscular control and knee joint neuromuscular control may provide a basis for more effective, targeted interventions for at-risk athletes.

CONCLUSION

The STASH demonstrates that poor overall neuromuscular control, approximated by total COM excursion, is also associated with injury predicting biomechanical variables at the knee joint that may be useful for ACL injury risk detection. Future studies on the STASH and its abilities to assess injury risk prospectively are needed.

INTRODUCTION

Throwing velocity is one of the most important components of a successful baseball pitch [1, 2]. Previous work by Matsuo et al. found significant differences in kinematic and temporal parameters between high velocity and low velocity pitchers in collegiate and professional baseball [2]. However, to our knowledge no study has examined the differences in kinematic and temporal parameters between high velocity and low velocity groups in high school pitchers. Additionally, there is a lack of research focusing on the relationship between kinematics and performance in high school baseball pitchers, which may be important for advancing to collegiate or professional baseball. Therefore the aim of this study was to investigate differences in kinematic and temporal parameters between high and low velocity high school pitchers. We hypothesized that there will be significant differences in kinematic and temporal parameters between high and low velocity high school pitchers, and specifically high velocity pitchers would demonstrate greater maximal shoulder external rotation, greater forward trunk tilt at ball release and greater lead knee extension angular velocity at ball release [2].

METHODS

Thirty-two high school male baseball pitchers (height = 1.83±0.07 m, mass = 75.6±10.9) were recruited. The Ohio State University institutional review board approved this study. All participants signed assent forms and permission was obtained from their parents. Before testing, the pitchers were instructed to warm up and prepare themselves just as they would do for an actual game. Once the pitchers were ready, they were instructed to throw 15 fastball pitches from a pitcher's mound towards a target. A passive optical three-dimensional motion capture system (Vicon Inc., Oxford UK), was used to collect marker trajectories at 300 Hz. Trajectories were filtered using a 4th order Butterworth low-pass filter with a cut-off frequency of 13.4 Hz [2]. Twelve kinematic parameters and nine temporal parameters were calculated to match the previous study done by Matsuo et al [2]. Three representative trials with the most complete trajectory data from each pitcher were selected for further analysis. The 10 pitchers with the greatest hand velocity (23.1±0.83 m/s) and lowest hand velocity (18.9±0.95 m/s) were assigned to the high and low velocity groups, respectively. Student's t tests were used to compare differences between groups for all the parameters, with statistical significance set *a priori* at p<0.01.

RESULTS AND DISCUSSION

Means and standard deviations of kinematic parameters of the two groups are presented in Table 1. To compare the high school pitchers with the low velocity collegiate and professional pitchers, data from Matsuo et al. [2] was added in the Table.

The high velocity group showed significantly greater peak trunk rotation velocity and peak glenohumeral internal rotation angular velocity, and showed trends toward significantly greater peak elbow angular extension velocity and maximum knee extension angular velocity at ball release (p<0.02). No differences were observed between groups for temporal parameters.

Similar to collegiate and professional pitchers, we found that high velocity pitchers trended towards having greater knee extension velocity at ball release [2]. However, contrary to our expectations, we did not find any differences in maximal external shoulder rotation and forward trunk tilt, which have been related to greater ball velocity in professional

and collegiate pitchers [2]. In addition to those variables, we found that glenohumeral internal rotation angular velocity and peak trunk rotation angular velocity were greater in the high velocity group than in the low velocity group. Because the time between strike foot contact and ball release is very short, high angular velocities are required to throw efficiently [1] and it is likely that these significant differences drive the higher ball velocities in that group.

These results suggests that there may be different kinematics distinguishing high velocity pitchers from low velocity pitchers in high school, compared to the more experienced collegiate and professional pitchers who may already have a baseline level of motor expertise. Pitching experience, body maturation, body adaptation and coordination may also play a role in the different kinematic variables affecting performance of high school pitchers as opposed to collegiate or professional pitchers. As shown in Table 1, our groups did not match Matsuo's low velocity group in any of the measured variables, except for lead knee extension angular velocity at ball release.

Understanding the kinematic differences between high velocity and low velocity pitchers may help

determine which pitching mechanics produces maximal ball velocity in high school pitchers. The differences between the groups in our study and those in Matsuo's study suggest that it would also be very valuable to investigate how pitching mechanics change with maturation and experience from youth to elite baseball.

CONCLUSIONS

High school pitchers who throw with high velocity showed greater peak trunk rotation angular velocity, and peak glenohumeral internal rotation velocity, with trends towards greater maximum knee extension angular velocity and peak elbow extension velocity when compared to those who throw with low velocity. These differences do not match the differences between high- and low-velocity groups at elite levels, suggesting that results from adult pitchers cannot be assumed to be generalizable across ages and experience levels.

INTRODUCTION

The Functional Movement Screen™ (FMS) is a clinical tool used to assess 7 fundamental movements. Summing the scores from the fundamental movements creates the FMS composite score (CS). The FMS CS has been linked to injury risk in some studies[1], but not others.[2] Therefore, it is important to begin to investigate the mechanics of the FMS as this area is not well studied and may contribute to the discrepancy in injury risk.

The FMS purports to assess coordination of functional movements [3], which may be related to core function. Further, superior performance on the FMS has been linked to increased hamstring flexibility;[4] however, the role of flexibility in other lower extremity joint motions has not been established. Understanding the association between lower extremity range of motion (ROM) and core function with FMS score may improve the interpretation and intervention for specific scoring.

The purpose of this study was to evaluate the ability to predict FMS performance based on lower extremity ROM and core function. Our first hypothesis was that lower extremity ROM and core function would predict FMS CS.   Our second hypothesis was that lower extremity ROM and core function would predict performance on the FMS movement patterns.

METHODS

This was a cross sectional study with the independent variables of lower extremity ROM and core tests. The dependent variables were FMS CS and movement patterns. Forty recreationally active adults (Table 1) volunteered to participate in this study. Recreational activity was defined as performing 30 minutes of physical activity on at least two days/week. Participants were excluded if they had a current injury that limited activity or they answered "yes" to any question on the Physical Activity Readiness Questionnaire (Par-Q).

Table 1. Means and Standard Deviations (SD)

	N	Age (yr±SD)	Weight (kg±SD)	Height (m±SD)
Female	24	23.2±2.4	64.8±9.7	1.7±0.1
Male	16	24.0±2.7	82.4±10.9	1.8±0.1
Total	40	24.0±2.5	71.8±13.4	1.7±0.1

Following informed consent and screening, all participants completed a 5 minute warm up on a stationary bike. Next, dorsiflexion ROM was measured with an inclinometer during the weight bearing lunge. All additional ROM was measured in the following order using standard positioning and a goniometer: knee flexion (prone); knee extension (90/90 Active Knee Extension Test); hip flexion (supine); hip extension (prone).   Three ROM measurements were obtained for each joint motion and the average was used for analysis. Participants then completed two single leg core endurance tests bilaterally: single leg wall sit hold (SLWS) and repetitive single leg squat (RSLS). The SLWS required the participant to sit for as long as possible with the back against a wall in a position of 90° knee and hip flexion; the time began when the one leg was lifted from the ground. The RSLS required the participant to perform repetitive single leg squats, (one repetition every 6 seconds) reaching 60° knee flexion and 65° hip flexion, while

maintaining less than 10° hip adduction/abduction and less than 10° knee varus/valgus, until they could no longer complete the task correctly; the number of squats was recorded.

The fundamental movement patterns of the FMS were performed in the standard order: deep squat, hurdle step, inline lunge, shoulder mobility, straight leg raise, trunk stability, and rotary stability; clearing tests were performed as indicated.[3] The movement patterns were scored using an ordinal scale of (0-3) with a 3 representing perfect movement without compensation; while a 0 was reserved for pain with movement pattern or clearing test.[3] The FMS CS was calculated by summing scores from the movement patterns (max score: 21).

Descriptive statistics were calculated as means ± SD (Tables 1). Data were checked for outliers ($1.5x<25^{th}\%$; $1.5x>75^{th}\%$). Independent t tests were used to assess differences between right and left limb in ROM and core function tests (Table 2). Linear and ordinal logistic regressions were used to determine the best predictors of FMS CS and movement patterns, respectively. Data analysis was completed in SPSS v.20 (IBM, Armork, NY) and SAS 9.4 (SAS Institute, Inc. Cary, NC). The alpha level was set at 0.25 when all predictors were simultaneously entered into the regression equation to determine which variables were most predictive of FMS CS and movement patterns. After which, only those predictive of performance were entered into the final prediction equation; $p < 0.05$.

Table 2. T test for Means [Standard Deviations (SD)] between left and right limb core tests and ROM

	SLWS (sec)	RSLS (reps)	DF (°)	KEXT (°)	KFLEX (°)	HEXT (°)	HFLEX (°)
MeanL (SD)	23.38 (14.78)	22.22 (12.03)	47.78 (9.10)	20.06 (12.07)	135.61 (11.97)	15.48 (6.16)	120.07 (13.70)
MeanR (SD)	26.44 (17.22)	25.76 (17.96)	47.57 (8.65)	20.24 (11.17)	135.83 (12.25)	17.19 (6.61)	119.08 (13.37)
P	0.04	0.12	0.76	0.82	0.65	0.02	0.33

MeanL – mean for left limb; MeanR – mean for right limb; SLWS – single leg wall sit; RSLS – repetitive single leg squat; DF – dorsiflexion; KEXT – knee extension; KFLEX – knee flexion; HEXT – hip extension; HFLEX – hip flexion; n = 37

RESULTS AND DISCUSSION
There were significant differences between right and left limb in SLWS and hip extension (Table 2). Therefore, two separate regression models were developed; one for right predictors and one for left

predictors for each dependent variable. After outliers were removed, 37 data points remained for analysis and indicated, on the left side, that reduced DF and SLWS significantly predicted lower FMS CS ($R^2=0.39$; $p < 0.001$). On the right side only reduced DF significantly predicted lower FMS CS ($R^2=0.27$; $p = 0.001$).

Ordinal logistic regression models for the movement patterns demonstrated that reduced DF ROM (left OR=0.92[CI=0.85-0.98]; pseudo $R^2=0.86$; right OR=0.92[CI=0.85-0.99]; pseudo $R^2=0.78$) was significantly associated with lower performance in deep squat. Reduced left knee extension was significantly associated with better performance in left straight leg raise (OR=1.11[CI=1.04-1.18]; pseudo$R^2=0.85$); while reduced right hip flexion was significantly associated with reduced right straight leg raise (OR=0.95[0.90-1.00]; pseudo$R^2=0.85$). Lower SLWS (left OR=0.92[0.88-0.98]; pseudo$R^2=0.91$; right OR=0.94[0.90-0.98]; pseudo$R^2=0.91$) was associated with reduced trunk stability performance.

CONCLUSIONS
Reduced DF ROM and SLWS resulted in worse FMS CS and the deep squat. The straight leg raise was impacted by hip/knee flexibility; trunk stability was associated with SLWS. Our results suggest that FMS movement patterns are affected by lower extremity ROM and core function. Thus, injury risk may be affected by lower extremity ROM and/or core function, as these appear to affect FMS CS and some movement patterns. Although we did not measure limb dominance, reduced left compared to right SLWS and hip extension ROM may indicate that these two variables are affected by dominance. Researchers should consider evaluating bilateral lower extremity ROM, core function, and limb dominance in addition to FMS to determine implications in injury risk and targeted intervention programs.

GLUTEAL ACTIVITY DURING PITCHING: COMPARING THE TRADITIONAL LEG KICK AND SLIDE STEP DELIVERIES

[1] Amanda J. Concha, [1]Marcus A. McClary and [1]David W. Keeley

[1] New Mexico State University, Las Cruces, NM, USA
email: ajconcha@nmsu.edu,web: http://hpdr.education.nmsu.edu/index-5/hpdr-research-laboratories/biomechanics-lab/

INTRODUCTION

The baseball pitching motion is a series of complex dynamic movements that must be properly synchronized. When this is not achieved, the possibility of injury may increase greatly. Currently it is estimated that 1.72 injuries occur per 10,000 athletic exposures [1]. Although there have been a number of studies attempting to identify mechanisms of injury in baseball pitchers, there appears to be no decline in the rate.

The majority of investigations have focused on the upper extremity but there are few that have investigated muscle activity of the lower extremity during pitching. In order to achieve proximal stability for distal mobility, effective and efficient muscle activation of the lower extremity is required, particularly with regard to the role of the gluteal group [2]. Unfortunately, not only have these muscles not been readily investigated, they also have not been investigated regarding the various mechanisms of delivery (e.g. – wind-up, traditional leg kick and slide step). Thus, the purpose of this study is to compare gluteal activity of the stride and drive legs during the two primary stretch deliveries; the traditional leg kick and slide step. It was hypothesized that gluteal activity would differ between the two delivery styles.

METHODS

Eleven male high school baseball pitchers volunteered to participate after completing the fall baseball season. Each pitcher was deemed free of injury and throwing arm dominance was not a limiting factor for participant exclusion. All of the testing protocols were reviewed by the University's Institutional Review Board prior to testing.

Upon arriving, the location of the preferred (drive leg) and non-preferred (stride leg) gluteus maximus and medius were identified by palpation. Adhesive bipolar surface electrodes were attached over the muscle bellies and positioned parallel to the muscle fibers. Manual muscle tests were conducted for each muscle using standard techniques to identify the maximum voluntary isometric contraction for each muscle to establish a comparative baseline for each muscle[3]. Test trials consisted of 5 maximal effort fastball pitches thrown for strikes and surface electromyography (sEMG) data describing muscle activity during test trials were collected via a Noraxon Myopac 1400L 8-channel system (Noraxon USA Inc. Scottsdale, AZ). All sEMG were system amplified with a gain set at 1000 and then processed within MATLAB version 2013B (Mathworks Inc. Natick, MA). Briefly, all sEMG signals were filtered for the removal of 60 Hz noise and then full wave rectified. The data were normalized by their mean to remove any offsets present prior to filtering and filtered using a single lowpass 2nd order Butterworth filter, with a cutoff frequency of 20 Hz. Following data processing, paired sample t-test analyses were conducted to compare muscle activity across the two deliveries.

RESULTS AND DISCUSSION

All data describing lower extremity muscle activity were determined to be normally distributed and the model assumptions of the means test were met. Of the mean comparison tests conducted, three returned significant results.

During the stride phase, the drive leg gluteus maximus was observed to be significantly more active (Fig 1.) during the leg kick delivery ($t_{(11)} = -2.539$; $p = 0.028$). During the arm acceleration phase, the drive leg gluteus medius was observed to

be significantly more active during the leg kick delivery ($t_{(11)}$ = -2.438; p = 0.033). Finally, during the arm acceleration phase, the stride leg gluteus medius was observed to be significantly more active for the leg kick delivery ($t_{(11)}$ = -2.264; p = 0.045).
Figure 1: Magnitudes of muscle activity for the muscles observed to differ significantly during the pitching motion.

During the stride phase of the pitching motion, the drive hip extends and laterally rotates. This is done in order to initiate pelvic rotation. During this time the gluteus maximus of the drive leg should be highly active. It is thought peak drive leg gluteus maximus activity occurs just prior to peak pelvis axial rotation velocity during this phase [4]. The differences observed between the two deliveries may be due to increased pelvic instability in the traditional leg kick delivery. At the onset of the stride phase of this delivery, the high leg kick utilized may place the pelvis in a more unstable position as compared to the slide step delivery. This in turn may require greater activation in an effort to stabilize the base on which the trunk sits.

During the arm acceleration phase of the pitching motion, the drive leg medially rotates about the hip. This is done in order to achieve forward trunk tilt allowing more force to be transferred to the upper extremity. During this phase, high muscle activation of the gluteus medius drive leg should occur in an

effort to exert more force onto the ball. At the same time, the stride leg laterally rotates about the hip. This is done in order to support the trunk as it accelerates forward through the pitching motion. The gluteus medius of the stride leg may work to accentuate pelvic rotation and tilt [4]. During the traditional leg kick delivery, the gluteus medius of both the drive and stride legs were significantly more active during arm acceleration. It is possible that this higher activation is the result of differences in the intent of two deliveries. It may be that the main focus when utilizing the traditional leg kick is to exert as much velocity on to the ball as possible but when the slide step is utilized, focus is placed on delivering the ball as quickly as possible. Therefore it may be that not as much conscious effort is placed on imparting maximal force on the ball when the slide step is performed, resulting in lower gluteus medius activation during arm acceleration in comparison to the leg kick style.

CONCLUSIONS

These data indicate that there is greater gluteal muscle activation in the leg kick style of pitching in comparison to the slide step. The underlying reasons for these findings may be a function of differences in both pelvic stability and the primary intent of the two deliveries. This may result in traditional leg kick delivery being a more demanding pitching method when compared to the slide step delivery.

QUANTIFYING WARFIGHTER PERFROMANCE DURING A PRONE-RUNNING-PRONE MOVEMENT TASK USING WIRELESS INERTIAL SENSORS

INTRODUCTION

In a combat scenario, the performance of a warfighter is paramount to the safety and success of a mission. In these situations however, a warfighter is expected to carry over 18kg of advanced armor, weapons, ammunition, and support gear, while simultaneously maneuvering through a complex and often random environment. These additional load constraints often restrict/alter key movements and increase the fatigue rate, contributing to a rapid decay in warfighter performance.

One key aspect of warfighter performance, known as the 'bounding rush,' is the ability to quickly transition from a prone position to a standing/running position, then back to a prone position, which simulates changing cover by exiting one firing position and moving to another. The bounding rush is used in combat scenarios to safely advance upon an enemy position. Increases in load have negative effects on a warfighters ability to perform the maneuver, specifically regarding the amount of time the warfighter is in an upright position and therefore exposed to enemy fire [1].

An array of wireless inertial measurement units (IMUs) provides the ability to measure 3D segmental dynamics in simulated combat environments where use of traditional motion capture technology is not possible. By employing an array of IMUs, this study aims to quantify differences in warfighter performance metrics during a loaded and unloaded bounding rush task.

METHODS

A pilot group of 6 subjects (4 Male/2 Female, 19.17±1.17 years old) was recruited from an athletic collegiate population. Participants were outfitted with a sacrum mounted IMU (Opal, APDM, Portland, OR) capable of measuring tri-axial acceleration and angular velocity. Participants wore military issue generation III improved outer tactical vests (IOTV-III), mock-ballistic plates and mock-tactical assault panel attached to the IOTV-III anteriorly (18kg) during the loaded condition. A mock-M4 assault rifle was carried in both load conditions.

The bounding rush task consisted of five cones spaced 4.6m apart in a zigzag pattern (Figure 1) in addition to starting and ending gates. Participants ran to the first cone and dropped into a prone shooting position while aiming at a target down range. After aiming at the target for at least 2 seconds, subjects were given a verbal cue to stand and run to the next cone and to drop to a prone aiming position as before. A synchronized trigger allowed accurate marking of the verbal cues in the data. This method resulted in four distinct prone-to-prone transitions.
Figure 1: Layout of the bounding rush task. Cones were laid in a zigzag pattern with the participant assuming a prone position at each cone.

Prone-to-prone transitions were analyzed using custom MATLAB software (Mathworks, Natick, MA). Acceleration and angular velocity data were used to calculate three distinct variables: 1) total time between prone positions (total time), 2) time

until maximum vertical displacement of the sacrum (time to standing) and 3) maximum horizontal velocity (running speed). Paired t-tests were used to identify significant differences between loaded and unloaded conditions ($\alpha=0.05$).

Performance degradations were expected to emerge in the data via increases in the total time and time to standing, and decreases in running speed.

RESULTS AND DISCUSSION

As expected, load carriage resulted in performance degradation. The total time of the bounding rush movement increased by an average(std.) of 0.88s(1.20s, p=0.16). Running speed decreased significantly with load, dropping by an average(std.) of 0.44m/s(0.31m/s, p=0.02). Time to standing increased, though not significantly, with load taking an average(std.) of 0.61s(0.75s, p=0.13) longer to reach the standing position. A linear fit was used to reveal how total time relates to with time to standing (Figure 2) and running speed (Figure 3).
Figure 2: Time to standing versus total time. Linear fit: slope=0.56, $R^2 = 0.72$

Though preliminary, the above results illustrate the potential for deploying a body-worn IMU array to quantify performance and performance degradations in a bounding rush task. Specifically, the correlations between total time and both running speed and time to standing are significant evidence that both time to standing and running speed have the potential to be strong predictors of bounding rush performance.
Figure 3: Total time versus running speed. Linear fit: slope=-0.18, $R^2 = 0.43$.

CONCLUSIONS

A body-worn array of IMUs enables the analysis of performance during a bound rush task by providing synchronized kinematic data (accelerations and angular velocities) of the major body segments. Three performance metrics, deduced from the IMU data, reveal performance degradation with added load. In particular, the addition of load increases the total time to execute the maneuver as well as significantly decreasing the running speed. Further analyses may reveal other potential performance predictors as well as potential methods for reducing the negative effects of load.

INTRODUCTION

Golf swing mechanics have received a lot of attention in the literature as a means to understand swing demands, golf performance and potential golf injury mechanisms, across skill levels and age groups [1-5]. Specifically, many of these studies track the movement of the center of pressure (COP) and/or measure joint moments throughout the swing [1-4]. In order to mimic driving range conditions, artificial grass turf is often fixed to the force plates [1, 2, 5-7]; however, it is unknown how the turf affects the force plate measurement of the COP. Inverse dynamics is dependent upon the location of the applied force (COP) and errors in COP measurement will affect the resulting joint moment calculations [8]. Therefore, the purpose of this study was to assess the validity of COP measurements with artificial turf fixed to a force plate.

METHODS

In order to assess the validity of the COP measurements, force was applied through the handle of a golf club (2.7 cm diameter) at different locations on two separate force plates. Ten locations were arbitrarily picked and marked with tape (Figure 1) on two AMTI force plates (OR6-6-1000; Newton, MA). The location of the marked locations was measured by two separate researchers to the nearest millimeter. These same locations were then marked with tape on Dura Pro™ Tuff-Turf™ (1.25 inch thickness) consisting of a base pad and knitted nylon turf cut to the size of the force plates. To ensure accurate placement of the marks, the X and Y coordinates were measured from the same anterior and lateral edge, respectively for all measures. A second researcher measured the locations on the turf and if the marks were more than 3 mm different from the corresponding location on the force plate, the location was re-marked and re-verified until all measures on the force plate and the turf were within 3 mm of one another.

To measure the center of pressure location, a researcher placed the center of the club handle at each marked location on the force plate (NoTurf) and applied vertical force for five seconds. Force plate data was collected at 1500 Hz. This same procedure was repeated for all 10 locations on each force plate a total of 4 times at each location. The turf was then fastened to each force plate with Velcro and the anterior and lateral edges were lined up with the respective anterior and lateral edge of the force plate. A turf mat was placed around the force plates to mimic the standard set-up during golf swing analysis (Figure 1). The same procedure was repeated for each of the ten locations on each force plate (Turf). In order to assess the reliability of the assessment, the turf procedure was repeated on a separate occasion by both the same researcher and a second research associate.
Figure 1. Experimental set-up for the NoTurf (left) and Turf (right).

Data was visually inspected with Qualysis Track Manager Software (Qualysis, Gothenburg, Sweden)

to ensure the direction of the applied force was constant throughout collection. 500 ms of data was extracted from the middle of the five second period. The COP in both the X and Y direction was averaged over the 500 ms and then averaged across the 4 trials for each location. The difference in COP between NoTurf and Turf was calculated for each location.

Pearson product-moment correlations between the NoTurf and Turf COP were calculated to assess the validity of the Turf COP for the X and Y coordinates. The intraclass correlation coefficients were calculated to assess test-retest and inter-rater reliability of the Turf COP for the X and Y coordinates. All statistical calculations were conducted using PASW Version 18.0 (IBM Corporation; New York, USA).

RESULTS AND DISCUSSION

Descriptive statistics for differences in COP location are presented in Table 1.

The Pearson correlation coefficient for COP was high for both the X ($r=0.999$, $p<0.001$) and Y ($r=1.0$, $p<0.001$) coordinates indicating the NoTurf COP is similar to Turf COP. The test-retest reliability was excellent as indicated by high intraclass correlation coefficients for both the X (ICC=0.999) and Y (ICC=1.000) coordinates. Inter-rater reliability was also excellent as indicated by high intraclass correlation coefficients for both the X (ICC=0.995) and Y (ICC=1.000) coordinates.

CONCLUSIONS

Assessment of the COP with artificial grass turf fixed to the force plates is both reliable and valid. While statistically valid, it is important to recognize that there were differences between the NoTurf COP and Turf COP that ranged from 0.348 mm to

13.527 mm. Slight changes in the location of the COP could affect either the magnitude of the calculated joint moment or the direction (extensor/flexor) if the COP is close to the joint axis [8]. It is unknown whether the differences in COP location are the result of errors from the turf being fixed to the force plates or errors due to improper placement of the golf club end. The marked locations on the force plate and turf were within 3 mm of one another. The differences in the COP location between NoTurf and the hand measured location were 1.488 ± 1.173 mm (Range: 0.036 mm − 3.958 mm) and 1.857 ± 0.230 mm (Range: 0.006 mm − 3.530 mm) in the X and Y direction, respectively, demonstrating inherent error within the center of pressure measurements even when turf is not applied. With a small mean difference of 4.414 mm to 7.841 mm in the X and Y direction respectively, it appears that fixing turf to the force plates does not greatly affect the COP location as compared to COP measurements without turf. Therefore, this procedure is a valid method for assessing COP movements and joint moments during the golf swing.

THE COUNTERMOVEMENT JUMP IS MORE FUNCTIONAL THAN THE SQUAT JUMP IN MEASURING ELITE BASKETBALL PLAYER PERFORMANCE

INTRODUCTION

Predicting athletic performance from quantitative tests is of the utmost interest to strength and conditioning professionals, biomechanics, and coaches. For example, sports like basketball host combine events with the goal of highlighting future player performance. However, due to the basketball's multifaceted nature no single test predicts an athlete's abilities [1]. Nevertheless, the force from a player's vertical jump has been linked to increased playing time [2]. The two most commonly tested vertical jump conditions are the countermovement jump and the squat jump [2, 3]. It is argued that the countermovement jump is more sport-specific, allowing for greater vertical height [4] whereas the squat jump is a better measure of lower body power [5]. The various forms of the vertical jump, including squat and countermovement with no arm involvement, one-, or two-arm swings, may be why no one jumping form has been recommender for player testing to date [2, 3, 6, 7].

The purpose of this study is to evaluate the force profiles of the countermovement and the squat vertical jumps in elite basketball players to determine if one jump is superior to the other as a measure of performance.

METHODS

All fifteen players from an elite men's basketball team were recruited to perform six jumps on a portable BERTEC force plate (BERTEC Corporation, Columbus, OH, USA). Three countermovement jumps and three squat jumps were performed, each with an arm swing. A Vertec vertical jump tester (Power Systems Incorporated, Knoxville, TN, USA) was placed 0.25 meters forward of the force plate at a base height 2.90 meters of to give the players a target. Seven identical data collections took place across the playing season during scheduled practice times, averaging one collection every three weeks. Due to injuries accrued during the season the incomplete data of two players were ignored.

A custom script using MATLAB (The Mathworks Inc., Natick, MA, USA) determined the maximum vertical force, rate of force development, maximum velocity, and maximum power from the ground reaction force.

The data was analyzed using SPSS Statistics (IBM, Corporation, Armonk, NY, USA). The mean values across the season of the maximum vertical force, rate of force development, maximum velocity, and maximum power were calculated for each player by jump type. A bivariate correlation compared the types of jump while a paired sample t-test evaluated the absolute differences of the measured values.

RESULTS AND DISCUSSION

The high correlations of the maximum vertical force, maximum velocity, and maximum power between the jumps demonstrate that the countermovement and squat jump are similar (Table 1). However, the correlation of the rate of force development between the jumps was low ($r = 0.504$). The mean value of the rate of force development of the countermovement jump ($M = 1932$ N/s, $SD = 636$ N/s) was larger than that of the squat jump ($M = 1769$ N/s, $SD = 732$ N/s). This difference may be explained by the initial countermovement before jumping which has been linked to increase force production and muscle activity [4].

In the case of the maximum vertical force (Figure 1), rate of force development, and maximum power, the absolute difference values of the measures did not demonstrate significant differences ($p<0.01$) between jump types. However, the maximum velocity was higher in the countermovement jump. This difference is due to the increased work produced in the countermovement by the leg muscles [4].
Figure 1: Comparison of maximal vertical forces of the countermovement and squat jumps.

The squat jump is a more direct measure of lower limb strength, as it does not require generating the countermovement with the upper body. Nevertheless, in basketball the squat jump is not common. Players are required to manipulate their upper bodies to achieve a transfer of energy allowing them to successful shoot or to gain possession of a rebound.

Given the high correlations between the squat and countermovement jump suggests that the jumps are similar. However, the increased rate of force development seen in the countermovement jump suggests that it is the recommended jump to use in basketball field collections.

CONCLUSIONS

In assessing athletic performance, the tactical demands of the particular sport must be assessed ahead of technical considerations [7]. Using the countermovement vertical jump, the lower body power, force, and rate of force development can be assessed while also accounting for a greater vertical jump height than the squat jump.
The sport-specific nature of the countermovement jump, combined with an arm swing, may permit basketball players to jump in a manner most natural to them without sacrificing data about the force profile of the jump itself.

THE EFFECTS OF TWO DIFFERENT PULLING STRATEGIES ON BARBELL KINEMATICS DURING THE CLEAN PULL EXERCISE

[1] Travis Ficklin, Natalie Sinnwell, Robin Lund, Ben Thoma, and Ross Curtis

[1] The University of Northern Iowa, Cedar Falls, IA, USA
email: travis.ficklin@uni.edu

INTRODUCTION

In the sport of Weightlifting, research has suggested that a rearward foot displacement and bar trajectory from the start to the catch phase of a clean is advantageous over other techniques. This may be done by shifting the foot center of pressure (COP) rearward toward the heels during the first pull and maintaining a flat-footed position as long as possible before the second pull [1]. Additionally, it is possible that having a center of pressure toward the metatarsophalangeal (MTP) joints pulls the lifter forward and causes a looping effect [2].

Contrary to these suggestions, it has been proposed that the center of pressure during the first pull should never be as far back as the heels [3]. In fact, some recommend that the center of pressure should be through the MTP joints of the feet. The purpose of this study is to compare these two pulling strategies in terms of COP location and barbell kinematics during the clean pull exercise.

METHODS

All methods were approved by the IRB of the university and all subjects signed informed consent agreements before participating in the study. Ten injury-free subjects with at least one year of experience and training in USA Weightlifting technique participated in the study.

Each subject executed four clean pulls each using a load 95% of their self-reported one repetition maximum (1RM). For safety, the subjects were not required to catch the bar at the top of the pull. The subject was instructed to "pull through the heels" during the first pull for two trials and to "pull through the toes" during the first pull for the other two. The order of pulling condition was quasi-randomly counterbalanced between subjects.

The ends of the weightlifting bar were marked with retro-reflective markers for use in a multi-camera motion capture system (Nexus, Vicon, Denver, CO). The 3D locations and velocities of the markers were tracked during each lift at 200 Hz. Additionally, the vertical ground reaction force (GRF_Z) and COP location were recorded during each lift using a force platform sampling at 400 Hz (Accupower, AMTI, Watertown, MA).

The first pull was defined as the period of time during which GRF_Z was greater than the weight of the lifter-plus-load system as measured in a static calibration, and the second pull was defined as the second such period [4].

Bar height (H) in each frame was calculated as the vertical location of the centroid of the two bar end markers. Its vertical velocity (v) in each frame was calculated as the average vertical velocity of the markers. The peak height (H_{PK}) and maximum upward velocity (v_{MAX}) of the centroid during the whole movement were determined for each trial. H_{PK} was then normalized to subject stature for the purpose of between-subject comparisons.

Fore-aft COP data were used to verify the pulling conditions. The placement of the toes of each subject was standardized to a line marked on the surface of the force platform which was a known distance from the plate's geometric center. Then, the fore-aft location of the COP with respect to this line was calculated during the lift. Using the measured foot length for each subject, fore-aft COP position was normalized to foot length such that a location that was even with the geometric midfoot lines of the feet was zero, a location at a maximum forward limit that was even with the toes being +1.00, and a location at a maximum rearward limit that was even with the heels being -1.00. The average normalized fore-aft location of the COP

was then averaged over the time of the first and second pulls.

Descriptive statistics (mean ± SD) were calculated for all variables. A multivariate dependent t-test was used to determine the effect of the pulling condition on average fore-aft COP during the first and second pull, peak barbell velocity v_{MAX}, and normalized barbell height H_{PK}. Alpha was set at $p<0.05$ for all tests.

RESULTS AND DISCUSSION

Descriptive statistics of demographic variables and performance variables by technique can be found in Tables 1 and 2. The multivariate dependent t-test showed a significant pulling condition effect ($F(4,6)=5.27$, $p=0.04$). COP was more forward in the "toes" condition for both the first and second pulls. H_{PK} and v_{MAX} were also both greater for the "toes" condition.

CONCLUSIONS

The COP data confirm that the subjects were in fact using significantly different pulling strategies between conditions. Interestingly, although the COP was more rearward in the "heels" condition, subjects did not actually pull "from the heels" during these trials as indicated by average COP

positions during the pull that were forward of the midline of the feet.

Clearly the subjects attempted to start with the COP further back during the first pull but intuitively shifted the COP forward, perhaps in order to get into a more favorable position for the second pull. Despite the shift of the COP forward for the second pull, the heel pulling strategy most likely resulted in a more simultaneous extension of the hips and knees resulting in significantly less v_{MAX} and H_{PK}. Weightlifters should consider shifting their COP forward, closer to the MTP joint when initiating the clean pull exercise.

THE EFFECT OF DIFFERENT START STYLES ON BASE STEALING KINEMATICS IN DIVISION I SOFTBALL PLAYERS

[1] Keegan Parrott, Brian Rohrbach, Travis Ficklin, Natalie Sinnwell, and Robin Lund

[1] The University of Northern Iowa, Cedar Falls, IA, USA

email: parrottk@uni.edu

INTRODUCTION

There are many advantages associated with the successful steal attempt of a base in the sport of softball [1]. In particular, the advancement to the next base without giving up an out increases the run expectancy for that inning. The rules of softball prohibit leading off, and the baserunner cannot leave the base until the pitcher releases the ball. However, there are no specified constraints regarding the manner in which the baserunner maintains contact with the base before leaving, nor on the manner in which she initiates the takeoff when legally leaving the base to start a steal. Despite the lack of constraint there has been no identifiable research examining the efficacy of different techniques. The purpose of this study is to compare base stealing kinematics when using static and dynamic takeoff styles in base stealing for Division I softball players.

METHODS

All procedures were IRB-approved and all subjects provided their informed consent prior to data collection. Thirteen Division I softball players participated in the study. After a dynamic warm-up period, each subject executed six sprints from first to second base as though executing a steal. The first two trials were executed using their own current game starting style, and were executed before any feedback or instruction were given. These first trials served as the control condition for all subjects. After these control trials, subjects were then taught two other takeoff styles: one from a static ready position and the other from a dynamic countermovement. In order to obtain the best possible time of stealing (t_{STEAL}) for each trial, subjects were not required to stop at the base but were allowed to run at full speed past it after stepping on it.

Two cameras were used to record each trial (GC-PX1, JVC Corp, Tokyo, JP). The first captured the first 5.0 m of the run at 300 Hz. It was positioned approximately 20 m from the basepath with its optical axis perpendicular to the vertical plane containing the basepath line. The lead edge of first base (closest to second base) was used as the origin and marks at 2.5 m and 5.0 m were used both for distance calibration and for timing purposes. The second camera recorded the entire run at 300 Hz from the time the subject left first base to the time when she touched second base. This camera was allowed to pan to follow the subject throughout the run.

The instant of leaving first base ($t_{START} = 0.0$ s) was determined to be the video frame in which foot contact with the base was broken. Times from start to 2.5 and 5.0 m ($t_{2.5}$ and $t_{5.0}$, respectively) were measured using data from camera 1. To do this, the forewardmost point of the subject's trunk was digitized in each video frame from t_{START} to when the subject had clearly surpassed the 5.0 m mark using MaxTraq software (Innovision Systems, Columbiaville, MI). Additionally, the origin and the marks at 2.5 and 5.0 m were digitized in each trial.

These digitized data were then exported for use in custom Matlab software (Mathworks, Natick, MA) to analyze the batch of trials. For each trial, $t_{2.5}$ and $t_{5.0}$ at which the leading point of the trunk crossed the 2.5 and 5.0 m marks were determined by interpolation between frames of the point's location data for the instant at which it had crossed each mark.

The time of the entire run was calculated using frame number data from camera 2. First, the number of frames captured between t_{START} and the nearest estimated half-frame at which second base was contacted was calculated. Then, this number was multiplied by (1/300 s) to calculate t_{STEAL}.

Descriptive statistics were calculated for all performance variables. A repeated measures MANOVA was used to determine any treatment effect. Mauchley's test was used to test the sphericity assumption. Three repeated variance ANOVAs were administered to determine which variables were affected. Bonferroni-adjusted paired t-tests were used as post hoc analysis. The level of significance was set at $p<0.05$ for all inferential analyses.

RESULTS AND DISCUSSION

Descriptive statistics of all performance variables can be found in Table 1. The sphericity assumption was tenable for both $t_{2.5}$ (p=0.19) and $t_{5.0}$ (p=0.34) but not for t_{STEAL} (p=-.001) resulting in a Greenhouse-Geisser penalty for that variable. The repeated measures MANOVA indicated a significant treatment effect (F(6,42)=2.39, p=0.045). The three repeated measures ANOVA indicated that the observed treatment effect was not significant for $t_{2.5}$ (p=0.06). There were, however, treatment effects for $t_{5.0}$ (p=0.002) and t_{STEAL} (p=0.03). The results of the post hoc analysis are summarized in Table 1.

By the time the player reaches second base, the dynamic takeoff condition has yielded an advantage over both the static and self-selected takeoffs. However, this advantage does not materialize at all within the first 2.5 m, and only surfaces over the self-selected takeoff after 5.0 m. Due to the stretch reflexes associated with dynamic starts and the subsequent improvement in forward lean and horizontal impulse, it was expected that this strategy would be more effective than the other conditions early in the run but not necessarily as the run progresses [2].

Instead, the effect of dynamically starting the steal seems to continue further into the run than in previous similar studies [2]. This could be because of sport or sex differences, being that the previous similar study examined takeoff technique in male football players. Regardless, the advantages of using the dynamic takeoff style in the present study are realized most fully over the course of the entire steal.

CONCLUSIONS

Practitioners should consider experimenting with dynamic takeoff techniques for base stealing. There may be many ways to adapt dynamic takeoffs for individual players. Coaches should also take into consideration that the dynamic strategies may make it more difficult to time the start accurately with the ball release of a live pitcher. Practice with the timing of the technique must be employed to gain full advantage of its use.

INFLUENCE OF A SELF-INDUCED DROP ON VERTICAL JUMP PERFORMANCE

INTRODUCTION

Countermovements are valuable because of the exploitation of the stretch-shorten cycle. In a traditional countermovement vertical jump athletes lower the center of gravity by flexing the hips and knees, stretching the muscles eccentrically, before changing directions and forcefully extending in the direction of motion. A slight alteration of the countermovement was witness by Angle, Gillette, and Weimar (2012) in canine sprinters. The authors noted that unlike the traditional countermovement (CM) typically seen in humans, canines flexed the elbows and knees to raise the paws 4-8cm from the ground allowing the center of mass to free fall toward the ground. Upon contacting the ground the joints flexed farther prior to take-off [1]. Canines appear to perform a self-induced drop Drops have been associated with higher rate of force development (RFD), which is associated with improved vertical jump performance [2, 3]. Hence, a self-induced drop should lead to increased RFD and increased jump height. Therefore, the purpose of this study was to compare rate of force development and vertical jump height in the self-induced drop (SD) to the countermovement (CM) and squat jump (SJ) conditions.

METHODS

17 males and 17 females were recruited for participation. Participants performed a minimum of 3 maximum vertical jumps utilizing 3 different loading conditions (SD, CM, SJ). Arm swing was not allowed in any of the jumps. The order of the loading conditions was randomized. The SD required participants to lift their feet from the ground without vertical rise in the center of mass, and fall into a countermotion. The second condition was the CM in which the center of mass lowers prior to the push phase with the feet in contact with the ground. Additionally a SJ condition was performed with the knees pre-flexed to a self-selected depth. Each jump was recorded using a 10-camera Vicon® MX motion capture system (Vicon®, Los Angeles, CA, USA) with a sampling frequency of 200 Hz. Jump height was defined by the difference in maximum height achieved of the greater trochanter marker and its height during the static calibration trial.

RESULTS AND DISCUSSION

A two-way repeated measures ANOVA was used to analyze differences in jump height (Figure 1). The results of the analysis indicated significant differences among conditions ($F(2,64) = 33.738$, $p < 0.001$, $\eta^2 = 0.513$, $Power = 1.000$) and both sexes had the same response to the imposed conditions ($F(2,64) = 2.512$, $p = 0.089$, $\eta^2 = 0.073$, $Power = 0.486$). Pairwise comparisons demonstrated that jump height in the CM was significantly greater than the SD ($p = 0.014$) and the SJ ($p < 0.001$). Additionally, height in the SD was significantly greater than the SJ ($p < 0.001$).
Figure 1: Mean vertical jump height for each SSC condition. * denotes significance at the $p = 0.05$ level.

A two-way repeated measures ANOVA was used to analyze differences in RFD. RFD results violated the sphericity assumption requiring the Greenhouse-Geisser adjustment to the degrees of freedom. The results of the analysis indicated significant differences among conditions ($F(1.297,41.491) = 15.104$, $p < 0.001$, $\eta^2 = 0.321$, *Power* = 0.987) and both sexes had the same response to the imposed conditions ($F(1.297,41.491) = 1.875$, $p = 0.177$, $\eta^2 = 0.055$, *Power* = 0.300). Pairwise comparisons demonstrated that RFD in the SD was significantly greater than the CM ($p < 0.001$) and the SJ ($p = 0.025$). Additionally, RFD in the SJ was significantly greater than the CM ($p = 0.009$).
Figure 2: Mean vertical rate of force development for each SSC condition. * denotes significance at the $p = 0.05$ level

Results indicate that the CM is superior to both the SD and SJ conditions in producing maximum jump height. This occurred despite greater rates of force development in the SD condition. It is possible that the rate of force development is too high in the SD condition, especially since the condition was novel to all participants. High rates of force development can lead to muscle fiber lengthening [4]. Muscle fiber lengthening, although it allows for force enhancement, may necessitate greater shortening of the muscle during the concentric phase of the jump. Increased shortening suggests the muscle operates too far to the right on the force-velocity curve, which leads to non-optimal force production.

However, participants did jump higher in SD compared to SJ. The results demonstrate that utilizing the stretch-shorten cycle improves performance.

CONCLUSIONS

This studied examined the CM, SD and SJ vertical jump conditions. Utilization of a stretch-shorten cycle improved RFD and vertical jump height. Although the CM appears to be the superior method, this may be due to non-optimal muscle coordination in a novel jumping technique, which could be corrected with training. Furthermore, the efficacy of the SD condition should be examined in horizontal accelerations, since this is the circumstance noted by Angle, Gillette and Weimar (2012).

NO ANGULAR SWING KINEMATIC DIFFERENCES IN FEMALE SOFTBALL PLAYERS WITH DIFFERENTLY WEIGHTED WARM-UP BATS

[1] Yang-Chieh Fu, [2] Nicole C. Dabbs, and [1] John C. Garner

[1] The University of Mississippi, Oxford, MS, USA
[2] California State University, San Bernardino, CA, USA

INTRODUCTION

Baseball/softball coaches and players display a constant interested in methods to increase bat swing kinematics for competition. A common method to increase swing velocity is utilizing different weighted warm-up bats prior to maximum performance. These warm-up bats may be lighter or heavier than a regular weighted bat used in regular game. However, there is no agreement on efficacy of using the warm-up protocol [1-3], and coaches and players still utilize it based on their own experience or beliefs.

One major concern for this controversy is due to no previous study, up to authors' knowledge, has analyzed the movement using three dimensional (3D) techniques, and no angular swing kinematics has been reported. Therefore, the purpose of this study was to examine the 3D kinematics of three different weighted warm-up bats.

METHODS

Ten female college softball players were recruited (age: 20.1 ± 1.1 yrs; mass: 76.4 ± 21.3 kg; height: 165.7 ± 8.4 cm). All participants were fully informed and signed the consent form. Data collection was conducted in a typical biomechanics laboratory. Seven reflective markers were placed on the bat (1 top marker on the center of the bat top, and 6 on the barrel), and 27 markers were places on participant's head, trunk, pelvis, and upper limbs. Marker trajectories were recorded by a seven-camera motion analysis system (Vicon, CA, USA) at 100 Hz. Three weighted bats/session (normal weighted, NW, 29 oz.; heavy weighted, HW, 45 oz.; light weighted, LW, 13 oz.) were tested and order was randomized. For each session, each participant performed a self-selected warm-up protocol (instructed to be consist with their on-deck routine) using assigned bat and followed by 5 maximal swing with NW bat. There was 3 minutes resting between each condition. The best trial of each condition was analyzed. Marker data was filtered with 4th order Butterworth filter at 6 Hz cut-off prior subsequent analysis.

Data were analyzed from the beginning of loading phase to the end of the follow through phase of bat swing. Angular kinematics were obtained by steps as followed. First, a best-fitted bat swing plane was generated from the top bat marker at global coordinate system (BAT_g) using least squares method (Figure 1). BAT_g were then projected onto the best-fitted plane (BAT_{g-proj}). Three arbitrary points were selected from BAT_{g-proj} to define a local coordinate system embedded on the plane, and rotation matrix R_{swing} and translation vector V_{swing} were also generated. BAT_{g-proj} were transferred from the global to the local coordinate system by following equation:

$$BAT_{l-proj} = R_{swing}{}^T * (BAT_{g-proj} - V_{swing})$$

Angular trajectories (BAT_{ang}) were obtained by converting BAT_{l-proj} from Cartesian to polar coordinates. At last, angular velocity of the swing was calculated by differentiation of BAT_{ang}. Plane angle between the best-fitted plane and the ground plane (x-y plane) was also calculated.

Peak angular velocities, time to peak velocity, relative time to peak velocity, and plane angle were tested using a 1x3 (group by condition) repeated measures ANOVA. The significant level was set at $\alpha = 0.10$ for omnibus test due to small sample size and 0.05 for pairwise comparison to minimize familywise errors. All tests were conducted using SPSS (IBM Corp., Version 21.0. Armonk, NY).

Plotting plane z=(-0.443526)*x+(0.519701)*y+(1988.187976)
Figure 1: Example of best-fitted swing plane.

RESULTS AND DISCUSSION

For angular kinematics, differences were only found at relative time to peak velocity (Table 1). The HW condition reached peak angular velocity approximately 5% later than the NW condition ($p = 0.014$). No differences were found in other angular variables as well as the plane angle.

Current study aimed to investigate efficacy of using differently weighted warm-up bats by 3D angular kinematic analysis. In general, results do not agree with many coaches and players' believe: using differently weighted bat warm-up protocol can enhance maximum performance by increasing swing velocity, which agrees with Szymanski's study [3].

Reason for the delayed relative time to peak angular velocity of HW bat compared to NW is not clear. It was presumed that this delay might be due to the altered rotation axis of the whole body. However, it was partly rejected since there was no difference at the plane angle between conditions. Although the normal axis of the best-fitted plane is not the true axis of rotation of the whole body, theoretically they are close. Thus, advance study is needed to explain this finding.

Gender and sports type differences might be potential factors affect swing kinematics. Most studies [1-3] recruited male baseball players while female softball players were recruited in current study. Gender differences such as physical strengths might affect swing kinematics. Also, the 'normal' bat used in current study is similar to that has been used in regular baseball competition. It might be heavy to female softball players thus affect swing kinematics.

The study is mainly limited by relatively small sample size and selected athletes. Thus, it is recommended that some caution is necessary when interpreting the results and generalize to different sports. Also, camera sampling rate might be low for the high velocity bat swing movement. A higher sample rate is suggested for future study.

CONCLUSIONS

Evidence from our study suggests that there is no notable angular kinematic difference with differently weighted warm-up bats prior maximum performance in female varsity softball players. Further investigation on whole body kinematics as well as kinetic changes of bat swing is necessary to further support finding in current study.

DETRENDED FLUCTUATION ANALYSIS OF RUNNING GAIT TRACKS CHANGES IN PERFORMANCE WHEN ATHLETES ARE OVERTRAINED

INTRODUCTION

Stride-to-stride fluctuations in running stride interval display long-range correlations that breakdown in the presence of fatigue accumulated during an exhaustive run [1]. The presence of long-range correlations in the stride interval of running suggests that small fluctuations in stride interval occur at a high frequency whilst large fluctuations occur at a low frequency [2]. This pattern of scaling is thought to result from motor control processes operating on different time scales. In a healthy state, these processes interact to produce a signal containing long-range correlations [1,3]. However, in the presence of fatigue, injury, aging and pathology the resultant signal is more random, with only weak long-range correlations present [1,3].

Overtraining is a pathological condition that occurs in athletes when training load is too high or recovery from training is too short [4]. Methods for monitoring training status have predominantly focused on measuring changes to heart rate variability and have had mixed success [4]. The recent observation that long-range correlations in stride interval are sensitive to fatigue [1] suggests that the stride interval may provide a new means for monitoring training status. The aim of this study was to investigate whether a state of temporary overtraining, as indicated by a decrease in performance in response to heavy training, is reflected by changes to stride interval long-range correlations measured during sub-maximal running.

METHODS

A prospective intervention design was used to investigate stride interval long-range correlations after two weeks of light training, two weeks of heavy training designed to induce a temporary state of overtraining and two weeks of subsequent tapering (light) training. Ten trained male runners (Age: 21-53 years; mass: 62-84 kg) completed this study. Stride interval long-range correlations were assessed at the completion of each training phase during 5-min of submaximal running at 8, 10.5 and 13 km/h. Training status was assessed using a 5-km treadmill time trial (5TTT).

Force-sensitive resistors were placed underneath the first metatarsal head and heel regions of each shoe insole during sub-maximal running. This allowed the moment of initial foot contact to be recorded wirelessly at 2000 Hz using a Delsys Trigno system (DelSys Inc, Natick, USA). Stride intervals were calculated as the time between peak forces at initial contact. Peak forces were identified using the findpeaks function in MATLAB (R2013a, MathWorks, Natick, MA). An example stride interval time series is shown in Fig. 1.
Figure 1: Stride interval time series.

To determine the degree of long-range correlation in each stride interval time series, the initial 30-seconds of data were first removed from each time series. A median filter was then used to remove

values that were outside the inter-quartile range (IQR) by a magnitude of 1.5 times the IQR. A separate detrended fluctuation analysis was then performed on the first 300 strides, for each of the three running speeds [5]. Briefly, the time series (N) was first integrated. Next the integrated times series, $y(k)$, was divided into windows of length n. In each window of length n, a least squares line was fit to the data to represent the local trend, $y_n(k)$. We then detrended the integrated times series by subtracting the local trend in each window. The root-mean-square fluctuation of this integrated and detrended time series was then calculated by:

$$F(n) = \sqrt{\frac{1}{N}\sum_{k=1}^{N}[y(k) - y_n(k)]^2}$$

This calculation was repeated across all windows sizes from 4 to 75 strides. The coefficient (α) relating fluctuations to window size on a log-log plot was used to assess the degree of long-range correlations [5]. A running stride with long-range correlations across all times in a time-series has a scaling exponent $\alpha=1.0$. In contrast, stride-to-stride fluctuations that occur in an entirely unpredictable sequence have a scaling exponent $\alpha=0.5$.

RESULTS AND DISCUSSION

There was a significant main effect of training on performance (P<0.01). The heavy training induced a state of temporary overtraining as evidenced by a decline in 5TTT performance following heavy training and an improvement in performance following taper training (P<0.03; Fig. 2).
Figure 2: Percentage change in performance and α. * significantly different to light training (P<0.05).

There were no significant main effect of training on α (P>0.54). However, changes in α at the 10.5 km/h speed and changes in performance between light and heavy training were moderately correlated (r -0.41; P=0.02). Stride interval α decreased when time to complete the 5TTT increased (Fig. 3).
Figure 3: Change (Δ) in performance and α.

Despite not changing significantly in response to alterations in training status, stride interval α shows potential as a marker for tracking changes in training status. The ability of stride interval α to track changes in performance may be improved by using individualised running speeds for assessment of α that are relative to an individual's maximum or preferred running speed. Previous research has shown that gait speed influences α [2] and the fixed running speeds used in the present study would have represented different relative running speeds for each runner. This potential heterogeneity could have made it difficult to detect a consistent effect of training status on stride interval α across runners. Future research should investigate the ability of stride interval α assessed at relative running speeds to monitor training status.

JUMP PERFORMANCE VARIABLES ARE NOT DIFFERENT IN FEMALE D1 LACROSSE ATHLETES WITH GENERALIZED JOINT HYPERMOBILITY.

Christopher F. Geiser, Carolyn Meinerz, Philip J. Malloy, Michael Kiely, and Kristof Kipp

Marquette University, Milwaukee, WI, USA
email: christopher.geiser@marquette.edu, web: http://www.marquette.edu/exercise-science/

INTRODUCTION

Generalized joint hypermobility (GJH) is defined as a form of systemic joint laxity[1] thought to occur from genetic difference in the collagen makeup of these individuals.[2] Severe forms of hypermobility are a component of Ehlers-Danlos syndrome and Marfans syndrome. Unlike these often debilitating forms of hypermobility, individuals with GJH are generally not impacted during activities of daily living and are often referred to in common vernacular as "double-jointed." A greater incidence of GJH is found in females and children.[2] GJH is also reflected in the athletic population, where the incidence of GJH among female athletes is estimated to be as high as 43%.[3,4]

There is growing evidence that athletes with GJH are at greater risk of knee injury during athletic participation,[4] that overall they are injured more frequently, and miss participation for longer periods of time.[3] Previous investigators have attempted to pinpoint descriptive differences in the movement of individuals with GJH to identify a direction for interventions. Alterations in kinetic variables and muscle activation patterns have been reported in the GJH population during gait and during landing from a jump.[6,7] Differences in muscle contractile functions have been noted in people with severe forms of hypermobility.[8] These differences could play a role in increasing injury risk. However investigations to determine if a component of the increased injury risk noted in GJH could be attributable to differences in physical performance. have not been done, or have reported inconsistent findings.[9]

The purpose of this investigation was to evaluate for differences in countermovement jump performance variables in NCAA DI female Lacrosse athletes with GJH and matched controls.

METHODS

After acquisition of informed consent, all healthy uninjured women's lacrosse players on a NCAA DI University roster were tested for GJH according to the number of positive Beighton's signs,[10] which are an evaluation of 9 specific movements including hyperextension of the knees and elbows past 10 degrees, dorsal flexion of the 5th digit past 90 degrees, thumb and forearm approximation, and the ability to touch the palms flat to the floor with the knees in full extension. Five or more positive signs were needed for inclusion in the hypermobile group.[4] The experimental (GJH) group consisted of 8 players (19.4 ± 1.0yrs, 71.0 ± 9.4kg, 165.1 ± 7.1cm) with 5 or more Beighton's signs (range 5-7, mean 6.0). Eleven matched controls (Ctrl: 19.9 ± 1.2yrs, 65.3 ± 7.0kg, 167.6 ± 3.0cm) were included with zero or one Beighton's sign (range 0-1, mean 0.1). After a warm up period, participants performed three trials of a countermovement jump (CMJ) standing with each leg on a separate AMTI force plate, with the instructions to keep hands on their hips and jump "as high as they can." One practice jump was required prior to data collection, more were allowed if the participant wanted. Force data were collected at 960 Hz in Vicon Nexus software and filtered with 4th order Butterworth filter with a cutoff frequency of 12 Hz in a custom Matlab program. Right and left leg vertical reaction forces were summed and the following dependent variables were calculated and exported from Matlab for statistical analysis: Vertical Jump Height, Reactive Strength Index, Peak Vertical Force, Time to Peak Force, Peak Concentric Force, Peak Eccentric Force, Peak Rate-of-Force Development, Peak Rate-of-Force Development normalized to Body Weight, Peak Concentric Rate-of-Force Development, Peak Eccentric Rate-of-Force Development, Take-off Velocity, Peak Power, Force at Peak Power, Velocity at Peak Power, Positive Work, Negative Work, Eccentric Time and Concentric Time. Group comparisons were made between the three trial

averages and the best of the three trials. Independent t-tests were used to compare all means between groups with significance set at p<0.05. As this study was exploratory in nature, no correction for multiple comparisons was made to minimize Type II error possibility.

RESULTS
Data met the assumptions of normality and equal variance for parametric testing. No differences were found between GJH group or controls for anthropometric data.
No differences were noted between groups for any of the CMJ data variables.

DISCUSSION
This exhaustive evaluation of jump performance variables in individuals with GJH failed to identify any differences between those participants with and without GJH. This differs from the work done on isolated muscle fibers in hypermobile individuals where lower peak torque had been reported in isolated muscle fibers, but greater twitch torque[8] in individuals with a more severe form of hypermobility versus controls. Another single fiber study found that peak force was equal between groups, but that resting tension in the muscle fibers was greater in hypermobile individuals.[11] Greater resting tension is thought to be the reason that rate-of-force development was higher in GJH groups[9] as well as a higher single-fiber twitch torque.[8]

Despite the differences noted at the single level in individuals with hypermobility, the current study did not detect any performance differences between those with GJH and controls during a large, functional movement. This discrepancy is probably due to a task difference. The CMJ task allows for coordinated muscle activity between large groups of muscles. This may allow differences in muscle performance to be compensated for by timing, coordination, or some other factor during the jump. Perhaps future studies of performance variables in GJH should consider a "reactive" component to capture any differences in muscle resting tension or twitch response that a planned CMJ may not have effectively evaluated.

The current results may also be impacted by an underlying selection bias in examining individuals from the same team. The athletes in this study all play Division 1 Lacrosse, and are therefore different than those evaluated in the single fiber studies. This in itself is interesting, demonstrating that at least some individuals with GJH are capable of jump performance at the same level as their less flexible counterparts. Thus, by demonstrating that athletes with GJH can perform a CMJ equal to non-GJH individuals, this study allows us to move on to considering other variables, including more isolated components of muscle function, that predispose GJH individuals to greater injury risk.

CONCLUSIONS
Participants with GJH participating at a high level in athletics do not appear to exhibit differences during isolated measures of athletic performance when compared to similar level teammates. Thus, the reported differences in injury rates and severity of injury in people with GJH appears be driven by factors other than those related to jump performance. Future studies must examine other variables that could potentially drive the risk of lower extremity injury in hypermobile individuals so that scientifically based effective interventions can be designed.

INTRODUCTION

A heightened awareness of athletic safety in the field of sports has increased the development of various injury prevention studies. The majority of this research has focused on traumatic injuries, such as concussion prevention and impact related injuries. However, the predominant injury type in sports occurs with overuse and fatigue [1]. Such injuries occur in athletes with repeatedly incorrect biomechanics, improper conditioning and poor stretching. In an attempt to limit injuries, Functional Movement Screening (FMS) and the Landing Error Scoring System (LESS) were developed to identify athletes that are at risk for an overuse injury [2]. Both tests consist of various dynamic movements that are qualitatively scored based upon the athlete's performance. Studies have shown that there is a correlation between the athletes score and the risk the athlete has for an injury [3]. The problems with these tests are that the scores are subjective to each assessor, resulting in human error, inconsistent scoring and misdiagnosis of the motion.

The main objective of this project is to utilize quantitative techniques to measure human movement and develop training protocols that will result in a reduced risk of athletic injury and increased performance. This initial study primarily focuses on injuries related to the lower extremity and will be used as a preliminary training protocol for future work using the LESS test.

METHODS

To develop the testing protocol, one subject participated in the IRB approved study (male, age: 20 years) that utilized quantitative techniques to collect human movement data. Figure 1 shows that the subject was affixed with 23 passive reflective markers based on the anatomical locations specified in a previously developed musculoskeletal model. Using the VICON Nexus software, a subject-specific model was developed from a generic template of marker locations using the static stance position shown in Figure 1A. Next, rigid bodies were fitted to the marker locations on the individual subject, resulting in Figure 1B. Once this model was complete, the subject performed the LESS test. This test consisted of both vertical and horizontal movements as the subject jumped from a 13.5 inch plyometric box. The subject first jumped to a distance of 50% of their height away from the box, and then immediately jumped as high as they could vertically from that position. The subject was able to practice the test before it was recorded and then four trials were performed.

A   B   C
Figure 1: Reflective markers shown on the subject's lower extremity (A) along with the corresponding marker locations on the VICON Nexus model (B) and the corresponding musculoskeletal model in OpenSim (C).

The collected data for the LESS test were processed and filtered in the VICON Nexus software. To process the data, unmarked markers were labeled, gaps in the trajectories were filled using various spline techniques implemented in the software, and unwanted reflective interference were deleted.

The processed files were then exported as ASCII files for further analysis. The ASCII files contained the three-dimensional positioning of each marker throughout the trial and were able to be formatted and loaded into OpenSim. Figure 1C displays the lower extremity model that was scaled using the same static trial previously used for the calibration in the VICON Nexus software. This model was used to determine the inverse kinematics of each jump test.

For the preliminary results, the inverse kinematics determined the angles of hip flexion, hip adduction, hip rotation, lumbar extension, knee flexion, and ankle flexion for each leg. The results were then processed to remove any signal noise using a 4th order low pass Butterworth filter in MATLAB. The results were also normalized with respect to time to compare across trials of the same test, and plotted versus the normalized time. Figure 2 shows the inverse kinematics of the four trials of the LESS test for the single subject.

RESULTS AND DISCUSSION

For the purpose of the preliminary results, the results from the LESS test were analyzed by determining hip flexion, adduction and rotation versus normalized time, lumbar extension versus normalized time, knee flexion versus normalized time, and ankle flexion versus normalized time. By initially examining only this test, it was possible to effectively demonstrate results consistent with prior research, while also not presenting excess information in this exploratory study.

As illustrated in Figure 2, the similar curves shown in each of the plots suggest that the subject performed the jump test in a consistent manner during each trial. There are also noticeable similarities between the right and left legs in the hip flexion and knee flexion plots. These two degrees of freedom are perhaps easiest to visually observe during qualitative analysis of the trials. Differences in the right and left leg exhibited in the remaining plots suggest that the subject favored a leg during the test. This could mean that one leg is stronger and is being used to compensate for stability during the movement, resulting in a potential injury. Because this data represents a small number of

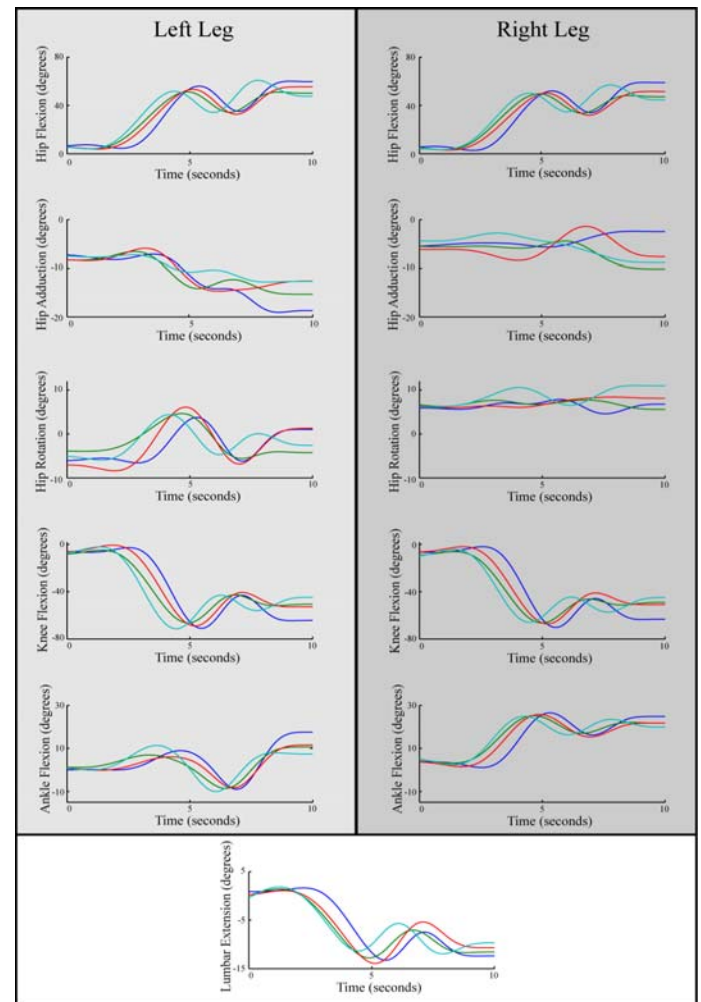
trials, no statistically relevant conclusions can be made.


Figure 2 : Initial kinematic results from musculoskeletal simulations of the LESS test.

Future work will build off of this preliminary study and examine a series of functional motions including the LESS test, the FMS tests, and additional jump tests. Once a sufficient library of subject data has been collected, statistical methods will be used to develop the desired metric.

IMPACT OF ERROR SONIFCATION AUDITORY FEEDBACK FOR NEROMUSCULAR TRAINING ACROSS TWO DEGREES OF FREEDOM

Rena Hale, Jerome Hausselle, and Roger V. Gonzalez
The University of Texas at El Paso, El Paso, TX, USA
email: rvgonzalez@utep.edu

INTRODUCTION
When performing fundamental maneuvers such as squatting, technique is vitally important as such motions are usually conducted while conducted when lifting weigh. Therefore, if preformed incorrectly, the risk of joint of injury is magnified. Recent studies have demonstrated that neuromuscular training of technique can be beneficial in reducing the risk of anterior cruciate ligament injury through modification of joint kinematics [1-2]. However, the studies tested elite athletes who have access to professional monitoring for proper performance. Such studies cannot be directly applied to the average recreational athlete who suffers from joint injury. Recent studies on visual feedback on multiple degrees-of-freedom (DOF) have shown promising results when training for simple and complex motor control tasks [3]. However, such feedback increases cognitive load and requires the presence of an instructor. Auditory feedback (AF), though only used for one DOF, allows increased quantified instruction while decreasing the cognitive response time needed by athletes to master a motion [3-4]. We propose to investigate the change in individual knee kinematics and kinetics due to error sonification auditory feedback (ESAF) training of proper squat technique. More specifically, our goal is to test the viability of ESAF training over two DOFs in the sagittal plane during a squat maneuver.

METHODS
Six recreationally active males (age 21-35 years old) were selected to participate in this study. IRB approval was obtained and informed consent given by each participant. Subjects were randomly categorized into ESAF and control groups. Subjects participated in two motion capture sessions (pre and post-training), where they performed 40 squats on two tri-axial force plates (Bertec Columbus, OH) while instrumented with a 42-marker set for the lower body (Northern Digital, Ontario, Canada). The dominant leg of ESAF subjects was also instrumented with an electric goniometer (Biometrics Ltd, Newport, United Kingdom) to measure knee flexion angle. Subjects were informed how too properly squat based on the assessment criteria of Myer et al. [5]. A 'prefect squat' [5] was collected during the Pre training motion capture session where individual Target Maximum Knee Flexion Angle (TMFA) and center of pressure (COP) were determined for each subject. Training sessions consisted of 40 squats per day Monday through Friday for 4 weeks.

During training sessions, ESAF subjects were instrumented with an electric goniometer on their dominate limb and stood one foot on each force plate. Sessions consisted of four sets of five squats with concurrent feedback and five squats with terminal feedback. Concurrent feedback is categorized as any form of augmented feedback during the task and terminal feedback is after the task has been completed. Sets started with a COP calibration during which the location of their heels (0% COP) and toes (100% COP) were recorded on the force plate. Concurrent feedback emitted two sounds simultaneously, a high-pitched sound signaling error regarding TMFA and a low-pitched sound signaling error regarding COP. As the subject descended into to his TMFA, volume of each sound proportionally decreased as the deviation from the target decreased. If the subject descended below his target angle an alarm sounded. Terminal Feedback consisted of two sounds after the squat was performed. The first beep informed the subject if 30% COP was achieved and the second beep if the TMFA was achieved within $\pm 4°$. The control group performed 40 squats per day in the lab without any feedback. After the 4-week training period, subjects participated in the post-training motion capture session.

Pre and post-training marker and force data was filtered through a 6Hz low-pass Butterworth filter. Maximum achieved flexion angle was subtracted from the target angle to determine error. Range of COP was determined by calibration and percent of COP range was calculated at the time maximum flexion angle was achieved. Pre and post-training target flexion error and percent of COP were averaged over the 40 trials.

RESULTS AND DISCUSSION

Our results revealed that, post-training, the ESAF subjects were able to shift their COP posteriorly at maximum knee flexion angle when compared to control subjects (Figure 1). The ESAF group also achieved TMFA within ± 4° (Figure 2).
Figure 1 Center of pressure location at maximum knee flexion angle. Pre-training (Blue) and post-training (red) bars represent the average and the whiskers represent ± 1 standard deviation over 40 squats.
Figure 2 Error from target maximum flexion angle during the squat. Pre-training (blue) and post-training (red) bars represent the average and the whiskers represent ± 1 standard deviation over 40 squats.

These preliminary findings highlighted that error sonification auditory feedback over two degrees of freedom is a viable neuromuscular training modality to further study. Though subjects in the control group also decreased their maximum knee flexion angles after the training period, they also shifted their COP anteriorly, which is not in accordance with proper squatting technique. Thus, the subjects in the control group increased their maximum flexion angle at the expense of proper form, which can lead to joint injuries.

CONCLUSIONS

Over the course of a 4-week fully automated error sonification auditory feedback training protocol, subjects were able to achieve both the target flexion angle and the proper COP location when performing a squat. Results indicated that, for the average 21-35 year-old recreational male, a multiple degree of freedom ESAF neuromuscular training program is a viable training technique for fundamental maneuvers. Further research will address the retention of proper squat terminal position and the effects of neuromuscular squat training on landing phases of complex plyometric maneuvers such as countermovement and depth jumps. Ultimately, these studies could lead to independent individualized neuromuscular training programs to reduce the risk of joint injuries in recreational athletes

PLIÉ FLEXIBIILTY IN DANCERS: DIFFERENCE BETWEEN POSITIONS, MEASUREMENT METHODS AND LIMBS

[1]Lindsay Harmon-Matthews, PT, DPT; [1]Mariah Nierman, DPT, AT, OCS; [2]Nienke Willigenburg, PhD; [2]Rachel Tatarski, MS, ATC-L; and [2]Timothy E. Hewett, PhD

INTRODUCTION

Since foot and ankle injuries are the most common injuries in dancers [1, 2], understanding ankle biomechanics in dancers is imperative. While dancers regularly utilize maximum ankle plantar flexion, closed chain ankle dorsiflexion is necessary for plié. Plié, a movement similar to a mini squat, involving closed chain knee and hip flexion, is a fundamental dance movement used in nearly every dance genre and is necessary for dancers' jumps and turn preparations. A plié can be performed with neutral hip rotation (parallel plié) or in the turned out position, which involves maximal hip external rotation. Although dancers typically have large plantar flexion ranges of motion, they may lose dorsiflexion with training [3].

Literature on ankle dorsiflexion in dancers is limited. Most studies have limited sample sizes and use either closed chain or open chain measurement methods. Additionally, there have been no known studies that explore dorsiflexion in parallel plié versus turned out plié. Thus, the purpose of this study was to compare ankle dorsiflexion measurement methods by limb. Based on previous literature, greater dorsiflexion angles were expected in closed chain methods. The hypothesis tested was that there would be no difference in angles between parallel and turned out pliés. A second hypothesis tested was that there would be a difference in dorsiflexion between limbs only in open chain.

METHODS

Dorsiflexion was measured three ways during routine screens: open chain with the knee flexed (soleus angle), closed chain in first position plié (dorsiflexion angle with turnout), and closed chain in parallel plié (dorsiflexion angle in parallel). All angles were measured with a goniometer, which is a reliable method for measuring ankle dorsiflexion in plié [4]. One hundred twenty-six dance academy students gave written informed consent and participated in this study. A 3x2 analysis of variance (ANOVA) compared dorsiflexion measurement methods by limb.

Figure 1: Measurement of ankle dorsiflexion in turned out plié.

RESULTS

As shown in Figure 2, a main effect of ankle dorsiflexion measurement method ($p<0.001$) was observed. No significant interaction between limb and measurement method ($p=0.812$) and no significant main effect of limb was observed ($p=0.495$). Regardless of limb, open chain soleus angle was significantly less than the closed chain dorsiflexion angles both with turnout ($p<0.001$) and in parallel ($p<0.001$).
Figure 2: Mean dorsiflexion angles by measurement method and limb.

Specifically, mean soleus angles (12.8°±5.7° left, 12.7°±6.3° right) were about half the magnitude of both closed chain dorsiflexion angles (turnout: 23.3°±6.2° left, 27.8°±5.9° right and parallel: 28.2°±5.9° left, 27.8°±5.9° right). Also, soleus angles had low significant correlations with both the turned out plié (r=0.334, p=0.004 left and r=0.358, p=0.002 right) and the parallel plié (r=0.31, p=0.008 left and r=0.434, p<0.001 right) methods (Figure 3).
Figure 3: Right soleus angle and right dorsiflexion angle with turnout correlation.

DISCUSSION

These results indicate that measurement of open chain ankle dorsiflexion does not accurately reflect dancers' plié depths. Although these dancers spend more time training in turnout, the parallel position allows dancers to achieve slightly greater closed chain ankle dorsiflexion than turned out plié and may be a more accurate reflection of their functional flexibility. Consistent with previous literature, soleus angle had a small correlation with the closed chain plié angles, indicating that dorsiflexion should not only be clinically assessed in open chain but also in closed chain positions to understand a dancer's functional plié depth. Future studies should take these differences into account and examine if a relationship exists between ankle dorsiflexion angles and injury occurrence to develop effective injury prevention programs for dancers.

CONCLUSIONS

In dancers, deeper plié dorsiflexion angles could be expected in parallel compared to the turned out position. Non-weight-bearing dorsiflexion angles may not necessarily reflect a dancer's plié depth; therefore, clinical measurement in weight-bearing plié may provide a more accurate representation of the functional closed chain dorsiflexion range of motion utilized in dance movements.

TURNOUT IN DANCE: EXAMINATION OF MEASUREMENT METHOD AND LIMB ASYMMETRY ACROSS TRAINING LEVELS

INTRODUCTION

Turnout in dance requires bilateral lower extremity external rotation, and smaller functional turnout angles may be related to nontraumatic lower extremity and back injuries [1]. While turnout involves active hip external rotation, hip rotation measurements are less than standing functional turnout measurements due to below knee contributions such as tibial version [2]. Dancers who use more functional turnout than available passive hip external rotation have more self-reported lower extremity and back injuries [3]. No gold standard method for measurement of turnout is currently available, although turnout has been previously measured functionally in standing, functionally on rotation discs, and goniometrically in supine and prone [1-5]. Turnout asymmetries have been detected in standing turnout angles when landing jumps [1] and in amounts of tibial torsion [2]. Turnout has not previously been compared between levels of dancers. The purpose of this study was to compare functional standing turnout angles between dancers of different training levels and between floor and disc measurement methods. The hypotheses tested were that 1) dancers would have greater turnout angles on the floor protractor compared to the rotation discs, 2) turnout angles would increase with training level, and 3) right turnout angles would be greater than left turnout angles.

METHODS

Measurements were taken during routine dance screens of 23 professional dancers, 46 academy dance students, and 26 collegiate dance students. Standing functional turnout angles were measured using Functional Footprint® rotation discs and a floor protractor. Dancers' second metatarsals were aligned with the discs' sagittal plane lines with knees fully extended. Measurements were recorded in degrees from the discs, which allow friction-free external rotation. On the floor protractor, subjects' heels were aligned on the coronal plane line and were asked to turnout as they would in dance class; measurements in degrees were recorded from the line of the second metatarsal. Turnout angles were recorded for left and right limbs, separately. Left and right limb measurements were summed to produce a total turnout angle on the disc and on the floor for each dancer. The absolute difference in turnout angle between limbs was calculated to quantify the magnitude of limb asymmetry. To quantify the direction of limb asymmetry, the right turnout angle was subtracted from the left turnout angle. Three 3x2 analyses of variance (ANOVAs) were used to determine how training group and measurement method affected total turnout angles as well as magnitude and direction of limb asymmetry. A priori alpha level was set at 0.05 to determine statistical significance.

Figure 1: Measurement of functional turnout on floor protractor (background) and Functional Footprint® rotation discs (foreground).

RESULTS

As shown in Figure 2, dancers in each training group demonstrated greater total turnout on the floor compared to the discs ($p<0.001$), and collegiate dancers had significantly smaller total turnout angles compared to both professionals and academy students ($p<0.001$). No main effects or interactions of measurement method or training group were observed for magnitude of limb asymmetry. The absolute differences between limbs for each group averaged $4.6° \pm 4.7°$ on the discs and $3.9° \pm 3.4°$ on the floor.
Figure 2: Mean total turnout angles on disc and floor methods for each group.

In the measurement of directional limb asymmetry, a significant interaction between measurement method and training group ($p=0.047$) indicated that in professionals, left turnout angle was significantly greater than the right turnout angle on the discs ($4.30° \pm 6.64°$) but not on the floor ($0.17° \pm 4.57°$). There was no significant difference in limb asymmetry between methods in academy students ($p=0.801$) or in collegiate dancers ($p=0.415$).

DISCUSSION

Regardless of training group, all dancers had ~10° greater turnout on the floor compared to the disc measurement method, which is consistent with previous literature [4,5], indicating floor protractor measurements may reflect not only active hip

external rotation but also below knee turnout contributions, compensatory patterns, and use of the friction of the floor to maintain standing functional turnout. Collegiate dancers had smaller turnout angles compared to both the professionals and the academy students, while the professionals and academy students showed similar turnout angles. The only asymmetry that was observed between limbs was detected with the disc method and was shown only in the professional dancers with left turnout angels about 4° greater than right turnout angles; this is in contrast to our hypothesis and to previous studies that found asymmetries in MRI-detected tibial torsion and in total standing turnout following dynamic movements.

CONCLUSIONS

Assessment of functional turnout angles on rotation discs, in addition to on the floor, will provide information about dancers' compensatory patterns below the hip joint when turning out over ground. Turnout did not increase with training level, but was ~20° lower in collegiate dancers who primarily trained in modern dance, which may indicate that less turnout can be expected in modern than ballet dancers. Limb asymmetry was observed in professionals on the discs, which may indicate a training effect may lead to limb dominance and limb asymmetry. Future studies will examine if turnout and limb asymmetry are related to injury risk in dancers.

RELATIONSHIPS BETWEEN QUADRICEPS STRENGTH SYMMETRY, INTERNAL KNEE AND HIP EXTENSION MOMENT IMPULSE SYMMETRY IS STRONGER IN WOMEN THAN MEN

[1] Erin H Hartigan, [1] Mike Lawrence, [2] Thomas Murray, [2] Bernadette Shaw

[1] The University of New England, Portland, ME, USA
[2] OA Centers for Orthopedics, Portland, ME USA
email: ehartigan@une.edu

INTRODUCTION

Reduced internal knee extension moments are ubiquitous following anterior cruciate ligament (ACL) reconstruction and persist 6 months after progressive rehabilitation in men and women.[2] The hip joint may compensate for aberrant knee mechanics and the strategy appears to be sex-specific.[1] Preliminary evidence suggests that responses to challenging walking tasks such as walking while towing a weighted sled or wearing a weighted vest are also sex-specific.[3] Whether asymmetrical quadriceps strength is related to asymmetrical knee and hip extension moments during normal and challenging walking is unknown. Also unknown is whether asymmetrical knee extension moments is related to the hip extension moment during normal walking and whether knee extension moments during normal gait are related to knee and hip extension moments during challenging tasks. Given the evidence that sexes respond differently to interventions, we chose to investigate these relationships in men and women separately. [1]

METHODS

Our 32 subjects (Table 1) met the criteria of an isolated ACL rupture, underwent ACL reconstruction (ACLR) using the hamstring, patella tendon or allograph, were between 5-12 months post ACLR, discharged from physical therapy, and cleared by their surgeon to return to sport.

Testing: Three maximum voluntary isometric quadriceps contractions (MVIQC) were obtained using a Biodex S4 dynamometer set at 90 degrees of knee flexion. The subject's peak torque generated was used for analyses. Gait was analyzed during normal walking and two challenging walking tasks

(load of 50% body weight [BW] while towing a weighted sled attached at the shoulder and wearing a weighted [50% BW] vest). Gait speed was controlled at 1.3 m/s $\pm$ 5% for all 3 tasks. Subjects walked normally first and then the order of the two challenging walking tasks was randomized. Motion analysis data were collected using 3D cameras (Qualisys) and force plates with 6 degrees of freedom (AMTI). Data were processed using Visual 3D software (C-Motion). Internal knee and hip extension moment impulses (IKEMI and IHEMI, respectively) were calculated during the initial 25% of the stance phase of gait using inverse dynamics. Five trials of IKEMI and IHEMI were normalized to body weight, and averaged for each limb (Nms/kg). Limb symmetry index [LSI: (involved /uninvolved) *100] were calculated for MVIQC, IKEMI and IHEMI. Descriptive statistics [mean (standard deviations)] were calculated for our variables of interest. Pearson Product-Moment Correlations (PPMC) (r = PPMC coefficient) were used to determine associations between MVIQC LSI and KEMI and HEMI LSI during walking, sled, and vest tasks for men and women. Additionally, PPMC were run to determine whether KEMI LSI is related to HEMI LSI during walking, and if KEMI LSI during walking is related to the KEMI and HEMI during challenging tasks for men and women. Significance was set at p=.05. (SPSS, IBM)

RESULTS

Descriptive statistics were run for all variables for men and women (Table 2). For women, MVIQC LSI was associated with HEMI LSI during the sled task only (r = .58; p = .01). KEMI LSI during normal walking was associated with the KEMI LSI during the sled and vest tasks (r = .64 and .56,

respectively; p $\leq$ .01) and the HEMI during normal walking (r = -.66, p < .01).

For males, MVIQC LSI did not significantly relate to any KEMI or HEMI LSI for any task. KEMI LSI during walking was associated with the KEMI LSI during the vest task (r = .60; p = .04).

DISCUSSION

Relationships between variables were different for men and women. For women, asymmetrical quadriceps strength was only associated with HEMI during the sled task. Asymmetrical knee moments used by female subjects during walking were associated with the magnitude of knee asymmetry during more challenging tasks: towing a sled and wearing a weighted vest. For men, no significant relationships between strength symmetry and KEMI and HEMI symmetry were found. For men, the only significant relationship was found between KEMI symmetry when walking normally and KEMI symmetry when wearing a weighted vest.

CONCLUSIONS

Interestingly, relationships between asymmetrical isometric quadriceps force and asymmetrical internal knee extension moments during normal and challenging gait were not found for men or women after ACLR. However, a stronger relationship between asymmetrical KEMI during walking normally and when challenged existed in women than men.

PERFORMANCE BIOMECHANICS OF RUNNING AND CUTTING TASKS

Kathryn L. Havens, Susan M. Sigward

INTRODUCTION

The ability to change direction quickly while running is a prerequisite for participation in multi-directional sports. Athletes must be agile, changing direction quickly in response to many types of stimuli. [1] The importance of agility in sports is underscored by its use as an indicator of talent [2] as well as a determinant of player selection into teams. [3]

Many factors have been proposed that may influence the ability of an individual to perform change of direction tasks effectively. Among these factors are anthropometrics, leg muscle quantities, straight running speed, and technique. [4] While some studies have suggested that straight running speed is not related to agility performance, [1,5] others have found the opposite is true. [4] These studies have only studied completion time. However, the biomechanics underlying these relationships has not been investigated.

While changing direction is important for athletic performance, cutting is also associated with non-contact anterior cruciate ligament (ACL) injury. [6,7] Because of this, research has focused on the relationship between change of direction mechanics and potentially injurious knee joint loading. [8,9] However, the biomechanics underlying successful performance of cutting tasks is less well understood.

Performance of cutting tasks likely relies on both effective change of direction mechanics and fast running performance. However, it is currently unclear whether the biomechanics associated with fast cutting performance are the same as those associated with fast running performance.

The purpose of this study was to identify relationships between 3-dimensional (3D) hip, and sagittal plane knee and ankle kinetics and 3D ground reaction forces (GRF) and performance of running and cutting tasks.

METHODS

Twenty-five healthy soccer players (12 females) with no history of previous knee injury participated. Average age, height and weight were 22.4 ± 3.9 yrs, 1.74 ± 0.1 m and 70.9 ± 9.3 kg, respectively.

Subjects performed a straight running task, and a sidestep cutting tasks to 45° as fast as possible. For the running task, subjects ran for 15 meters. For the cutting task, subjects ran 7.5 meters, planted their dominant foot on the force plate and changed direction away from the plant leg at 45° and continued running for 7.5 meters. (Fig. 1).
Figure 1: Experimental set-up for right dominate subject. Open arrow indicates original line of progression.

Three-dimensional kinematics were collected using a 10-camera motion capture system (Qualisys, Inc. Sweden), 250 Hz. Ground reaction forces (GRF) were quantified using AMTI force platforms (Newton, MA, USA), 1500 Hz. Laser timing gates (Brower, UT, USA) were used to determine the time to complete the tasks. Inverse dynamics was used to calculate net joint moment and power. Peak 3D hip and sagittal plane knee and ankle moments, peak GRFs and average power were determined. Data was normalized to body weight.

Pearson's correlations were used to determine the relationship between task completion time and variables of interest ($p<0.05$).

RESULTS AND DISCUSSION

Better performance (shorter completion times) of the 45 degree cutting task was associated with better performance of the run task (r=0.942, p<0.001), greater average hip sagittal power generation, peak ankle plantarflexor moment, and peak anterior GRF **(Table 1)**.

Better performance of the running task was associated with greater peak hip extensor and external rotator moments, average hip sagittal power generation and peak anterior GRF.

Unlike other studies, [1,5] the results of this study indicate that cutting performance is highly related to running performance. This may be related to the tasks used. While some agility tasks require many changes of direction as well as movement in other planes, [10] this cutting task, with only one change of direction, may be more similar to straight running.

Interestingly, the results showed some but not complete overlap in the mechanics associated with the two tasks. For both tasks, anteriorly directed GRF and hip sagittal plane power generation were related to performance of both tasks. Together, these results suggest the importance of propulsion for fast performance, with athletes using the hip joint to drive the body forward.

Hip engagement may be more beneficial to running, as the majority of mechanics related to run performance were hip variables. In contrast, these data suggest that sagittal plane engagement at the ankle as well as the hip may benefit cutting performance.

This study provides insight into the relationship between the biomechanics associated with running and cutting tasks. More data is needed to understand if these relationships hold with other types of cutting or agility tasks.

ACL INJURY TRENDS BY POSITION AND TEAM ACTIVITY IN THE NATIONAL FOOTBALL LEAGUE BETWEEN 2009-2014

[1]Joshua T. Hoffman, MS, [2]Christopher Nagelli, BS, [1]Samuel C. Wordeman, PhD, and [1-5]Timothy E. Hewett, PhD

[1]Sports Health and Performance Institute (SHPI) OSU Sports Medicine, [2]Department of Biomedical Engineering, [3]School of Health and Rehabilitative Sciences, [4]Department of Orthopaedics, [5]Department of Physiology and Cellular Biology and Family Medicine, Ohio State University, Columbus, OH

INTRODUCTION

The average National Football League (NFL) player that suffers an anterior cruciate ligament (ACL) rupture requires approximately 10.8 months prior to return to sport (RTS) [3]. While reconstructive surgery and physical therapy after ACL injury cost approximately $17,000, the time lost by high-profile NFL athletes may amount to millions of dollars in player compensation and a loss of athletic prowess [1]. Most injuries per athletic exposure (AE) occur during games, but the effect of activity (i.e. games and practices) and position on the total number of ACL injuries per season is less clear [3]. Therefore, the purpose of this study was to determine the impact of activity and position on the number of ACL injuries per season.

METHODS

ACL injuries were recorded between the 2009-10 and 2013-14 seasons, for a total of five seasons. A full season was described as the period between the conclusion of the previous Super Bowl to the end of the Super Bowl of the season in question. Several websites (including, but not limited to, http://www.pro-football-reference.com/, http://www.rotoworld.com/ and http://espn.go.com/) that list NFL injuries were utilized for this study. A compilation of knee injury listings were investigated to determine whether that injury was an ACL rupture. For each player listed with a knee injury, a Google search that included the athlete's name, year of injury, and keywords, such as "ACL rupture" or "ACL injury", was performed. News articles and team reports were used to confirm injuries. Once an injury was confirmed, the activity and position were recorded.

Activity was divided into game scenario, practice, and not available. The activity associated with not available injuries was unable to be determined. Player position was categorized as skill, lineman, special teams, or other. Skill players included running backs, wide receivers, quarterbacks, and defensive backs. Offensive and defensive linemen were classified as linemen. Special teams was comprised of kickers, punters, and long snappers. Finally, linebackers and tight ends comprised the 'other' category.

Descriptive statistics for all injury categories were calculated for each of the five seasons. Finally, a pair-wise t-test was used to determine if there was a significant difference between game and practice ACL injuries per season.

RESULTS AND DISCUSSION

During the five seasons studied, a total of 253 ACL injuries occurred for an average of (mean ± standard deviation) 50.6±7.6 per season. Of these, game scenarios and practices were responsible for 37.0±2.4 injuries per year and 12.8±6.0 injuries per year, respectively. Games were responsible for a significantly greater ($p<0.001$) number of ACL injures per season. Injuries that could not be attributed to a game or practice accounted for 0.8±0.8 injuries per season. Offensive and defensive skill players accounted for 23.8±4.9 injuries per season, and offensive and defensive linemen suffered 13.0±4.9 injuries per season. Special team players suffered an average of 1.8±1.3 injures per season, and other players accounted for 12.0±2.5 injuries per season.

Injury surveillance data from the 2009-10 to 2013-14 seasons support previous findings that games are responsible for a greater number of ACL ruptures than practice [2]. However, the current findings indicate that injuries that occur during practice, training camp, and OTA account for nearly all of the variability in total ACL injuries throughout the season. (Figure 1). Therefore, the change in the total number of ACL injuries each season is most likely a result of the nature of team practice. As such, changes in training methods outside of games may be

effective in reducing total ACL injuries throughout the season.
Figure 1. ACL Injuries per Season in the NFL: This figure demonstrates the number of ACL injuries that occur during games and practices [top (a)] and in skill, linemen, other players [bottom (b)] compared to the total number of injuries.

The recent collective bargaining agreement reduced the contact allowed and decreased the time allotted for practice. However, the current data indicates that since the rule change ACL injuries during practice have more than doubled. While these rule changes limit athletic exposures and should prevent contact injuries, approximately 70% of ACL ruptures are caused by a non-contact injury mechanism [2]. Analysis of strength and neuromuscular control can be utilized to identify athletes that are at increased risk for a non-contact ACL injury. Subsequently, neuromuscular training protocols can be used to improve landing mechanics and decrease risk. Currently, the NFL utilizes several tests, such as the functional movement screen (FMS), to address individual injury risk, but these methods must be improved. Furthermore, proper neuromuscular training should be integrated into team activities to supplement rule changes directed to decrease injuries.

This study was limited by a lack of public access to comprehensive injury reports. While the authors have gone to exhaustive lengths to ensure that our injury data represents all ACL injuries during each season, it is possible that some players were left off the injury lists that we utilized. In addition, injury rates are generally reports per athletic exposures. However, we were unable to attain the number of athletic exposures per activity or position.

Future research should focus on the effects of rule changes on ACL injury rates. In addition, more inclusive injury lists are necessary to determine the total number of ACL injuries. With this information, the NFL can institute proper rules and training programs to reduce ACL injuries.

Fatigue Effects on Lower Extremity Coordination and Coordination Variability During Multi-joint Ballistic Movement

Adam E. Jagodinsky, Christopher Wilburn, Lorraine Smallwood and Wendi H. Weimar

Auburn University, Auburn, AL, USA
email: aej0015@auburn.edu

INTRODUCTION

Lower extremity multi-joint movements are abundant in sport and sport-related training, often occurring in a repetitive, ballistic nature. When fatigue is evident, understanding coordination strategies adopted by an athlete during ballistic tasks has implications for performance outcomes and injury prevention. As a tenet of dynamic systems theory, variability in coordination patterns is thought to provide information regarding the state of the motor system during a given task and can be used to describe the integrity of a given movement strategy [1]. However, application of such concepts to lower extremity ballistic movements related to sport is lacking. Therefore, the purpose of this project was two fold: (1) to assess coordination and coordination variability (CV) during a repetitive lower extremity ballistic motion; and (2) to investigate the influence of fatigue on lower extremity coordination patterns while performing a ballistic movement.

METHODS

Five healthy and currently resistance training males (age: 23.4±3.4yrs; weight: 89.73±10.5kg; height: 1.75±0.1m) participated in the study, which was approved by the Institutional Review Board. Participants were asked to report on Day 1 for familiarization of the experimental task. During Day 2, participants performed the experimental protocol. The experimental protocol asked the participant to perform kettlebell swings using a 24kg load. The specific movement consists primarily of a loading phase (flexion at the hip, knee, and dorsiflexion at the ankle) followed by a propulsion phase (extension at the hip and knee with ankle plantar flexion), similar to a vertical jump motion. The protocol consisted of one continuous set of repetitions of the experimental movement until the participant reached self-reported exhaustion. Each repetition represented one cycle of movement and data from each cycle was interpolated to 150 points to allow comparison between cycles. To avoid including unrepresentative cycles related to movement initiation and cessation, the first and last three trials were excluded from analysis. Subsequently, the first ten (T1) and last ten (T2) cycles represented movement from a pre-fatigue and fatigue state respectively.

A ten-camera optical motion capture system (VICON Technology, Los Angeles, CA) was used to obtain kinematic measurements during the experimental protocol. Lower extremity joint angles and velocity were calculated from marker data and used to construct phase portraits (joint angular displacement versus its rate of change) for the hip, knee and ankle joints.

Continuous Relative Phase (CRP) was used to assess the relative motion of the hip, knee and ankle throughout the entire movement cycle [2]. From the phase portrait, phase angles were obtained and relative phase angles were calculated for knee-hip (K-H), ankle-hip (A-H) and ankle-knee (A-K) by subtracting the proximal joint phase angle from the distal joint phase angle at each point within the time series. The relative phase angle represents the spatial/temporal disparity or congruity between joints within a cycle of movement. Mean absolute relative phase (MARP) was calculated as the average absolute value of relative phase mean ensemble. Larger MARP values indicate more sequential or out-of-phase relative motion while smaller values indicate more simultaneous or in-phase relative motion. Deviation Phase (DP) was calculated to assess the stability of the organization of the neuromuscular system and was determined by taking the mean of the standard deviations of the

ensemble relative phase points. Lower DP values indicate a more stable joint coupling relationship while larger DP values suggest reduced stability joint coupling relationship.

RESULTS

Results from paired-samples t-tests indicated that for all joint couplings, changes in coordination (K-H, p=0.30; A-H, p=0.49; A-K, p=0.49) and CV (K-H, p=0.38; A-H, p=0.53; A-K, p=0.26) from T1 to T2 were not statistically significant.
Figure 1: Mean absolute relative phase, as a measure of joint coordination for each joint coupling at T1 and T2.
Figure 2: Deviation phase for each joint coupling as a measure of coordination variability at T1 and T2.

DISCUSSION

This project adopted a novel approach to assess coordination and CV during a repetitive ballistic movement. Although the data failed to reach statistical significance, this project has yielded some interesting findings. First, statistical outcomes suggest that from a pre-fatigued to fatigue state, lower extremity coordination patterns during a ballistic movement are similar. However, for all three joint couplings a considerable difference is noted for the MARP (Figure 1). Data presented in Figure 1 indicates a trend of more in-phase relative motion during pre-fatigue cycles. However, each joint coupling exhibited more out-of–phase behavior with fatigue, suggesting more independent joint motion. In general, lower extremity coordination strategies were highly flexible for each joint coupling (Figure 2), which may be beneficial when high loads are imposed on the system. However, with fatigue A-H and A-K motion became less variable. The less flexible arrangement between A-H and A-K was contrasted by greater variability between K-H during T2. This could be explained by the reduced capacity of the motor system to control more distal joints with fatigue while great flexibility in K-H motion was required for satisfying task requirements.

To account for limitations, expansion of this project will consider the loading and propulsion phases independently in addition to increasing the sample size.

UNLOADING REACTIONS DURING SUDDEN ANKLE INVERSION IN INDIVIDUALS WITH FUNCTIONAL ANKLE INSTABILITY

[1]Tarang Jain, [2,3]Wen Liu, and [3]Clayton Wauneka

INTRODUCTION

Functional ankle instability (FAI) is defined as a condition whereby an individual reports feelings of ankle joint instability and/or frequent episodes of ankle "giving way" [1]. The neurophysiological mechanisms causing FAI are unknown, but FAI is considered to be heterogeneous clinical issue that involves multiple factors such as impaired proprioception, neuromuscular control, postural control, and strength deficits [1]. Recently, Santos et al. [2] demonstrated that during a potential injury event, individuals may utilize flexion reflexes, also known as "unloading reactions", to reduce the vertical load on the supinated foot and thus reduce the risk of ankle sprain injuries. These unloading reactions were characterized by simultaneous movement of the body downwards and a shift of body weight towards the non-stimulated foot. Santos et al. [3] further compared a group of individuals with FAI to a healthy control group and found a hyper-reactivity to unloading reaction in FAI ankles under a normal static ankle stretch. The findings suggested that a static stretched ankle position led to significantly greater unloading reaction in healthy ankles, and ankles with FAI showed greater unloading reaction compared to the healthy ankles. However, the amount of unloading reaction observed was far less than a drastic reaction that usually occurs during ankle giving way. Therefore, the purpose of the present study was to test the sensitivity of unloading reactions in individuals with FAI under a combined sensation of dynamic stretch and nociceptive stimuli. We hypothesized that individuals with FAI would show increased magnitude of unloading reactions on the involved ankle under a combined sensation of dynamic stretch and nociceptive stimuli when compared to uninvolved ankle.

METHODS

We conducted our experiments on twenty-four subjects with FAI (8 males, 16 females; age: 433.9±7.5 years, height: 171±9.24 cm; weight: 75.5±13.4 kg). Participants were at least four weeks but not beyond one year after an unilateral ankle sprain (>grade II), with ongoing ankle giving way incidence during functional activities, and active in exercise. The individuals were excluded if they had severe ankle pain and swelling, ankle surgery, gross limitation in ankle inversion (<15º), lower extremity injuries other than ankle sprain in past 12 weeks, current enrollment in formal rehabilitation program, any severe joint disease, or any previous experience of intolerance to electrical stimulation.
Figure 1: Illustration of the experimental setup.

Two force plates were used to record ground reaction forces of both limbs. Two surface electrodes (3x3 cm) were placed at the lateral aspect of the tested ankle, below and anterior to the lateral malleolus, to deliver nociceptive stimulation. A newly developed trapdoor had a tilt platform held at a level position by a remote-controlled deadbolt which, when released, allowed the platform to rotate 30° before hitting a mechanical stop **(Figure 1)**. The subjects distributed equal weight on both feet while keeping one foot on a level wooden box and the tested foot on the tilt platform centered over the pivot joint.

During unloading reaction test, the trapdoor was released without a warning. The subject went through the first five trials of the trapdoor drop test without nociceptive stimulation ("no stim"), followed by five trials of the combined trapdoor drop and nociceptive stimulation ("with stim"). The nociceptive stimuli were delivered to the tested ankle at a level of 20% above the tolerable pain threshold when the trapdoor rotated for about 20-25 degrees. The vertical force variation (VFV) defined as the magnitude of decrease in the combined vertical ground reaction forces was measured for both the involved and uninvolved limb. Paired t-test was used in statistical analysis.

RESULTS

The magnitude of the unloading reactions increased progressively in the following order: (1) Uninvolved 'no stim' (54.48 N), (2) Involved 'no stim' (57.57 N) (3) Uninvolved 'with stim' (61.93 N), and (4) Involved 'with stim' (120.63 N) **(Figure 2)**. The time to peak VFV on the stimulated foot demonstrated similar values under the four testing conditions. With the number of subjects available (n = 24), the VFV magnitude and time to peak VFV were not significantly different between the four conditions ($p > 0.05$).
Figure 2: The mean ± S.E. of the vertical force variations (VFV) during the four conditions.

Based on the video recordings during the testing, seven subjects (age, 38.3 ± 6.6 years; 2 males; weight, 82.0 ± 15.1 kg; height, 171.3 ± 7.5 cm) were identified to have drastic response (hyper-reactivity) to the unloading reaction test. During the trapdoor drop test, these seven subjects were unable to maintain an upright standing position and unloaded their body weight onto the safety harness. The mean magnitude of the unloading reactions in these seven

subjects was greatest during the involved 'with stim' condition (325.05 N) when compared to involved 'no stim' (111.47 N), uninvolved 'with stim' (117.19 N), and uninvolved 'no stim' (94.59 N) conditions. The time to peak VFV was similar during the four testing conditions.

DISCUSSION

The magnitude of unloading reactions in the four testing conditions were found to be significantly stronger than the unloading reactions reported by Santos et al. [3]. Although the VFV magnitude did not differ significantly between the four testing conditions, some subjects demonstrated drastic reaction (hyper-reactivity) to the unloading reaction when a combination of dynamic ankle stretching and nociceptive stimuli was applied on their affected ankles (involved 'with stim' condition). The video recording during the testing revealed that these subjects were unable to maintain control of upright standing position and unloaded their body weight to the safety harness. Previous studies have indicated that in healthy individuals, hierarchy of postural control is prioritized [4]. During a potential injury event, the flexor reflex is suggested to be modulated in such a way that the primary importance is given to preservation of balance while ensuring an appropriate withdrawal. It appears that in individuals with FAI, modulation of the flexion reflex is affected resulting in impaired descending inhibitory control and/or increased sensitivity to the spinal reflex loop and thus, lack of appropriate use of the unloading reaction.

The drastic reaction (hyper-reactivity) in some subjects may not have occurred because the intensity of ankle stretching or nociceptive stimuli did not reach individual threshold for triggering a drastic reaction. It is also possible that some individuals with FAI might not have hyper-reactivity to unloading reaction. Nevertheless, the drastic reactions showed in involved "with stim" trials indicated a unique reaction pattern in some individuals with FAI.

The effects of an exhaustive run on multi-muscle patterns in forefoot runners

[1] Carl Jewell, [2] Vinzenz von Tscharner and [1] Katherine Boyer

[1] University of Massachusetts Amherst, Amherst, MA 01003
[2] Human Performance Laboratory, University of Calgary, Calgary, Alberta, Canada
email: cjewell@kin.umass.edu

INTRODUCTION

In recent years, a significant increase in popularity has brought forefoot running into greater prominence in the running community. Despite this popularity, much remains unknown about the effects of forefoot (FF) running on muscle function and mechanics over long distances. Previous literature has indicated that maintenance of a FF strike pattern is impaired during endurance events, and that these changes may indicate fatigue in the plantar-flexor muscles [1]. To combat this plantar-flexor fatigue, an alternative coordination of lower extremity muscles may be used. In the present study, an exhaustive run protocol was used to investigate potential changes in multi-muscle electromyographic (EMG) intensity patterns in forefoot runners to test the hypothesis that there are changes in muscle coordination patterns between the beginning and end of, as well as progressively throughout, the exhaustive run.

METHODS

Thirteen recreational (>22 km/week) habitual forefoot runners were recruited for this study. Each subject performed an exhaustive run on an instrumented treadmill at a pace determined by prior race data (mean run duration: 15.4±2.2 minutes) while EMG data were collected at one-minute intervals using a Trigno Wireless System (Delsys, Inc) sampling at 2000 Hz. Skin and electrodes were prepped and placed according to SENIAM guidelines for the following: Medial and Lateral Gastrocnemius (MGAS, LGAS), Soleus (SOL), Tibialis Anterior (TA), Rectus Femoris (RF), Vastus Medialis (VM), and Biceps Femoris (BF) .

EMG signals were decomposed into both time and frequency space using a previously developed method of wavelet analysis [2]. Foot strike was determined from vertical ground reaction forces and EMG signals were analyzed for 200 ms pre and post-foot strike. Raw EMG from five strides were averaged together to create mean activation patterns for 10 trials evenly spaced in time throughout the run. From these data, each signal was decomposed into 13 wavelets for each muscle and plotted against time [2] (Figure 1). These wavelets were then transformed into a single *1×7371* column vector containing the data from all 7 muscles for each subject and time-point in the run. These column trial vectors were concatenated to create a *130×7371* input matrix for further analyses.

Principal component analysis was performed on the input data matrix as previously described [3]. The eigenvectors, or principal components (PC), and eigenvalues of the covariance matrix were calculated. These represent the primary directions of variation and the amount of variation explained, respectively, in the EMG data. Each of these PC represents a principal pattern (PP) of EMG activation for all lower extremity muscles tested. The PP used in further analyses were selected as those that described at least 1% of the variance in the data. The data vectors for each subject can further be represented as a set of coordinates in a new *pattern space (p-space)*. Thus, each subjects' trial vector can be represented as a mean waveform plus a weighted linear combination of the PP. Each of these weight factors was determined by projecting the trial vectors onto the respective PP.

Multiple paired t-tests were performed to compare the weight factors of the retained PP between the first and last trials of the run. Linear mixed effects models were used to test for changes occurring throughout the run, varying by trial with subject as a random factor. A X^2 test was used to determine if

time in run had a significant effect on the PP weight factor. The alpha level was set at p=0.05.

RESULTS AND DISCUSSION

Ten PP were found explaining at least 1% of variation in the EMG intensity patterns. Together these PP explained 88.1% of the overall variance in the data. The most variation explained by the first principal pattern (PP1) was 57.6%. Of these 10 selected patterns, only PP2, which explained 8.4% of the variance, was found to be significantly different between the weight factor at the beginning and end of the run (p=0.04). This supports our hypothesis that coordination patterns of lower extremity muscles were altered by run's end.

A significant effect on time on the weight factors was found for PP1 and PP2, with $X^2 = 4.11$; p=0.043 and 9.75; p=0.002, respectively. The slopes corresponding to these models indicated a reduction in the weight factor over time throughout the run. These results indicate that as the length of time running increased, the contributions of PP1 and PP2 to the original EMG signals were reduced, supporting our second hypothesis that muscle activation changes occurred progressively throughout the exhaustive run.

CONCLUSIONS

The results of this study suggest that forefoot runners experienced a change in patterns of EMG activation of major lower extremity muscles over the course of the exhaustive run. It is likely that these changes in muscle coordination patterns are closely related with changes in joint kinematics previously identified with this same protocol. Further investigations will address the specific nature of the PP changes and the relationship with changes in joint kinematics.

EFFECTS OF FOOT STRIKE PATTERN AND STEP FREQUENCY ON ACHILLES TENDON STRESS DURING RUNNING

Michael Lyght, Matthew Nockerts, Thomas Kernozek, and Robert Ragan

University of Wisconsin-La Crosse, La Crosse, WI, USA
e-mail: tkernozek@uwlax.edu

INTRODUCTION

Distance running is a common activity for adults with over 29 million in the United States running weekly [1]. Injury to the lower extremities is common in running athletes with Achilles tendon (AT) injuries accounting for 5-18% of all running-related injuries [2]. During running high magnitude forces are transmitted to the AT. The repetitive loading may lead to micro tearing, inflammation and degeneration of the AT.

The human AT may experience greater magnitudes of stress relative to other tendons. Most tendons experience peak stress values below 30 MPa; however, during dynamic activities such as hopping the AT undergoes peak stresses that approach 80 MPa [3]. General running technique influences tendon stress due to the transmission of forces to the AT as it is influenced by the muscle forces of the gastroc-soleus complex and motions at the ankle. Current interventional strategies to reduce the risk or reoccurrence of running-related injuries include altering step rate and foot-strike pattern [4, 5].

The objective of our study was to examine the effects of foot strike pattern and step frequency on AT stress during running.

METHODS

Nineteen female runners (age: 21.5 ± 1.3 yrs; height: 166.4 ± 5.6cm; mass: 59.5 ± 8.7kg; weekly mileage: 31.9 ± 18.8km) participated. Individuals were not eligible to participate if they reported pregnancy, cardiovascular pathology, surgery within the last year, current lower extremity pain and/or less than 5 on the Tegner Activity Level Scale – a measure for regular participation in recreational activities that require running.

Prior to running trials, 2D transverse images of the AT cross-sectional area were measured in prone of the right ankle via ultrasound imaging. Participants were fitted with the same model of footwear and equipped with 47 markers for 3D motion capture. After instruction, participants ran down a 20-meter runway under six conditions including a rearfoot strike (RFS) and non-rearfoot strike (NRFS) pattern at their preferred cadence, +5% preferred cadence and -5% preferred cadence.

Step frequency for each condition was established with a metronome and visually monitored. Speed was controlled to 3.33-3.68 m/s using a photoelectric timing system and foot strike pattern was verified with an inshoe pressure system. Mid- and fore-foot strike indices were combined such that a NRFS pattern was defined as the subject's center of pressure (COP) located on the anterior two-thirds part of the foot at initial contact; RFS was defined as a subject's COP occurring on the rear third. Kinematic data were captured at 180Hz using 15 motion analysis cameras while kinetic data were simultaneously collected using a force platform at 1800Hz. Muscle forces were estimated using static optimization. Strain and strain rate were estimated from the AT elastic properties presented by Wren et al. [6]

Multivariate statistics with repeated measures were used to examine differences between foot strike patterns and cadence (α=0.05). Bonferonni post-hoc analyses were used to examine pair-wise comparisons.

RESULTS AND DISCUSSION

Peak AT stress (p<0.001, ES= 4.87) and peak force (p<0.00, ES=4.59) were different between the NRFS and RFS patterns. Additionally, the RFS pattern exhibited reduced strain (p<0.00, ES= 4.91) and strain rate (p<0.001, ES= 4.22) compared to the

NRFS pattern with differences of 24% and 15%, respectively. Figure 1 illustrates the time-normalized AT stress in the stance limb over the stance phase during the running cycle for each foot strike pattern.

A reduction in peak AT stress and strain was exhibited with a 5% above preferred step frequency relative to the preferred condition using a RFS ($p<0.001$, ES= 0.16) and NRFS ($p=0.005$, ES= 0.14) pattern. Strain rate was not different ($p>0.05$) between either foot strike condition.
Figure 1: Ensemble average AT stress during stance for RFS and NRFS patterns.

Our findings demonstrate a reduction in peak AT stress and strain between RFS and NRFS patterns. Estimated peak Achilles stress in this study ranged from 57 MPa to 75 MPa at 3.5 m/s (+/- 5%) using subject-specific AT measurements. In comparison, a study performed by Ker [7] measured peak AT stress at 53 MPa while running at 4.5 m/s. Komi [8] reported peak AT stress of 110 MPa in barefoot running at 3.8 m/s in two subjects using buckle transducer data as well as strain values of up to 5% per stride. Our study estimated strain values to be between 6-7%. The difference in values obtained may be attributed to methodological differences including running speed and methods we used for estimating muscle forces.

CONCLUSIONS

Th results suggest that running with a RFS pattern may reduce peak AT stress compared to a NRFS pattern. Increases in step frequency of 5% above preferred, regardless of foot strike pattern, resulted in lowered peak AT stress. The utilization of a RFS pattern and changes to step frequency may be beneficial in the treatment and prevention of AT-related injuries.

Runners may consider altering their foot strike pattern as it has been shown to occur with minimal instruction [9]. We recommend a progressive, transitional period be implemented if changes in foot strike pattern and step frequency is indicated as changes appear to introduce novel loading on the AT during running.

VERTICAL GROUND REACTION FORCE MAGNITUDES AND RATES NOT POSITIVELY CORRELATED WITH PROSPECTIVE RUNNING INJURY

[1] Dovin Kiernan, [1,2] Jae Kun Shim, and [1] Ross H. Miller

[1] University of Maryland, College Park, MD, USA [2] Kyung Hee University, Yong-in, South Korea

INTRODUCTION

Running is a popular physical activity that can provide numerous health benefits. Running itself is, however, associated with high rates of injury; anywhere from 18.2-92.4% of runners sustain a musculoskeletal injury each year [1]. Thus, identifying the aetiological variables that contribute to running injury is an important goal for injury prediction and prevention.

One relatively easy-to-measure variable proposed to precipitate running injury is vertical ground reaction force (VGRF). High VGRF magnitudes and loading rates during the first, "impact," phase are theorized to lead to injury. Several studies have examined connections between VGRF and injury, but findings have been equivocal [2].

A limitation of many previous studies on VGRF and running injuries is that they have used cross-sectional and retrospective designs, limiting the ability to infer causality. In the present study, we (1) used a prospective design, and (2) employed a principal component model (PCM) to objectively identify waveforms that contribute to the overall variance in VGRF across participants, along with traditional VGRF measures of impact peak and loading rate.

Given the theoretical connection between VGRF and injury, we hypothesized that – if VGRF does cause injury – greater VGRF magnitudes and/or loading rates at baseline would positively correlate with injury variables (number of injuries, days of training lost due to injury, and pain). Alternatively – if VGRF does not cause injury – no such positive correlations should emerge.

METHODS

Participants were drawn from an ongoing prospective investigation of lower extremity injury causation in running. Participants were over 18 years old, ran three or more times per week, participated in other sport activities two times per week or less, and reported no running-related or lower limb injuries in the past year. Data collection consisted of two phases: (1) baseline biomechanical data collection, and (2) a six-month prospective follow-up period. Forty-four participants (22 male, age 30 ± 10 years), out of a total enrollment of 100, have completed the full six-month prospective period and are included in the present report.

Baseline biomechanical data collection was conducted on a 50-m indoor running track with 8 tandem force plates (Kistler, Amherst, NY) sampling GRF at 1000Hz. Participants ran in their own footwear at a constrained speed where the experimenter provided feedback if the participant deviated from 3.3m/s $\pm$ 5%, and at a self-selected typical speed that participants "ran the majority of their mileage at." Vertical GRF from 10 left and 10 right steps were used to calculate VGRF impact peak magnitude and loading rate (calculated as the slope between 20-80% of stance onset [VGRF > 15 N] and impact peak). Stance time was then normalized to 101 points and used to create a PCM to identify VGRF waveform features that explained 90% of the total variance in VGRF [3].

Prospective data were collected via 26 weekly online surveys (Qualtrics, Provo, UT). Surveys included a large battery of questions, including: number of injuries, location of each injury, pain caused by each injury (rated from 0 or "no pain" to 10 or "worst pain imaginable" on an 11-point scale), and days of running missed due to each injury.

Using the location data, injuries were categorized as "left" or "right" for the purposes of correlating them with VGRF, assuming contralateral VGRF does not affect injury (bilateral injuries were added to both the left and right injury data pools). The number of injuries reported, pain caused by each injury, and days missed were summed across all weeks for each participant and divided by the number of surveys completed to account for any missing data points (96.5% of surveys were completed successfully).

Pearson product-moment correlations were calculated between ipsilateral VGRF variables (magnitude, rate, and PC scores) and injury variables (number of injuries, pain, days missed). Using a very liberal approach, no adjustments were made for multiple tests and significance for all tests was set at $p < 0.05$.

RESULTS AND DISCUSSION

Results were statistically similar for both speed conditions, so the more ecologically valid condition (self-selected typical speed) results are discussed in detail here. Contrary to our hypotheses, positive correlations between VGRF magnitude or loading rate and injury were not observed. In fact, VGRF loading rate was *negatively* correlated with both the number of injuries reported ($r = -0.31, p < 0.01$) and the severity of pain reported ($r = -0.26, p = 0.01$).

Results from the PCM suggested a similar conclusion. Significance was found only for PC2, which accounted for 18.9% of total VGRF variance and was interpreted as capturing the VGRF impact peak and loading rate, as well as acting as 'difference operator' on the size of impact peak relative to overall VGRF peak (Fig. 1). Positive correlations emerged between this PC and both the number of injuries reported ($r = 0.31, p < 0.01$) and the severity of pain reported ($r = 0.25, p < 0.05$).

In summary, when participants had low impact peak magnitudes and rates of loading but higher second peak magnitudes (Fig. 1), they were more likely to report injury or pain. These results are contrary to the notion that high impacts cause injury but are consistent with an earlier prospective study [4].
Figure 1: Principal component 2 from the typical speed PCM. High PC scores were associated with lower impact peak magnitudes and rates of loading but higher second peak magnitudes.

CONCLUSIONS

The results of the present PCM suggest this method may be a useful approach for objectively identifying VGRF features that may predict injury. However VGRF parameters alone may be insufficient to accurately and consistently identify runners at risk for injury. Future work will extend the present analysis to additional variables that may be more effective predictors of injury (e.g. kinematics, joint moments, estimates of internal loading).

Energy Absorption in Subjects with Ankle Instability during a Forward-Side Jump

Hyunsoo Kim, Seongjun Son, Matthew K. Seeley, and J. Ty Hopkins

Brigham Young University, Provo, UT, USA
email: hyunsoo_kim@byu.edu

INTRODUCTION

Lateral ankle sprains are common sport-related injuries which often lead to ankle instability (AI) [1]. Specifically, AI has been shown to impair neuromuscular control and dynamic joint stability of the lower extremity [2]. During the landing phase, an impact force occurs and it is attenuated through the lower extremity joints [3]. These joints contribute to shock absorption via energy dissipation by work performed using eccentric muscle contraction around the joints [4]. Thus, a failure of shock attenuation can place excessive stress on joints, resulting in lower extremity injury such as ligament sprain, articular cartilage damage, and menisci lesions [5]. It is important to examine energy absorption by calculating the amount of work done by the joints to identify how AI affects the absorption strategy adopted by the ankle, knee, and hip joints during functional activity. Therefore, the purpose of this study was to examine the effect of AI on energetic patterns of the lower extremity during a forward-side jump.

METHODS

72 AI (37M, 35F: 22.2±2.3yrs, 173.9±9.5cm, 70.0±13.1kg), and 72 matched healthy control subjects (39M, 33F: 22.0±3.2yrs, 171.1±14.6cm, 71.2±20.3kg) were categorized according to the FAAM (ADL: 82.2±9.9%, Sport: 60.5±13.0%) and MAII (3.7±1.2). Subjects were tested on the dominant limb, and fifty-nine reflective markers were place over anatomical landmarks to calculate joint powers (W/kg). Subjects performed five trials of a forward-side jump on the force plate, which was to jump forward 1 m to the center of the force plate, land with the dominant leg, and then immediately jump to the contralateral side. Joint power was measured during the landing phase of a forward-side jump which was from initial foot contact (0%) to peak knee flexion (100%). A functional linear model (p<.05) was used to evaluate differences between AI and control groups for lower-extremity joint powers. This analysis compared variables as polynomial functions rather than discrete values. Functions (power curves) were compared between groups. Pairwise comparison functions as well as 95% confidence interval (CI) bands were plotted to determine specific differences. If 95% CI bands did not cross the zero line, we considered the difference significant. Eccentric joint work (J/kg) was calculated as the area under the negative power curve for ankle, knee, and hip joints. Total lower extremity energy absorption was calculated by summing the negative joint work at each joint. Then, relative energy absorption of each joint (%) was calculated as a percentage (each joint work/total lower extremity energy absorption x 100). Independent *t*-tests were used to compare relative energy absorption of each joint during the landing phase of the forward-side jump between the AI and the control groups.

RESULTS AND DISCUSSION

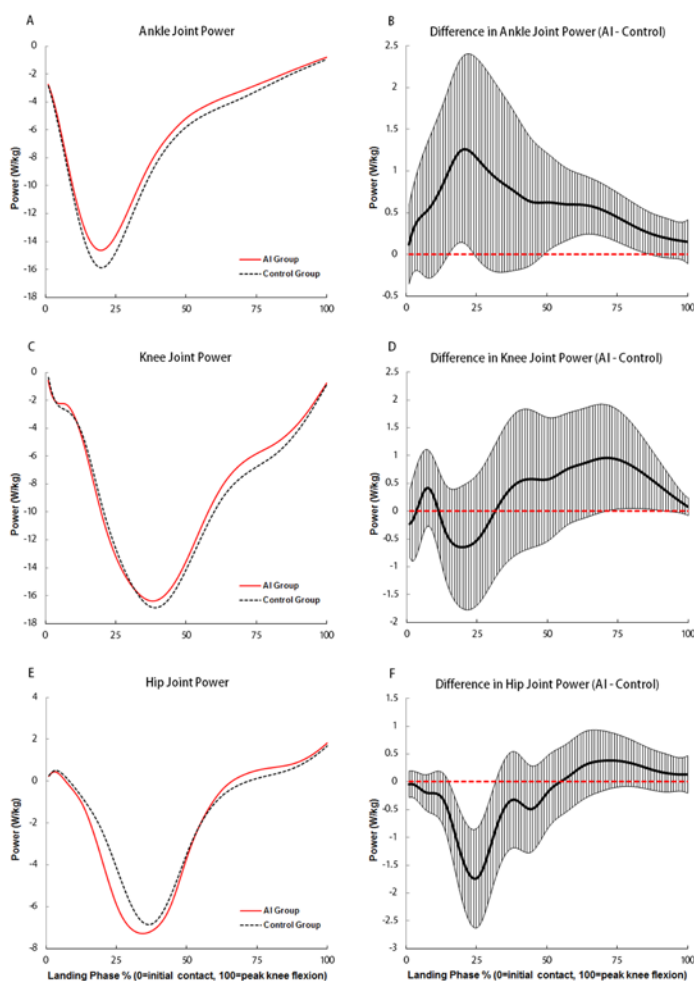
The AI group had less ankle joint power (p<.05) during 15-25% and 50-85% of landing phase than the control group (Fig.1-A and B). Compared to the control group, less knee joint power (p<.05) was observed during 70-95% of the landing phase in AI group (Fig.1-C and D). Unlike ankle and knee joints, the AI group demonstrated greater hip joint power (p<.05) during 15-32% of the landing phase than the control group (Fig.1-E and F). A group difference was found in the relative percentage of hip joint work of total lower extremity energy absorption (AI: 12.3±7.0% vs Control: 10.1±6.4%; t_{142}=2.036, p=.044) (Fig. 2). In the current study, individuals with AI showed decreased ankle energy absorption in the early landing phase of a forward-side jump while increased hip joint energy absorption compared to the control group.


Figure 1: Ankle, knee and hip joint power during the landing phase of a forward-side jump between AI and control groups.
Figure 2: Relative energy absorption of each joint (%) for the AI and the control groups. † indicates significant group difference in hip joint contribution to total energy absorption (p<.05).

Less shock attenuation by the ankle joint may place more stress on ankle joint, resulting in ankle injuries such as ligament sprains, and articular cartilage lesions [4, 5]. Thus, this finding suggests that patients with AI focus on improving ankle muscle function to dissipate more shock during landing of functional activities. Overall, the AI group increased the hip joint contribution to the total energy absorption during the landing phase of a forward-side jump. The hip joint has the mechanical advantages of its surrounding musculature (greater cross-sectional area, longer muscle fibers, and relatively shorter tendons) to absorb more energy during landing compared to that of the knee and ankle joint [6]. Increased energy absorption by the hip joint may be an effort to compensate for decreased ankle joint power/work. Subjects with AI altered their energetic patterns, redistributing joint power/work to the hip joint to attenuate shock by dissipating ground reaction force to proximal joints (hip) during a forward-side jump. Our findings suggested that subjects with AI demonstrated altered lower extremity energetic patterns during the landing phase of a forward-side jump. The results of the current study may provide useful information in developing lower extremity muscle training programs and prevention programs for lower extremity injury.

INTRODUCTION

In this study, force-displacement curves (FD curve) of countermovement jumps were obtained from experiments with multiple level heights and the data were examined whether there is any meaningful change that describes the characteristics of each countermovement jump.

METHODS

Subjects
Ten healthy young subjects (mean body parameters: 28±2 yrs, 177±5 cm, 70±6 kg) participated in this study, after signing the consent form approved by the Institutional Review Board of the KAIST.

Experimental protocols
The subjects were instructed to jump straight up to five different levels ranging from 10 % to 35 % of their body heights (Fig. 1). Black colored markers attached to a ceiling pole were used for vertical height guidance. The force data on the center of mass (CoM) were measured using a force plate (Accugait® , AMTI, US), and the data were double integrated to estimate the CoM displacement [1,2].
Figure 1: Sequential steps in standing vertical jumping with countermovement.

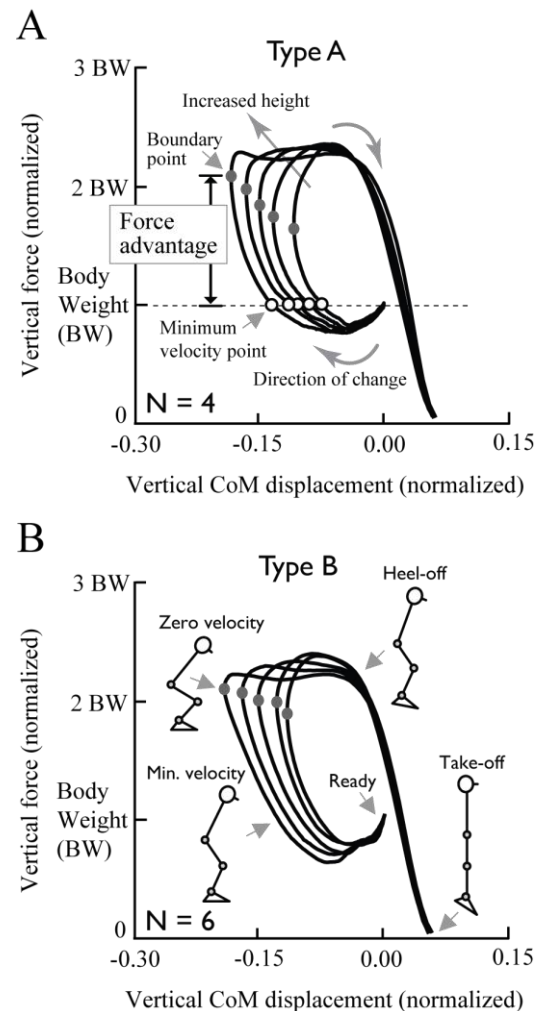
RESULTS


Figure 2: Average force-displacement curves. The trajectories were categorized into two general types of countermovement jumps (A and B), depending on the curve shape.

All subjects generated larger vertical forces compared with their body weights from the countermovement action and gradually lowered

their CoM positions as the vertical jump height increased (Fig. 2).

Particularly, the peak forces appeared to be nearly constant across the range of vertical jump heights and the latter half of the FD curves were almost identical, which means the push-off trajectories between countermovement phase and aerial phase might be roughly estimated when the vertical jump heights were determined (Fig. 2).

The boundary point, which is located between two trajectories of countermovement phase and push-off phase, gradually changed with increasing jump height. The boundary points continuously, as well as progressively, moved toward the left with an upward bend, not discretely or irregularly, on the FD curve (Fig. 2).

DISCUSSION
Figure 3: Force-displacement curves of actual data (solid line) and virtual trajectories (dotted lines). The virtual curves were assumed to have the same vertical jump height, which indicates that the positive works done by CoM are exactly same. The black solid circles (P_1, P_2, and P_3) represent the boundary points just before the push-off. The arrow indicates the direction of change.

The force-displacement curves obtained from the empirical data and virtual data can be used to better understand the countermovement jump strategy for

the higher elevation (Fig. 3). Assuming that all three pathways, including the boundary points P_1, P_2, and P_3, perform the same amount of positive CoM work, the vertical jump height is the same for all the cases (Fig. 4). However, the subjects have no choice other than to reach point P_3 because of the limited amount of peak force and the limited rate of force generation, i.e., it takes a certain amount of time and distance to attain a high level of force.
Figure 4: Calculation of vertical jump height from the force-displacement curve. The difference between the work done by ground reaction force (W_{grf}; dark gray area) and the work done by body weight (W_{BW}; light gray area) determines the vertical jump height (H_{ver}).

The results may imply that the subjects are aware of body dynamics being subjected to various jump heights and may select appropriate jumping strategies that satisfy feasible force constraints, without violating the maximum allowable force.

MUSCLE ARCHITECTURAL PARAMETERS PREDICT FORCE-VELOCITY PARAMETERS DERIVED FROM LOADED COUNTERMOVEMENT JUMPS

Kristof Kipp, Matthew D. Giordanelli, Philip J. Malloy, Tia M. Jandrin,
Michael T. Kiely, Christopher F. Geiser,

Marquette University, Milwaukee, WI, USA
email: kristof.kipp@marquette.edu

INTRODUCTION

Muscle architectural parameters have been associated with performance parameters measured during the execution of jumping tasks [1, 2]. For example, resting muscle thickness, pennation angle, and fascicle lengths have been associated with jump height, jump power, and rates of ground reaction force development across a variety of jumping tasks [2, 4]. While these studies highlight the associations between muscle architecture and jump performance parameters, it is currently not known if muscle architecture predicts force-velocity parameters across a broad spectrum of movement tasks that require different combinations of force and velocity production, such as during loaded countermovement jumps with different external loads [5].

PURPOSE

To investigate the association between muscle architectural parameters and force-velocity parameters derived from countermovement jumps of different loads.

METHODS

Ten healthy, female volleyball players were recruited from a local NCAA DI team to participate in this study. All players performed multiple counter-movement jumps on a force plate (Type 9290BD, Kistler). Jumps were performed at five different absolute loads: bodyweight (BW), BW + 10 kg, BW + 20 kg, BW + 30 kg, and BW + 40 kg. Load was adjusted through dumbbells held in each hand. Each player performed two jumps at each load. Vertical ground reaction forces were sampled at 500 Hz and filtered with a 12 Hz low-pass Butterworth filter. Peak force (F_{max}) and take-off velocity, which was

derived from the flight time (T_f) of each jump, were calculated from the vertical ground reaction force data (Figure 1), and averaged from the two jump trials that were performed at each absolute weight.
Figure 1: Sample ground reaction force data from a countermovement jump.

After filtering, peak force was normalized to body-mass. Peak force and take-off velocity were then plotted as x-y graphs for each individual. Linear regression lines were fitted to the force-velocity data points through least-squares procedures [3, 5]. The resulting regression lines were then used to extrapolate data to estimate theoretical peak force (F_0) at zero velocity and theoretical peak velocity (V_0) at zero force [3, 5]. In addition, the slope of the force-velocity regression line (S_{F-V}) and the theoretical peak power (P_{max}) were calculated [3, 5].

Muscle architectural parameters of the vastus lateralis (VL), medial (MG) and lateral (LG) gastrocnemius were determined with B-mode ultrasound at 8 MHz (LS128 EXT-2Z, Telemed). All architectural parameters were measured at pre-determined sites along lines between skeletal landmarks (Figure 2) [1, 2]. Two images were taken at each site. First, muscle thickness (h) and pennation

angle (θ) were measured from ultrasound images, fascicle lengths (FL = h·sinθ^{-1}) were then calculated from the former two measures [1, 2]. Architectural measures were made twice at each image and averaged for statistical analysis.
Figure 2: Ultrasound image used to study muscle architectural parameters. The dotted line shows the pre-determined site for architectural measurements.

Simple linear regressions were used to determine the correlations between architectural parameters (h, θ, FL) of the three lower extremity muscles (MG, LG, VL) and force-velocity parameters (F_0, V_0, S_{F-V}, P_{max}). The standard of proof for statistical significance was set at an alpha-level of 0.05

RESULTS AND DISCUSSION

The least-squares fits (i.e., r^2) for each players' force-velocity regression line ranged from 0.72 to 0.95, which indicated acceptable model fits.

Several muscle architectural parameters were correlated with force-velocity behavior of countermovement jumps. Specifically, V_{max} was significantly correlated with MG pennation angle (r = 0.769; p = 0.006). F_{max} was significantly correlated with LG thickness (r = -0.635; p = 0.049). P_{max} was significantly correlated with MG pennation angle (r = 0.650; p = 0.042) and LG fascicle length(r = -0.659; p = 0.038).

Greater peak power outputs were associated with shorter lateral gastrocnemius fascicle lengths. In addition, greater pennation angles of the medial gastrocnemius were associated with greater peak power outputs and theoretical peak velocities. Overall, these findings are similar to those reported by Earp et al. (2010) who found that greater gastrocnemius pennation angles and shorter gastrocnemius fascicles positively predict vertical jump height and power. Our results extend these findings in that medial gastrocnemius pennation angles predicted both, peak velocity and peak power, from which it could be inferred that peak power is driven primarily by theoretical peak velocities.

Greater theoretical peak force was associated with thinner lateral gastrocnemius muscles. This finding is somewhat surprising because a muscles cross-sectional area, which is related to a muscles thickness, is generally correlated with its force-generating capacity. Further, this finding is also contrary to other reports that have found that muscle thickness is a good overall predictor of absolute power for squat jumps, countermovement jumps, and drop vertical jumps [1]. One contributor to the apparent difference between our finding and those reported in the literature may lie in the fact that our force and power values were normalized to body-weight of the participants whereas those from others were not.

CONCLUSIONS

The results of this study indicate that several muscle architectural parameters are correlated with global force-velocity parameters derived from counter-movement jumps that are performed across a spectrum of external loads.

DIFFERENCE IN FORCE GENERATION WHILE DEADLIFTING WITH CHAINS

Michael Lawrence, Chad Lyons, Lara Carlson

The University of New England, Portland ME
Email: mlawrence3@une.edu, web: http://www.une.edu/wchp/mal

INTRODUCTION

The primary goal of using accommodating resistances is to help maintain force generation throughout the entirety of the range of movement. When using a normally loaded barbell, force generation decreases and the bar can begin to decelerate at approximately half way through the range of motion in a bench press [1] or between 73-85% of the deadlift [2]. Although deadlifting with chains has not shown to inhibit bar deceleration, this has only been tested with lighter loads (70% of 1 repetition maximum and below [2]. Many strength and conditioning programs routinely use more than 70% when during the strength development phase of training. The utilization of chains may allow an athlete to maintain positive acceleration longer throughout heavier loads and may also have the added benefit of developing greater force and power throughout the movement. Furthermore, research using chains as accommodating resistance usually employs an equation based on bar height in order to calculate how much load the chain was applying to the bar. Regrettably, this method ignores any influence of momentum on the chains. Therefore this investigation will use a load cell to measure the force the chains are applying to the bar.

METHODS

Five male competitive powerlifters (age 26.4 ± 7.9 y, mass 87.6 ± 17.7 kg, height 1.80 ± 0.05 m, 1.8 ± 1.3 y competing in powerlifting, and deadlift one repetition maximum (RM) 234.8 ± 38.7 kg) performed a heavy (3-RM) deadlift using a normally loaded barbell and a barbell loaded with a combination of weights and chains. The amount of chains used was determined from recommendations of the retailer (Elite Fitness Systems, London, Ohio). All participants were loaded with two chains (1.5 m in length, 0.95 cm in diameter, 36.4kg total load). The chains were attached to each end of the barbell with custom weight clamps. The middle link of each chain was attached to the barbell with the chain completely unloaded at the beginning of the lift and coming off the floor (adding mass to the barbell) as the lift was completed. On one end of the barbell the chains were attached to a linear force transducer (Interface, Scottsdale, USA) to measure resistance provided by the chains. Due to the length of the chains, attachment of the force transducer, and height of the subjects, the chains did not completely come off the ground for all subjects. Subjects were allowed to take their preferred stance on a force plate to perform each lift. Subjects first performed a dynamic warm-up and sub-maximal (25%, 45%, 65%, and 85%) repetitions prior to testing of the 3-RM.

Reflective markers were placed on the ends of the barbell and the position of the markers was tracked with eight Oqus Series-3 Cameras (Qualisys AB, Gothenburg, Sweden). Visual 3D (C-motion, Germantown, USA) was used to calculate peak bar force, peak acceleration and the last point of deceleration (percentage of lift). A repeated-measures analysis of variance was used to determine there were significant differences between the normally loaded barbell and the barbell loaded with weights and chains. The level of significance was set to $p = 0.05$.

RESULTS AND DISCUSSION

The 3-RM with the normally loaded barbell (216.4 ± 27.6 kg) was significantly greater than the barbell loaded with weights and chains (205.5 ± 22.9 kg) ($p = 0.02$). There were no significant differences found between conditions in peak bar force, peak acceleration, or point of deceleration (Table 1); most likely due to the low number of subjects collected in this pilot study. However, there does

seem to be a trend for the point of deceleration to be occurring later in the lift when the chains are attached to the barbell (Figure 1).

The force of the chain increased in a linear fashion until the sudden large decrease in force before the completion of the lift (Figure 2). This may be due to the lifter applying a large amount of force to complete the lift, which imparted a large amount of force to the chains. The momentum of the chains would then cause an upward motion leading to the decrease in force prior to completion of the lift.
Figure 1: Bar Position vs. Time with Point of Deceleration
Figure 2: Transducer Force vs. Position in the lift

CONCLUSIONS

Although there were no statistically significant findings, this is likely due to the small number of participants recruited to date. However, the trend with the point of deceleration moving to later in the lift is consistent with previous findings. Also, this study suggests that the chains may be deloading at the top of the lift due to the upward momentum of the chains.

DIFFERENCES IN LOWER EXTREMITY, PELVIC AND TRUNK KINEMATICS BETWEEN SINGLE LEG SQUAT AND STEP DOWN TASKS

[1] Cara L. Lewis, [2] Eric Foch, [1] Marc M. Luko, [1] Kari L. Loverro, and [1] Anne Khuu

INTRODUCTION

The single leg squat and the single leg step down are two commonly used functional tasks to assess movement patterns. In the single leg squat, the participant stands on one leg and squats either to a predetermined knee angle or as far as possible. In the step down, the participant stands on the top of a box or step where the height is either fixed or is adjusted based on the participant's height or tibial length. In a controlled manner, the participant lowers him/herself until the non-stance heel touches the ground and then returns to upright standing on top of the box. Both tasks have been found to be reliable and useful in identifying abnormal movement patterns in the trunk, pelvis, and lower extremities. For example, increased ipsilateral trunk lean [1], contralateral pelvic drop [1], hip adduction [1,2], and knee abduction [1] have been noted during the single leg squat in patients with patellofemoral pain (PFP) in comparison to controls. During the step down task, participants with PFP have also demonstrated increased ipsilateral trunk lean, contralateral pelvic drop, hip adduction, and knee abduction when compared to controls [3].

Despite the similarities between tasks, there are differences which may affect the observed movement pattern during the task. For the single leg squat, the goal is to keep the non-stance limb off the ground. In contrast, the goal of the step down task is to touch the non-stance heel to the ground. It is unknown how the kinematics compare between these tasks. The purpose of this study was to identify kinematic differences in the lower extremity, pelvis, and trunk between the single leg squat task and the step down task.

METHODS

Fourteen healthy individuals (females = 10, males = 4; age 23.9 ± 2.0 years; height 1.70 ± 0.12 m; mass 68.7 ± 14.0 kg; UCLA activity score 8.5 ± 1.5) participated in this research and provided informed consent. Kinematic data were collected using a motion capture system (Vicon Motion Systems Ltd, Centennial, CO) while participants performed three different single leg weight-bearing tasks: single leg squat (SLS), step down from a 16 cm step (SD16), and step down from a 24 cm step (SD24). For the single leg squat task, participants held the non-stance limb extended anteriorly, squatted as low as possible, and then returned to the upright standing position. For the step down tasks, participants stood with both feet on top of a wooden box, lowered the non-stance leg until the heel lightly touched the floor, and then returned to the starting position. Participants completed five trials of each task on each limb. Visual3D (C-Motion, Inc., Germantown, MD) was used to calculate knee and hip joint angles, and pelvis and trunk segment angles.

Separate repeated measures analyses of variance (ANOVA) were performed for each dependent variable with task (SLS, SD16, and SD24) as the within-subject factor. The dependent variables were the knee, hip, pelvis, and trunk angles of the right stance limb in the sagittal, frontal, and transverse planes at peak knee flexion and at 60° of knee flexion. Post-hoc paired t-tests with a Bonferonni correction were used to determine significant pairwise differences.

RESULTS AND DISCUSSION

The tasks resulted in kinematics differences at the knee, hip, pelvis, and trunk. At both peak knee

flexion and 60° of knee flexion, the SLS was performed with more knee abduction (p≤0.030), less hip adduction (p≤0.030), less anterior pelvic tilt (p≤0.007), less pelvic drop (p≤0.011), and more backward trunk rotation (≤0.004) than either step down task. Additionally, at peak knee flexion, the SLS had more knee flexion (p<0.001), more hip external rotation (p=0.001), and more trunk flexion (p=0.007) than the SD16. Compared to the SD24, the SLS also had less hip flexion (p=0.013), more backward pelvic rotation (p<0.001), and less ipsilateral trunk flexion (p=0.001). At 60° of knee flexion, the SLS also had more backward pelvic rotation than either step down task (p≤0.011).

While there were multiple differences in the knee, hip, pelvis, and trunk angles between SD16 and SD24 at peak knee flexion, the only difference at 60° of knee flexion was in trunk flexion (p < 0.001) with less flexion in the SD16 than the SD24.

The results of this study highlight the importance of three things: 1) goal of the task, 2) point of comparison, and 3) exercise selection. First, the instructions for the single leg squat and for the step down are fundamentally different and result in different movement patterns. The goal of the SLS is to maximize squat depth while maintaining balance and keeping the non-stance limb off the ground. Hiking the pelvis and minimizing stance hip adduction would help achieve this goal. In contrast, the goal of the step down is to touch the non-stance heel to the ground. This can be achieved with less hip and knee flexion by adducting the stance hip and dropping the pelvis.

Second, the point of comparison between tasks affected the results. The SD16 seemed very different from the SD24 when compared at peak knee flexion, but these differences were almost nonexistent at 60° of knee flexion. This finding indicates that, for a range of step heights, the same movement pattern is used for the step down task. It also indicates that comparisons can be made across studies with slightly different step heights, if analyzed at the same knee angle. Conversely, the single leg squat task continued to be different from the step down tasks at both time points. This finding, again, indicates that the single leg squat

task and the step down task use different movement patterns.

Third, the kinematic differences noted between tasks are important when selecting exercises for a patient. The single leg squat task was performed with more knee abduction (dynamic valgus) while the step down task was performed with more hip adduction. While the rehabilitation goal of the exercise would likely be to reduce both knee abduction and hip adduction, the exercises may have varying degrees of difficulty and could be used in an exercise progression. For example, a single leg squat task might be a more appropriate exercise for a patient with femoroacetabular impingement (FAI), a structural hip condition exacerbated by combined hip adduction and flexion [4,5].

CONCLUSIONS

The results from this study indicate that the single leg squat task and step down task result in different lower extremity, pelvis, and trunk kinematics. The findings from this study provide the clinician with more information when selecting the most appropriate task or exercise for patients with lower extremity movement dysfunction.

DOES MEDIAL KNEE DISPLACEMENT REPRESENT KNEE ABDUCTION ANGLE DURING SINGLE-LEG SQUATS IN FEMALES?

[1] Lukas D. Linde and [1] Dr. John Z. Srbely

[1]University of Guelph, Guelph, ON, Canada
Email: jsrbely@uoguelph.ca

INTRODUCTION

Female athletes are 4-6X more likely to suffer non-contact anterior cruciate ligament (ACL) injuries than males [1]. One of the largest predictors of non-contact ACL injuries is greater knee abduction angle (valgus) and moment during dynamic tasks such as drop jumps [1] or single-leg squats [2]. Identifying individuals prone to greater knee valgus during dynamic tasks is of primary importance in the prevention of ACL injuries, however, the most reliable method of measuring valgus is currently through expensive and technically onerous 3D motion capture technology which is difficult to integrate within a clinical setting. Consequently, cost-effective clinical tools, which can reliably quantify gold standard 3D kinematic measurements, are needed to aid in the clinical diagnosis, rehabilitation, and prevention of ACL injury.

Medial knee displacement (MKD) has recently been used to visually discriminate between individuals with and without knee abduction [2]. While individuals with greater MKD also demonstrate greater knee abduction angle [3], the strength and nature of the relationship between MKD and knee abduction angle has not been quantified.

The primary objective of this study was to examine the statistical correlation between the change in medial knee displacement and knee abduction angle during a single-leg squat task in healthy females. We hypothesized that a strong positive correlation exists between medial knee displacement and knee abduction angle throughout the descent phase of the single-leg squat.

METHODS

Nineteen right-foot dominant healthy females (age: 21.37±1.27, height 168.91±8.45cm, weight 63.94±7.35kg) each performed a total of 30 single-leg squats. Trials consisted of 3 consecutive squats, 6 seconds in duration, to a depth of 65 degrees of knee flexion. All trials were conducted in time with a metronome at 60 bpm. Kinematics of the pelvis, right thigh, and right shank were recorded using an optoelectric motion capture system (Optotrack 3DI: NDI, Waterloo, Canada). Knee abduction angle was calculated using a 6 degrees-of-freedom model constructed in Visual 3D software (Version 5, C-Motion, Germantown, USA). Knee abduction angle was calculated as the angle between the shank and thigh segment about the knee with respect to the Carden rotation to the global coordinate system [4]. MKD was quantified as the horizontal displacement in the frontal plane between two kinematic markers placed on the right kneecap and midline of the foot.

The change in MKD and knee abduction angle was quantified at four times points during the descent phase of each single-leg squat: 25%, 50%, 75%, and 100% of squat depth. The change in MKD and knee abduction angle were normalized to one-legged standing, as the change in knee valgus angle has been shown to have greater validity and reliability than peak angle in visual screening tests [5].

Statistical analyses were performed in SPSS (Version 22, IBM Corp). The Pearson's correlation coefficient (r) and the coefficient of determination from a simple linear regression (r^2) were calculated between the change in MKD and knee abduction angle at squat depth values of 25%, 50%, 75%, and 100% during the descent phase of single-leg squats (Table 1).

RESULTS AND DISCUSSION

A strong positive correlation between MKD and knee abduction angle was observed at all squat depths (Table 1). The strength of the relationship

between MKD and knee abduction angle progressively increased from 25% (r = 0.725) to 100% (r = 0.911) of squat depth (Table 1).
Figure 1: Medial knee displacement and knee abduction angle at 100% squat depth, normalized to one-leg standing. Linear regression equation with the coefficient of determination (r^2) and Pearson's correlation coefficient (r) included.

The strong relationship between the change in MKD and the change in knee abduction angle throughout the single-leg squat further validates and supports the use of MKD as a simple clinical test to screen individuals for knee valgus and ACL injury risk. The strength of the relationship between MKD and knee abduction angle was the highest at the greatest level of squat depth (Table 1; Figure 1).

CONCLUSIONS

The change in MKD throughout a single-leg squat demonstrated a strong linear relationship with the change in knee abduction angle. Greater knee abduction angles are associated with increased risk of ACL injury [1]. The robust correlation between MKD and knee abduction angle observed in our study provides support for the application of MKD as a reliable clinical measure of knee valgus. The MKD is a simple and cost-effective substitute for expensive and elaborate 3D motion capture technology currently employed in experimental settings to measure knee valgus (abduction angle). The MKD outcome can be routinely employed in the clinical setting to identify individuals at high risk of ACL injury, as well as measuring therapeutic responses to preventative training/rehabilitation programs in the treatment and prevention of ACL injury.

ABDOMINAL MUSCLE ACTIVATION TECHNIQUES REDUCE PEAK KNEE ABDUCTION AND PEAK HIP ADDUCTION DURING SINGLE-LEG SQUATS IN FEMALES

[1] Lukas D. Linde, [1]Eve C. Lampert, [1]Jessica Archibald, and [1] Dr. John Z. Srbely

INTRODUCTION

Greater knee abduction (valgus) excursion during dynamic tasks has been associated with an increased risk of non-contact anterior cruciate ligament injury (ACL), especially in females [1]. Greater knee abduction is thought to be the result of increased hip adduction caused by decreased hip strength and neuromuscular control [2]. As a consequence of this, therapeutic exercise programs specifically targeting hip muscle strength and movement coordination have demonstrated improvements in hip adduction and knee abduction during dynamic tasks such as single-leg squats [2]. Many of these hip neuromuscular training programs also include core training and strengthening exercises [2,3], however, the specific impact of core activation techniques on knee abduction is poorly understood. In particular, two common core activation techniques known as abdominal hollowing and bracing selectively increase activation of core muscles [4,5], however, their effect on knee abduction and hip adduction during dynamic activities has not been studied.

The purpose of this study was to investigate the influence of two core muscle activation techniques on knee abduction and hip adduction angles during a single-leg squat task. We tested the hypothesis that both abdominal hollowing and abdominal bracing techniques would reduce peak knee abduction angle and peak hip adduction angle during single-leg squats in females, when compared to no abdominal activation controls.

METHODS

Thirteen females (21.3±0.88years, 1.68±0.07m, 58.27±5.46kg) were trained in the performance of two different abdominal activation techniques, abdominal hollowing and abdominal bracing. Abdominal hollowing selectively activates the transversus abdominus muscles bilaterally [4] while abdominal bracing involves activation of the entire abdominal wall [5]. Proper application of both techniques was validated through surface electromyography measured from bilateral internal and external oblique muscles and erector spinae muscles at the L3 level. Muscle activation levels for both techniques were maintained at 20% of maximum voluntary contraction throughout single-leg squat trials.

Participants completed single-leg squats under three different conditions of abdominal activation, no instructed activity (control), hollowing, or bracing. Single-leg squat trials consisted of three consecutive 6-second single-leg squats to a depth of 65 degrees of knee flexion. All trials were conducted in time with a metronome at 60 bpm. Five practice trials were completed to familiarize participants with the depth and timing of the squatting procedure, with no feedback on posture or technique given. Participants then completed four blocks of single-leg squat trials, with three trials per block, one control, one hollowing, and one bracing trial, in random order. Rest was given between each trial and block to minimize fatigue.

Knee and hip kinematics during single-leg squats were recorded using an optoelectric motion capture system (Optotrack, NDI, Waterloo, Canada). Rigid body markers attached to segments and imaginary markers were used to construct a 6-degrees-of-freedom model in Visual 3D software (Version 5, C-Motion, Germantown, USA). Peak hip adduction and peak knee abduction were calculated during the descent phase of each squat, normalized to one-leg standing prior to squat descent. A repeated measures ANOVA was preformed to compare differences in abdominal activations between abdominal conditions (control, hollowing, bracing) and to assess the influence of abdominal condition

on peak hip adduction and peak knee abduction. Individual post-hoc comparisons (Tukey's) were performed at an alpha of 0.05.

RESULTS AND DISCUSSION

Abdominal hollowing and bracing demonstrated significantly greater activations for all core muscles recorded (Table 1). Abdominal bracing also showed significantly greater activations for all muscles when compared to abdominal hollowing (Table 1).
Figure 1: Peak knee abduction angle and peak hip adduction angle during the descent phase of single-leg squat trials across control, hollow, and brace abdominal activation conditions. * Denotes significance at alpha <0.05.

Both abdominal hollowing and bracing significantly reduced peak hip adduction angle during the descent phase of the single-leg squat when compared with controls, however, only abdominal hollowing reduced peak knee abduction angle (Figure 1).

CONCLUSIONS

The reduction of knee abduction angle during dynamic tasks is of prime importance in the prevention of ACL injuries, especially in females [1]. Although greater hip adduction and knee abduction both contribute to greater knee valgus, previous research suggests that knee abduction angle is one of the strongest predictors of ACL injury in female athletes [1]. Our data support the notion that core activation techniques may be important in maintaining dynamic stability of the lower limb [5], and suggests that the abdominal hollowing technique may be an important inclusion in ACL injury prevention programs.

MUSCLE ACTIVATION DURING SINGLE LEG SQUAT IS AFFECTED BY POSITION OF THE NON-STANCE LIMB

INTRODUCTION

The single leg squat (SLS) is a commonly used assessment and treatment tool [1,2]. As an assessment tool, the SLS is used to determine movement patterns of the trunk, pelvis, and lower extremity during single-limb stance. Commonly observed faults include increased ipsilateral trunk lean, contralateral pelvic drop, hip adduction, and knee abduction [3]. As a treatment tool, the SLS is used for both strengthening and neuromuscular retraining to increase control of the hip and knee in the frontal and transverse planes [1]. The majority of this control is thought to come from appropriate activation of the hip abductors and lateral rotators [4]. As with other hip abductor exercises, gluteal muscles are targeted for strengthening while attempting to minimize the use of others (e.g., tensor fascia lata) [4].

There is no widely accepted way to perform the SLS, especially in regard to the position of the non-stance (NS) limb. The three most common positions are with the NS limb in front, in the middle, or behind the stance limb. Different positions may change the neuromuscular demands of the trunk, pelvis, and lower extremity resulting in altered movement and/or muscle activation. No previous studies have evaluated the activation of the gluteals and surrounding muscles during the SLS in the three common NS limb positions. Therefore, the purpose of this study was to compare muscle activation of selected lower extremity muscles during the SLS in the three commonly used positions NS limb: front, middle, and back.

METHODS

A preliminary sample of ten healthy young adults (6 female, 4 male; 23.8±3.7yrs) were analyzed for this study. Participants completed five trials of the SLS in each of the three NS limb positions: front (hip flexed/knee extended with NS foot in front: SLS-Front), mid (NS hip and knee flexed with foot held in line with stance ankle: SLS-Mid), and back (NS knee flexed while maintaining vertical thigh position: SLS-Back). Instructions given for each squat were to start from standing, lift the NS limb off the ground to the tested position, do a controlled squat as far as possible on the stance limb, rise back up and place NS foot back on the ground. Both sides were tested.

A surface electromyography (EMG) system (Delsys Inc.) was used to obtain muscle activity. Electrodes were placed over the muscle bellies of gluteus maximus, posterior portion of the gluteus medius, semimembranosus, biceps femoris, rectus femoris, and tensor fascia lata (TFL) bilaterally. Kinematic data of the trunk, pelvis and lower limbs were collected using a 10-camera motion capture system (VICON®). EMG and kinematic data were analyzed using Visual3D. Raw EMG signals were band-pass filtered between 10 Hz and 390 Hz using a 4th order Butterworth filter with zero phase lag. Filtered EMG signals were processed using root-mean squared (RMS) smoothing with a moving window of 100 msec. Average RMS activation of the stance limb was extracted for two phases of movement: descent (start of stance knee flexion to maximum knee flexion) and ascent (maximum knee flexion to return to standing). Participant-based mean activation of the five trials for each side in each position was exported for further analysis.

Repeated measures ANOVA was used to compare mean muscle activation within subjects for SLS position. Additional pairwise comparisons for significant differences of position were completed.

RESULTS AND DISCUSSION

Preliminary analysis indicates that NS limb position significantly affected muscle activation during both

the descent and ascent phase of the SLS (Table 1). Most notably, the TFL exhibited significantly greater average RMS activation in the SLS-Front position during both the descent and ascent phases compared to both the SLS-Mid (p=0.006) and SLS-Back (p≤0.013) positions. NS limb position also significantly increased muscle activation of the gluteus maximus during descent of the SLS-Front compared to SLS-Back (p=0.012). There was a main effect for the gluteus medius during descent; however, the pairwise comparisons were not significant. The TFL was the only muscle to have significantly different muscle activation during the ascent phase with the gluteus medius approaching significance.

CONCLUSIONS

Non-stance limb position affects muscle activation of the stance limb during the SLS. This is important information for both clinicians and the general public to facilitate selection of the appropriate SLS variation for individual strengthening goals. This is the first study to indicate specifically that TFL activation is significantly increased during both descent and ascent of a SLS when the NS limb is placed in front. Increased muscle activation of the TFL could suggest that it is being used to control hip

adduction or produce hip flexion during this task, but it may also increase a tendency to internally rotate the hip. Additionally, increased activation of the TFL during SLS-Front may suggest that less focus is being placed on the gluteals (the muscles often targeted during strengthening) to drive the movement. Further analysis is needed to assess if there is a trade-off between gluteal and TFL activation during the SLS.

INTRODUCTION

The FIFA Medical Assessment and Research Center (F-MARC) developed the FIFA11+ injury prevention program for soccer players. The FIFA11+ is an injury prevention program that combines eccentric, proprioceptive, plyometric and stabilization exercises into a structured warm-up. The program has led to promising results ranging from reduced risk of injury and time loss due to injury in teenage female soccer players [1] and male collegiate players [2] to overall reductions in injury rates in youth players [3] and severe injuries in veteran men [4]. Risk assessments have been reported based on injury rates comparing cohorts who participated in the FIFA11+ to control groups. However, no studies to date have assessed changes in the biomechanics of individuals who participated in the exercise program.

Numerous clinical tests are utilized qualitatively to determine an athlete's likelihood for injury and/or return to play after injury. One of these tests is the lateral cut. Previous biomechanical analyses of a cutting maneuver involved dividing the stance phase of cutting into weight acceptance, peak push off and final push off [5], however the phases were defined as a proportion of the total (e.g. final push off was final 15% of stance).
The purpose of this study was to develop processing algorithms and define variables of interest during a lateral cut maneuver using kinetic and kinematic variables. The developed algorithms will be used to assess changes in kinetic, kinematic, and temporal variables in players who participate in the FIFA 11+ program.

METHODS

Players from a Division I men's collegiate soccer team were invited to participate in the study. Each participant underwent biomechanical testing of six maneuvers, single leg step down, triple hop, deceleration, lateral shuffle, lateral cut, and drop jump prior to and following a 20 game competitive season. The focus of this presentation is on the lateral cut. To complete the lateral cut, players were instructed to run forward, plant their foot on the force plate, complete a 90 degree turn, and continue running(Figure 1). The players were encouraged to complete the movement with speed and explosively, as if they were in a competitive situation and had to quickly change directions. Each leg was tested separately for three trials.
Figure 1. Example biomechanical model of a player performing a lateral cut.

Kinetic and kinematic data were collected during the lateral cut using an 8 camera motion capture system (Vicon, Lake Forest, CA) synchronized with two force plates (Bertec Corp, Worthington, OH).

Retro-reflective markers placed bilaterally on 11 anatomical landmarks and on thermoplastic shells affixed to the thigh, shank, pelvis and torso were tracked and used to create subject specific models. Visual3D software (C-Motion Inc., Germantown, MD) was used to process and calculate kinetic and kinematic variables through inverse dynamics. Marker data were sampled at 240 Hz and force data were sampled at 1080 Hz.

RESULTS AND DISCUSSION

Twenty-four players from a Division I men's soccer team completed the preseason testing (18-25 yrs). All players, but one player who had an ACL injury, completed the cut maneuver with both legs.

Each trial was defined by a stance phase (Figure 2) from Initial Contact (IC, > 5N threshold of vertical ground reaction force) through Toe Off (TO, < 5N threshold of vertical ground reaction force). The stance phase was further divided into three phases: Weight acceptance (WtAcc), defined from IC to the first trough in the ground reaction force. Peak push-off (PPO), defined from the first trough in ground reaction force to peak knee flexion. Final push off (FPO), defined from peak knee flexion to TO. Other variables of interest included peak loading rate, peak impact, and the second peak in vertical ground reaction force.

The algorithm was successfully used to process the lateral cut maneuver for numerous players. The algorithm provides a consistent, objective, and automated method for processing this task utilizing kinetic and kinematic variables.

CONCLUSIONS
The kinetic and kinematic variables and regions of interest defined by the algorithm will provide the methodology that will be used to assess biomechanical changes during the lateral cut maneuver in soccer players who participate in the FIFA11+ injury prevention program.

EYES-CLOSED SINGLE LIMB BALANCE IS NOT RELATED TO HYPERMOBILITY STATUS IN DANCERS

INTRODUCTION

Hypermobility may be associated with decreased lower extremity proprioception, which may be associated with increased injury risk.[1,2] Joint hypermobility is common in student dancers; however, incidence of hypermobility is lower in professional dancers.[3] Although hypermobility may result in deficient proprioception in the general population, it is unclear whether hypermobility affects proprioception and increases injury risk in dancers. If hypermobility increases risk of injury, it could contribute to shorter dance careers for hypermobile dancers and be a possible explanation for decreased incidence of hypermobility among professional dancers.

Single leg stance with the eyes closed is considered a feasible method to evaluate proprioception. It is straightforward to assess since adequate proprioceptive feedback is required to successfully perform such a balance task in the absence of visual input. Thus, the primary aim of this study was to define how hypermobility affects eyes-closed single leg stance balance, as a measure of proprioception in dancers. Our secondary aims were to compare hypermobility and balance between dancer levels. The hypotheses tested were that hypermobility would negatively affect balance time and that students would be more hypermobile than professionals dancers.

METHODS

Subjects: Forty-five professional, 11 collegiate, 227 student dancers, and 15 pre-professional dancers consented for this study. Data was collected during routine dance screens.

Hypermobility: Dancer hypermobility status was assessed via the Beighton-Horan Laxity test (Figure 1). Dancers were deemed hypermobile if at least four of eight Beighton-Horan Laxity tests were positive. The forward bend item was excluded as it is not considered to be sensitive to differences in joint mobility in this population. Increased hip flexion range of motion is believed to be acquired through dance training and is common to most dancers.[4]
Figure 1: Beighton-Horan Laxity Test[5] Items 1-4 are performed bilaterally.

Balance/Proprioception: Single limb balance time was assessed in parallel, with the eyes closed and without the non-weight-bearing foot touching the weight-bearing leg. Balance time was measured in seconds, up to a maximum balance time of sixty seconds. Non-weight bearing leg touch down, hopping or torso/hip bending was considered loss of balance. Dancers performed this balance task on both their left and right legs. The average of both balance times was used for further analysis.

Statistical Analysis: We used a t-test to compare balance time between hypermobile and non-hypermobile dancers. An ANOVA with Bonferroni adjusted pairwise comparisons was used to assess the effect of affiliation group (i.e. dancer level) on

hypermobility scores and balance time. The significance level was set to alpha=0.05.

RESULTS

Hypermobile and non-hypermobile dancers showed very similar balance times (p=0.819) (Figure 2).
Figure 2: Hypermobile versus non-hypermobile dancer balance times.

Also, incidence of hypermobility was similar across all dancer levels (p=0.148) (Table 1). However, a significant difference in balance time was observed between dancer levels. Specifically, professional dancers had almost 20 seconds longer balance times than collegiate dancers (p=0.018) (Table 1).

Table 1: Incidence of hypermobility and average balance times by affiliation.

Dancer Affiliation	Incidence of Hypermobility	Average Balance Time (s)
Professional	16 (36%)	39
Collegiate	3 (27%)	21
Pre-Professional	10 (62%)	35
Student	106 (47%)	34

DISCUSSION

In contrast to our hypothesis, hypermobility status did not affect single limb balance time in this large population of dancers. Therefore, single limb static balance with the eyes closed may not be a valid test of dancers' relative proprioception levels. In addition, hypermobile dancers may compensate for proprioceptive deficits through dance and balance training. Furthermore, hypermobility scores did not differ between students and professionals, which may be due to a relatively limited sample of professional dancers in our population. Another potential limitation is that balance testing may not be a sufficiently sensitive test of proprioception to distinguish differences between these groups. Professional ballet dancers demonstrated enhanced balance compared to collegiate dancers, who trained mainly in modern dance. This may be due to differences in ballet or modern as a primary a dance style and differences in training. We recommend that future studies examine dancers' dynamic balance, joint position sense, other sensitive measures of joint proprioception and the relationship to hypermobility and injury occurrence.

CONCLUSIONS

Hypermobility did not affect eyes-closed single leg balance and was similar between age groups of dancers. However, collegiate modern dancers showed lower balance times than professional ballet dancers.

INFLUENCE OF FOREFOOT ANTHROPOMETRY ON PAIN IN MINIMALIST RUNNERS

Erica M. Casto, Kyla M. Galbreath, and Jean L. McCrory

[1]West Virginia University, Morgantown, WV, USA
email: jlmccrory@hsc.wvu.edu

INTRODUCTION

Distance running is among the most popular exercise activities in society today. However, rate of overuse injury in runners ranges from 19.4 to 79.3% (1). Common running injuries include patellofemoral pain, IT band syndrome, shin splints, plantar fasciitis(PF), Achilles tendinitis(AT) (2), and metatarsal stress fractures(3). Proponents of minimalist running purport it will attenuate injury rates by reducing landing impact forces(4). However, evidence that barefoot running actually reduces injury remains inconclusive(5).

As a counterpoint to this phenomenon, researchers assert barefoot running is not a substantiated preventative measure and should be assessed on an individual basis(6). Several researchers have suggested that a having Morton's foot or hallux valgus may be related to injury(7). Lower extremity anthropometry may influence the type of injury sustained. We have previously reported minimalist runners with pes planus were more likely to sustain a soft-tissue injury(8). However, a search of relevant literature revealed no studies that examined the influence of forefoot anthropometry on running injury in barefoot or minimally shod runners.

The **purpose** of this study was to determine if having a Morton's foot, hallux valgus, or angular splay between the first and second toes are related to type of pain, general location of pain, or specific location of pain in minimally shod runners.

METHODS

Sixteen experienced minimalist runners participated (age: 27.4±10.1yrs, hgt: 170.3±25.0cm, mass: 78.1±18.0kg, gender: 8M, 8F). All subjects reported running > 10 miles/week in minimalist shoes for at least three months. Minimalist shoes were defined as having a midsole drop of 4mm or less.

Informed consent was obtained. Subjects were surveyed about the type and location of pain. Pain at sites of common running injuries was quantified using a validated visual analog scale (VAS)(9). Based on survey data, injuries were then classified as soft-tissue or bony. Subjects were considered to be injured if pain on the VAS >3.

Static forefoot anthropometry measures were taken from superior view photos. While the subject stood in quiet stance with weight distributed equally between both legs, a digital camera (Canon EOS Rebel T2i, Tokyo, Japan) was placed 26 cm directly above the left or right foot. This procedure was repeated for the contralateral foot. The digital images were calibrated using a ruler placed adjacent to the foot in each picture.

Morton's Foot: A foot was classified as Morton's foot if the most distal aspect of the second toe was anterior to the great toe (10) on the digital image.

Hallux Valgus: Using Image-J software (NIH, Bethesda, MD), the angle was determined between a line from the midpoint of the proximal phalanx of the hallux to the midpoint of the first metatarsal head, and a second line drawn from the midpoint of the first metatarsal head to the base of the first metatarsal. Those feet in which the angle was > 15° were classified as having hallux valgus(11).

Toe Splay: To assess the angle of toe splay between the first and second digits, the angle between the line from the interphalangeal joint midpoint of the hallux to the metatarsal line, and a line from the midpoint of the proximal joint of the second toe to the metatarsal line was determined. Those feet with an angle > 45° were classified as having toe splay.

Statistics were performed using IBM SPSS software (v21, Armonk, NY). All data were categorical

(yes/no). Left and right feet were considered separately such that we had 32 total feet from 16 subjects. Independent variables were: Morton's foot, hallux valgus, and toe splay angle. The dependent variables were pain type (soft tissue, bony), general location of pain (foot, ankle, knee /shank, above knee), or specific location of pain (AT, PF, metatarsals, IT band, anterior knee, anterior shank). Chi squared analyses were performed to determine if injury type and location were equally distributed among each category of the independent variables. In this pilot study, our alpha was 0.10.

RESULTS AND DISCUSSION

Of the 32 feet in the study, eight were classified as Morton's feet and 24 as regular feet. Seven of the feet were classified as hallux valgus and 25 were not. Twenty feet had toe splay between the first and second toes and 12 did not.

Several of these forefoot classifications were related to pain in minimalist runners (Table 1). Runners who did not have a Morton's foot were more likely to have soft-tissue pain than runners with a Morton's foot. Seventy-five percent of minimalist runners without a Morton's foot reported soft tissue pain, while only 25% of those with a Morton's foot reported pain. Subjects with a Morton's foot were more likely to experience pain in the foot (100% vs 66%), and less likely to experience pain in the knee and shank (0% vs 33%). The second metatarsal is more mobile in individuals with a Morton's foot(11). This heightened mobility may be related to greater interjoint instability and increased foot pain in those with Morton's feet, but protective of pain at the knee and shank. Subjects with hallux valgus were less likely to experience ankle pain than those without hallux valgus (0% vs 82%). Conversely, runners with toe-splay were more likely to experience ankle pain (35% vs 8%). Given these two divergent toe alignments, it is not surprising that the results differ. However, because "ankle pain" was defined as having >3 on the VAS scale and the exact nature of the injuries is unknown, the rationale for why individuals with hallux valgus have less ankle pain is elusive.

Our study was limited by the small sample size. Also, our data were based on self-reported pain and not clinical diagnoses. All data were from static photos not dynamic gait parameters. In the future, we plan to increase the sample size to quantify the influence of forefoot anthropometry and specific injury, rather than general location of pain.

CONCLUSION

Forefoot anthropometry is related to pain in minimalist runners. This should be a consideration in the choice to minimalist run as well as in the treatment of running injuries in this group.

EFFECTS OF LOAD ON THE HIP-TO-KNEE TORQUE RATIO IN A SQUAT EXERCISE

Ben W. Meyer

Shippensburg University, Shippensburg, PA, USA
bwmeyer@ship.edu

INTRODUCTION

A common technique to increase muscular strength involves performing multiple exercise repetitions close to an athlete's maximum muscular tension. The typical method used to increase muscular tensions is to increase the external load used during the exercise. Previous work [1,2] has examined the influence of variations in the external load on lower extremity joint torques during conventional back squats. Although hip and knee extension torque values have been reported in previous studies, limited attention has been given to the hip-to-knee torque ratio. A conventional back squat can be executed in any of the ways shown in Figure 1 (as well as with even more extreme forward leans of the trunk). The hip-to-knee torque ratio gives us information about which muscle groups the athlete is choosing to emphasize in the lift. A conventional back squat with a large hip-to-knee torque ratio emphasizes the relative use of the hip extensors over the knee extensors. Powerlifters (athletes who perform the squat, deadlift, and bench press exercises in competition) tend to emphasize the hip extensor musculature when lifting heavy loads. Therefore, it is expected that powerlifters would exhibit a large hip-to-knee torque ratio (by adopting a larger forward lean of the trunk).

The purpose of this study was to determine the influence of variations in the external load on the hip-to-knee joint torque ratio and trunk angle in conventional back squat exercises (for both powerlifters and non-powerlifters).

METHODS

Five male powerlifters (standing height = 1.72 ± 0.04 m; mass = 93 ± 12 kg) and five male non-powerlifters (standing height = 1.80 ± 0.07 m; mass = 82 ± 13 kg) volunteered for the study. The subjects performed conventional back squats at 60%, 70%, and 80% of their raw one-repetition maximum. (Raw lifts are those performed without the use of knee wraps or squat suits.)

Each trial was recorded with a Vicon 370 motion analysis system, and the ground reaction forces and torques exerted on the right foot were measured with an AMTI OR6-7-1000 force platform. The sampling rate was 60 Hz for both. Joint torques were computed using the method proposed by Andrews [3,4]. Trunk lean was defined as the angle between the vertical and the line pointing from the midpoint of the two hip joints to the suprasternale. Data were calculated for the low point of the lift, defined as the instant of minimum thigh angle. At the low point, the thigh was approximately parallel to the ground (5 ± 8°). Differences between measures were assessed using ANOVA tests with a cut-off for statistical significance set at α = 0.05.
Figure 1: Variations in back squat technique.

RESULTS AND DISCUSSION

Figure 2 shows that the hip-to-knee torque ratio did not significantly change across the loads tested in the study (p > 0.05) for either the powerlifters or the non-powerlifters. However, significant

differences in hip-to-knee torque ratio ($p < 0.05$) between the two types of lifters were present at each load tested.

Figure 3 shows that the trunk angle did not significantly change across the loads tested in the study ($p > 0.05$) for either the powerlifters or the non-powerlifters. However, significant differences in trunk angle ($p < 0.05$) between the two types of lifters were present across the range of tested loads.

The present study used a force plate under a single leg and full kinematic and kinetic data to calculate three-dimensional (3D) hip and knee torques, following the kinetic chain of the analyzed leg from the ground upward. The methods used by other authors involve various assumptions and simplifications. Previous work [5] has shown that 2D methods do not properly represent the hip and knee extensor torques during conventional back squats. It is difficult to compare hip and knee torques from different projects, due to variations in body mass, barbell load, body dimensions, relative emphasis of the subjects on hip or knee torque, linear and angular accelerations, and methodological differences.

CONCLUSIONS

The conventional back squat is an effective exercise for working the lower extremity musculature. Powerlifters tend to emphasize the use of the hip extensors, as shown by the large hip-to-knee torque ratio (~1.9) and trunk angle (~41 degrees) in the present study. Non-powerlifters use a more even balance between the hip and knee extensors (hip-to-knee torque ratio ~1.2) as well as a more conservative forward lean of the trunk (~31 degrees).

A GRF COMPARISON BETWEEN LANDING FROM A COUNTERMOVEMNT JUMP AND LANDING FROM HANGING AND DROPPING: A PILOT STUDY

Erin Miranda and Mostafa Afifi Hegazy

Movement Sciences Department, University of Idaho, Moscow, ID, USA

INTRODUCTION

The interest in the biomechanics of landing has increased in the last few decades as injuries from landing are common, especially injuries to the anterior cruciate ligament (ACL) costing approximate $1.7-2.5 billion annually in the United States alone (Afifi & Hinrichs, 2012). This is a huge concern, especially for female athletes as they are about 4-6 times more likely to injur their ACL than males (Myer et al., 2004). With the introduction of title IX, the number of female athletes participating in college sports has gradually increased, with approximately 10k participating in sports in the early 70s to more than 107k by the mid-90s (Lewis, 2000) and that number continues to grow.

A common practice when studying landing mechanics is to have individuals step off a box or drop from a hanging bar. The idea behind these techniques is to make sure every individual lands from the same height (Afifi & Hinrichs, 2012). However, as individuals step off a box they tend to lower their foot resulting in a different step-off height for each individual (Afifi & Hinrichs, 2012). In addition, the mechanics of landing are different from that of a countermovement jump (CMJ) with the step-off landing showing greater peak landing ground reaction force (GRF) and maximum loading rate (Afifi & Hinrichs, 2012; Edwards et al. 2010).

To our knowledge, the mechanics of landing when dropping from a hanging bar has never been compared to that of a CMJ. If the mechanics are the same, then hanging and dropping may serve as a model for simulating landing from a jump. Thus, the purpose of this to study was to compare the GRF experienced during hanging and dropping to that experienced during a CMJ landing.

METHODS

Seven active female college students (21.8±2.6 years of age and 64.3±9 kg) performed 3 maximal vertical jumps and their highest jump was determined using a Vertec device (Sports Imports, Columbus, Ohio). A bar was then set at 75, 50 and 25% of their maximum jump height in a counterbalanced order. The participants then perform 3 CMJ to high enough to touch the bar and 3 drop landings (Drop) where they hung from and released from the bar height. The order of jumping and dropping was also counterbalanced.

Ground reaction force (GRF) data was collected using two force platforms (1000 Hz, AMTI, Watertown, MA) as participants landed with one foot on a separate platform. The peak GRF, peak normalized ground reaction force (nGRF) and maximum loading rate of the two different landings were measured. Data from each condition's 3 landing trials were averaged. Data from each lower limb and two limb average were statistically compared.

A series of two-way ANOVA with repeated measures (landing type × height) with both landing type (CMJ vs. Drop) and height (75, 50, and 25 % maximum height) as within subject factors were conducted for each variable.

RESULTS AND DISCUSSION

Our analysis showed a significant main effect of height for peak GRF and maximum loading rate for each lower limb as well as the two leg average ($p<0.05$). Simple effects did not show significant differences between height pairs for both the CMJ and Drop, however, Drop approached significance for both variables (Table 1). This trend suggests that during CMJ participants were able to adjust their

landing technique to maintain a relatively constant peak GRF at the different heights thus keeping landing impact relatively safe. The gradual increase in peak GRF and maximum load rate during the Drop condition suggest participants were less prepared to the increase of height.

Our analysis also showed a significant main effect of landing type for maximum loading rate for each lower limb as well as the average of both sides ($p<0.05$). Simple effects showed a significant difference between landing types at 75% of maximum height only ($p<0.05$; Figure 1). There may be a height threshold after which the changes in landing mechanics become distinguishable. CMJ and Drop landings were similar at 50 and 25% of maximum height.
Figure 1. nGRF in BW for the CMJ and Drop landings from 75% peak height for a typical participant. Greater peak nGRF for Drop in a shorter period increasing peak loading rate.

Based on our results, it seems the use of hanging and dropping to study landing mechanics would be an acceptable practice when analyzing submaximal landings of 50% or less of maximum jump height.

The results found in this pilot study warrant a revisit to comparing stepoff landings to CMJ landings.

Afifi and Hinrichs (2012) stated that step-off landings were different from CMJ landings; however, they compared maximum jump landings. Based on our findings, these results may be height specific, but this remains to be tested. Edwards et al. (2010) showed a difference between step-off and CMJ landings from the submaximal height of 33 cm. However, their participants had to hit a ball in the process. Multitasking while landing adds another dimension as central nervous system resources are not just focused on landing.

Any questions about this study should be addressed to:

Mostafa Hegazy, PhD
mhegazy@uidaho.edu

CONCLUSIONS

A comparison was made between vertical GRF when landing from a countermovement jump and drops in female college students. Results suggest that these landings are not similar when the landing height is 75% of maximum jump height but similar at 50% and 25%. These preliminary results suggest that dropping from a height may be used to assess landing mechanics for landings from a height 50% or less but not 75% of maximum jump height. Additional work needs to be done to see how these force differences are reflected in patterns of muscle activity and kinematics of landing.

A BIOMECHANICAL PROFILE OF FEAR IN ACL RECONSTRUCTED ATHLETES

Christopher Nagelli, Samuel Wordeman, Stephanie Di Stasi, and Timothy E. Hewett

Sports Health and Performance Institute OSU Sports Medicine, Department of Biomedical Engineering,
The Ohio State University, Columbus, OH USA
email: christopher.nagelli@osumc.edu

INTRODUCTION

Anterior cruciate ligament (ACL) tears are traumatic and devastating knee injuries that frequently occur during sports participation. Most often, ACL-injured athletes undergo ACL reconstruction (ACLR) to regain knee stability and return to sports (RTS) in a timely manner. Despite surgical stability and restoration of normal function, only 65% of athletes return to the pre-injury level of sport at the conservative time point of one year after ACLR[1]. Fear of reinjury is the most common reason for a reduction or cessation in sports participation among athletes after ACLR.[2] Athletes who report less fear of reinjury, and a greater psychological readiness to RTS, are more likely return to their preinjury level of sport after ACLR.[3] Furthermore, the athletes who do RTS are at an elevated risk for a secondary ACL injury. Altered biomechanics at the hip and knee have demonstrated to be were predictors of a secondary ACL injury.[4]

Therefore, the purpose of this study was to determine if there is an association between athletes with greater self-reported levels of fear of reinjury after ACLR and biomechanics during a dynamic single-leg landing task. We tested the hypothesis that the magnitude of frontal plane movement in the lower extremities would be associated with the athlete's fear of reinjury.

METHODS

Eighteen athletes approximately 9 months (8.5±4.2 months) from ACLR were recruited for this study. Basic demographics and anthropometrics of the cohort are provided in **Table 1**. The Anterior Cruciate Ligament Return-To-Sport after Injury (ACL-RSI) scale was utilized to measure psychological preparedness and fear or reinjury in the ACLR cohort. There are a total of 12 questions on the ACL-RSI outcome survey and each question is scaled from 0-100. The lower the score the more fearful or unprepared an athlete felt. Reliability and validity of the ACL-RSI scale to identify athletes who find RTS to be challenging has been demonstrated.[5]

Subsequently, the athletes underwent biomechanical testing using a 12 infrared camera, three-dimensional motion analysis system. The athletes were fitted with 55 retro-reflective markers in a modified Helen Hayes configuration, and completed 5 single-leg landing tasks from a 31 cm box onto two embedded force plates. A trial was deemed successful if the athlete was able to drop off the box unilaterally, land on a single limb, and regain control without adjusting their foot from its initial landing position. Bilateral isokinetic knee extension/flexion strength testing was conducted at 60 °/sec using a dynamometer (Biodex, System 3). A paired t-test was used to evaluate the difference in mean peak knee extensor and flexor torque in the injured and uninjured limb. A multivariate linear regression analysis was used to describe the relationship between fear and lower extremity biomechanics ($p < 0.05$).

Table 1: Demographics of athletes (Mean ± SD)

Subjects	Age (yrs)	Height (m)	Weight (kg)
Male (n=9)	23.6±9.0	1.7±0.07	81.5±11.8
Females (n=9)	16.3±2.1	1.6±0.06	64.0±10.2

RESULTS AND DISCUSSION

The average ACL_RSI score for the ACLR athletes was 66.7±22.5. Interestingly, the questions that received the lowest average scores for this cohort were: (1) are you fearful of re-injuring your knee by playing your sport? (56.6±31.9) and (2) are you afraid of accidentally injuring your knee by playing your sport? (52.7±30.2). This demonstrates that

regardless of psychological preparedness, a fear of reinjury existed amongst the cohort.

A multivariate linear regression model was built based on frontal plane excursions. For the ACLR limb, the model that included frontal plane excursions at the hip and knee explained a significant portion of the variance in ACL-RSI scores (p=0.025, R^2=0.39) **(Figure 1a)**. However, for the uninjured limb, the same model that included frontal plane excursions at the hip and knee was not significant (p=0.51) and only described 8% of the variance **(Figure 1b)**.
Figure 1: A multivariate linear regression model predicted ACL_RSI scores based on frontal plane excursions at the hip and knee in the injured (a) and uninjured (b) limb during a unilateral landing task.

Isokinetic testing showed significant differences between injured and uninjured limbs in peak extensor (INJ: .61±.14 Nm/kg*m; UNINJ: .67±.16 Nm/kg*m; p=0.012) and flexor (INJ: .30±.06 Nm/kg*m; UNINJ: .33±.06 Nm/kg*m; p=0.010) torque. However, the average LSI for the cohort was 91.2±20.0. A healthy population with no prior knee injury typically demonstrates quadriceps and hamstrings LSI within the range of 80-100%.

Interestingly, altered neuromuscular control in the frontal plane at the hip and knee during a drop-landing task are predictive of primary and secondary ACL injury. The results of this study indicate that there may be an association between the psychological preparedness of athletes and frontal plane mechanics. An absence of confidence in the ACLR limb may manifest as high-risk biomechanics.

Peak knee extensor and flexor torques were not included in the multiple linear regression model due to the limited sample size in this cohort. The recovery of quadriceps and hamstring strength in the ACLR limb could influence an athlete's confidence in dynamic tasks such as single-leg landing. Furthermore, a unilateral landing task from a 31 cm tall box does not provide an opportunity for compensatory landing strategies by reliance on the uninjured limb. The physical demand of a single-leg task likely requires greater confidence in the injured limb.

CONCLUSION
Current evidence-based ACLR rehabilitation guidelines do not address strategies to build confidence in the ACLR limb of athletes. Fear and its associated biomechanics have not been previously described in an ACLR cohort. High secondary ACL injury rates and the low number of athletes that return to preinjury level of sport indicate that the current rehabilitation guidelines are not sufficient for physical and psychological recovery from the initial injury. Further research is necessary to delineate the effects of fear on biomechanics.

WEARING A WETSUIT ALTERS ARM MOTION DURING SIMULATED SURFBOARD PADDLING

Jeff A. Nessler, Madison N. Silvas, and Sean C. Newcomer

California State University, San Marcos, San Marcos, CA, USA
email: jnessler@csusm.edu, web: http://www.csusm.edu/kinesiology/research/nessler.html

INTRODUCTION

By some estimates over 20 million people participate in the sport of surfing worldwide (International Surfing Association). Growing popularity in the sport has lead to an increased demand for surfing related equipment. Wetsuits have become an important piece of surfing equipment, with annual sales exceeding 100 million USD (Board-trac Inc., 2009). However, relatively little is known regarding their effects on human performance.

Wetsuits are primarily utilized for their thermoregulatory properties [1], though surfers may also experience some benefit from increased buoyancy and reduced drag in the water [2]. In addition, there is evidence that wearing a neoprene sleeve may help to enhance proprioceptive acuity [3, 4]. In surfers, improved sensory feedback may lead to beneficial changes in the control of arm motion during repetitive paddling. Control of arm motion has previously been associated with movement variability and complexity [5-7], and measures of entropy and local dynamic stability might lend insight to alterations in the control of repetitive paddling. To date, no study has focused on these aspects of human performance while wearing a neoprene sleeve over any aspect of the body. Therefore, the purpose of this study was to determine the effects of a wetsuit on the complexity and variability of paddling in recreational surfers.

METHODS

Twelve male, recreational surfers were recruited from the local population (age 33.0±8.6yr, height 1.82±0.07m, mass 79.9±9.4kg). All subjects were free of any cardiovascular, musculoskeletal, or neurological condition that might have affected their performance. All procedures were approved by the Institutional Review Board at California State University, San Marcos and all participants gave their informed consent prior to data collection.

Following a brief orientation and warm-up, each participant paddled at a submaximal level for 2 minutes while wearing a wetsuit and 2 minutes without a wetsuit (in random order). Paddling was simulated in the laboratory using a commercially available swim bench ergometer (VASA Inc., Essex Junction, VT) that was modified by attaching a short surfboard to the top aspect of the bench. Resistance to paddling was provided by a cable and pulley system that actuated a small flywheel. Subjects were instructed to maintain an output of 20 Watts throughout each trial and were given quantitative, verbal feedback every 5 seconds. Subjects were also instructed to align their strokes with an audible metronome at 25 bpm. Arm movement was relatively unrestricted, though subjects were instructed to paddle in a manner that was similar to their normal motion while in water.

An 8 camera motion capture system (Vicon Motion Systems, Oxford, UK) was used to track the motion of a reflective marker placed over the right wrist of each subject at 120 Hz. Long (λ_{long}, 1-10 strokes) and short (λ_{short}, 0-1 stroke) term maximal Lyapunov exponents were then calculated for wrist trajectories in the antero-posterior, cranial-caudal, and medio-lateral directions (with respect to a prone, paddling position) using the method described by Rosenstein et al [8]. The time series data were then reduced by calculating individual stroke lengths, heights, and widths across each 2 minute trial. These data were then analyzed using the approximate entropy (ApEn) technique described by Pincus [9]. Finally, mean stroke lengths, heights and widths were calculated, and paired t-tests were utilized to compare differences between the wetsuit and no-wetsuit conditions.

RESULTS AND DISCUSSION

Wearing a wetsuit resulted in significant increases in average stroke height, stroke variability, and stroke complexity (λ_{short} and ApEn, p<0.05, Table 1). These differences were only noted for motion in the vertical (antero-posterior) direction and not in either of the other directions of movement.

These results suggest that wearing a wetsuit influences the control of arm motion in repetitive paddling. This affect might be related to a change in the sensory feedback that has been reported to occur when a neoprene sleeve is worn [3, 4]. In particular, ApEn values measured here suggest that arm motion in the vertical direction became more complex when additional sensory feedback was provided. Increased complexity has been associated with learning a motor skill [5] and decreased complexity has been associated with aging, injury, and abnormal physiology [6].

Estimates of maximal Lyapunov exponents were significantly increased (λ_{short} only) when a wetsuit was worn. This suggests that wearing a wetsuit leads to an increase in movement variability and/or local dynamic stability, consistent with the observed increase in movement complexity (ApEn). Several studies have provided evidence for the idea of an optimal level of movement variability that is not too low (periodic and inflexible) or too great (noisy or random) [7]. An increase in λ_{short} for surfers may therefore reflect an increase in movement flexibility or divergence from a strict behavioral attractor for paddling. Changes in the variability of repetitive movements may hold implications for musculoskeletal injury [10] and should be investigated further in paddling surfers.

CONCLUSIONS

Wearing a wetsuit appears to have a beneficial effect on repetitive paddling in surfers by increasing movement complexity and variability. These results may have implications for wetsuit design and for prevention of upper extremity overuse injuries.

INTRODUCTION

Three-dimensional (3-D) motion capture is a valid method to quantify human motion [1]. However, this technique requires expensive equipment and a specialized laboratory that are not available in a clinical or athletics environment. Tri-axial accelerometers pose a portable, cost-effective solution to analyze human motion in the clinic. While previous research indicates that accelerometers can predict peak vertical ground reaction forces (vGRF) during low-impact tasks, such as gait and running, these units have not been validated for dynamic, high-impact landings, like the drop vertical jump (DVJ) and single leg drop (SLD). The objective of this study was to develop a multivariate model that utilized anthropometric measures and peak accelerations to estimate peak vGRF during dynamic jumping tasks.

METHODS

Ten (n=10, males=6, females=4) healthy subjects were recruited for the study. Activity monitors developed at Mayo Clinic (Rochester, MN) were secured bilaterally to the foot, medial tibial surface (shank), lateral femoral epicondyle (thigh), and midpoint between the right and left anterior superior iliac spine (waist). Each monitor incorporated a tri-axial MEMS accelerometer ($\pm16g$, 100Hz, Analog Devices). Subjects performed 10 DVJ tasks and 10 bilateral SLD tasks off a 31cm tall box onto two floor embedded force plates that recorded ground reaction forces at 1200Hz. All tasks were performed during continuous collection of 3-D motion capture data and tri-axial accelerations.

Peak vGRF was extracted from motion capture data for each DVJ and SLD trial. Acceleration magnitude was calculated from tri-axial acceleration data. The peak acceleration was extracted for each DVJ and SLD trial from the continuous acceleration magnitude data. Individual trials that did not have continuous vGRF data or acceleration data from all seven activity monitors throughout the task were excluded from the study.

Multivariate linear regression models that incorporated anthropometric data and peak acceleration magnitudes were separately developed to predict peak vGRF for DVJ and SLD trials. R-squared (R^2) values were calculated for each model. Both the DVJ and SLD multivariate models only included significant parameters ($\alpha = 0.05$).

RESULTS AND DISCUSSION

Height, weight, peak waist acceleration, and peak thigh acceleration were significant predictors of vGRF during a DVJ task (Table 1). Peak waist, thigh, and shoe accelerations were significant predictors of vGRF during a SLD task (Table 1). The correlations between recorded vGRF and predicted vGRF for both DVJ and SLD trials were excellent (DVJ: R^2 = 0.7451; SLD: R^2 = 0.7266) (Figure 1).

Models that utilize anthropometric data and activity monitors to accurately predict vGRF provide a cost-effective method to collect human motion data. Furthermore, clinicians can incorporate testing with activity monitors into current screening strategies conducted both in and out of athletic seasons. The ability to quickly and accurately measure human motion data will provide a portable method to assess athletic health.
Figure 1: Fit vGRF vs calculated vGRF using parameters from multivariate linear regression

Future work will incorporate sex and task differences into one model. Previous work with running and gait trials has utilized repeated measure mixed effects regression statistics to account for variation between subjects and tasks [2]. Similar models for high-impact landings must be investigated. In addition, future work will attempt to validate activity monitors to measure lower extremity kinetics and kinematics during dynamic tasks.

Limitations to this study include individual activity monitor malfunction, which caused certain acceleration data to be discarded before the final regression analysis. In addition, these models need to be validated with disparate data sets.

CONCLUSIONS
Multivariate models that utilized anthropometric data and peak accelerations successfully predicted peak vGRF. This study is the first to our knowledge to utilize multiple activity monitors to produce these results during dynamic, high-impact landing tasks. Application of this model provides clinicians and performance specialists to expand the environment in which they can measure the forces created by athletes during dynamic tasks. The long-term goal of the study is to validate the use of activity monitors to assess injury risk in a non-laboratory athletic environment while subjects perform sport specific tasks.

SOFT TISSUE MOVEMENT OF THE SHANK DURING LANDINGS

INTRODUCTION

High-speed video has shown that during impacts, the soft tissues of the lower limb move relative to the underlying rigid bone. This movement occurs in a wave-like manner, and Zelik and Kuo (2010) suggested this movement may help dissipate force and energy. By using lightweight surface markers, the characteristics of the wave can by quantified with changes indicative of the mechanical properties of the underlying soft tissues as in comparison to the skin the muscle-tendon complex has high stiffness. Deformation away from the contact site during a landing is hence not due to skin motion as much as it is due to the motion of the underlying muscle because of the low stiffness of the skin at low strains not propagating forces well. The aim of this study was to investigate the characteristics of mechanical waves propagating through the shank during drop landings with the shank highly activated and in a more passive condition.

METHODS

Following university ethical committee approval, six healthy, recreationally active males (age: 23 ± 3 years, height: 1.81 ± 0.08 m, mass: 81 ± 5 kg) provided written informed consent to participate in this study. All were familiar with the performance of a drop jump task. A total of 48 spherical retro-reflective markers, 7.9 mm in diameter, were attached around the shank in a 6x8 array using standard double-sided adhesive tape. A ten-camera motion analysis system (700 Hz, 612 series, 1.3 megapixel cameras, Oxford Metrics Group PLC., Oxford, UK) recorded the position of the 48 marker array on the shank (15-75% of shank length). Two test conditions were utilized. During the active

condition, subjects were instructed to heavily favor landing on the test leg and land on their forefoot. During the passive condition, subjects were instructed to initially land using the control limb and then allow the test limb to land on the force plate heel first. Drops were performed from 0.3, 0.5, 0.7 and 0.9 m onto a force plate sampling at 1200 Hz (Kistler 9281B-11, Amherst, NY, USA). All data pre-processing was completed using Vicon Nexus 1.4.116 with any incomplete marker trajectories reconstructed using the quintic spline gap filling procedure.

Marker data were subsequently analyzed in Matlab (MathWorks, Natick, MA., USA) to calculate the motion of the 48 markers and the 40 sectors defined by the 48 markers (eight columns with five sectors in each) during a 90 ms window surrounding the time of impact, approximately 10 ms prior to impact and 80 ms post-impact. Data were filtered at 50 Hz with a second order, zero lag Butterworth filter. Four of the eight columns were selected for analysis of changes in sector area, those located most anteriorly, medially, laterally and posteriorly. Sector area was calculated from the three-dimensional co-ordinates to account for movement of the soft tissue in all three planes, with percentage changes in area calculated relative to sector area measured during a static trial. Marker velocities were calculated as the difference between the minimum and maximum marker position divided by the time delay between each event after impact. Fast Fourier Transforms were used to determine the frequency content of the signal.

RESULTS AND DISCUSSION

The results support the presence of wave motion in the soft tissues of the shank during a drop landing,

with some characteristics varying dependent on muscle activation conditions. Across all markers, average marker velocity was 10.8 ± 6.1 and 10.6 ± 6.9 m.s^{-1} during the active and passive contraction conditions, respectively. Increased muscle activation increases the stiffness of the underlying muscle-tendon unit, with increased stiffness associated with increased speed of wave transmission. The similarity observed is hence unexpected, but it is possible the task was of insufficient difficulty to result in the required activations to produce large enough changes in stiffness.

The dominant frequency of the change in area was approximately 12 Hz during both conditions. This is similar to the frequencies observed during other lower limb motions during impact.

The largest changes in marker sector area were observed at the proximal medial and proximal posterior shank where the muscle: bone ratio is highest (Table 1). The largest increases were 10.5% and 14.4% at the medial and posterior shank, at 30% of shank length. The largest decrease was 12.8% at 15% of shank length, in the posterior sector. Changes are greater than those observed by Pain and Challis (2002) during impacts using the forearm, likely due to the increased soft tissue mass in the shank. Wakeling et al. (2003) proposed

decreased soft tissue movement with increased muscle activation as a strategy to decrease the stress on the body. These results suggest otherwise with larger changes observed with activation. This is potentially due to increased effective mass of the tissues during impact resulting in greater ground reaction forces during this condition which may confound results, or a lower than expected difference in activation between conditions.

CONCLUSIONS

The characteristics of the 3D soft tissue movement during impact can be quantified using motion analysis with similar results to Pain and Challis (2002). Further work is required to determine the relationship between activation and area changes, and to investigate the characteristics of the wave-like motion of the soft tissue during landing to provide insight into the body's response to impact.

ABSOLUTE AND RELATIVE CMJ PERFORMANCE ACROSS DIFFERENT AGE GROUPS AND SPORTS IN YOUNG MALE ATHLETES

Dino A. Palazzi, Benjamin K. Williams, Jonathan A. Glynn and Philip Graham-Smith

Aspire Academy, Sport Science Dpt., Doha, QATAR
email: dino.palazzi@aspire.qa, web: http://www.aspire.qa

INTRODUCTION

Counter movement jump (CMJ) has been extensively used by sport scientists and coaches to assess lower extremity explosive strength in athletes [1, 2]. When CMJs are performed on force platforms (FP) many variables can be obtained such as jump height, force, power, impulse and derivatives of these [3]. The aims of this study were to profile the absolute and relative indices of jumping performance on juvenile athletes, and determine which ones are the most likely to show progress on the performance due to growth and training.

METHODS

236 healthy, male student-athletes from 11 to 17 years-old, training up to 8 times a week in 10 different sports, volunteered for the study. Their performances were tracked 5 times along 16 months, totaling 597 testing sessions. The age of the subjects was calculated on the day of testing and the data allocated into the age ranges 11-13, 13-14, 14-15, 15-16 and 16-17. Group characteristics are shown in Tables 1 and 2.

All subjects practiced a minimum of 3 CMJs for warm-up prior to performing the jumps for analysis. CMJ performances were assessed on two portable FPs (Kistler type 9286AA and Bioware V5.0, Switzerland), sampling at 1000Hz and treated with a 7-point moving average filter.

CMJs started from a stationary position with the subjects' feet symmetrically set about shoulder width apart. CMJ trials were performed with the subjects' hands remaining on their hips throughout the whole movement. A trial was considered successful when both feet clearly landed wholly on their toes on the surface of the FPs. The FPs were zeroed before every trial, and data collection started by measuring the athletes' body weight (BW) on

both FPs to ensure that they registered the same force, prior to performing 3 maximal effort jumps. Following landing, the subjects adjusted the feet position and maintained a stationary position on the FPs for at least a second before jumping; this was to ensure a reliable initial vertical velocity of 0 m/s. The onset of movement was automatically set to the point when the total vertical force deviated -20 N from BW, and the take-off was set to the point when the total vertical force dropped below 10 N. Jump height was calculated using the impulse method with the total vertical force. Results of those 3 jumps were averaged, obtaining a single representative value for every variable in the testing session.

RESULTS AND DISCUSSION

The most relevant general findings related to CMJ performance are shown in Figs. 1 and 2, where moderate relationships between age and absolute measures of jump height ($R^2 = 0.40$, $p \leq .001$) and concentric power ($R^2 = 0.42$, $p \leq .001$) were found.
Figure 1: CMJ height in absolute and relative to BW scales, across all ages and sports.

With respect to the specific sports, the athletics group consistently jumped higher than the football players, who in turn outperform the remainder of the sample (Fig. 3).
Figure 2: Maximum power during CMJ in absolute and relative to BW scales, across all ages.
Figure 3: CMJ height (avg. ± std. dev.), in absolute and relative scales, related to age groups and sports.

The mean football CMJ height is typically one year behind the athletics group, and this may be associated with a different emphasis of training. The athletics group likely devoted more time to power work and work in vertical direction. By the age of 16-17 the athletes jumped 0.37 m and the footballers 0.33 m. In comparison to elite senior norms, horizontal jumpers would typically jump 0.53 ± 0.07 m [4], and professional football players 0.42 ± 0.04 m [5]. The results found no relationship between CMJ height related to BW and age, when all the data was examined together. However, without the athletics and football groups, the trend revealed a steady rise in CMJ height related to BW from the age of 14-17, increasing from 0.51 to 0.6 m/N x 1000; in contrast, the footballers seemed to maintain an average performance of 0.56 m/N x 1000 through the ages of 13-17.

CMJ relative concentric power produced a slightly lower relationship with age compared to the absolute measure ($R^2 = 0.31$, $p \leq .001$).

CONCLUSIONS

The results highlight that the trend in the development of jump performance is dependent on the sport and the main focus of the training modes adopted. Whilst year on year improvements are seen in youth football players, the relative change in performance is equivocal to increases in BW. Conversely, athletes appear to have performance gains that outweigh their increase in BW.

Are Variables Associated With Knee Injuries In Runners Different Before And After A 40min Run?

[1] Max R. Paquette and [1] Dan A. Melcher

[1] The University of Memphis, Memphis, TN, USA
email: mrpqette@memphis.edu, web: http://memphis.edu/hss/enl/

INTRODUCTION

The high frequency of knee injuries in runners has inspired scientists to study a number of running biomechanical variables. A number of discrete variables have been identified as possible risk factors for running knee injuries. Indeed, runners with knee injuries generally exhibit higher peak knee flexion [1], contralateral pelvic drop [2], peak hip adduction [3] and peak internal hip rotation [2] compared to non-injured runners.

To date, the majority of biomechanical studies have assessed injury-related variables during a one-time laboratory test while runners are in non-fatigued states. As postural control is reduced following a fatiguing run [4], the clinical implications of injury-related variables for injury risk may be better understood if studied following a typical training run when runners may be more fatigued.

The purpose of this work was to compare previously identified variables associated with knee injuries at the start and end of a 40min training run in runners with and without a history of knee injury. We expected 1) an increase in the magnitude of injury-related variables following the run and 2) a larger increase in the injury group.

METHODS

Twelve competitive runners who were injury-free (*Healthy*; 8 men; 72.5 ± 12.5 kg; 1.78 ± 0.08 m) and 12 runners who suffered a running-related knee injury in the past year (*Injured*; 7 men; 69.2 ± 17.6 kg; 1.76 ± 0.13 m) participated in the study. Written consent approved by the Institutional Review Board was obtained for all participants before testing begun.

All participants filled out an online survey regarding their running and injury history. Before testing, neoprene wraps were secured on both thighs and shanks and around the waist. Runners then ran at an easy effort on the treadmill for 5 minutes to allow the straps to set into place. An 8-camera motion capture system (120Hz, Qualisys AB, Gothenburg, Sweden) was used to collect kinematic data. Anatomical markers and tracking marker clusters were placed on both lower extremities to define segment coordinate systems. Following a standing calibration trial, only anatomical markers were removed and runners completed a 40-minute treadmill run. The run speed was set to 75% of the runners' best 10 km race time in the past 5 years to ensure a moderate run effort based on running ability. Two 6-second motion capture trials were collected after 10 and 40 minutes to obtain knee and hip angular position data at the start and end of the run.

Visual3D biomechanical software (C-Motion, Germantown, MD, USA) was used to process and analyze all data. Kinematic data were interpolated using a least-squares fit of a 3rd order polynomial with a three data point fitting and a maximum gap of 10 frames. Data were then filtered using a fourth-order Butterworth low-pass filter at 8 Hz. The start and end of stance phase was identified using a kinematic method with the vertical pelvis velocity. Dependent variables included peak knee flexion, peak contralateral pelvic drop, peak hip adduction and peak internal hip rotation. The average of each variable for five consecutive stance phases during the 10 and 40-min collection times was used for analysis.

A two-way (Group × Time) mixed design analysis of variance (ANOVA) with Time as the within-subject factor and Group as the between-subject factor, was used to evaluate all variables (22.0 SPSS, Chicago, IL, USA). Significance was set at an alpha level of 0.05. Cohen's d effect sizes (ES) were also reported to further assess mean differences.

RESULTS AND DISCUSSION

Peak knee flexion and contralateral pelvic drop showed no interaction or main effects ($P < 0.05$; Table 1). Peak hip adduction showed a Group x Time interaction and a Time main effect (Table 1). *Post-hoc* Paired t-tests showed greater peak hip adduction at 40-min compared to 10-min in the healthy group ($p = 0.014$; *ES* = 0.34) but no time difference in the previously injured group ($p = 0.87$; Figure 1). The time effect for peak hip adduction in healthy runners could suggest the importance of assessing certain biomechanical variables when runners are fatigued.
Figure 1: Average peak hip adduction angle during five stance phases of Healthy and Injured runners at 10-min and 40-min points during a run (mean±SD). *: Time difference within Healthy group.

Contrary to previous findings, peak knee flexion [1], contralateral pelvic drop [2] and peak hip adduction [3] were not different between groups. However, these studies compared healthy and *currently* injured runners whereas we studied previously injured runners. The current study included both men and women and it is possible that gender differences masked potential group effects. The small sample size did not allow for statistical adjustments for gender differences.

Peak internal hip rotation showed a Group effect (Table 1). Regardless of testing time during the run, the previously injured group showed greater hip internal rotation compared to the healthy group (*ES* = 1.29). This group difference is consistent with previous findings in currently injured runners [2] and may suggest that runners who suffer a running-related knee injury continue to exhibit increased peak internal hip rotation when symptoms subside. The causal effects of greater peak internal hip rotation on injury risk in runners still remain unknown.

CONCLUSIONS

Findings from this study suggest that differences in most knee and hip kinematic variables between runners with knee injuries and healthy runners are not consistent when comparing healthy and previously injured runners. Peak internal hip rotation was the only variable that showed a similar difference between groups. A time effect within the healthy group for peak hip adduction may suggest that biomechanists should consider assessing joint variables at different time points during a run and not only in non-fatigued states.

The Effects of MSM Supplementation on Knee Kinetics during Running, Muscle Strength, and Muscle Soreness following Eccentric Exercise-Induced Quadriceps Damage

[1] Shelby A. Peel, [1] Daniel A. Melcher, [1] Brian K. Schilling, [1] Richard J. Bloomer, [1] Max R. Paquette

INTRODUCTION

Runners are constantly seeking new approaches to optimize performance and training gains. Delayed onset muscle soreness (DOMS) is elevated following eccentric knee extensor damage (i.e., downhill running) [1]. Along with elevated DOMS, reductions in ankle and knee range of motion (ROM) and knee stiffness have been reported following eccentric knee extensor damage in the 48 hours following damage [1].

Strategies to reduce the duration of DOMS and associated changes in joint biomechanics are important for runners to ensure safe continuity in training. Many strategies have been suggested to speed up recovery. The degree of muscle injury may be influenced by nutritional interventions [2]. Methylsulfonylmethane (MSM) has anti-inflammatory properties [3] that may aid in reducing the duration of DOMS following muscle damage.

The purpose of this study was to investigate the effects of MSM supplementation on knee joint kinetics during running and DOMS following eccentric knee extensor damage. It was expected that the MSM intervention would reduce the negative effects of muscle damage on these variables compared to a placebo.

METHODS

Forty healthy, resistance trained men (age: 25.28±6.31 y, ht: 177.63±6.57 cm, BMI: 26.65±2.47 kg·m^{-2}) were recruited to participate. Subjects were randomly assigned in double-blind manner to one of two groups: MSM at 3 grams per day (n=20) or placebo (rice flour; n=20). Subjects underwent a one-month supplementation period prior to testing sessions.

Subjects were tested over a period of five consecutive days: Baseline, 0 hrs, 24 hrs, 48 hrs, and 72 hrs. All daily testing procedures were the same. For the muscle damage protocol subjects performed 10 sets of 10 repetitions (or reps to failure) of eccentric seated knee extension exercise on a 4-second count using 100% of concentric one-repetition maximum. Subjects were given a 2-minute rest period between sets.

Self-reported lower extremity muscle soreness was measured each testing day using a 10-point visual analog scale (VAS) rating for soreness during a body squat and passive knee flexion stretch. Muscle damage was quantified with maximum voluntary isometric knee extensor force using a load cell (MLP-1K, Transducer Techniques). The average of the force plateau of three maximal trials was used for analysis. An 8-camera motion analysis system (120Hz, Qualisys AB,) and a force platform (1200Hz, AMTI, Inc) were used to obtain 3D kinematic and ground reaction force (GRF) data, respectively. Subjects performed three over-ground running trials over a 20 m runway at 3.35 m·s^{-1} ±5% contacting the force plate with their right foot. Visual3D biomechanical analysis software suite (C-Motion, Inc.) was used to compute 3D kinematic and kinetic variables of the right limb during running. Sagittal knee stiffness was computed as the ratio of the change in extensor moment and knee flexion ROM. Since dependent variables were different between groups at baseline, data were normalized using the difference between baseline means.

Mixed design repeated measures ANOVA (Group x Time) were used to compare dependent variables. *Post hoc* paired t-tests were used for pairwise comparisons. Mann Whitney U test was used to compare the VAS rating of soreness results between

interventions and test times (i.e., non-parametric data) ($P<0.05$).

RESULTS AND DISCUSSION

Maximal isometric force to assess muscle damage showed no interaction ($P=0.38$) or group effects ($P=0.85$) but showed a time main effect ($P<0.001$; Figure 1). Maximal force was reduced at every time point ($P<0.05$) compared to baseline except for 72hrs post ($P=0.12$). By 72hrs post damage, values returned to baseline for subjects in the MSM condition but remained approximately 8% below baseline for those in the placebo condition (Figure 1); however, the difference was not of statistical significance. DOMS during squat was not different between groups at any time ($P>0.05$) but was different at every time point compared to baseline ($P<0.001$). DOMS during passive stretch was lower in MSM group but remained elevated above baseline. These findings confirm that muscle damage and DOMS persist after 48 hrs [1] and that DOMS remain up to 72 hrs following muscle damage.

No interaction or group effects were found for biomechanical variables. Knee stiffness ($P=0.002$), knee moment ($P<0.001$), knee eccentric power ($P<0.001$) and loading rate ($P=0.02$) all showed time effects. All variables, except for loading rate, did not returned to baseline levels following damage (Table 1). Loading rate was decreased at 24, 48 and 72 hrs compared to 0 hrs, but not compared to baseline. Although not significant, loading rate was slightly higher than baseline at 0 hrs ($P=0.09$) which likely explains why 24 to 72 hrs were not different than baseline.
Figure 1. Maximal isometric knee extensor strength at each testing time. [*]: different than baseline.

CONCLUSIONS

Our findings suggest that MSM does not favorably influence knee biomechanics following eccentric exercise-induced muscle damage using knee extension exercise. MSM supplementation may positively impact muscle force recovery, as well as DOMS during passive stretch.

A Prospective Comparison of Biomechanical Variables Associated With Running-Related Injuries in Collegiate Cross Country Runners

[1] Daniel J. Kuhman, [1] Daniel A. Melcher, [1] Shelby A. Peel, [1] Max R. Paquette

[1] The University of Memphis, Memphis, TN, USA
email: mrpqette@memphis.edu, web: http://memphis.edu/hss/enl/

INTRODUCTION

Various biomechanical variables have been linked to runners with a history of injuries. Specifically, runners who use a rearfoot strike (RFS) have shown a higher rate of retrospective injuries compared to mid or forefoot striking (FFS) runners [1]. Greater values of ankle eversion and peak eversion velocity, and smaller ankle dorsiflexion have been observed in currently injured versus non-injured runners [2]. Another study showed a trend for smaller ankle eversion and eversion velocity in previously injured runners. Differences in injury status (i.e., previously vs currently injured) likely explain discrepancies in results between these two studies. Finally, a higher loading rate of the vertical ground reaction force (GRF) has been linked with retrospective injuries in female and male runners [3, 4]. Since these studies compared retrospectively or currently injured runners with non-injured runners, it is difficult to establish causal relationships between these biomechanical variables and running injuries.

The purpose of this collection was to *prospectively* compare biomechanical variables previously associated with injuries in collegiate runners who developed any lower extremity injuries compared to those who did not over the course of a cross country season. We expected higher loading rate, eversion ROM and eversion velocity but smaller dorsiflexion ROM in runners who developed injuries compared to those who did not.

METHODS

Data was collected on 24 non-injured, competitive collegiate runners prior to the start of a Division 1 NCAA cross country season. Written consent approved by the Institutional Review Board was obtained for all participants before testing began.

At the start of the season, 3D joint kinematics and ground reaction force (GRF) data for both limbs were collected using a motion capture system (240Hz, Qualisys AB) and force platform (1200Hz, AMTI Inc.), respectively. Participants completed a total of 10 over-ground running trials (five trials per leg). Based on preferred training speeds, men ran at 4.5 m/s while women ran at 4.0 m/s ($\pm$ 5%). At the end of the season runners completed a survey regarding, among other training and lifestyle factors, injuries sustained throughout the season. Of the 24 runners who were tested at the start of the season, five sustained injuries that were not running-related (e.g., ankle sprains, falls) and were not included in analyses. Of the other runners, 10 sustained running-related injuries (6 women; 57.8 $\pm$ 7.5 kg) and 9 had no injuries (7 men; 66.6 $\pm$ 8.9 kg). Data from these 19 runners were analyzed.

Visual3D software (C-Motion, Inc.) was used to compute all variables. Kinematic and GRF data were filtered using a fourth-order Butterworth low-pass filter at 8 and 40 Hz, respectively. Dependent variables included strike index (position of center of pressure at foot contact expressed as a percentage of foot length), peak instantaneous loading rate of the vertical GRF, dorsiflexion range of motion (ROM), eversion ROM and peak ankle eversion velocity. The injured side in injured runners and the right side of non-injured runners were included in analyses.

Independent t-tests were used to compare biomechanical variables between the healthy and injured groups ($P<0.05$). Cohen's d effect sizes were also computed for mean comparisons.

RESULTS AND DISCUSSION

The ANOVA showed that strike index (*ES*=0.24), peak instantaneous loading rate (*ES*=0.28), and dorsiflexion ROM (*ES*=0.04) were not different between groups (Table 1). Eversion ROM (*ES*=1.21) and peak ankle eversion velocity (*ES*=1.26) were both smaller in injured compared to uninjured runners (Table 1).

Our finding of smaller eversion ROM and peak eversion velocity in injured runners differ from previous findings comparing runners injured at the time of testing to uninjured runners [2]. Their currently injured runners may have altered their running mechanics as a result of pain at time of testing. Further, their study assessed differences between groups for specific types of injuries (e.g., IT band syndrome, shin splints, and plantar fasciitis) whereas all types of injuries were included in the injured group in the current study. Interestingly, our results of frontal plane ankle kinematics are similar to previous findings comparing retrospectively injured and uninjured runners [3]. The authors suggested that a greater eversion velocity may ensure that the foot reaches a stable position prior to mid-stance in preparation for push off. The similar findings of lower ankle eversion and eversion velocity in runners who developed injuries in our prospective study and in their retrospective injury study may indicate that comparisons of retrospective injury rates are more appropriate than comparing currently injured and uninjured runners to assess running injury risk.

Strike index, loading rate and dorsiflexion ROM were not different between groups. RFS pattern yields greater loading rates and lower dorsiflexion ROM than FFS. Thus, since strike pattern (i.e., same strike index) were not different between groups, it is unsurprising that loading rate and dorsiflexion ROM were not different between groups.

The current study included a preliminary analysis of prospective data currently being collected on a larger sample of collegiate runners. The small sample size makes it difficult to conclude with confidence that ankle eversion ROM and peak eversion velocity are valid predictors of injury-risk in collegiate runners. In addition, the injury group had twice as many women (6) than men (3). The small sample size made it difficult to assess gender difference with adequate statistical power, but a *post hoc* comparison (independent t-tests) suggested no gender differences for all five variables (*P*>0.05).

CONCLUSION

Our preliminary findings suggest that lower eversion ROM and eversion velocity may be predictive of injury risk in runners. We will continue to use this prospective approach to identify injury risk factors in a large sample of collegiate runners.

Effects of Imposed Foot Strike Before and After a Long Run on Joint Stiffness in Rearfoot Strike Runners

[1] Daniel A. Melcher, [1] Max R. Paquette, [1]Brian K. Schilling

[1] Musculoskeletal Analysis Laboratory, The University of Memphis, Memphis, TN, USA
Email: dmelcher@memphis.edu

INTRODUCTION

Biomechanics research has recently focused on the effects of acute foot strike pattern transitions, specifically on the differences in lower extremity joint kinetics and stiffness [1, 2]. Joint stiffness may be related to injury risk in runners [1]. As approximately 75% of recreational and elite runners use a rearfoot strike (RFS) pattern [3], it is worthwhile to study these runners. Since runners often complete long runs as part of their training, it is important to understand potential changes in biomechanical variables during a long run as runners become fatigued.

Here we examine the effects of imposed strike pattern before and after a long treadmill run on ankle and knee joint stiffness in habitual RFS runners. We expected a decrease in joint stiffness following the long run. We also expected a greater decrease in knee joint stiffness following the run during RFS compared to imposed forefoot strike (FFS). Finally, we expected greater knee stiffness during imposed FFS and greater ankle stiffness during RFS.

METHODS

Fifteen experienced male habitual RFS runners were recruited (1.80±0.07m; 74.4±12.0kg; 31.7±9.3yrs; 47.2±14.1mi/wk). Written consent approved by the Institutional Review Board was obtained for all participants before testing.

Runners completed a 5 min running warm-up before testing. Maximal isometric ankle and knee extensor strength was measured while subjects pushed against a strap for 3-4 seconds. The strap was connected via chain to a load cell (Transducer Techniques, Temecula, CA). Ankle and knee joint angle were maintained at 90 degrees. Three trials

for both ankle and knee were collected and averaged over the trials. These data were collected before and after the fatiguing run.

An 8-camera motion capture system (240Hz, Qualisys AB) and force platform (1200Hz, AMTI) were used to collect kinematic and ground reaction force (GRF) data. Anatomical and tracking marker clusters were secured on the right leg. Subjects completed five over-ground running trials with their habitual RFS and imposed FFS pattern over a 20m runway while contacting a force platform with their right foot. Five successful trials were completed using both their habitual strike pattern and imposed FFS, respectively. A speed of ±5% of their long run pace was used. Once markers were removed, all runners then completed a long treadmill run equivalent to 25 % of their average weekly mileage in the past 3 months (11.8±3.5miles; 90.4±23.4min). Immediately following the run, maximal strength and running tests were repeated.

Visual3D software (C-Motion, Inc.) was used to compute all variables. Kinematic and GRF data were filtered using a fourth-order Butterworth low-pass filter at 8 and 40 Hz, respectively. Joint moments were normalized to body mass (Nm/kg). Joint kinetic variables were computed using inverse dynamics and moments were reported as net internal moments. Dependent variables included sagittal plane ankle and knee stiffness. The change in sagittal plane ankle and knee joint moment during stance and joint ranges of motion (ROM) were also measured. Joint stiffness was computed using the following equation:

$$k = \frac{\Delta M}{\Delta \theta}$$

Where k represents joint stiffness, $\Delta\theta$ represents the joint angle range of motion (ROM) from foot strike to peak angle, and ΔM is the change in the joint moment from foot strike to the peak moment. The

average for the five trials of each condition was used in the statistical analyses. A 2X2 within-within factorial repeated measures ANOVA with strike pattern and time were conducted. Alpha level was set at 0.05 for all tests. Cohen's d effect sizes (ES) were calculated for pairwise comparisons using pooled standard deviation.

RESULTS AND DISCUSSION

Knee extensor fatigue following the run was confirmed as knee extensor maximal isometric force was reduced following the long run (ES=0.39; Table 1). Plantarflexor maximal isometric force was not different before and after the run (ES=0.16) (Table 1).

Contrary to our hypothesis, no foot strike and time interaction were found for ankle (p=0.30) and knee joint stiffness (p=0.25). Ankle (p<0.001, ES=1.62) and knee joint stiffness (p<0.001, ES=0.91) both showed foot strike effects. Consistent with previous literature [2], knee stiffness was greater during imposed FFS while ankle stiffness was greater during RFS (Figure 1). Sagittal plane ankle ROM was greater during imposed FFS (ES=0.96) while knee ROM was greater during RFS (ES=3.07; Table 1). In addition, knee ROM was reduced following the long run which may explain the unchanged knee stiffness before and after the long run.

Although no interactions were found in sagittal plane joint kinetics, it is possible that fatigue altered frontal and transverse plane ankle and knee joint kinetics between strike patterns. Further biomechanical analyses on the effects of fatigue and strike pattern along with their relationship with injury risk are needed to examine these hypotheses.
Figure 1: Mean (±SD) of sagittal plane ankle and knee stiffness between RFS and imposed FFS pre & post treadmill long run.

CONCLUSIONS

Our findings indicate that changes in ankle and knee joint stiffness between RFS and imposed FFS in habitual RFS runners are independent of fatigue.

Does Fatigue And Imposed Forefoot Strike Alter Strike Pattern Variability And Loading Rate In Rear Foot Strike Runners?

[1] Max R. Paquette, [1] Dan A. Melcher

[1] The University of Memphis, Memphis, TN, USA
email: mrpqette@memphis.edu, web: http://memphis.edu/hss/enl/

INTRODUCTION

A higher rate of injuries has been linked with rearfoot striking (RFS) during running [1] but the correct strike pattern for reducing injury risk is highly debated. Many runners have attempted to switch from a RFS to a forefoot strike (FFS) pattern. Clinicians often advise these runners to do so gradually as a sudden increase in stress applied to the Achilles tendon from an imposed FFS may be injurious. Movement variability has been hypothesized to broaden stress distribution on musculoskeletal tissue [2, 3]. As differences in strike patterns alter joint kinetics in running, greater variability in strike pattern could promote greater dispersion of loads and potentially reduce the risk for tissue injury. In addition, higher loading rate of the vertical ground reaction force (LR) have been observed in female runners with a history of tibial stress fractures measured during running trials in a non-fatigued state [4]. Finally, considering most competitive runners often complete longer runs as part of their training (i.e., 60 min or more), it would be insightful to study changes in strike pattern variability and loading rate before and after a long run.

There, the purpose of this study was to compare strike pattern variability and instantaneous loading rate between habitual RFS and imposed FFS before and after a long run. We expected lower strike pattern variability and a higher LR following fatigue. Higher variability and lower LR during imposed FFS compared to RFS was also expected.

METHODS

Fourteen experienced male habitual RFS runners were recruited (1.79±0.07m; 73.5±11.4kg; 31.5±9.6yrs; 48.3±14.0mi/wk). Written consent approved by the Institutional Review Board was obtained for all participants before testing.

Runners completed a 5 min running warm-up before testing. An 8-camera motion capture system (240Hz, Qualisys AB) and force platform (1200Hz, AMTI) were used to collect kinematic and ground reaction force (GRF) data. Anatomical and tracking marker clusters were secured on the right leg. Subjects completed five over-ground running trials with their habitual RFS and imposed FFS pattern over a 20m runway while contacting a force platform with their right foot. Five successful trials were completed using both their habitual strike pattern and imposed FFS, respectively. A speed of ±5% of their long run pace was used. Once markers were removed, all runners then completed a long treadmill run (11.8±3.5miles; 90.4±23.4min) equivalent to 25 % of their average weekly mileage in the past 3 months. Immediately following the run, markers were placed back on the runners and running tests were repeated. Ink marks were used to ensure high reliability in marker placement before and after the long run.

Visual3D software (C-Motion, Inc.) was used to compute all variables. Kinematic and GRF data were filtered using a fourth-order Butterworth low-pass filter at 8 and 40 Hz, respectively. Dependent variables included strike index, its coefficient of variation (CV) and peak instantaneous loading rate of the vertical GRF. Strike index is the ratio of the location of the center of pressure location as a percentage of foot length at time of foot strike. The strike index CV was calculated as a percentage of the ratio of the standard deviation over the mean of five trials. The average values of these variables for the five trials of each strike pattern condition before and after the long run was used in the statistical analyses.

A 2X2 within-within factorial repeated measures ANOVA with strike pattern and time ($\alpha = 0.05$). Paired t-tests were used to compare means when

interaction effects were found. Cohen's d effect sizes (ES) were calculated for pairwise comparisons using pooled standard deviation.

RESULTS AND DISCUSSION

RFS and FFS patterns were confirmed at every time point as strike index was greater for imposed FFS compared to RFS (Table 1). Habitual RFS runners appear to be able to acutely adopt a FFS pattern even following a long fatiguing run.

A strike pattern by time interaction was not found for strike index variability (CV; Table 1). Although stride index variability was reduced by 20% during RFS and 21% during imposed FFS after the long run, no time effect was found (Table 1). Lower strike index variability was found during imposed FFS compared to RFS (Table 1). This finding is unsurprising since runners were likely highly focused on performing the FFS as per their instructions. Changing foot strike pattern may introduce new stresses to musculoskeletal tissue that, if too sudden, may be injurious. Movement variability has been hypothesized to broaden stress distribution on musculoskeletal tissue [2, 3]. Thus, the reduced variability in strike index when RFS acutely adopt a FFS pattern could be linked with injury development potential following an acute strike pattern transition. This hypothesis still needs to be tested using a prospective approach.

A strike pattern by time interaction trend ($P = 0.064$) was observed for loading rate (Figure 1). As expected, loading rate was lower before (ES = 2.21; $P < 0.001$) and after (ES = 2.20; $P < 0.001$) the run during imposed FFS compared to RFS. During RFS, loading rate was slightly higher following the run ($P = 0.064$; ES = 0.17) but the small effect size suggests a non-meaningful change. Finally, loading

rate was unchanged following the long run ($P > 0.05$).
Figure 1: Instantaneous loading rate of the vertical GRF in RFS and imposed FFS pre and post run. Notes: [*]: difference between strike patterns within test time; [#]: trend for difference between test times within RFS pattern. Means ± SD.

CONCLUSIONS

Changes in strike pattern, its variability and loading rate between habitual RFS and imposed FFS appear to be unchanged following a long run. However, the ability and the injury risk of habitual RFS runners to use a FFS pattern for an entire long run remain unknown.

HIP LOADING DURING FORWARD AND SIDE LUNGES

Jaimee M. Zorn and Michael J. Pavol

Oregon State University, Corvallis, OR, USA
email: mike.pavol@oregonstate.edu

INTRODUCTION

Hip fractures have serious consequences for older adults, and a major risk factor for these fractures is osteoporosis [1]. Encouragingly, exercise can slow aging-related bone loss at the hip, as a result of the associated loading [2]. However, there is little evidence as to what exercises are most effective in this regard. Notably, little is known about femoral loading at the hip during forward and side lunge exercises, despite the common inclusion of these exercises in programs aimed at osteoporosis prevention. This study thus determined the peak joint contact force at the hip during a lunge exercise as a function of lunge direction, limb, and use of a weighted vest for added resistance.

METHODS

Seven healthy, physically active women, aged 38-54 years (mean ± SD: 44 ± 4 yrs, 165 ± 4 cm, 57 ± 5 kg), gave their informed consent to participate. Participants began with a task-specific warm-up/ practice. Next, a set of 26 reflective markers was attached to the lower limbs and torso. Participants then performed two blocks of lunge trials: one with and one without a 5.4 kg weighted vest (CAP Barbell, Houston, TX). Each block included one set each of forward and side lunges, each set consisting of 3-4 trials with a pause between. Orders were counterbalanced. In each trial, participants stepped forward or right with the right foot to a marked position at a step length of 110% of their leg length to execute the lunge. Participants were to lower their hips as far as they felt they safely could during the lunge (without touching the left knee to the ground during forward lunges), then step back to their original position. Each lunge was to be performed in a continuous manner at a self-selected, unhurried pace, the arms crossed across the chest and the back kept straight. A chair was placed within reach for the participant to grasp if needed. During each lunge, kinematic data were recorded at 60 Hz by a motion capture system (Vicon, Los Angeles, CA) and the ground reactions under the feet were recorded at 600 Hz by three force platforms (Bertec, Columbus, OH). Height, weight, and selected body dimensions were also measured.

Motion capture and ground reaction force data were filtered at 9 and 45 Hz, respectively, and cropped to the period from 0.1 s before foot contact of the right (lunging) limb until 0.1 s after foot-off. Marker positions relative to body segments and joint centers were estimated (BodyBuilder, Vicon), and the pelvofemoral contact force at each hip was then calculated from the data using a rigid-body model of the torso and lower limbs within the AnyBody Modeling System (Aalborg, Denmark). The Twente Lower Extremity Model (AnyBody Managed Model Repository, v1.2) was modified to include a ball-and-socket knee joint with torsional springs for passive restraint. Each lower limb consisted of five segments (thigh, leg, patella, talus, foot) with nine degrees of freedom and 55 muscles divided into 169 fascicles, each modeled by a 3-element, Hill-type muscle model. Dimensions, inertial properties, and strength of the model were scaled to the participant. To solve for the contact forces at the hip, inverse dynamics solutions were found to minimize the sum of the squared muscle fascicle forces, normalized to the fascicle's strength, in each frame of data.

Peak contact forces at the hip were extracted and normalized to body weight (BW), with values averaged across correctly-performed trials within a condition. Effects of lunge direction, limb, and weighted vest use on the peak contact force were identified by a 3-factor repeated-measures ANOVA, with effects considered significant at p<.05. Two participants were excluded from the analysis, one as an outlier and the other due to a model singularity.

RESULTS AND DISCUSSION

Consistent patterns of hip loading were observed during forward and side lunges. For forward lunges, the contact force at both hips peaked shortly after the low point of the lunge, as participants propelled upward (Figure 1). A similar pattern was seen in the left (non-lunging) limb during side lunges, but the contact force at the hip of the right (lunging) limb peaked later, as participants propelled medially.

Peak contact forces at the hip were approximately 44% larger for forward lunges than for side lunges (p=.023; Figure 2). Peak contact forces were also about two times larger for the right (lunging) limb than for the left (non-lunging) limb (p=.002). The addition of a 5.4 kg weighted vest did not affect the peak contact force (p=.075). These effects were seen regardless of lunge direction, limb, and/or weighted vest use (p>.05 for all interaction effects).

The peak contact forces found for forward and side lunges are larger by factors of about 4 and 2.5, respectively, than femoral forces directly measured during running or jumping [3]. These peak forces found may overestimate the actual contact forces, as model-predicted contact forces are sensitive to assumed muscle moment arms. However, it is also reasonable that lunges would result in large contact forces at the hip. The large distance of the lunging foot from the hip during forward lunges necessitates large hip extensor moments for weight support.

Figure 2: Mean ± SD peak contact force at the hip during lunges as a function of lunge direction, limb, and weighted vest use. * p<.05 vs. Forward Lunge; † p<.05 vs. Right (Lunging) Limb. NV = No Vest.

Large hip extensor moments are also needed during side lunges to support the forward-inclined torso, and those will come disproportionately from the lunging limb, as it supports more of one's weight. With the large muscle forces needed to produce these moments and the large hip contact forces that result, the effect of wearing a 5.4 kg weighted vest was neither significant nor meaningful. That hip contact forces were smaller for side lunges than for forward lunges may be due to a smaller distance of the lunging foot from the hip. Differences between limbs likely reflect differences in weight support.

CONCLUSIONS

The present findings suggest that both forward and side lunges produce enough force at the hip of the lunging limb to stimulate bone formation, even without adding a weighted vest, and forward lunges are more beneficial in this regard. The findings thus support the inclusion of lunges, particularly forward lunges, in osteoporosis prevention programs.

INTRODUCTION

Increasing neck strength has been promoted as a player-specific strategy for lowering the severity of impacts to the head and the incidence of concussion [1,2]. Specifically, the rate at which neck muscle force (RFD) can be developed prior to or early post-contact is a variable of neck strength which could modify the biomechanics of concussive and upper cervical spine injuries [3]. The sternocleidomastoid (SCM) muscle is a key feature of this protective response as it is the only muscle of the neck that can adjust the position of the head and neck in three-dimensional space to optimize alignment of the response to the line of application of the external force. Therefore, applying principles of motor learning to train athletes to improve RFD of the SCM would, theoretically, be an important outcome of neck strength training programs for contact sports.

The aim of this feasibility study was to evaluate the short-term effects of a motor learning program on the RFD along the line of force of the SCM.

METHODS

This study received clearance from our institution's Faculty of Health Sciences and Affiliated Hospitals Research Ethics Board. Participants were eight physically active males recruited from the university community. The mean (SD) values of relevant characteristics of the study group were: age, 22.5 (1.8) years; height, 1.8 (7.3) m; weight, 80.1 (9.2) kg; neck length, 8.7 (0.8) cm; neck-to-head circumference (NH) ratio, 0.7 (0); and right-hand dominant (n = 7).

Static neck strength was measured using the Multi-Cervical Unit (MCU, BTE Technologies; Hanover, MD, USA). The MCU was retrofitted with a custom head frame assembly system designed and fabricated at Queen's University (Pelland and Gilchrist) for measurement of maximum voluntary efforts (MVEs) along eight directions covering 360° at increments of 45° in the transverse plane of the head, and positioning of the head along the sagittal plane in up to 20° of extension and 20° of flexion (see Figure 1).

Figure 1: Standard positioning for assessment and training in the custom-adapted MCU. The head-neck is held in neutral position along the sagittal plane for all testing and for training.

Maximal voluntary efforts (MVEs) were produced under static conditions and with ballistic intent; on a 'go' signal, participants were asked to push against the force transducer 'as fast and as hard as possible' and to hold their maximum force until the end of the three-second trial. Near-instantaneous visual feedback of force output was provided on a computer screen placed directly in front of participants.

The line of application of force of the SCM was considered to be along the 45° plane of right (R45) and left (L45) forward flexion. The structure of the motor learning program was as follows: baseline measure of MVE, three trials along R45 and L45; 2 sets of 5 MVE contractions, blocked randomized along R45 and L45, the order being randomly selected between participants; 10-minute rest period; post-training measure of MVE, three trials along

R45 and L45, obtained at 10 and 20 minutes and 2 days post-training.

Three variables were calculated from the force-time curve: RFD at 0-50ms and 50-100ms (Nm·s^{-1}), the area under the force-time curve at 0-50ms (*AUMC*, Nms), where AUMC is proportional to the short-latency impulse of force [4], and peak force (N). Percent change from baseline was calculated for each variable, and effects of training evaluated by repeated measures 'split-plot' ANOVA, with hand-dominance as the between-subject factor and force variables measured at baseline, post-test 1 (PT1, 10 mins), post-test 2 (PT2, 20 mins), and post-test 3 (PT3, 2 days). All statistical analyses were performed using SPSS (v.21, IBM Corp., Chicago, IL).

RESULTS

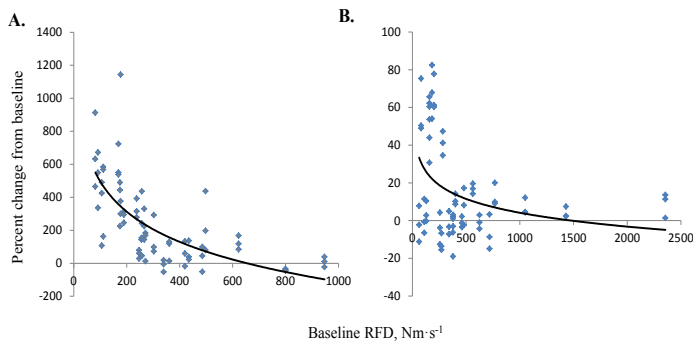
There was no effect of hand dominance on calculated outcomes ($P > 0.05$). Overall, performance improved on all measured outcomes ($P < 0.001$) from baseline to PT1. There were no significant differences between measures evaluated post-training (PT1, PT2, PT3; $P > 0.05$). While training effects were significant, calculated coefficients of variation (CV) of outcomes were high, ranging between 13% and 100%. The fit of the data was improved by plotting baseline MVE values against the percent change at PT1 for each of the calculated variables. For RFD at 0-50 ms, the


Figure 2: Percent change in RFD (0-50ms) from baseline to PT1 (y-axis) is plotted as a function of baseline RFD (x-axis) for the non-dominant (A) and dominant (B) sides. The best fit curve was logarithmic, with r^2 of 0.49 for non-dominant and 0.13 for dominant side.

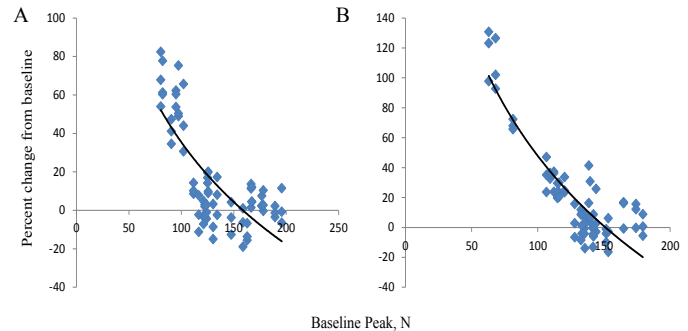
A logarithmic curve also predicted training effects on AUMC, with r^2 of 0.21 for non-dominant and 0.51 for dominant side. The resultant effects of facilitated short-latency R45 and L45 force are shown in Figure 3.


Figure 3: Percent change in peak (N) from baseline to PT1-3 (y-axis) is plotted as a function of baseline peak force (x-axis) for the non-dominant (A) and dominant (B) sides. The best fit curve was logarithmic, with r^2 of 0.59 for non-dominant and 0.81 for the dominant side.

Increases in RFD at 0-50ms were significantly correlated to percent increase in peak force ($p < 0.05$, r = 0.42). The training effect was stronger at lower baseline peak neck force.

CONCLUSIONS

This feasibility study yielded good evidence to support the integration motor learning into neck strength training programs for concussion.

DEVELOPMENT OF A NOVEL PROTOCOL TO TEMPORARILY REDUCE CORE STABILITY

Margaret E. Raabe, Scott M. Monfort, Tom M. Best, Jimmy A. Oñate, and Ajit M.W. Chaudhari

The Ohio State University, Columbus, OH, USA
email: raabe.23@osu.edu, web: http://u.osu.edu/osusportsbiomechanics

INTRODUCTION

In recent years, core stability has become an extremely popular topic among clinicians, researchers, and physically active people in general. It is believed that the core musculature (muscles of the abdomen and lower back) contracts to stabilize the spine and provide a solid foundation of movement for the lower extremities [1]. Consequently, this has led to the popular notion that insufficient core stability may lead to inefficient movements that may ultimately lead to injury [2].

The scientific data supporting the relationship between core stability and lower extremity injury is limited and primarily cross-sectional or retrospective [2]. Causal conclusions cannot be drawn from these studies or from the prospective studies that also exist. Therefore a new paradigm is needed to determine causal relationships between core stability and lower extremity movement.

The purpose of this study was to develop a core stability knockdown protocol (CSKP) that reduces one's ability to control movement of the torso. By allowing core stability to be reduced in an isolated, controlled manner this paradigm will permit within-subject analyses during a single testing session. Such a protocol could then be used to determine the influence of core stability on various biomechanical variables.

METHODS

Five subjects (1 female, age = 24.8±2.9 years, height = 1.78±0.08 m, mass = 77.6±18.7 kg) provided IRB-approved informed consent prior to participating in this study. Each subject had their core stability measured before and after the CSKP using a novel unstable quiet sitting test developed by our research team, shown in Figure 1. We

designed this test in order to objectively and quantitatively measure core stability in a way that could also be replicated in the clinical setting. In this test, a participant sat on top of the rounded end of a BOSU ball positioned on a platform high enough so that their feet did not touch the ground. This platform was placed on top of two Bertec 4060-10 force plates embedded in the ground. Participants were instructed to sit as still as possible for 60 seconds with their eyes closed while performing a secondary task of counting backwards in increments of 4. Recent postural control research has utilized a similar secondary task during quiet standing because it may be a more functional measure of stability since typically attention is divided between multiple tasks and not solely focused on postural control [3].

Figure 1. Unstable quiet sitting test used to quantitatively measure core stability.

During the trial, center of pressure (COP) data were recorded and used as measures of core stability. Measured variables included: COP path length, average anterior-posterior (A-P) COP velocity, and average medial-lateral (M-L) COP velocity. For

each condition (baseline/pre-CSKP, post-CSKP) three trials were collected and the median was used for analysis.

After a participant's baseline core stability was measured, they completed the CSKP. The CSKP consists of 4 dynamic and 4 isometric exercises chosen by our research staff to target both the superficial and deep core musculature with minimal involvement from the lower extremity muscles. All subjects completed each exercise to voluntary exhaustion or until proper form could not be maintained in the following order: 1) right side bend on a BOSU ball, 2) left side bend on a BOSU ball, 3) back extension reps on a BOSU ball, 4) sit-ups on a Swiss ball, 5) right side plank, 6) left side plank, 7) back extension hold, and 8) traditional plank. All exercises were completed consecutively with minimal to no rest between each. Following the CSKP, participants were given a 3 minute rest to allow their breathing rate to return to normal. A participant's post-CSKP core stability was measured immediately after this rest as previously described.

Two sided paired t-tests were used with a significance level $\alpha = 0.05$ to test the hypothesis that after the CSKP participants had significantly different COP measures following the CSKP, signifying a change in core stability.

RESULTS AND DISCUSSION

The average change in COP measures from pre- to post-CSKP is shown in Table 1. We found that both COP path length and mean M-L COP velocity were significantly different and mean A-P velocity trended toward significance when tested 3 minutes after the conclusion of the CSKP. Looking at the mean difference in COP measures from pre- to post-CSKP we found all COP measures increased for all subjects, confirming a reduction in core stability. Since the core stability measurements took an additional 3 minutes, this protocol significantly increased these measures for at least 6 minutes following the conclusion of the CSKP. This demonstrates that the CSKP negatively affected postural control of participants indicating that the knockdown protocol was successful in temporarily reducing a person's core stability.

This approach minimizes confounding variables and eliminates retention and compliance issues that frequently arise in long-term intervention studies. The protocol should allow for causal conclusions to be drawn when studying core stability and has the potential to be used in a variety of settings to further establish the relationship between core stability and lower extremity function. Knowledge gained from studies utilizing this approach will be able to determine the degree to which core stability changes are associated with various biomechanical changes. This knowledge may assist in the development of improved injury prevention and rehabilitation protocols.

BIOMECHANCICAL CONSEQUENCES OF RUNNING WITH DEEP CORE MUSCLE WEAKNESS

Margaret E. Raabe, Thomas M. Best, Jimmy A. Oñate and Ajit M.W. Chaudhari

The Ohio State University, Columbus, OH, USA
email: raabe.23@osu.edu, web: https://u.osu.edu/osusportsbiomechanics

INTRODUCTION

In recent years core stability has become a popular topic among sports medicine clinicians, physically active people in general, and especially runners. Its popularity is stimulated largely due to the theory that insufficient core stability during physical activity may lead to movements that are less efficient and ultimately lead to injury [1].

The deep core muscles (quadratus lumborum (QL), psoas major (PS), multifidus (MF), and the deep fascicles of the erector spinae (deep ES) are believed to be vital to postural control and stabilization of the lumbar spine [2]. One mechanism by which core musculature contributes to stability of the lumbopelvic-hip complex is through axial compressive spinal loads [3]. Inadequate compressive spinal loads may not stabilize the spine sufficiently, but excessive loads have been associated with low back pain (LBP), so a balance between these extremes is necessary to minimize injury.

The role of the deep core muscles during everyday tasks and especially during running is not well understood. The purpose of this study was to use simulations to identify compensation strategies for weakness of the deep core musculature and changes in spinal compressive loads during running.

METHODS

Three subjects (2 female, height = 1.71 ± 0.03 m, mass = 63.16 ± 4.73 kg) from a healthy population provided informed consent participated in a previously published IRB-approved study [4]. We collected marker trajectory and ground reaction force data during continuous overground running at a self-selected comfortable speed in our motion analysis laboratory. Multiple subject-specific kinematically-driven simulations were generated for each subject using OpenSim. A full-body generic musculoskeletal model we developed from three previously built OpenSim models was scaled to match each subject's anthropometry. This model is comprised of 21 segments, 30 degrees-of-freedom, and 324 musculotendon actuators. The trunk contains the 8 major muscle groups of the lumbar spine (rectus abdominis (RA) external and internal obliques (EO and IO), latissimus dorsi (LD), erector spinae (ES) which is comprised of the superficial (sf) and deep longissimus thoracis (LT) and iliocostalis lumborum (IL), QL, MF, and PS), each of which is modeled as multiple fascicles. The spine consists of the sacrum, five lumbar vertebrae, and lumped thoracic and cervical vertebrae. After solving for the model's joint angles and moments that best matched the experimental marker data, static optimization (SO) was performed to resolve the net joint moments into individual muscle forces at each time instant. Lastly, a joint reaction analysis was performed to calculate internal joint loads acting on each of the lumbar vertebrae.

A baseline simulation of running was created for each subject. Additional simulations were then created for each subject at progressively higher levels of deep core muscle weakness. The QL, MF, PS, and deep ES were weakened individually and simultaneously from 20-100% weakness in increments of 20%. Trunk muscle force production and axial compressive loads on the lumbar vertebrae were recorded at each level of muscle weakness. When individual muscles were weakened, compensating muscle forces were recorded at the point of the weakened muscle's baseline peak force production. When the four deep core muscles were weakened simultaneously, peak muscle force was reported for compensating muscles.

RESULTS AND DISCUSSION
Compensations for individual and total deep core muscle weakness are shown in Table 1. Based on

the level of required compensations, these results suggest the deep ES may be most crucial to maintain running kinematics, followed by the Psoas, MF, and QL, respectively. Of the weakened deep core muscles, the deep ES produced the highest muscle forces during running and therefore, the largest compensations were necessary, while the contrary was true with the QL. When all deep core muscles were weak, muscles that compensated were those that also attached to the lumbar vertebrae.

For individual muscle weakness, axial spinal loading was most affected when the deep ES was weakened. Axial compressive loads on all lumbar vertebrae decreased when the QL and PS were each individually weakened. In all other cases loading on the higher lumbar vertebrae increased and loading on the lower lumbar vertebrae decreased with muscle weakness. Increased axial spinal loads could be detrimental since elevated loads are believed to be associated with LBP, while decreased loads similarly may also signify a loss of spinal stability. Changes observed in these loads with our simulations suggest that all deep core muscles contribute to maintaining stability of the spine, and the MF and deep ES fascicles may be most influential in minimizing elevation of normal (baseline) axial compressive loads.

One limitation of this study is that running kinematics were forced to stay the same after the muscle weakness was implemented. It is likely some people may choose to alter kinematics rather than muscle forces in order to compensate for muscle weakness. Also, the deep core muscles could successfully be weakened 100% individually and together in the model. This may have occurred because the model has an abundant number of trunk muscle fascicles that are able to compensate and SO is a robust, frame-by-frame solver. It is unknown if this phenomenon is entirely realistic clinically, however these simulations will still provide valuable insight into compensations and consequences of core muscle weakness.

INTRODUCTION

Peak power and average power are essential components in assessing the performance of an athlete. In terms of evaluating sports performance, power is used to evaluate the effectiveness of strength training programs over time, evaluating an athlete's aptitude towards a specific sport. A number of prediction equations [1-3] have been developed to estimate peak and average jump power from jump height. Studies have shown that each population may require a specific regression equation to ensure accuracy of prediction [4]. Hence the purpose of this study was to develop new regression equations for female athletes and to develop a regression equation for long jump power that can be used to assess athletic performance.

METHODS

Twenty female university soccer players (age, 19.3 ± 1.12 years; mean weight 61.30 ± 7.80 kg; and height 1.66 ± 0.07 m) agreed to participate in this study, which was approved by the institution's human subject review board. Anthropometric measurements included body mass (BM), height, inter-anterior superior iliac spine (ASIS) distance, leg length, knee width, and ankle width. All limb measurements were taken from both limbs.

For the motion capture, an 8 camera VICON MX-T40S retro-reflective motion analysis system was used. This system was synchronized with two AMTI Optima force plates. The cameras acquired data at 100 Hz and the force platform at 2000 Hz. Sixteen skin-surface retro-reflective markers were placed with tape on the trunk and legs according to the protocol of the lower body Plug-in-Gait model (PiG) [5]. The kinematic and force plate data obtained were filtered using the Butterworth routine and processed using the VICON Nexus software

that incorporated the PiG model to calculate pelvis center of mass (CoMP) location during each trial.
Figure 1: Force components during vertical jump
Figure 2: Force components during long jump

The jump techniques were demonstrated to each subject followed by one practice jump. All jumps were performed barefoot and no restrictions for hand position were enforced. Each subject performed 5 maximum effort trials where they stood on force platforms in such a way that each leg was placed on a separate plate. The vertical jump height (VJ_{height}) was the difference between the standing pelvis CoMP height and the maximum height attained by the pelvis CoMP during the vertical jump. The long jump distance ($LJ_{distance}$) was the minimum distance between the heel motion-capture markers during take-off and landing positions for both feet.

Power output of the subject was calculated as a product of force and velocity [6]. Force exerted by the subjects resulted in vertical ground reaction forces (VGRF) at the feet which are assumed to act at the CoMP. The VGRF is the vertical component of force platform output and CoMP vertical velocity (CoMPVV) is obtained from the result of the PiG model. The resulting equation is:

Vertical Jump Power (W)
$$= \text{VGRF (N)} * \text{CoMPVV (m.} s^{-1}) \quad\quad (1)$$
Figure 3: Power versus force and power versus velocity during vertical jump.

Instantaneous power was calculated throughout the jumping movement using Eqn.1 from the loading position to the landing position for all 5 trials. Peak VJ_{pk} was the highest instantaneous power output value achieved; average VJP was calculated by computing the area under the positive instantaneous power output curve achieved during the vertical jump.
Figure 4: Power versus force and power versus velocity during long jump.

Instantaneous power was calculated throughout the jumping movement using Eq.1 from the loading position to the landing position for all 5 trials. Peak VJ_{pk} was the highest instantaneous power output value achieved; average VJP was calculated by computing the area under the positive instantaneous power and was calculated throughout the jumping movement using Eq. 2 from the loading position to the landing position for all 5 trials. Similarly long

jump peak power (LJ_{pk}) and average power (LJ_{avg}) were calculated.

Vertical Jump Power (W)
$$= \text{VGRF (N)} * \text{CoMPVV (m.} s^{-1}) \quad + \text{AGRF (N)}$$
$$* \text{CoMP(m.} s^{-1}) \quad\quad (2)$$

RESULTS AND DISCUSSION

The purpose of this study was to develop more accurate regression equations to estimate power during long jump and vertical jump for a sport, gender and age specific group as shown below. Both regression models employed vertical jump height, jump distance and body mass (BM) as independent variables.

$$VJ_{pk} \text{ (W)} = -2259 + 36.49 * \text{BM (kg)} + 6983 * VJ_{height}\text{(m)}$$
$$\text{Adjusted } R^2 = 0.83$$
$$\text{RMSE} = 197.5 \text{ W}$$
$$VJ_{avg} \text{ (W)} = -1831 - 1.753 * \text{BM (kg)} + 7510 * VJ_{height}\text{(m)}$$
$$\text{Adjusted } R^2 = 0.75$$
$$\text{RMSE} = 160.6 \text{ W}$$
$$LJ_{pk} \text{ (W)} = -2722 + 47.03 * \text{BM (kg)} + 1423 * LJ_{distance}\text{(m)}$$
$$\text{Adjusted } R^2 = 0.78$$
$$\text{RMSE} = 247.5 \text{ W}$$
$$LJ_{avg} \text{ (W)} = -1382 + 24.44 * \text{BM (kg)} + 837.1 * LJ_{distance}\text{(m)}$$
$$\text{Adjusted } R^2 = 0.64$$
$$\text{RMSE} = 186.7 \text{ W}$$

Over the course of an athlete's career, they will most likely gain or lose weight which affects their jumping ability. By calculating the power from the jumps, the practitioner can better evaluate the athlete's power production capability, allowing them to more effectively evaluate their strength training program. Also, the long jump and vertical jump can be more accurately compared as both units are in Watts and more closely related in nature.

INTRODUCTION

Various applications for rehabilitation and assistive technologies require quantitative assessment of the specific performed task, such as the measurement of joint motion. Within the clinical or research setting several methods exist to provide such precise estimates. For instance, the Vicon® motion capture system uses IR cameras and markers placed on the subject to estimate joint motion. Organic Motion Biostage is a markerless system capable of delivering positions and orientations for 21 segments which can be further processed into joint angles. These systems are accurate, but are expensive and typically only used in a laboratory setting. More recently wearable sensors such as inertial sensors (accelerometers and gyroscopes) have become more common for kinematic measurements in clinics, athletic training and in home settings as they are small, portable and inexpensive. Despite their advantages, motion estimates from these systems are often inflated with various kinds of errors such as signal noise and drift. Also, sensors must be placed securely and accurately and the measured parameters are limited. More recently, the Microsoft Kinect™ (Microsoft, Redmond, WA) sensor has gained momentum as a tool for quantitative assessment in clinics [1-3] due to its ability to extract a 3-D virtual skeleton, its affordability, and portability.

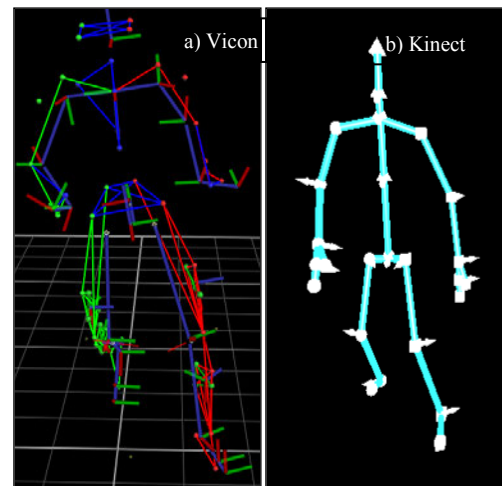
The first system presented is the affordable Microsoft Kinect™ v2, which is available either bundled with the Microsoft X-Box or as a stand-alone Windows PC device with a supplied SDK and drivers. The second system, which is at the high end of the price range, is an 8 camera motion capture system (VICON MX-T40S, Oxford Metrics, UK), which uses the Plug-in-Gait (PiG) model with functional calibration (PiG-FJC) to estimate 3-D angles. This study compares joint angles derived from the new Kinect v2 to Vicon PiG-FJC joint angles calculated during simultaneous capture. Absolute segment orientation provided by the Kinect v2 was used to calculate a relative Cardan rotation sequence for the knee.


Figure 1 – Side cut motion model output in (a) Vicon and (b) Kinect™ motion capture systems.

METHODS

After providing informed consent approved by the institution's human subjects review board, three females and four male subjects (26.6 ± 4.0 years, 1.72 ± 0.09 m, 71.8 ± 12.3 kg) participated in this study. Data was simultaneously recorded using the Vicon MX motion capture system, sampled at 100 Hz using Vicon Nexus 2.1 software and Microsoft Kinect™ v2, sampled at 30 Hz using Kinect™ Studio. The Kinect™ sensor was positioned directly in front of the subjects at a height of 43 cm above the floor. Retro-reflective markers were placed according to the full body PiG protocol along with four-marker clusters which were attached to the anterior-lateral aspect of the thigh and shank as required by PiG-FJC. Relevant anthropometric

measures were taken as required by the PiG-FJC protocol. The subjects performed 3 trials of a right-left-right side cutting maneuver. Peak knee flexion was used to synchronize data obtained from the two systems.

KINECT PREDICTIVE MODEL

The Kinect sensor and its SDK provide a 3-D virtual skeleton. The virtual skeleton consists of the position and orientation of 25 joints. For each joint, the position is reported using X, Y, Z coordinates and the orientation are reported in terms of a quaternions (w, x, y, z). Each quaternion is the absolute orientation of the parent with respect to the global coordinate system.
Figure 2 – Kinect^{TM} model displaying absolute quaternions

To obtain the relative 3-D knee angles our method uses the relative quaternion achieved by multiplying the absolute quaternion of the ankle joint by the inverse absolute quaternion (the quaternion conjugate) of the knee joint. The relative quaternion is then converted into Cardan angles to represent flexion/extension, varus/valgus, and internal/external rotation in order to directly compare them with the Vicon acquired knee angles.

RESULTS AND DISCUSSION

The peak flexion angles measured by the Kinect^{TM} were smaller than the Vicon system consistently for all the cases. The peak extension angles were consistently greater for the Kinect^{TM} for all cases indicating that the Kinect often interpreted full knee extension as hyperextension. Knee internal/external

rotation and knee abduction/adduction revealed poor waveform for Kinect^{TM} when compared to Vicon as indicated in Table 1. It may be possible to improve the accuracy of the joint angles by re-orienting the local coordinate systems to represent the anatomical axes of rotation especially in the non-sagittal plane. Before it can be used in the clinical setting several improvements should be made to the predictive model in terms of fixed segment length, anatomically accurate rotation axes, accuracy and smoothness of joint center location. Although some improvements are necessary the Kinect^{TM} v2 displayed promising initial results for use as an affordable tool in the clinical setting.

BILATERAL SYMMETRY DURING A POWER CLEAN IN RECREATIONAL VS. COMPETITIVE WEIGHTLIFTERS

[2] National Institute for Occupational Safety and Health, Morgantown, WV, USA

email: riderp@ecu.edu, web: http://www.ecu.edu/cs-hhp/exss/biomechanics-members.cfm

INTRODUCTION

High intensity weightlifting has grown in popularity with recreational exercisers. This style of training often includes performing power cleans. Power cleans are bilateral weightlifting exercises that involve explosive generation of lower extremity joint torques to vertically accelerate a heavy load as rapidly as possible. The goal of this lift is to increase an individual's ability to generate lower extremity power [1].

There are concerns towards increased risk of musculoskeletal injury by taking part in this type of exercise [2]. Complex, bilateral movements, such as the power clean, typically exhibit symmetry between left and right limbs in elite weightlifters [1,3], however, joint injuries that occur during these movements are typically unilateral. The relationship between lower limb bilateral asymmetries and level of experience during the power clean has not been fully explored.

The purpose of this study was to compare bilateral lower extremity kinetics during the pulling phase of a power clean between recreational and competitive weightlifters. We hypothesized that competitive weightlifters would show more symmetry than the recreational lifters in all lower extremity joint torques and peak ground reaction force (GRFs) values.

METHODS

Four males and three females between the ages of 18-35 years old participated in this study. Each participant was placed in one of two groups, competitive or recreational weightlifters. Groups were determined using the following criteria: Participants that had received at least 6 months of power clean training from a qualified coach were placed in the competitive group (n = 4). Individuals who had regularly performed power cleans within the past 3 months but had not received consistent coaching (n = 3) were placed in the recreational group.

After completing several warm-up trials, each participant completed four single power clean trials at 70% self-reported 1-RM. This percentage was chosen to simulate a typical training load. Full-body, three dimensional biomechanical data were collected using two AMTI force plates (force data captured at 960Hz) and a motion capture system (markers captured at 240Hz). Markers were also placed at each end of the weight bar to track bar movement. Each trial included a 60 second rest period to minimize fatigue. Lower extremity joint torques and peak ground reaction forces were calculated and absolute differences between left and right sides were compared between groups. Percentage differences were calculated by dividing the absolute difference left to right by the average absolute torque produced at each joint.

RESULTS AND DISCUSSION

Peak ground reaction forces showed significantly greater asymmetry in the recreational group (18% vs. 9%). Peak hip joint torque asymmetry was no different between the groups (13.0% Recreational vs. 12.9% Competitive). Peak knee joint torques showed significantly greater asymmetries in the recreational vs. competitive group (30.4% vs. 11.2%). Peak ankle joint torques also showed greater asymmetry in recreational vs. competitive (14.4% vs. 9.5%). Absolute values and associated standard deviations for left and right peak GRFs and torque values are located in Table 1.

CONCLUSIONS

The results partially supported our hypothesis that competitive weightlifters would show less asymmetry in lower extremity joint torques and ground reaction force values. Interestingly, the hip joint showed similar amounts of asymmetry between groups. Individuals may be able to more effectively produce symmetrical motion at the hip joint as each joint is connected through a rigid body (the pelvis). This may provide more proprioceptive feedback for the hip joint.

Although the left to right differences in peak ground reaction forces in competitive weightlifters were small (9%), larger percent differences were observed at the individual joints (11%) within this group. This may indicate kinematic asymmetries these joints. Lower extremity kinematic and kinetic asymmetries might also impact upper extremity symmetry and weight bar movement and play a role in the higher rates of injury in the shoulder and wrist joint in recreational high-intensity weightlifters. Further investigation should examine if any relationships exist between lower extremity kinematic and kinetic asymmetry and upper extremity and bar path kinematics and kinetics.

The most asymmetrical lower extremity joint was the knee in recreational lifters. This might help explain the relatively high injury rates at the knee joint in participants in high intensity training programs. These data might be especially useful for exercise practitioners who prescribe power cleans as a method of training to recreational individuals. Coaching has shown to be effective at improving power clean performance [4] and these individuals may consider reducing the power clean load until lifting technique has been mastered to improve symmetry between left and right limbs.

THE EFFECTS OF A FOOT STRENGTHENING PROGRAM ON INTRINSIC FOOT MUSCLE SIZE AND STRENGTH – A PILOT STUDY

[1] Sarah Trager Ridge, [2] Irene S. Davis, [1]Tiffany D. deVries, [1]J. William Myer, [1]A. Wayne Johnson

INTRODUCTION

Recent studies have shown that the transition to running in minimalist or partial minimalist shoes can result in greater incidence of injury than running in traditional running shoes[1,2]. Based on those results, it has been suggested that transitioning to minimalist shoes should be preceded by a preparatory strengthening program.

Intrinsic foot muscles help control motion of the foot, support the medial longitudinal arch, and assist with shock absorption. It has been hypothesized that the structure of traditional or supportive shoes results in weakened intrinsic foot muscles, which may be related to the increased injury rate in runners transitioning from traditional to minimalist running shoes.[3] Stronger intrinsic muscles will be able to better support the metatarsals as well as the plantar fascia, thereby reducing the risk of injury to these structures.

Two studies have shown that performing activities in minimalist shoes increases intrinsic foot muscle size, but the studies did not directly measure increases in strength[4,5]. Therefore, the purpose of this study was to determine whether a foot strengthening intervention alters intrinsic muscle size and strength. It was hypothesized that both size and strength of these muscles would be significantly increased following this program.

METHODS

Ten recreational runners (5 male, 5 female; average age 22 ± 2 years, average mileage 15-30 miles/week) with no experience running barefoot or in minimalist shoes have participated in this ongoing study to date. Runners participated in a pre-training testing session, then performed 8 weeks of strength training, This program included a progression of single and double leg calf raises, foot doming, doming and hopping and toe flexion exercises. Intrinsic muscle size and strength were measured post-training. Pre- and post-training testing included ultrasound assessment of intrinsic foot muscle size, and strength.

Ultrasound images were recorded from the abductor hallucis (ABDH), flexor hallucis brevis (FHB), flexor digitorum brevis (FDB) and quadratus plantae (QP). Images were recorded using a 10 MHz GE LogiqP5 linear probe. For the FHB the probe was aligned with the shaft of the first metatarsal, using the metatarsal head as a consistent bony landmark. The FDB and QP were recorded after finding the navicular tuberosity, then moving the ultrasound probe to the plantar surface of the foot. The probe was oriented transversely across the sole of the foot. The ABDH was recorded with the probe in the same orientation, using the navicular as a reference landmark. Measurements taken from the images included the thickness of the FHB and cross-sectional areas (CSA) of the ABDH, FDB, and QP.

Muscle strength measurements were recorded using a hand-held ergoFet dynamometer, which was secured to a custom built wooden support system (Figure 1). Strength was assessed during doming (arch flexion) and toe flexor activities. During the doming testing, subjects stood with one foot in a Brannock device and the lower leg strapped to a support beam (Figure 1A). The dynamometer was placed on the dorsum of the foot, above the navicular tuberosity (Figure 1B). The subject performed the doming movement using a maximal voluntary isometric contraction for approximately 3 seconds. Toe flexor strength was assessed from the big toes individually (1Toe Flexor), and the 2nd, 3rd, and 4th toes together (234Toe Flexor). The subject's foot was placed on a raised, flat surface with the heel against a support and the toe(s) gripping either an S-beaner or bar and flexed their toes (Figure 1b). The S-beaner or bar was secured to the dynamometer by

an adjustable turn buckle. Trained researchers observed the motions throughout the testing in an effort to ensure subjects were limiting the recruitment of extrinsic muscles. Strength data were monitored and recorded in real-time.

Figure 1. Foot strength testing devices. A. The doming test with dynamometer on the dorsum of the foot. B. Testing of the 2nd, 3rd, and 4th toe flexion test. The S-beaner used for the 1st toe flexion test can be seen at the bottom right of image B.

Runners were given a set of 5-7 exercises to do at least 5 days/week for 8 weeks. The exercises got progressively more difficult through the 8 weeks. Participants were asked to maintain their typical running in their traditional running shoes. Following the 8 weeks, the same set of tests were performed again.

Pre- and post-training data for each side were compared using paired t-tests ($\alpha=0.05$), with feet separated into dominant and non-dominant sides.

RESULTS AND DISCUSSION

All muscle sizes on both feet increased significantly from pre- to post-training. Doming and 234Toe flexor strength of both feet also increased significantly from pre- to post-training, while 1Toe flexor strength increased significantly on the non-dominant side only.

Based on these data, this intervention appeared to produce the intended result of significantly increasing intrinsic foot muscle strength. These results are promising for runners who want to transition to minimalist footwear. This type of footwear removes cushioning and arch support, placing greater demands on foot and arch musculature. This type of strengthening may also be beneficial to runners who want to move away from motion control shoes or foot orthoses. Stronger intrinsic muscles may reduce the risk of injuries associated with arch flattening such as plantar fasciitis and stress fractures...

RE-EXAMINATION OF THE RELATIONSHIP BETWEEN BI-ARTICULAR MUSCLE COACTIVATION AND RUNNING ECONOMY

Barbara J. Schornstein, Kevin D. Dames, and Gary D. Heise

University of Northern Colorado, School of Sport & Exercise Science, Greeley, CO, USA
email: barbara.schornstein@unco.edu, web: http://www.unco.edu/biomechanics/

INTRODUCTION

Running economy (RE) is strongly associated with distance running performance, but researchers from various disciplines have had limited success explaining the inter-individual variability in RE [1]. Biomechanists have identified certain kinematic and kinetic descriptors of the running cycle which are related to RE, but the findings between RE and muscle activity are mixed.

EMG analysis offers great potential in addressing this interindividual variability. Research from our lab showed, in two separate samples, that more economical runners coactivated rectus femoris and gastrocnemius during stance for a longer duration when compared to less economical runners [2,3]. We suggested that greater coactivation during stance may increase joint stiffness, which would allow for efficient use of stored elastic energy.

Recently, Moore et al. [4] examined muscle coactivations during stance at multiple running speeds and, in direct contrast to our previous findings, reported positive relationships between energy cost and muscle coactivations. These results further cloud the issue of muscle activity and its relationship to running economy. Methodological differences play a role in explaining why different results have been reported.

It is with these issues in mind that the present study was designed. We re-examined the relationships between running economy and muscle coactivations during stance at multiple speeds. In order to address methodological concerns, we used the same EMG activity threshold identification procedure as Moore et al. [4] and runners ran on a force-measuring treadmill to better identify stance phase.

METHODS

Nineteen healthy, active adults (6 women, 13 men) free from any existing neuromuscular or skeletal injury volunteered for the study (Mean ± SD: Age = 34 ± 10 yrs.; Body Mass = 67.4 ± 9.1 kg). A performance inclusion criterion was a 5 km time less than 23 min.

After appropriate skin preparation, electrodes were placed over the lateral head of gastrocnemius (LG), rectus femoris (RF), and the long head of biceps femoris (BF). Participants then completed 5-min running trials at 3.3, 3.5, and 3.7 m/s in a randomized order. Expired gasses were collected during the final 1 min of each trial and analyzed using indirect calorimetry (Parvo Medics). Cost of running (C_r) was then calculated by normalizing $\dot{V}O_2$ to running speed and expressed in mL/kg/km. EMG data (2000 Hz, Delsys Trigno) and ground reaction forces (2000 Hz, AMTI) were simultaneously collected. The vertical component of the ground reaction force was used to determine when stance occurred.

EMG data were full-wave rectified and low-pass filtered (F_c = 15 Hz). Thresholds for identifying onset/offset times were set at 20% of max for BF, and 7% of max for RF and LG [4]. Coactivation of muscle pairs (RF & LG, BF & LG, and RF & BF) as a percent of stance were calculated using a custom Matlab script. Correlation coefficients were used to relate C_r and EMG measures (α = .05).

RESULTS AND DISCUSSION

The ranges of C_r, expressed as a percent of their mean, for all speeds were 33%, 37% and 37% (3.3, 3.5, and 3.7 m/s, respectively). This is slightly higher than previously reported ranges (20-30%)

from the literature [1]. Values for C_r at each speed are shown in Table 1.

Coactivation ratios of each muscle pair at each speed are shown in Table 1. The largest r-value between a coactivation value and C_r with men and women grouped together was -.37 (RFLG), but this did not reach significance. RFLG had a higher coactivation during stance than the other two muscle pairs. The scatterplot of RFLG against C_r for each speed is shown in Figure 1 (linear trend lines are included). Other scatterplots were similar.
Figure 1. Scatterplot of C_r versus rectus femoris-lateral gastrocnemius coactivation at all speeds.

When men and women are separated (Figure 2), these groups appear to follow trends in opposite directions. However, one male runner exhibited very low coactivation of RFLG, which pulls the trend into the opposite direction of the women. If that participant were removed, the relationship between C_r and RFLG coactivation for men is greatly reduced. These different trends appear across all speeds and muscle pairs in varying strengths. With only six women, we can only call this a trend. It agrees with previous research by Heise, et al. [3], who showed that more economical

women demonstrate a higher coactivation of bi-articular muscles during stance.
Figure 2. Scatterplot of C_r versus rectus femoris-lateral gastrocnemius coactivation. Data points and linear trend lines are shown for men and women.

CONCLUSIONS

While a strong correlation between C_r and coactivation of bi-articular muscles was not shown in the current study for all participants, several interesting trends emerged suggesting that men and women coactivate lower extremity muscles differently. A trend for women was shown, while not strong enough for significance, that more economical women have higher coactivation ratios across all speeds and muscles tested. Further investigation into the differences of men and women is needed in the area of coactivation of bi-articular muscles and C_r.

INTRODUCTION

Pursuing faster sprint velocity is one of most interesting topics, but it is also a great challenge for athletes, coaches, and researchers. Previous studies [1, 2, and 3] indicated that fast sprinters showed rapid leg retraction during the terminal swing phase; closer landing distance, greater landing angle, shorter contact distance, greater taking off angle during foot contact phase. However, how these landing and taking off kinematic variables related to maximum running velocity is still not clear at present. Therefore, the purpose of the current cross sectional study was to determine the relationship of those landing and taking-off kinematic variables with maximum running velocity performance.

METHODS

Twelve male (mass: 75.28 ± 6.39 kg, height: 1.79 ± 0.04 m, age: 19 to 21 years old) NCAA Division I sprinters participated in the study.

Two sprints from standing position were performed by each participant. Electronic timing gate system (Brower system, UT, US) were placed at 10 m intervals from the start line for 60 m. The Maximum 10 m interval running velocity (V_60) were used for further analysis.

Kinematic data (between 50 m and 57 m) were collected using Vicon Nexus system (Vicon, UK) with six cameras at a sampling rate of 240 frames/s. Reflective markers were placed based on Vicon Full Plug-in-gait marker set. An analyzable trial was a trial in which all kinematics data for two running step were recorded successfully by the system.

Phase of landing, and taking-off kinematic variables determination were according to [4, 5, and 6]. Touch down distance (TD_D), touch down angle (TD_A), contact distance (Con_D), take-off distance (Off_D), take-of angle (Off_A), leg retraction acceleration (Re_A), maximum center of mass velocity (V_{max}), minimum center of mass velocity (V_{min}), and velocity loss during the foot contact phase (V_{loss}) were used for further analysis.

Pearson correlation were used to test relationship of kinematic variables between two steps, no statistical significance was found between them indicating that both limbs were not asymmetrical. Thus, average values of kinematics variables from two steps were used to further analysis. Correlation of kinematics and sprint variables, were performed using Pearson Correlation Coefficient test (SPSS 21). Statistical significance was set at $p \leq 0.05$.

RESULTS AND DISCUSSION

Descriptive statistics were shown in table 1. Correlation of landing and taking-off kinematic variables with maximum running velocity performance were listed in the table 2. Only a few landing and taking-off kinematic variables were correlated with each other. Except center of mass velocity (V_{max} and V_{min}) and leg retraction prior to the foot contact with ground (Re_A), none of the kinematic variables showed correlation with maximum running velocity performance.

Results of the current study consistent with previous studies [1, 2, 3, 7] that horizontal center of mass velocity (V_{max} and V_{min}) highly correlated with maximum running velocity; Moreover, It also supported that landing kinematic variables is

function of the foot speed relative to the ground at landing and the distance between the foot and the CoM (TD_D and TD_A; TD_A and Con_D; Re_A and Off_A). However, among those kinematic variables only Re_A correlated with V_{max} and maximum running velocity performance. Therefore, those landing and taking-off kinematic variables may not impact maximum running velocity performance as most people believed, however, the current study recruited homogenous group of sprinters, further study need to recruit heterogamous group sprinters to confirm the results from the current study.

EFFECTS OF WEARING TOE CAGE ON KNEE BIOMECHANICS DURING STATIONARY CYCLING

Guangping Shen, Hunter J. Bennett, Songning Zhang

Biomechanics/Sports Medicine Lab, The University of Tennessee, Knoxville, TN, USA

email: gshen1@vols.utk.edu, web: web.utk.edu/~sals/resources/biomechanics_laboratory.html

INTRODUCTION

Studies have shown that the internal knee abduction moment (KAM) in walking is closely associated with the development of medial knee osteoarthritis (OA) [1]. Many non-surgical recommendations for the management of knee OA have been proposed to slow down the progression of the disease. Cycling is frequently prescribed by health professionals to improve physical fitness, muscle strength, and function in rehabilitation programs. During the cycling workout, cyclists are putting most of body weight on the saddle, which allows weight-bearing joints such as knees and hips to experience relatively lower compressive force than in walking and jogging [2].

In cycling, a toe cage is used to stabilize the foot on the pedal to keep the foot in a parallel orientation, while a pedal without toe cage provide a self-selected and float foot alignment. However, it was suggested allowing some freedom of movement between foot and pedal is beneficial to the knee injury prevention during cycling. Furthermore, two patterns of the knee frontal plane movements were observed during cycling where some people tended to cycle with knee adduction while others cycled with knee abduction [3]. It is currently unknown whether wearing toe cages during cycling would adversely affect knee frontal plane biomechanics. Therefore, the purpose of this pilot study was to investigate effects of two foot alignment methods, with and without toe-cage, on knee biomechanics during stationary cycling.

METHODS

Four healthy male subjects (age: 27.3±3.6 years, mass: 77.9±10.2 kg, height: 1.8±0.1 m) were included in this study. Participants did not have any history of major lower extremity injury and surgery. A nine-camera motion analysis system (240 Hz, Vicon Motion Analysis Inc., UK) was used to obtain the three dimensional (3D) kinematics during the test. Reflective anatomical and tracking markers were placed on both sides of feet, ankles, legs, knees, thighs, and hips during testing.

A Monark cycle ergometer (828E, Monark, Sweden) equipped with a weighted brake system was used in the study. A customized instrumented bike pedal was used on the left side of the cycling ergometer, which records three dimensional pedal reaction forces (PRF). The assembly contained two 3D force sensors (Type 9027C, Kistler, Switzerland) coupled with two industrial charge amplifiers (Type 5073A, Kistler, Switzerland).

The saddle height on the cycle ergometer was adjusted so that the angle of the knee joint was about 30° when the crank was at the bottom dead center. The horizontal saddle position was adjusted so that the knee was in line with the pedal spindle when the crank was in the forward horizontal position. The position of the handlebars was set so that the angle between the subject's trunk and thigh was 90 ° when the crank is in the forward horizontal position. The participants pedaled in six cycling conditions: pedaling at 80 rpm with workloads of 0.5 kg (40 Watts), 1.0 kg (78 Watts), and 1.5 kg (117 Watts) without (an unrestricted foot position on the pedal) and with toe cage (a restricted foot position). Participants performed a 2-minute cycling in each condition, where five consecutive pedaling cycles were recorded at last 30 seconds. A 2-minute rest was provided between the conditions.

All data were processed and analyzed using Visual3D (5.0, C-Motion, Inc.). Hip joint centers were determined using the CODA pelvis (determined by ASIS and PSIS), where each anatomical marker was corrected for the diameter of the markers and its base. Both kinematic and PRF data were filtered using a low-pass 4th order Butterworth filter with zero lag at a cutoff frequency of 6 Hz. The joint moments were

computed as internal moments. The pedal cycle of a trial is defined from the top dead center (0°) to the following top dead center (360°). Due to the small sample size of this pilot study, paired t-tests were used to examine the effects of the toe cage and workloads on knee biomechanics (SPSS 22.0, SPSS Inc., Chicago, IL) with an alpha level set at 0.05 a priori.

RESULTS AND DISCUSSION

The PRF, foot angle, knee range of motion (ROM) and peak knee moment are provided in Table 1. There were no significant differences in any variables with or without toe cages when cycling at the same workloads ($p > 0.05$). In fact, toe cages did not alter the foot alignment on the pedal for the subjects from their self-selected foot alignment position. The peak vertical PRF was significantly greater in the conditions with larger workload when subjects were wearing the toe cage ($p < 0.05$). In addition, the peak knee extension moment was significantly greater in workload of 1.5 kg compared to workloads of 0.5 kg and 1.0 kg ($p < 0.05$).

Overall, our results showed wearing toe cage during cycling did not affect either knee kinematics or kinetics. This results are similar to the study by Gardner et al. (2015), where 5° and 10° of toe-in angles were applied to the healthy subjects and patients with knee OA during stationary cycling [3]. They showed that increased toe-in angles did not affect the KAM, although it did have influences on knee flexion and adduction angles. Workloads mainly affected the knee extension moment. However, increased workload did not affect peak knee abduction moment. The lack of differences may be related to the small sample size and a relatively large variability with one subject. As for the knee kinematics, they are barely affected by the workloads (Table 1).

A larger sample size is needed to strengthen the results. Further research is warranted to determine effects of foot fixation on other joints such as ankle and hip during stationary cycling.

CONCLUSIONS

Wearing toe cages during stationary cycling did not affect the knee biomechanics. Therefore, toe cages may or may not be used when cycling is prescribed as a rehabilitation program for patients with knee OA or other knee condition such as total knee replacement.

PREDICTORS OF LOADING RATE IN HEEL-STRIKE RUNNERS

Yo Shih, Hsiang-Ling Teng, Christopher M Powers

University of Southern California, Los Angeles, CA, USA
email: powers@usc.edu, web: http://pt.usc.edu/labs/mbrl/

INTRODUCTION

High loading rates are thought to contribute to lower extremity injuries in runners.[1,2] It has been reported that loading rates are higher in heel strikers than forefoot strikers during running.[3] However, not all heel strikers exhibit high loading rates.[4] To date, it is not known what kinematic or kinetic factors are predictive of high loading rates in heel strike runners.

METHODS

Twenty male (age, 27.1 ± 7.0 yr) and 20 female heel-strike runners (age, 26.2 ± 5.8 yr) were recruited for this study. Kinematic and kinetic data were collected while participants ran at a controlled speed of 3.4 m/s along a 14 meter runway with a force plate mounted flush to the floor. Average loading rate was quantified as the slope of vertical ground reaction force (GRF) curve from initial contact (IC) to the 1st peak of the GRF (20-80% time frame). Kinematic and kinetic variables of interest included lower extremity joint angles at initial contact, joint angle excursions from IC to 1st peak of the GRF (1PK), joint angle excursions from IC to peak angle, maximum joint moments, joint power from IC to the 1PK and to maximal GRF, leg stiffness and joint angular stiffness from IC to 1PK, maximal GRF and peak sagittal plane joint moments (ankle, knee, and hip). Pearson correlations were used to evaluate the relationships among the average loading rate and all kinematic and kinematic variables of interest. Step-wise multiple linear regression was performed to determine the best predictor(s) of loading rate. Only those variables that were significantly correlated with the loading rate were input to the regression model.

RESULTS and DISCUSSION

Five variables were significantly correlated with the average loading rate (Table 1), however, only 2 entered into the regression equation. Leg stiffness from IC to 1PK was the first variable that entered the stepwise regression model of loading rate (Fig 1, R^2=0.728). The second variable that entered was the knee angle excursion from IC to 1PK (Fig 2, . R^2=0.04) (Table 2). No other variables entered into the final model.
Figure 1: Correlation between loading rate and leg stiffness from IC to 1PK
Figure 2: Correlation between loading rate and knee excursion from IC to 1PK

CONCLUSIONS

Our findings suggest that increased lower extremity compliance immediately following initial contact may protect against high loading rates in heel strike runners. Further study is needed to test the feasibility of manipulating leg stiffness and knee excursion immediate following initial contact to minimize loading rates.

KNEE JOINT LOADS AND SURROUNDING MUSCLE FORCES OF SELECTED KNEE UNFRIENDLY MOVEMENT ELEMENTS IN 42-FORM TAI JI

[1]Chen Wen, [2]Jeffrey A. Reinbolt, [1]Songning Zhang

[1]Biomechanics/Sport Medicine Lab, The University of Tennessee, Knoxville, TN, USA
[2]Department of Mechanical, Aerospace, and Biomedical Engineering, The University of Tennessee, Knoxville, TN, USA

INTRODUCTION

Tai Ji, as a mind-body therapy, is a traditional Chinese martial art that includes natural postures as well as gentle and smooth movements [1]. The American College of Rheumatology recommended Tai Ji as one of the non-pharmacologic treatments for knee osteoarthritis (OA) [2], but it remains unclear if all Tai Ji movements would be suitable and beneficial for knee OA patients.

Tai Ji movements often require bending the knee to a squatting position, which may place high loads on the knee joint. In addition, repetitions of some Tai Ji deep knee flexion movements (e.g., twisting and single-leg stance) may further increase loading to harmful levels at the knee. A previous study showed a greater knee flexion range of motion (ROM) in Tai Ji gait caused a higher knee extension (rectus femoris) muscle activity compared to normal speed walking [3].

Musculoskeletal modeling and simulation provides an efficient way to estimate joint loading and corresponding muscle forces during a movement. However, no study has utilized musculoskeletal simulations to investigate knee joint loading in Tai Ji movements. Therefore, the purpose of this study was to investigate the knee joint loading of selected unfriendly Tai Ji movement elements performed in high-pose position compared to slow walking.

METHODS

A male subject (23 yrs, 1.78 m, 73.3 kg) with two months of Tai Ji experience participated in this study. He performed three trials of level walking at 0.8 m/s and each of four identified knee unfriendly Tai Ji movement elements: lunge, pushdown and kick performed in high-pose position (35 ± 5°) and pseudo-step[4].

Three dimensional (3D) kinematic data were collected using a nine-camera infrared motion capture system (120 Hz, Vicon Motion Analysis, Inc., Oxford, UK). Anatomical and tracking reflective markers were placed bilaterally on the trunk, pelvis, thighs, shanks and feet. Three force platforms (1200Hz, Advanced Mechanical Technology, Inc., USA) were used to collect ground reaction forces (GRF) with the 3D kinematic data simultaneously using Vicon Nexus software. Maximum knee flexion angle was monitored using an electrogoniometer (Biometrics Inc., Newport, UK) placed on the lateral side of the right knee joint. Visual 3D (C-Motion Inc., USA) was used to compute 3D kinematics and kinetics. Kinematic and GRF data were smoothed at cutoff frequencies of 4 and 50 Hz, respectively, using a fourth-order zero-lag Butterworth low-pass filter. All joint moments were computed as internal moments.

The processed individual trials of each movement condition were exported to OpenSim (version 3.2, SimTK, Stanford, CA, USA) to perform musculoskeletal simulations. A generic 12-segment, 19-degree of freedom, and 92 muscle-actuated OpenSim musculoskeletal model (Gait 2392 Model), originally developed by Delp, et al. [5], was scaled to the height and weight of the subject to generate subject-specific models. Muscle forces were estimated using static optimization minimizing the sum of squared muscle activations. Knee joint reaction forces (JRF) were computed using the joint reaction analysis tool with the muscle forces from static optimization as inputs. The compressive force was the vertical component of the JRF along the long axis of the tibia and the anterior-posterior shear component of the JRF was orthogonal to the axial component.

RESULTS AND DISCUSSION

Lunge, pushdown and kick demonstrated similar peak knee compressive JRF compared to slow

walking. Pseudo-step showed higher compressive JRF than other Tai Ji movement elements. In addition, Tai Ji movement elements showed greater peak knee anterior shear JRF than slow walking. Pushdown showed the greatest peak anterior shear JRF among the Tai Ji movement elements. The peak muscle forces of vastus medialis, vastus lateralis and vastus intermedius, and sum of knee extensor forces were greater for Tai Ji movement elements compared to slow walking. Kick showed the smallest peak muscle forces of vastus medialis, vastus lateralis and vastus intermedius, and sum of knee extensor forces compared with other Tai Ji movement elements. Tai Ji movement elements showed smaller peak sum of knee flexor forces than slow walking. Peak knee extension moments were higher in lunge, pushdown and pseudo-step than slow walking.

Our results are supported by the previous study of Tai Chi gait [3] which demonstrated rectus femoris had a significant higher activity level than semitendinosus. Xu et al. [6] also reported higher rectus femoris muscle activity level than semitendinosus in Brush Knees and Twist Steps, popular Tai Ji movements which include lunges.
Our results showed that the anterior shear JRF is relatively high in lunge, pushdown and pseudo-step as knee extensions are more heavily involved in maintaining flexed knee postures.

CONCLUSION

The high-pose lunge, pushdown and kick Tai Ji movement elements demonstrated similar knee compressive JRF as slow walking. Thus, these movements may be suitable for Tai Ji participants with knee OA and other knee pathological conditions to practice. However, high shear loading was found in all of the Tai Ji movement elements and there is cause for serious concerns. Future investigations are necessary to find ways of reducing the shear JRF during Tai Ji and other knee OA treatments.

INTRODUCTION

Wrestling is a man-to-man combat sport and it is described as an intermittent physical event to score points and falls. A technical-tactical analysis of profiles of freestyle wrestling indicated that leg attacks were the most used techniques of winners in international competitions [1]. Besides the importance of tackling to win the competitions, not much is still known about the mechanics of a tackle. The purpose of this experiment is to investigate the biomechanics of the tackling maneuvers of several elite and non-elite wrestlers.

METHODS

Twenty Japanese male wrestlers belonging to the light weight category (former 55-, 60-, or 66-kg) performed double leg tackles to a defender for at least 4 trials each. Eleven participants were elite level including 3 medalists of the 2012 London Olympic Games and nine were collegiate level. A defender was acted by an experienced wrestler throughout this experiment. At first, an attacker and a defender made contact in the hand fighting position while slightly touching each other's shoulders. Before tackling, the height of the defender's markers (shoulders and great trochanters) were monitored and adjusted to a predetermined height. Then, the attacker tackled the defender in the same way as a competition. For each wrestler, the trial with the highest subjective score was selected for detailed analysis.

Three-dimensional coordinates of the anatomical landmarks were acquired using a 3D optical motion capture system with 20 cameras (200 Hz; Vicon, Oxford, UK). Forty-six reflective markers were placed on each subject's body. The whole body centre of mass (COM) position was calculated as the weighted sum of the 14-segment model. The ground reaction force (GRF) at the trailing limb was recorded (1000Hz; Kistler, Winterthur, Switzerland). All GRF data were normalized by body weight. The start of the tackle and the contact were determined from the COM velocity data. COM and GRF data were rotated in order to align it with the local coordinate system using a rotation matrix. Axis alignment was determined using the COM trajectory because it in the horizontal plane during tackle was almost linear. Comparison between groups was performed using the unpaired t-test.

RESULTS AND DISCUSSION

Vertical displacement of the COM was lesser for elite wrestlers than for non-elite wrestlers (p = 0.025, 0.18 $\pm$ 0.07 m vs 0.25 $\pm$ 0.06 m in elite ad non-elite, respectively) (see Fig.1). Peak forward velocity of the COM tended to be slower for elite wrestlers than for non-elite wrestlers (p = 0.086, 2.27 $\pm$ 0.18 m/s vs 2.43 $\pm$ 0.17 m/s , respectively). Duration of tackle was shorter for elite wrestlers than for non-elite wrestlers (p = 0.0499, 401 $\pm$ 60 ms vs 458 $\pm$ 61 ms , respectively).

Peak forward GRF did not differ significantly between groups (p = 0.186, 1.00 $\pm$ 0.17 N/N vs 0.89 $\pm$ 0.19 N/N , respectively). However, time-to-peak forward GRF was faster for elite wrestlers than for non-elite wrestlers (p = 0.026, 243 $\pm$ 60 ms vs 322 $\pm$ 87 ms, respectively).

During a tackle, it seems important that an attacker move quickly and provided high momentum to a defender to score a takedown. However, Peak forward velocity of the COM for elite wrestlers tended to be slow than for non-elite wrestlers. They tackled quickly with a smaller downward movement. Therefore, it is suggested that to move forward quickly is effective for a successful tackle and to score points.

Further study is needed to focus on the interpersonal tackling mechanics because of the intragroup variability of the COM (see in Fig.1).

Figure 1: COM trajectory from the beginning of the tackle to the contact. Red and blue colors represent each trial of elite and non-elite level wrestlers, respectively.

INTRODUCTION

Tissue repair in musculoskeletal injuries is often slow, incomplete, and refractory to conventional therapies.[1,2] Regenerative therapies aimed at delivering growth factors, bioactive molecules, and accelerating healing locally has been a recent focus of scientific evaluation.[3,4] The purpose of our study was to compare the clot strength and efficiency of platelet- rich plasma (PRP) and concentrated platelet-poor plasma (cPPP) to citrated whole blood when activated by autologous thrombin, bovine thrombin or calcium chloride (CaCl2). Our study assessed the dynamic mechanical properties of fibrin and platelet bonding for surgery or injection when clot holding is desired.

METHODS

Six healthy horses were used as blood donors. PRP and cPPP were prepared by commercial devices and tested against autologous whole blood. Autologous blood, PRP and cPPP were activated by each of 3 clotting agents (autologous thrombin, bovine thrombin and CaCl2) and compared for clotting parameters using a thromboelastograph. Clotting tests were performed to establish normality of test subjects. Platelet counts of whole blood and PRP were measured.

RESULTS AND DISCUSSION

Whole blood, PRP, and cPPP clotted with all agents. Among blood products, PRP demonstrated the greatest clot strength and quickest clot rate; cPPP had the weakest clot strength, slowest clot rate, and longest clot initiation time. Among clotting agents, bovine thrombin had the shortest clot initiation time, quickest clot rate and tied CaCl$_2$ for greatest clot strength; CaCl$_2$ had the longest clot initiation time and time to reach maximum clot strength; autologous thrombin had the lowest clot strength.

CONCLUSION

When combined with either bovine thrombin (rapid clot) or CaCl2 (slow clot), PRP provided the top combination for clinical use. Autologous thrombin was suboptimal, but would be an autologous alternative to commercial fibrin for clinical application. As prepared here, cPPP had inefficient clotting, but may be sufficient for plasma spray indications.

WALKING-MEDIATED UPREGULATION OF FOLLISTATIN-LIKE 3 EXPRESSION IS INSUFFICIENT TO INCREASE MUSCLE CONTRACTILE FORCE

email: blazek.16@buckeyemail.osu.edu

INTRODUCTION

Molecular mechanisms coordinating muscle and bone strength and growth following exercise (EX) remain undefined. We have identified a TGF-β family protein, follistatin-like 3 (FSTL3), which is upregulated in mouse and human skeletal muscle, bone and serum in response to low intensity walking EX. We have previously determined by mineral apposition rate analysis of *Fstl3-/-* mouse bone that FSTL3 is required for EX-driven bone formation [1]. FSTL3 is known to bind and inhibit myostatin [2]; thus, this study was to determine if FSTL3 increases muscle hypertrophy and force generation through this mechanism to collectively regulate musculoskeletal function.

METHODS

C57/Bl6 mice (n=20, 10 male, 10-12 wks), wild-type (WT, n=5) or *Fstl3-/-* (FSTL3 knock-out, "FSTL3KO," n=5), were treadmill walked for 45 min/day at 8 m/min for 6 weeks, a protocol that increases bone formation. Ten mice (male n=5) were used as NonEX controls. Intact extensor digitorum longus (EDL) and soleus (SOL) muscles were dissected and mounted vertically between two stimulating platinum electrodes and immersed in bathing chambers containing modified Ringer solution. A constant stimulatory voltage was applied to equilibrate muscles at maximum force, followed by stimulation at frequencies from 1-150 hz to generate force vs. frequency curves.

RESULTS AND DISCUSSION

No differences in stimulated force were observed in WT EX and WT NonEX mice, indicating that the walking EX protocol used was not sufficiently rigorous to produce a training effect on muscle force production (Fig.1). Interestingly, no force differences were observed in FSTL3KO EX and FSTL3KO NoEX groups (Fig. 2). These results indicate that endogenous FSTL3 may not be sufficient to alter muscle contractile force generation in response to walking EX training.

CONCLUSIONS

FSTL3 regulates bone health in response to low intensity, low impact walking EX; however, the walking protocol used here is insufficient for increasing muscle force and hypertrophy. This study provides information on the efficacy of walking to increase muscle strength that may be applied to designing EX programs in a clinical setting. While walking may be prescribed as a treatment regimen for increasing bone growth in humans, clinicians should be aware that walking may need to be supplemented with a resistance EX program to increase muscle strength/hypertrophy. *In vitro* and human studies to address FSTL3 mechanisms are ongoing.

TEMPORAL GENE EXPRESSION PATTERNS REVEAL THAT WALKING-GENERATED BIOMECHANICAL SIGNALS MAINTAIN CARTILAGE HEALTH AND REGULATE GENES ASSOCIATED WITH OSTEOARTHRITIS

INTRODUCTION

The beneficial effects of exercise on bone and muscle tissues of the musculoskeletal system are well established [1, 2]. Biomechanical signals generated by exercise induce a multitude of physiological changes required for homeostasis of cartilage [3] that may ultimately play a critical role in exercise-mediated prevention or progression of osteoarthritis (OA). However, gene expression in healthy cartilage in response to these signals has not been comprehensively assessed. The objective of this study was to examine the stable alterations in gene expression of healthy rat articular cartilage in response to low intensity walking exercise.

METHODS

Sprague Dawley rats (n=15, 12-14 wk old females, Harlan Labs, IN) were exercised by treadmill walking at 12 m/min for 45 min daily for 2, 5, or 15 days. Rats were sacrificed 2 hours after the last exercise regimen, and femurs were harvested and snap-frozen in liquid nitrogen. RNA from cartilage was extracted using Trizol and analyzed using Affymetrix GeneChip Rat Gene 1.0 ST Array. This temporal, transcriptome-wide analysis on the cartilage of the walking rats was compared to the transcriptome of sham control rat cartilage. Gene networks activated by exercise were analyzed via Ingenuity Pathways Analysis (IPA).

RESULTS AND DISCUSSION

IPA analysis revealed five distinct categories of gene expression patterns: I), Tissue development and function (extracellular matrix (ECM) and proteases); II) Cell metabolism; III) Cell growth (growth factors and signals), IV) Inflammation, V) Cell Cycle (Fig. 1). Exercise significantly upregulated matrix associated genes (Cluster I) involved in cartilage scaffolding, synthesis of elastin fibers, cell-matrix interactions, and proteins involved in keratin sulfate, heparin, and proteoglycan synthesis. Importantly, expression of extracellular proteins not associated with cartilage was dramatically suppressed, and genes regulating proteins that degrade collagens and proteoglycans were significantly suppressed. Conversely, several inhibitors of proteolytic enzymes involved in cartilage degradation were dramatically upregulated. A significant number of genes involved in cell signaling and metabolism (Cluster II) were regulated by biomechanical signals generated by exercise. These included serine/threonine kinases, molecules associated with membrane lipid and proteins metabolism, Kreb cycle enzymes, ion channels, and genes affecting cytoskeletal arrangements. Signals generated by exercise also induced several growth factors involved in chondrocyte growth and differentiation (Cluster III), but inhibited cell cycle progression (Cluster IV). Anti-inflammatory activities of exercise were also apparent by the suppression of a significant number of genes that are upregulated during acute and chronic inflammation (Cluster V).

CONCLUSIONS

The exercise stimulus was found to be a strong cartilage regenerative signal that induced cell metabolism, ECM synthesis, and cell growth. Similarly, pathways regulating cellular structure and biomechanics were upregulated. Cell proliferation

and cell cycle genes, many of which are involved in pathological conditions, were suppressed by exercise. Importantly, exercise also suppressed many inflammation associated genes, some of which have been shown to be upregulated in osteoarthritic cartilage. While it has long been suspected that exercise is beneficial for cartilage health, these results indicate that exercise effectively maintains cartilage matrix homeostasis by increasing cell metabolism while decreasing potentially detrimental proteolytic and inflammatory processes. These results may provide a potential mechanism for the protective effects of exercise against the onset of OA in healthy articular cartilage.

Full field in vivo characterization of skin deformation under pressure loading

W. J. Bong[1], S. Daly[1,2], and K. A. Shorter[1]

[1] Department of Mechanical Engineering, University of Michigan, Ann Arbor, MI, USA
[2] Department of Materials Science and Engineering, University of Michigan, Ann Arbor, MI, USA
Email: kshorter@umich.edu

INTRODUCTION

Skin is the largest organ in the body. It plays an important role in the sensory system and is vital for thermoregulation. This multirole functionality is maintained all while providing a critical line of defense against the external environment. In general, the detailed characterization of skin's mechanical properties facilitates a better understanding of the tissue and advances fields such as disease diagnosis [1], tissue modeling, medical device design, cosmetics, and surgery. Full field deformation and strain measurements are key for the characterization of this viscoelastic composite. However, experimental techniques that provide these types of measurements for skin in vivo are currently lacking.

Digital image correlation (DIC) tracks unique features on the surface of a material during deformation to extract shape, deformation and motion measurements of the substrate. Recently, 3D DIC has been used to capture full-field measurements of deformation over relatively large test areas for a variety of substrates. This technique has been used in ex vivo bulge inflation tests to identify material parameters and perform stress-strain analysis for excised skin [2]. However, there are currently no methodological examples that use DIC to make in vivo measurements of intact skin. In this work, a portable device that combines pressure loading and DIC (termed here as PDIC) is used to compare the mechanical properties of skin at two different sites on the body.

METHODS

The experimental setup (Fig. 1) consists of two cameras rigidly mounted to a sealed housing that is evacuated using a venturi vacuum pump. The pump creates a partial vacuum in the housing while a pressure sensor logs pressures inside the housing at 20Hz. The housing is made up of four main components – a machined nylon cap; printed ABS
Figure 1: Experiments were conducted on the skin over the abdomen and on the upper back between the shoulder blades. The yellow box shows a representative subset size.

camera supports; a machined main PVC cylinder; and a silicone lip. The silicone lip provides a compliant interface and enhances the seal between the cylinder and the tissue. Each camera assembly is comprised of a camera lens (3.5 mm focal length, aperture range of f/2.4 to f/8) attached to a 1.3 megapixel monochrome USB digital video camera. The camera setup provides a near limit for depth of field of about 2 in from the cameras. Quartz glass inserts are set between the camera lens and the nylon cap to protect the lens and provide a good vacuum seal. Illumination for the cameras is provided by LED lights seated in a groove cut in the PVC housing.

The PDIC system was used to characterize the deformation response of skin from two test subjects at two anatomically distinct sites – the abdomen and the upper back between the shoulder blades. The two male test subjects were 29.5 (s.d. 7.8) years old, 72.0 (s.d. 4.3) in tall, and weighed 153 (s.d. 8.7) pounds. In this work the unique features for the DIC technique consisted of a speckle pattern printed onto temporary tattoo paper. Following preparation and cleaning of the sites, speckle pattern tattoos were applied and allowed to dry before testing.

The cameras were calibrated with a 12x9 grid before the start of each experiment. A preprogrammed cyclic pattern was used to apply

pressure loading over a range of magnitudes to the tissue. Each loading condition lasted for 30 s, and a set of preconditioning cycles of the same magnitude and duration were applied before data were collected. Maximum pressure was kept below 0.1 bar (73 N) for the abdomen and 0.12 bar (96 N) for the upper back. These limits ensured that the subjects did not experience discomfort as a result of the pressure loading. During the trials, pressure data were used to control the pump to achieve the desired loading profile. Images of the skin were captured using Correlated Solution's Vic-Snap 2012 software, at about 7 FPS, after the preconditioning phase. Images were analyzed using Correlated Solution's Vic-3D software to obtain full-field displacements, which were in turn analyzed using MATLAB.

RESULTS AND DISCUSSION

The shape of the average response obtained in our experiments agrees with load-deformation curves for collagenous tissues [3]. Peak displacements increased with increasing peak load, and hysteresis was evident during unloading for all trials at both sites. The energy dissipated during each cycle was quantified using the area within each hysteresis loop and was present during all loading conditions. Figure 2A compares the load-deformation curves from the two sites for one subject at similar loading conditions.

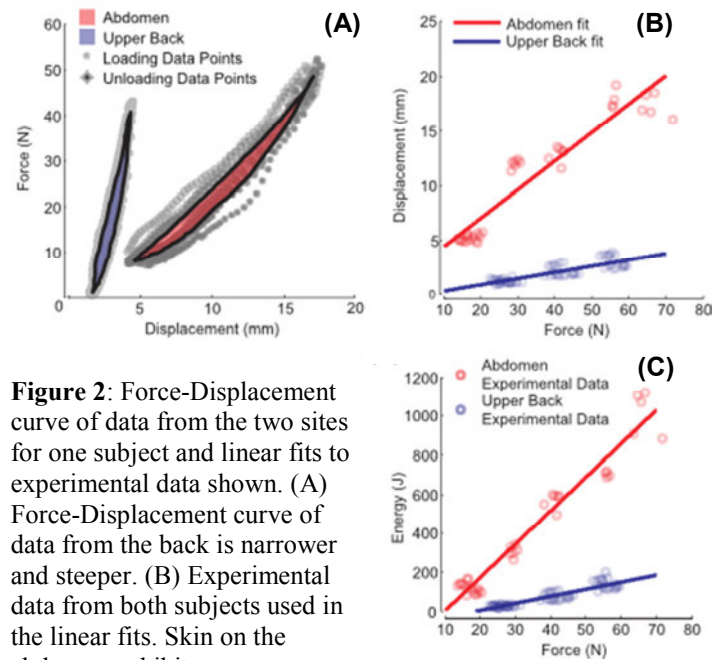
Both peak skin displacement and energy absorption were further characterized with linear fits. Peak out-of-plane skin displacements and the energy dissipated over each cycle increased linearly with force for the skin at both the abdomen and the upper back. Figure 2B illustrates the linear relationship between peak force and peak displacement. The r-squared value of the abdomen fit was 0.893 while the fit for the upper back fit was 0.710. While both are relatively good fits, data from the upper back differed more between the two subjects. Figure 2C presents the energy absorbed by the skin as a function of peak force. The r-squared value for the abdomen fit is 0.948 while that for the upper back fit is 0.839. Similarly, data for the upper back differed more between the two subjects, resulting in the lower r-squared value. Both figures present data from the two subjects at both sites.


Figure 2: Force-Displacement curve of data from the two sites for one subject and linear fits to experimental data shown. (A) Force-Displacement curve of data from the back is narrower and steeper. (B) Experimental data from both subjects used in the linear fits. Skin on the abdomen exhibits greater displacements for the same pressure. (C) Experimental data from both subjects used. The skin in the abdomen area dissipates more energy than the skin on the upper back.

The anatomy under the skin at the two sites was very different, and this significantly affected the resulting measurements. The lack of a boney substructure below the skin at the abdomen resulted in a softer loading response with more hysteresis (Figure 2A). This in turn created larger deformations with more energy absorption during all cyclic loading conditions (Figures 2B and C).

CONCLUSIONS

The PDIC system enables the capture of full-field in vivo deformation of skin under pressure loading. Future work will involve the use of this approach to characterize skin properties at multiple sites for a range of age groups. We will also explore the use of this device for medical device design and disease diagnostics.

STOPPED TEACHING PHYICS, STARTED TEACHING BIOMECHANICS AND FLIPPED THE CLASSROOM

[1] Scott P. Breloff

[1] University of Scranton, Scranton, PA, USA
email: scott.breloff@scranton.edu

INTRODUCTION

Team Based Learning (TBL) is a student centered 'flipped-classroom' teaching style which requires the students to work together in small teams on real life application activities during class time. A flipped classroom necessitates students to prepare for content prior to coming into lecture. Lecture time is then used to apply and build on the content students obtained on their own outside of the class.

TBL was developed by Larry Michaelsen in the 1970s [1]. The purpose was to have students learn by doing (i.e. active learning), rather than simply receiving all content via lecture. Adoption of TBL into the biomechanics course at the University of Scranton arose for several reasons; first, this style seemed like a logical fit with a difficult class like biomechanics. Second, with teaching three sections of the same course, it was difficult to lecture in all three sections. Third, the addition of TBL was to improve the students' learning by reducing lecture time and providing a more relaxed atmosphere where the students feel comfortable with discussion and asking questions.

The first iteration of TBL in biomechanics was spring 2013. The class was then completely overhauled for spring 2014. Physics is a pre-requisite for biomechanics at the University of Scranton and the first eight chapters of the text used in 2013 was essentially a physics review. Many student comments suggested to 'not simply repeat physics'. Biomechanics at the University of Scranton now uses a custom text which draws from ten different sources to allow students to learn what biomechanics is and how to apply biomechanical concepts in several different situations. This is how the classroom was flipped, teaching physics stopped and teaching biomechanics began.

METHODS

Team Based Learning is a modular learning style divided into three phases: Preparation, Readiness Test and In-class Application Activities. The Preparation phase requires students to complete specific reading in order to prepare for phase two. The second phase, readiness assurance process (RAP), is separated into four sub-sections:

 i. individual readiness assurance test (iRAT)
 ii. team reading assurance test (tRAT)
 iii. appeals process
 iv. mini-lecture.

The iRAT assesses how well the students comprehended the readings by themselves. The students then gather in their teams and take the same test to further their understanding of the material (tRAT). If students feel any of the selected answers are not correct, they are allowed to appeal that question through a previously approved process. Finally, a mini-lecture is provided to touch on the important and/or difficult concepts from the reading.

After the mini-lecture, students enter phase three which is in class application activities. Students work in teams to use their foundational knowledge to solve problems, prepare arguments and provide explanations.

A BIOMECHANICS TBL COURSE

Learning modules are designed to focus on one or two particular concepts. The modules for this course were chosen with the understanding the students have completed a 'Physics I' course which generally discusses mechanics, forces, etc. In addition, students are provided with a physics review of the concepts they are expected to know from the pre-requisite physics course.

The learning modules for the TBL course in Biomechanics:

- **Module 1: Orientation**
- **Module 2: Intro. Biomech. & Biomech. Tech.**
- **Module 3: Fluid Mechanics & Anthropometrics**
- **Module 4: Ground Reaction Forces**
- **Module 5: Inverse Dynamics**
- **Module 6: Clinical Biomechanics**
- **Module 7: Ergonomic Biomechanics**
- **Module 8: Forensic & Sport Biomechanics**

Students are assessed with the use of modular examinations, modular homework projects, the RAP, and team maintenance. Team maintenance allows each individual student in a team to rate the contributions of of their fellow team members during the end of the term. This portion of the grade (usually 5%) does not come from the instructor, but from the students themselves.

TECHNOLOGY/LEARNING AIDS

Many improvements and additions have been made to increase student learning and improve course effectiveness. These improvements range from technology to teaching assistants.

- *iClicker*: is a student response system used in RAP.
- *WhiteBoards*: a 2'x 3' whiteboard instead of an 8.5"x 11" sheet of paper.
- *Teaching Assistants:* former undergraduate students to help with in class activities.
- *Practice Problems:* Excel spreadsheets with modifiable input parameters.
- *Custom Book:* a custom packet developed from several sources.
- *iRAT recorder sheet:* to help with recall between the iRAT and tRAT.

BENEFITS AND CHALLENGES

Some of the benefits of this approach to biomechanics:
- More interaction with the students.

- Lecture time is more enjoyable for the students and professor.
- Students learn by doing (i.e. active learning).
- Though anecdotally, this approach has allowed the students to have a better understanding of biomechanics (not enough data to run statistics).
- Students come back later to tell the instructor how much they appreciated the style and how much they retained.

This format has had some challenges. Many of these have been addressed in the improvements:

- An unfamiliar system makes the students nervous.
- Students are uncomfortable with a student centered classroom.
- It has been documented that TBL will have better student learning as demonstrated by higher test scores but lower student evaluations [2].
- Students feel the instructors are not teaching, and making the students do all the work.
- As with any team based work, individual contributions are always a concern.

CONCLUSIONS
This approach to teaching biomechanics has been a welcome change to the instructor. It allows for more interaction with the students and reduces overall time spent on lecture by requiring the students to prepare content outside of classroom and learn by doing in the classroom. Currently, in the second semester using this approach, students are beginning to accept and embrace it. As with any new style of teaching, there have been challenges, but they have been addressed and the course continues to improve.

MODELING REPERFUSION RESPONSES IN PATIENTS WITH LEG WOUNDS

Wu Pan, Josh Drost, Amy Lenz, Seungik Baek PhD, Tamara Reid Bush PhD

Department of Mechanical Engineering, Michigan State University, East Lansing, MI, USA
email: reidtama@egr.msu.edu, web: http://researchgroups.msu.edu/reidtama

INTRODUCTION

Skin ulcers are a significant health problem affecting millions of people in U.S including the elderly, those with vascular deficiencies, and people with a reduction in mobility, such as wheelchair users [1]. These skin wounds take months to heal, are prone to infection, and can lead to amputation or death.

Reperfusion injury, which is the blood reflux back to tissues, usually results in inflammation and leads to tissue damage. In the study of skin ulceration, reperfusion injury has been investigated as an important factor in chronic skin wounds [2]. Currently, a model does not exist that can completely characterize the occlusion of blood flow and the reperfusion process. Development of a model that can characterize this process will provide insight into the pathophysiology of wound formation which will lead to improved treatment and care, benefiting the millions of patients who experience these painful, debilitating wounds.

In this study, a mathematical model using a Windkessel approach was developed to replicate and predict the capillary blood flow during reperfusion process in subjects with and without lower limb deep tissue wounds. The model was then evaluated by comparing output to experimental results obtained by testing healthy individuals and patients with wounds.

METHODS

Experimental methods: Patients with skin ulcers ("wounded") in their lower legs and healthy subjects ("healthy") were recruited for this study. A customized load applicator was built to allow normal and shear forces to be applied on the skin of lower legs of test subjects (Fig.1). A laser Doppler system was used to monitor and record the blood perfusion responses of the skin where the loads were applied. The perfusion-time history data were analyzed using three different phases: a) baseline, where no load was applied; b) under loading, either normal loading or combined normal and shear loading; c) recovery, where the blood reperfusion had a spike of hyperemia after load was removed and then returned to baseline.
Figure 1: Perfusion test configuration. A six axis load cell was mounted on a vertical frame, allowing force to be measured in the medial and vertical directions. The Perfusion sensor was attached to the lower leg skin of the subject.

Modeling method: Using the analogy of an electrical circuit, Ohm's law for electricity is equalized with Poiseuille's law for fluid dynamics of the blood vessel. In a Windkessel circuit, the voltage supply represents the hydraulic pressure of the vessel. Our model (Fig. 2) was proposed based on models developed by De Mul [3] and Vo, T. Van [4] and modified to represent the experimental procedure.
Figure 1: Model developed for reactive hyperemia. R_1 and R_2 represent the arterial and venous resistance respectively, C is the capillary capacitance. V_0 is the hydrostatic arterial pressure; V_{ext} is the external pressure (shown as a voltmeter EXT), I_2 represents venous blood flow.

The hydrostatic arterial pressure (V_0) was calculated as the arterial pressure at the heart plus the hydrostatic pressure with respect to the vertical distance between the heart and where the measurement was taken on the lower leg (Eq.1). The external pressure (V_{ext}) was calculated and normalized as the applied force over the contact surface area of the customized load applicator. The governing equation for this circuit was derived as Eq. 2.

$$V_0 = 100\text{mmHg} + 77.7\text{mmHg/m} \times 0.55\text{m} \qquad (1)$$

$$(R_1 + R_2)I_2 + CR_1R_2 \frac{dI_2}{dt} = V_0 - V_{ext} - CR_1 \frac{dV_{ext}}{dt} \qquad (2)$$

In our model, the V_{ext} served as the input and I_2 the output. Empirical values for parameters such as R_1, R_2 and C were obtained from literature and used as initial values for iteration. Iterations of the model were run until RCR values were obtained that could reproduce the experimental curve for that specific patient.

RESULTS AND DISCUSSION

Numerical simulation in MATLAB was used to perform the blood flow of the Windkessel circuit model. The experimental perfusion data (blue) are presented along with model results (red). The comparison between experimental data and the numerical simulation for two different patients and under different loading conditions are shown in Fig2 and Fig. 3.
Figure 2: Comparison of blood flow of leg with skin ulcers under normal loading.
Figure 3: Comparison blood flow of a healthy leg under combined normal and shear loading.

It can be seen from Fig. 2 and Fig. 3 that the current circuit model represents the *general* trend of a decrease in blood flow under loading and the hyperemia spike at the beginning of the reperfusion period upon the release of external loading. However, further modification and development of the model are required to better represent the magnitude of the hyperemia spike, as well as to accommodate the decaying trend from the hyperemia spike to the baseline value during the reperfusion period after the load was removed.

CONCLUSIONS

The model developed in this study aimed to address a computational solution to understanding blood flow occlusion followed by the reperfusion process in capillary flow of lower limbs. The proposed model successfully replicated the blood flow during loading and the hyperemia spike. A current limitation is the inability to characterize the hyperemia recovery slope (period right after the spike) during reperfusion. With further work in this area, the model has great potential to be an improvement on previous reported models in the literature and provide insight for the complex physiological problem of ulcers.

BLOOD PERFUSION RESPONSES OF LOWER LEGS: STUDY OF VENOUS STASIS ULCERS

[1]Wu Pan, [1]Joshua P. Drost, [2]Marc D. Basson, and [1]Tamara Reid Bush

[1] Department of Mechanical Engineering, Michigan State University, East Lansing, MI, USA
[2] Department of Surgery, Michigan State University, East Lansing, MI, USA
email: reidtama@egr.msu.edu, web: http://researchgroups.msu.edu/reidtama

INTRODUCTION

Venous stasis ulcers are skin wounds that occur most commonly on the lower leg. These chronic wounds are painful, can lead to infection, amputation and even death. They affect 2.5 million patients annually in the United States. Stasis ulcers also have high recurrence rates, resulting in multiple visits to wound clinics or hospitals [1].

Ulcer formation has been linked to external loads on the skin which impair blood circulation and the high blood flow that occurs after the loads are removed (called reactive hyperemia). Little work has been conducted to identify differences in perfusion responses (blood flow) between healthy individuals and individuals with stasis ulcers. **The goal of this work** was to identify differences in perfusion responses to force (both normal and shear forces) between legs with existing venous stasis ulcers and healthy legs.

METHODS

Eighteen individuals with wounds on their lower leg and twenty healthy individuals with no vascular issues participated in the testing. A total of seventy five legs were evaluated resulting in three groups: 20 legs with wounds ("wounded"), 15 non-wounded legs but from patients with leg wounds ("non-wounded") and 40 "healthy" legs.

Load was applied with a custom built device (Fig. 1). The normal loading was applied in the medial direction on the lateral portion of the calf; approximately 25 cm above the ankle. Shear load was applied to the skin when the load cell was shifted vertically while still applying a normal force so the load cell did not slip on the skin. Loading was never directly applied over a wound. If a wound was located at the test site; the test site was shifted slightly so loading was at least one inch away from the edge of the wound.
Figure 1: Perfusion test configuration with load cell. A six axis load cell was mounted on a vertical frame and was constrained to two degrees of freedom, allowing force to be measured in the medial and vertical directions.

The magnitude of normal loading was 75% of the subject's lower leg weight which was 4.5% of the subject's whole body weight[2]; shear loading, in the combined loading condition, was 50% of the applied normal loading. The forces used were comparable to those that the leg might experience intermittently during normal living, such as crossing one's legs or resting one's legs on a couch.

A Laser Doppler Perfusion Monitor was used to monitor and record the blood perfusion of the skin during the entire test period. Loading was applied around the region of the senor with a customized device surrounding the sensor. Each perfusion test consisted of 5 phases: baseline (no load), normal loading, recovery from normal loading, combined normal and shear loading, and recovery from combined loading. The order of normal load or combined loads was altered across the subject pool.

RESULTS AND DISCUSSION

Baseline Comparisons: A sample blood perfusion curve is provided in Figure 2. Statistically significant differences occurred between wounded

legs and healthy legs during baseline study (p=0.02). Wounded legs had the highest perfusion values during baseline while healthy legs had the lowest baseline perfusion values.

Perfusion during loading: Two different approaches were used to evaluate the perfusion changes. The first examined the difference with regard to the initial baseline data set ($\overline{A_0} - \overline{B_i}$ i=1, 2); while the second treated the period immediately prior to the trial as the "new baseline" and compared perfusion data to this value ($\overline{A_{i-1}} - \overline{B_i}$ i=1,2). Perfusion values of wounded legs decreased the most when loading was applied regardless of the approach used for comparison. Each approach yielded significant and similar differences between the wounded and healthy legs for the combined loading condition. (p=0.02 for $\overline{A_0} - \overline{B_i}$; p=0.0007 for $\overline{A_{i-1}} - \overline{B_i}$). Note: all individuals showed a 90% level or higher recovery after loads were removed and prior to the start of the next test.

Reactive Hyperemia: The reactive hyperemia value (C_1 and C_2) were compared. One-Way ANOVA and Tukey tests demonstrated significant differences between wounded and healthy legs for reactive hyperemia values (p=0.006 for normal loading; p=0.02 for combined loading).

Medium effect sizes (range 0.3~0.5) were found in comparison between non-wounded legs and healthy legs for blood perfusion values during baseline loadings. In addition, medium effect sizes were also shown between wounded legs and non-wounded legs for blood perfusion decrease under normal and combined loadings. This finding suggested that statistically significant differences might be expected for higher sample sizes when comparing reactive hyperemia between wounded and non-wounded legs; as well as for the comparison of perfusion values during baseline and loadings between non-wounded legs and healthy legs.

CONCLUSIONS
These data show that the legs with existing venous stasis ulcers are significantly different from healthy legs when comparing reactive hyperemia, baseline perfusion and the perfusion decrease under loading, whereas the non-wounded legs exhibited an intermediate trend between wounded and healthy legs. A progressive trend from healthy to non-wounded to wounded legs exists and the fact that individuals eventually develop an ulcer in the "non-wounded" leg [3] supports the possibility that changes in force-perfusion responses could serve as predictor of ulcer formation.

MECHANICAL WORK OF MASSAGE AFTER ECCENTRIC EXERCISE IN A RABBIT MODEL

[1] Scott K. Crawford, [1]Yi Zhao and [1]Thomas M. Best

[1] The Ohio State University, Columbus, OH, USA

email: crawford.606@osu.edu

INTRODUCTION

Skeletal muscle damage, often a result of unaccustomed eccentric exercise (EEC), is a common problem in sports medicine. One popular treatment utilized to accelerate recovery of muscle function following EEC is massage [1]. This therapy is theoretically based on the principles of mechanotransduction, wherein externally applied forces trigger production of molecular signals that modulate specific physiological responses. However, the forces applied to tissues during human massage are not quantified, which makes comparing results between studies difficult. Additionally, human massage typically involves a combination of both compressive and transverse (along the tissue) forces. We have investigated the magnitude of forces applied during massage, but have focused on compression and transverse forces in isolation rather than in combination [2,3]. This current analysis attempts to account for total loading during massage by analyzing the mechanical work performed on the muscle.

METHODS

Twenty-four skeletally mature New Zealand White rabbits were instrumented with bilateral peroneal nerve cuffs for consistent external stimulation of the tibialis anterior [2]. One hindlimb from each animal was randomly selected to undergo an intense bout of EEC. Animals were randomized for massage commencing immediately after or 48 hrs after EEC. Massage was applied using a customized mechanical device for 4 consecutive days. Each massage bout was approximately 24 hrs apart and utilized a previously determined optimal set of parameters for restoring ankle joint torque (10 N compressive force, 0.5 Hz, 15 min) [2]. A 300 second compressive ramp-and-hold stress relaxation test estimated the muscle's passive mechanical properties. Mechanical properties were measured pre- and post-massage for all days.

Mechanical work was defined as

$$W = \int F(z) dz \qquad (1)$$

where W was work, $F(z)$ was force as a function of displacement, and dz was the displacement in the direction of the applied force. Compression work (W_c) was calculated as

$$W_c = W_0 + W_{massage} \qquad (2)$$

where W_0 was the initial work input into the system by manually lowering the massage tip. $W_{massage}$ was the work done during massage due to the massage tip traveling deeper into the muscle as a result of tissue relaxation. The transverse forces, expressed as a function of time $F(t)$, were transformed and expressed as a function of displacement along the muscle belly $F(x)$. This function was then integrated (Eq. 1) to determine the work performed along the muscle belly (W_t). The total work was calculated as

$$W_{total} = W_c + W_t \qquad (3).$$

All variables had non-normal distributions therefore the data were transformed for subsequent ANOVA tests. Bartlett's test was performed and determined equal variance for all analyses ($p > 0.05$).

RESULTS AND DISCUSSION

Average daily values of W_c, W_t, and W_{total} are shown in Table 1. The average values of mechanical work in the immediate and delayed massage groups are shown in Table 2. W_0 was very small and on the order of 30 mJ. There was a difference in W_0 between groups ($p = 0.024$), but day (i.e. massage bout) ($p = 0.072$) and the interaction of day and group ($p = 0.356$) had no significant effect. ANOVA

showed no differences in W_c due to any factors (p=0.336). Day (p=0.010) and group (p=0.009) had a significant effect on W_t, but their interaction did not (p=0.732). *Post hoc* Tukey tests showed differences between days 1 and 2 (p=0.041), days 1 and 3 (p=0.015), and days 1 and 4 (p=0.040), as shown in Figure 1. All other comparisons were not significant (p>0.05). There was a difference in W_{total} between groups (p=0.002), but day (p=0.055) and the interaction of day and group did not have a significant effect (p=0.492).

Figure 1: Daily average transverse (W_t) and compression (W_c) work performed during massage.

The observed differences in W_0 between groups indicated that initial work input into the tissue was different between groups, which is not completely unexpected since the initial work was performed by manually lowering the massage tip to a 10 N compressive force. Moreover, any differences in W_c would be due to tissue relaxation, and previous work has shown that massage had no effect on

altering the muscle's relaxation response [4]. Interestingly, W_t was an average 3.25 times greater than W_c despite compressive forces being an average 2.9 times greater than transverse forces [3]. The finding that W_t was less in the delayed group compared to the immediate massage group is perhaps not surprising since transverse forces were higher in the immediate group compared to the delayed group [3] and the total displacement along the muscle is the same in all massage bouts. W_{total} was greater in the immediate group compared to the delayed group, which is most likely due to the differences in W_t. Taken in conjunction with previous work [2-4], we conclude that acceleration of functional recovery due to this particular massage protocol following EEC is primarily a result of work due to loading along the muscle belly rather than muscle compression. These findings may provide guidance to inform clinical practice and the use of massage.

INVESTIGATION OF NECK AND HEAD INJURY POTENTIAL DURING INERTIAL LOADING OF THE PEDIATRIC HEAD: IMPLICATIONS TO SHAKEN BABY SYNDROME CHARACTERIZATION

[1] Mark A. Davison, BS, [1]Brian Weaver, MS, PE, [1] Steven A. Rundell, PhD, PE
[1] Explico Engineering Co., Ann Arbor, MI, USA
email: steve@explico.com, web: www.explico.com

INTRODUCTION

It has been suggested that violent shaking of a child, in the absence of head impact, can result in closed head injury. Specifically, the symptoms associated with shaken baby syndrome (SBS) are relegated to the head, and include retinal hemorrhaging, cerebral hemorrhaging, and encephalopathy. Careful characterization of the injuries resulting from shaking is critical when determining a potentially abusive situation. Unfortunately, a paucity of real-world or empirical validation exists to confirm the SBS injury pattern.

Both real-world and empirically derived data from automobile collisions provides valuable information related to pediatric injury patterns during pure inertial loading of the head, which is similar to violent shaking. These data indicate the presence of cervical spine trauma in the absence of closed head injury [1,2].

Therefore, the objective of the current study was to evaluate pediatric neck and head injury potential during purely inertial loading of the head. Given the anatomical and biomechanical properties of the pediatric cervical spine, we hypothesized that inertial loading of the pediatric head provides a greater risk of injury to the cervical spine when compared with closed-head injury.

METHODS

Publicly available sled and full-scale crash testing was downloaded from The National Highway Traffic Safety Administration's website.

Frontal sled tests were performed at an approximate change in velocity (delta-V) of 30 mph. The full-scale crash tests were performed at a barrier equivalent speed of 35 mph. Both of these modes of testing utilized forward-facing Hybrid III, 3 year-old anthropomorphic testing devices (ATDs) restrained in age-appropriate child restraint systems.

Head Injury Criterion 15 (HIC_{15}) and upper neck peak tension force was documented for each of the ATD's (n=107). The published Hybrid III 3 year-old injury assessment reference values (IARVs) for HIC_{15} and upper neck peak tension force were 570 and 1,430 N, respectively [3]. The percentage of data points that exceeded either IARV was calculated. Additionally, HIC_{15} was plotted against peak neck tension in order to investigate the presence of a correlation, and graphically depict each data point in relation to the IARV (see Fig. 1 and 2)

Statistical outliers were identified and removed using the Tietjen-Moore method for multiple outliers. Any crash test that resulted in direct head contact was also removed. Pearson correlation coefficients were calculated to determine correlations between HIC and peak neck tension.

RESULTS AND DISCUSSION

Data from a total of 34 ATDs was obtained from the 30 mph sled tests. The average HIC_{15} was 305.3 (SD = 117.3). The average upper neck peak tension force was 1719.2 N (SD = 328.5). The Pearson Test indicated a positive correlation between HIC_{15} and upper neck peak tension force, r = 0.74, p < 0.05, with a R^2 = 0.55. Of the 34 data points gleaned from the sled testing reports, 27 (80%) exceeded the upper neck tension IARV while only 1 test (3%) surpassed the HIC_{15} IARV (Fig. 1).

Data from a total of 73 ATDs was obtained from the 35 mph full-scale crash tests. The average HIC_{15}

was 506.2 (SD = 174.2). The average upper neck peak tension force was 1935.5 N (SD = 248.5). The Pearson Test indicated a positive correlation between the HIC_{15} and upper neck peak tension force, r = 0.46, p < 0.05, with a R^2 = 0.22. Of these tests, 72 (99%) exceed the upper neck peak tension IARV and 17 (23%) exceed the HIC_{15} IARV (Fig. 2).

Figure 1: Sled testing of the Hybrid III, 3 year-old ATD compared to the head and neck IARVs.

Figure 2: Full-scale crash testing of the 3 year-old ATD compared to head and neck IARVs.

Results from the current study indicate generally injurious levels of neck tension. Conversely, HIC_{15} values tended to remain below the IARV. These findings support the hypothesis that inertial loading of the head provides a greater risk of injury to the cervical spine when compared with closed-head injury. At minimum, these data indicate a clear coupling of head and neck injury risk for the pediatric population in the absence of head impact.

The results from this study help corroborate and support the current IARV for three-year-old peak neck tension. Specifically, previously reported

cervical injury patterns for restrained young children during frontal collisions include atlanto-occipital dislocation. The mechanism for this type of injury involves a high level of tensile forces in the cervical spine. These data indicate good bio-fidelity of the HIII three-year old dummy.

Unfortunately, similar real-world validation does not typically exist in instances involving child abuse. Specifically, the injury pattern associated with violent shaking of a child has been suggested, but never reliably, empirically verified. Results from the current study provide valuable insight into the injury pattern associated with inertial loading of the head. Specifically, the results indicate a high risk of neck injury when compared with the risk of head injury. Moreover, the results indicate a statistically significant correlation between head and neck loading, which suggests a coupling of injury potential. Therefore, the injury pattern associated with violent shaking should be altered to include the presence of cervical spine injury. Moreover, during instances in which abusive shaking is suspected, special consideration should be paid to the cervical spine.

The current study shares the limitations associated with all ATD studies. Additionally, the current study relied upon IARVs to determine the relative risk of injury between the neck and the head. While this comparison provides insight into the general pattern of injury, it does not provide reliable information related to the relative severity of the injuries. Finally, the current study utilized HIC_{15} to evaluate the risk of closed-head injury. Ideally, rotational acceleration and velocity would have been included.

USING A HYBRID COURSE FORMAT TO TEACH BIOMECHANICS RESEARCH METHODS

Erin Feser

Arizona State University, Phoenix, AZ, USA
email: enharper@asu.edu

INTRODUCTION

Hybrid courses (also known as blended learning) are courses that replace a portion of the traditional in-person class time with online learning [1]. Often, the hybrid course format is utilized to address an access or convenience issue [2]. For example, a traditional class that meets in-person twice per week during the semester could be re-designed such that it is offered 50% in-person and 50% online. The students would meet for the in-person session one day per week, thus freeing up classroom space for the other day of the week.

The hybrid course structure can be utilized for reasons other than scheduling convenience. For many, designing or re-designing a course to a hybrid format allows one to incorporate the advantages that come from in-person course delivery with the advantages of online course delivery to provide a course that is most beneficial for the learner. This type of hybrid course is referred to as transforming, as the design intention is to allow for student learning experiences that are not possible without the incorporation of online course delivery [2].

The Kinesiology degree program at Arizona State University was met with the challenge of offering an undergraduate, senior level elective course on biomechanics research methods and technology. At the time of onset, elective courses were offered for enrollment of 40 students. However, there was not a formal biomechanics lab space that could accommodate large groups of students and equipment was limited. Therefore, a transforming-type hybrid course format was adopted to meet the course objective needs.

Many universities, with limited space and equipment, might also be encountering the challenge of offering undergraduate or graduate students hands-on laboratory experiences, and would therefore benefit from learning more about our experience with utilizing a hybrid course format to meet this challenge.

COURSE DESIGN

This course, entitled KIN 418 Experimental Neuromechanics, is delivered as two components, lecture and laboratory. The lecture component of the course serves to discuss the theory behind quantitative biomechanical analysis techniques, proper equipment usage, and the connection to biomechanical and motor control concepts. During the laboratory component, students gain hands on experience with the equipment by performing experiments. During these experiments, the students alternate their roles as both a technician and participant. Following laboratory experiences, students gain practice in analyzing, reporting, interpreting, and presenting data.

The course now has a maximum enrollment of 24 students, so there are a total of six experiments planned for the semester. Each experiment demonstrates a different concept and equipment usage. The class is divided into six groups, each assigned a different experiment. Experiments are scheduled throughout the semester and occur as the lecture material progresses.

When an experiment is scheduled for the class period, only the group that has been assigned to that experiment attends class for the entire period. Three other groups are assigned to different segments of the

class period to attend as a participant, while the other two groups are not required to attend.

The time of the groups that are not required to attend, or are required to attend for only a small segment of the class period, is instead allocated towards independent work online or small group project work. Having these students occupied outside of the formal class session allows the instructor to work one-on-one with the lab group. Additionally, it allows for only a small group of students to be in the lab at a time, which further allows for the students to be hands-on with the equipment.

Utilization of the hybrid class structure has provided the flexibility to largely transform the experience students receive when learning about biomechanics technology. Instead of simply observing, the students are able to be fully involved in all aspects of an experiment, from designing the methods to troubleshooting when something unexpected arises while carrying out their experiment. Naturally, this reinforces lecture material and permits higher level learning objectives.

BEST PRACTICES

When designing a hybrid course, there are many design considerations [3]. Once the learning objectives are set, the main point of focus should be on how and when the students will interact with the instructor. Currently, there is no standard ratio for how much of the course instruction is received by the student online versus in-person [1]. Students in KIN 418 Experimental Neuromechanics receive about 63% of the course in-person. This percentage was not decided on in advance; instead, how much class time was allocated for each group to spend on their experiments with the instructor was decided. Also, it was taken into consideration what material the other students would be able to work on asynchronously and independently.

It is essential when designing a hybrid course that a course outline is built to clearly communicate the expectations of when, where, and how the students will be actively engaging in course material. A course outline is especially important for this course, considering the asynchronous nature of some of the assignments. To address this, a table is provided to the students, in addition to the course schedule to indicate what will occur in the classroom (e.g., lecture, equipment demonstrations, exams, particular assignment instructions) and what will occur outside of the classroom (e.g., assignment instructions, materials presented online, small group work). This helps the students recognize the interaction of the in-person and online course components and stay informed as to what is expected of them during the duration of the course.

Lastly, the instructor must imbed opportunities for students to self-monitor progress. This is important to support online course component success. A variety of methods can be employed. Examples include guided reading questions, post-online lecture quiz, writing assignment examples, and breaking a group project down into phases with separate graded submissions.

CONCLUSIONS

While most Kinesiology degree program students do not continue to research careers, most do continue into careers that require use of evidence based practice. Their understanding of the research process is invaluable to their ability to critique research literature in the future. Therefore, it is important for students to receive learning experiences that support and bring forth a knowledge base of research methods for their respective discipline. A hybrid format course design allows for an active learning environment which has been identified and empirically validated for increasing student performance and recommended over traditional lecturing as a teaching method [4].

A JOINT COORDINATE SYSTEM TO DESCRIBE RELATIVE 3D MOTION BETWEEN THE REAR AND FRONT BODY SEGMENTS OF RODENTS: APPLICATION IN THE STUDY OF NEURODEGENERATIVE DISEASES

[1,2] Tasos Karakostas, [3] Lawrence Middaugh, and [3] Ann-Charlotte Granholm

[1] Rehabilitation Institute of Chicago, Chicago, IL, USA
[2] Northwestern University, Chicago, IL, USA

INTRODUCTION

Walking safely and smoothly requires intact visual, vestibular, proprioceptive and musculoskeletal systems information processing and integration at the brain. Aging and neurodegenerative disorders not only affect the quality and quantity of the information, but also the integration at the brain. Therefore, loss of motor function and gait has been found to parallel cognitive impairment, eventually leading to dementia [1]. On this basis, quantitative instrumented gait has been found a sensitive and measurable tool for determining risk for frailty and progression of dementia [2]. Parkinson disease (PD) is another such neurodegenerative disorder where only recently instrumented motion analysis has been used to track progression of the disease as well as the effects of surgical or pharmaceutical treatment paradigms [3]. However, because most drug trials for PD and dementia involve pre-assessment in models of the disease, translatable and accurate motion capture methods also need to be developed for mouse and rat models.

To the best of our knowledge, our group was the first to report, firstly on the feasibility of using an optical motion capture system to study aging-related changes on a mouse while walking [4], and secondly on a three body-segment rodent model comprised of the head, the anterior and hind body segments [5] with application to PD. This model provided the ability to quantify and study the distinct 3D motion patterns of each body segment between each body-segment's coordinate system and the laboratory coordinates, using an Eulerian approach, i.e., such that angular displacement data are not sequence dependent, unlike when they are derived directly from rotation matrices.

However, much like when human motion is considered, it may be of greater interest if the motion of the rodent's body-segments are described relative to each other. Consequently, the purpose of this study is to expand on our previous work and propose a model to describe the 3D motion of the anterior body-segment of the rodent relative to its rear body-segment.

METHODS

The development of the model has been described previously [5]. Briefly, for the purposes of this report, one GDNF$^{+/-}$ mouse and a wildtype littermate (WT) were anesthetized with isoflurane and 2mm diameter retro-reflective markers were fixed to their hair via hypoallergenic double-sided tape. The markers were placed on the anterior rim of the pelvis bilaterally (RR, RL), the greater tubercle bilaterally (FR, FL), and the middle of the back at the level of L4 (S) to define the posterior © and anterior body-segments (B) (Figure 1).

A 6-camera VICON optical capture system (ViconMotion Systems Inc, Lake Forest, CA) recording at 240Hz captured the 3D position of each marker as a function of time. Each marker trajectory was low-passes filtered with a zero lag 6th order butterworth filter. Rodents walked freely in a 4 feet constrained walkway, 1 foot wide and 5 inches high walls. Our kinematic model was implemented in a custom computer program. For the purpose of this report, the model ultimately determined the relative angles between the rear and anterior body-segments assessing flexion/extension, tilting and rotation or spin. The overall velocity of forward progression of the rodent's body was estimated from the marker positioned at L4 on the back.

Construction of each body-segment coordinate system and description of its 3D motion in space has been described previously [5]. To determine
Figure 1: Definition of the rear (C) and front (B) body-segments and coordinate systems. Motion was previously described with respect to the global coordinate system $\hat{I}_1, \hat{I}_2, \hat{I}_3$ representing the posterior-anterior, medial-lateral and vertical directions respectively Relative motion between the two body-segments is described from the joint coordinate system with unit vectors $\hat{e}_1, \hat{e}_2,$ and $\hat{e}_3$.

now the relative motion between (B) and (C), a joint coordinate system was constructed from the two body-segment coordinate systems with unit vectors $\hat{e}_1, \hat{e}_2,$ and $\hat{e}_3$. We selected $\hat{e}_2$ to coincide with the (medio-lateral) coordinate of the front body-segment coordinate system, and $\hat{e}_3$ to coincide with the (vertical) direction of the rear body-segment coordinate system. When the general motion of the two body segments is considered, $\hat{e}_2$ cannot be assumed to be perpendicular to $\hat{e}_3$, and, therefore, the joint coordinate system will not be an orthogonal system. In addition, there will not be a common origin. The third joint coordinate is chosen to be an axis which is mutually perpendicular to both of the other two coordinates:

$$\hat{e}_1 = \frac{\hat{e}_2 \times \hat{e}_3}{|\hat{e}_2 \times \hat{e}_3|}$$

Rotation about the $\hat{e}_2$ axis represents flexion/extension of the body segment; rotation about the $\hat{e}_3$ axis represents rotation in the transverse plane which quantifies the body-segment tilting that is taking place; and rotation about the $\hat{e}_1$ axis represents rotation in the frontal plane which quantifies the amount of spin.

RESULTS AND DISCUSSION

Table 1 demonstrates the results from the implementation of the model and the joint coordinate system to quantify the relative 3D motion between the rear and front body-segments of the rodent. The normal aging rodent walked almost twice as fast as its parkinsonian type counterpart. In the sagittal and transverse planes the motion of the WT rodent was also greater than that of the GDNF[+/-].

These results correlate very well with the current knowledge about the motor deficits of individuals with PD.

CONCLUSIONS

The model we have presented is the first to treat distinctly the rear from the front body-segments. The body-segment coordinate systems along with the joint coordinate system "ride" with the rodent and the angular displacement data are not sequence dependent. Finally, our results appear to be clinically valid.

INTRODUCTION

Peri-implant bone quantity has been measured to determine success of guided bone regeneration (GBR). However, there is a lack of research assessing how bone quality affects the ability of local bone tissues to resist mechanical damages around the implant in function. Thus, the objective of this study was to examine the mechanical properties of bone tissue at different regions of the dental implant system and to compare multiple GBR treatment methods at peri-implant bone defects.
METHODS

Fig. 1. Representative image of the indent locations as regenerated bone, pre-existing bone, and interfacial bone

Following IACUC approval, 38 dental implants were bilaterally placed into buccal dehiscence defects in mandibles of beagle dogs following 3 months of post-extraction healing. The implant systems were randomly assigned to 3 groups of GBR surgeries including: no treatment (control), demineralized bone matrix, and bone morphogenetic protein-2 groups. After 4 and 8 weeks of post-implantation healing, bone-implant constructs were dissected for nanoindentation. Total of 1921 indentations were performed for new bone tissue regenerated in the defects, bone adjacent to the implant, and old bone tissue away from the implant. Plastic hardness (H), elastic modulus (E), and brittleness (E/H) were obtained to assess the fracture resistance of bone tissue. ANOVA was tested ($p < 0.05$).

RESULTS

Averaged values of E, H, and E/H for regions of each implant were not significantly different between new bone tissues in the defect sites and adjacent to the implant ($p > 0.14$). Those of E and H of old tissue region were significantly higher than those of other regions ($p < 0.003$). The regional variation of those values was significant dependent on the tissue age and treatments ($p < 0.043$).

CONCLUSIONS

The less mineralized newly formed bone next to the implant had comparable quality independent of the peri-implant regions, which is different from the more mineralized pre-existing old bone tissue away from the implant. Treatments to stimulate bone regeneration could alter the regional variation of peri-implant bone quality.

INTRODUCTION

Recently, Korea has already become an aging society at the fastest rate in the world and approximately 12.7% of the entire population is 65 and older. As the proportion of the elderly continues to rise, prevalence of femoral fracture of the elderly caused by fall and other accidents is increasing as well. According to National Health Insurance Service, between 1999 and 2003, the number of femoral fracture cases in people aged 50 and older increased by 114% for men and 164% for women. Particularly, even though it is treated, 15% to 20% of patients die within a year. And, even after full recovery, many patients tend to suffer disability.

Generally, surgeons use different types of medical treatment for femoral fracture according to the fracture conditions. For instance, intramedullary nails can be inserted inside bone-marrow cavity for fixation, or a metal plate can be fixed on the bone fracture surface by nails. However, these methods could damage the bones and cause secondary bone fracture, which is fatal to the elderly. Therefore, it is recommendable to use a metal plate suitable for the patient's femur shape, and desirable to fix the metal plate on the bone fracture surface without screws.

In this study, we newly developed a prototype of a femoral fracture fixation plate made of shape memory alloy which has no screws for the fixation of the plate. Also, we fabricated test equipment to measure contact pressure of the plate using the test equipment.

METHODS

Femoral Fracture Fixation Plate made of Shape Memory Alloy

In this study, according to our previous studies on the anthropometrical measurement of Korean femurs using Korean Cadaver CT images, a prototype of a femoral fracture fixation plate made of shape memory alloy was newly developed, which is capable of providing clamping force based on reaction to body temperature (Figure 1). The clamping force can produce contact pressure between the plate and the bone surface.
Figure 1. Prototype of Femoral Fracture Fixation Plate made of Shape Memory Alloy based on Anthropometrical Information on Korean Femurs

Contact Pressure Test Equipment

In this study, we newly fabricated test equipment to measure contact pressure of the plate (Figure 2). The test equipment included a water tank, circulating pump, temperature sensor, and bone clamp, to secure behavior of the plate according to temperature change (cold water temperature to body temperature).

The test was performed using the pressure sensitive paper (MS, Fujifilm, Japan), the composite cylinder (Length: 500mm, Diameter 30mm, Sawbone, USA), the plate, and the test equipment.

Figure 2 Fabrication of Contact Pressure Test Equipment

Procedure of Contact Pressure Test

The procedure of the contact pressure test was as follows. First, the plate was immersed in cold water (4°C ice water) and the open area of the plate was transformed to the outside. A pressure sensitive paper was attached onto the composite cylinder before fixing it inside the test equipment. The tank was filled with hot water and the water temperature was set to human body temperature, 37.5-40°C. Finally, the transformed plate was placed on the composite cylinder with the pressure sensitive paper and completely immersed in the water tank. In this study, contact pressure was measured by repeating this process five times for the plates of 26mm and 28mm in diameter, respectively (Figure 3).
Figure 3 Contact Pressure Test of Femoral Fracture Fixation Plate made of Shape Memory Alloy

RESULTS AND DISCUSSION

In order to quantitatively analyze the measured contact pressure between the plate and the composite cylinder, a software of Pressure Distribution Mapping System (FPD-8010E, Fujifilm, Japan) was utilized. In case of the 26mm-diameter plate (Thickness: 2.4mm), the contact pressure range on the pressure sensitive paper was between 35MPa and 45MPa. Meanwhile, for the 28mm-diameter plate (Thickness: 2.4mm), the contact pressure range was confirmed between 30MPa and 40MPa (Figure 4).
Figure 4 Analysis Results of Contact Pressure on Pressure Sensitive Paper (28mm-diameter Plate)

CONCLUSIONS

In this study, contact pressure test equipment was developed to measure the contact pressure of a prototype of a femoral fracture fixation plate made of shape memory alloy. Based on the acquired results of the contact pressure of the plate, we will plan to conduct the same test using human femur sawbones for the next step. The measurement data of contact pressure are expected to provide important and basic design information for the development of the femoral fracture fixation plates made of shape memory alloy (Figure 5).

ACTIVITIES TO PROMOTE REFLECTIVE LEARNING IN THE BIOMECHANICS CLASSROOM

Laurel Kuxhaus

Clarkson University, Potsdam, NY, USA
email: lkuxhaus@clarkson.edu, web: http://people.clarkson.edu/~lkuxhaus/

INTRODUCTION

The basic premise behind reflective learning is that student reflection on educational experiences informs inform future actions and choices both in and outside of the classroom. For example, reflecting on a difficult homework assignment, a student might conclude that s/he is not well-suited to an engineering career. When asked to consider the challenge of the assignment relative to their motivation for studying engineering, the same student may conclude that engineering is just the challenging career they seek. Encouraging reflection in the classroom coaches students to view their learning experiences from different perspectives and influences their future actions, learning, and careers. Reflection in the engineering classroom is growing. [1, 2]

Given that undergraduate biomechanics course often attract students with diverse mechanics backgrounds, the pace of the technical content is often perceived as 'too fast' or 'too slow' by students in the same classroom.   Reflective activities can help all students to articulate the value of both the technical content and skills learned through the course and help form broad-thinking habits which will be carried throughout these young students' careers.   This abstract presents some ready-to-implement strategies to promote reflective learning in an undergraduate Biomechanics class, intended to be customized as needed.

METHODS

The activities described below have been implemented in six years of teaching biomechanics, and can be used as graded or ungraded activities.

In-class Reflective Writing.
5-10 minutes (can also a take-home activity).
Inspired by "Emergency Assessments" [3], this technique guides students to reflect on their course-related experiences through the 'lens' of their future selves. Students spend a few minutes writing in response to a prompt, such as:
You've applied for a job as a technical consultant for the next Batman movie. They have called you in for an interview. The person doing the hiring says "I see that you have taken a course in Biomechanics. How will a background in that make you a better member of our crew?" What will you reply? (modified from [3])

Journal Club.
Variable time; the author uses 25 minutes per week.
Journal Club helps students locate, read, analyze and discuss current biomechanics research topics. Briefly, students have structured discussions of self-chosen journal articles in groups of 3-4. During in-class discussion time, the instructor(s) spends a few minutes with each group to clarify student questions and offer insights.   To maximize effective discussions, students choose one of the following roles for each discussion (see [4] for more detail):

- Gatherer: Chooses the article, shares it with the group in advance, and summarizes the article prior to discussion.
- Questioner: Brings several questions about the chosen article to the discussion.
- Answerer: Reports answers to the questions after discussion.
- Historian *(groups of 4 only)*: Brings information about the authors and their previous work on the topic to the discussion.

Assessment of students can be performed via the quality and timeliness of preparation posts to Moodle (course management software) and participation during the in-class discussion time. Journal Club encourages students to reflect on the course topics relative to contemporary biomechanics research. Furthermore, students often choose articles pertaining to areas of personal interest (for example, students who have had ACL

replacement may choose read about kinematics following the procedure), [4] and may alter their future behavior based on their reading.

Pyramid Exams
Can be completed in standard exam time.
Pyramid, or Cooperative, Exams [5] demand that students immediately reflect on their exam-taking experience. In essence, students take an exam individually and then immediately retake the exam in a small group setting (2-3 students per group). Scores are computed as a combination of the Individual and Group scores. (The author typically uses the higher of the Individual Exam Score, or 90%*IndividualScore +10%*GroupScore.) Anecdotally, the author observes lively discussions among students during the Group Exam; on course evaluation surveys, students overwhelmingly report that they both like and learn from the Group Exams.

To effectively implement this technique, the author uses frequent short exams to permit completion of both Individual and Group Exams in the allotted time. There is an obvious increase in the number of exams to grade; it is noted that the Group Exams tend to be more accurate than the Individual Exams, minimizing the increase in grading time.

Dedicated Reflective Assignment.
Completed outside of class.
Dedicated assignments may guide students to reflect on their learning experiences. For example, a "Popular Press" assignment encourages students to reflect on the portrayal of scientific results in the media. Students identify a news story published during the current semester which reports the results of a biomechanical study. They must also read the original journal article before writing a 1-2 page discussion of how the results were accurately (or not) portrayed in the media.

Resubmission of Homeworks and Projects
No additional class time.
The author permits students to redo homework assignments at any point in the class to encourage students to reflect on and learn from their mistakes immediately. Redo assignments must include a reflective description of the previous errors or they are returned to the student without review. There is a penalty (-10 points out of 100) for students who delay the submission of a Redo beyond the class period immediately after an assignment is returned, and an additional penalty (-10 points) for delaying the Redo submission beyond the next Exam. In the authors' experience in an undergraduate Statics class, approximately 15% of homework assignments are resubmitted, which requires time to grade. However, like the Pyramid Exams, the additional grading time is minimized because the resubmission assignments tend to be more accurate.

A similar process can be implemented in student projects and reports. For example, consider a student report which analyzes a failed fracture fixation device and describes a possible failure mechanism. The author then requires students' reports to undergo peer review, where fellow students must reflect on the technical content and presentation of their colleagues' work. All students may then reflect on their colleagues' reflections and have the opportunity to revise their own report prior to grading by the instructor.

DISCUSSION
Reflective learning encourages broad thinking skills and deepens the learning experience for students. Simple activities, such as those described above, can encourage reflection both in and outside of the biomechanics classroom. They are generally well-received by students. Future work may assess the pedagogical benefits of these techniques on student outcomes. Furthermore, instructors can also benefit by using the feedback from students in the reflective exercises to inform their own teaching.

VALIDATION OF INERTIAL SENSORS FOR USE IN SHOOTING EVENT DECTION

Lindecker, PR, Higginson, BK
Gonzaga University, Spokane, WA USA
email: plindecker@zagmail.gonzaga.edu

INTRODUCTION
In tactical and competitive shooting it is common for the shooters and coaches to utilize an optical targeting system such as Noptel Sport II shooting training system. These systems can be extremely helpful for training purposes as they are able to measure and display shot data in real time. Some of the variables that are possible to collect are shot times, time on target, stability of hold, and placement of shots on target. One limitation of these systems is the lack of resolution for timing between shots. These measures are provided only in whole seconds. For applications such as rapid-fire events in competitive shooting, and multiple-shot, multiple-target tasks in tactical shooting, a greater resolution is required. Inertial sensors mounted to the weapons platform can be effectively used to quantify this measure with greater resolution, yet it is still unknown whether these inertial sensors can reliably provide other shooting outcome measures such as time on target.

The purpose of this study was to determine if inertial sensors can be reliably used to quantify shooting events, such as time on target, during tactical shooting applications.

METHODS
For this study 8 male novice shooters with little to no shooting experience were recruited to take part in the study. Each shooter participated in three different shooting conditions. In each condition subjects wore tactical body armor. In the first condition, only body armor was worn during the shooting task. In the second condition, a 35 lbs backpack was worn over the body armor. The third condition was the same as the second, only with load stabilizers added to the pack to improve pack contact with the armor system.

Then, using a weight matched airsoft M-4's, each subject completed a tactical shooting scenario in which they engaged three targets, one directly in front of them, one 60 degrees to the right and left of the center target. Shooters engaged the center target and then moved to the second target immediately following an auditory cue, and then engaged the remaining target.

Inertial sensors and the optical targeting system were attached to the rifle. Acceleration data was then collected using an inertial sensor system as well as an optical targeting system. Times between shots and target engagement times were collected using both systems.

RESULTS AND DISCUSSION
There was a moderate level of agreement between the two measurements techniques in detecting time on target (engagement times) during the tactical shooting tasks (ICC=.506, p<0.001) with a slopes approaching unity (β_1=0.770) and intercept values of (β_0=0.258) shown in Figure 1.
Figure 1. Scatterplot of time on target from the optical targeting system (OTS) versus the inertial sensor system (IS).

Given the moderate level of agreement between the optical targeting system and the inertial systems it is concluded that the use of inertial sensors maybe valid instruments for detecting time on target for tactical shooting tasks

CONCLUSIONS
The moderate levels of agreement between optical targeting system and the inertial sensor system indicates that inertial sensors could be used to determining the time subjects spend on the target during tactical shooting tasks. It is believed that the correlation could be improved with the use of trained shooters who are able to settle on target faster and more accurately than the untrained population used in this study.

THE EFFECT OF SKIN MOTION ON DYNAMIC ULTRASOUND OF THE VASTUS LATERALIS

[1,2] David B. Lipps, [1,2] Allison B. Wang, [1,2] Eric J. Perreault and [1,2] Sabrina S. Lee

[2] Rehabilitation Institute of Chicago, Chicago, IL USA
email: dlipps@ricres.org

INTRODUCTION

Muscles generate force and movement through contractions, with resultant length changes occurring at the whole muscle level and fascicle level. Quantifying these length changes provides insight into muscle function and mechanics. Musculoskeletal ultrasound is commonly used to quantify muscle strain and muscle architecture non-invasively and in real-time in healthy and impaired populations during passive and active dynamic movements [1, 2]. The transducer is primarily affixed to the skin such that movements of structures underlying the skin are measured as displacements relative to the skin (Fig. 1). Thus, errors in estimates of muscle displacement occur if there is skin motion. Our objective was to quantify how skin motion alters ultrasound estimates of muscle movement for the vastus lateralis (VL) in a static posture, as well as passive and active sagittal-plane knee flexion and extension.

METHODS

Five subjects (3 M, 2 F; mean±SD age 29±4 yrs, mass 73±13 kg, height 178±4 cm) seated in an adjustable chair were attached to a high-precision rotary motor centered at the knee (Fig. 2).

Figure 1. Illustration of the movement of a trackable muscle feature (+) as both the transducer and underlying muscle move to the right. (a) Ultrasound transducer with corresponding coordinate system. (b) The raw displacement of the muscle feature on the ultrasound video and the 3D movement of the ultrasound transducer can be summed to find the true displacement of the muscle feature.

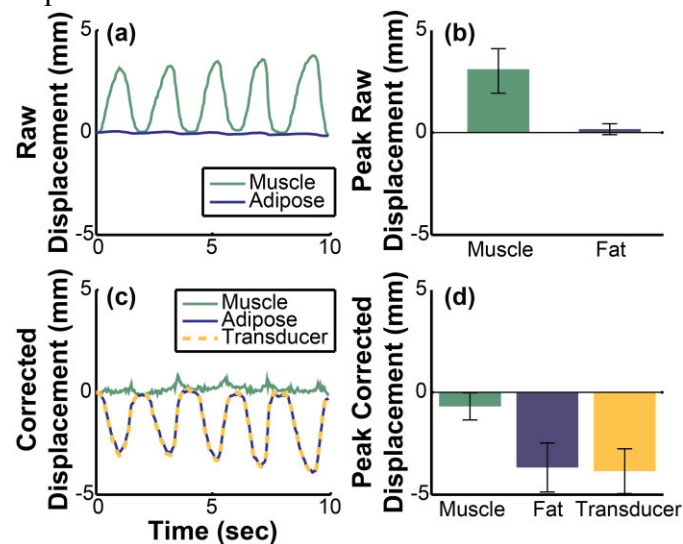
Figure 2. (a) Static condition: Subjects remained stationery as the skin was pulled with tape. (b) Dynamic condition: Subjects were attached to a rotary motor for passive and active movements. Infrared markers recorded the 3-D kinematics of the transducer to correct for skin motion errors.

The effect of skin motion was investigated both statically and dynamically. The static condition investigated the effect of skin motion on ultrasound videos when no underlying muscle movement is present (Fig. 2a). The dynamic condition investigated the effect of skin motion on ultrasound videos as the underlying VL moves (Fig. 2b). Subjects relaxed their VL while the motor flexed and extended the knee (range: 35°–80°) with a constant velocity (40 °/s). Subjects also actively moved their knee through a similar range and velocity to an audible cue. There were 10 movement cycles per subject for each movement condition.

In both conditions, dynamic ultrasound was collected (25 Hz) from the VL using a 49-mm transducer (Supersonic Imagine Aixplorer) aligned to the fascicle plane and secured around the thigh with a custom holder. A custom algorithm estimated local displacements of the VL's mid-belly and superficial adipose tissue on the ultrasound video, ad modum [2]. Movement of the transducer was quantified using infrared markers (Optotrak, 60 Hz). The 2D displacements estimated with ultrasound were transformed to 3D with respect to the transducer's initial position, allowing the observed muscle displacement to be corrected by the amount of transducer translation in the x-direction (Fig. 1). For each testing condition, paired t-tests compared the raw and corrected muscle displacements.

RESULTS AND DISCUSSION

The static condition allowed the effect of skin motion to be studied independent of muscle movement. Skin motion led to errors in the estimation of muscle motion, as the stationary muscle appears to move on the ultrasound videos while the superficial adipose layer was stationary (Fig. 3a,b). By correcting for the 3D kinematics of the ultrasound transducer, the muscle remained stationary (Fig. 3c,d). These results show tracking the adipose layer is not sufficient for assessing skin motion (contrary to [1]). Instead, tracking the 3D kinematics of the transducer is needed to correct for skin motion errors on ultrasound.

The effect of skin motion on ultrasound was further explored as the VL moved during passive and active knee flexion. Passive and active movements produced similar 3D transducer kinematics (Fig. 4a,b). Active displacement of the VL estimated from the ultrasound videos was significantly lower than the muscle displacement corrected for skin motion (p < 0.001) (Fig. 4c,d). No significant difference was found for the passive condition (p = 0.14), as both over- and under-estimation of muscle displacements were observed.


This is the first study to explore the effect of 3D skin deformations on ultrasound measurements; prior work has been limited to isometric conditions [3]. These results have important implications for musculoskeletal ultrasound since inaccurate estimations of muscle displacement will occur if these skin motion errors are not properly corrected. Future work will explore if the observed inter-subject variability was due to differences in adipose tissue and thigh circumference.

CONCLUSIONS

Estimated measures of vastus lateralis muscle displacement using dynamic ultrasound are affected under passive and active conditions by skin motion; these errors are correctable using motion analysis of the ultrasound transducer.

ACKNOWLEDGEMENTS

Figure 3. (a) Exemplar trial and (b) group results showing the raw displacement of adipose layer and VL's mid-belly on the ultrasound video as the skin is pulled above the static muscle. The raw ultrasound video gives the impression that the muscle is moving while the adipose is stationery. The displacements recorded with ultrasound were then corrected for the 3D kinematics of the transducer. (c) The exemplar trial and (d) the group results indicate the muscle was stationary as expected, while the adipose layer moves a similar amount as the transducer.

Figure 4. Mean 3D (a) translation and (b) rotation of the ultrasound transducer during passive and active knee flexion across subjects, relative to the transducer's initial position. Refer to Fig. 1 for coordinate system. The kinematics of the transducer were used to correct the raw displacement of the vastus lateralis from the ultrasound videos. The (c) mean difference and (d) percentage change between the raw and corrected muscle displacements for each subject are shown.

A Vision-Based, Hybrid-Reality, Wire Navigation Simulator

Steven A. Long, Geb W. Thomas, Leah K. Taylor, Colleen E. Rink, Don D. Anderson

[1] The University of Iowa, Iowa City, IA
Email: steven-long@uiowa.edu; web: http://tinyurl.com/UIOBL

INTRODUCTION

Advancements in simulation, particularly for laparoscopic surgery, have moved surgical skill acquisition from the operating room (OR) to safer environments. Orthopaedic surgical skill training, however, has remained largely unchanged for the past century. Orthopaedic residency training still relies on novices first observing expert surgeons performing a task, then attempting the task on a live patient under supervision. This training method is costly because it extends the amount of time in the OR and puts the patient at risk. Wire navigation is an important orthopaedic surgical skill in which the surgeon directs a wire to a target position in a bone, while visualizing the position with a fluoroscope. With approximately 247,000 hip fracture cases each year[1], trochanteric neck fractures often provide an important opportunity for junior residents to develop this skill. The simulator presented here helps residents develop the wire navigation skill in the context of directing a surgical wire (a K-wire) towards the tip of the femoral head, a common first step in performing surgery for a trochanteric neck fracture.

METHODS

The simulator has five main components: a pair of USB web-cams, a plastic foam bone surrogate, a K-wire driver, a laser-etched K-wire, and a laptop computer (Figure 1). The cameras, located above and on either side of the workspace, capture a stereo image pair that is used to determine the position, angle and depth of the wire relative to the bone. The flowchart in Figure 2 illustrates how the data is gathered, processed, and presented back to the user.
Figure 1 – A Display of the simulator. The laptop is not shown here.

The image processing proceeds in three stages: gross edge detection, fine edge detection, and address assessment. The gross edge detection stage finds the wire edges within both images. It relies on the difference between (a) the image including the current wire position and (b) a previously stored image of the empty working space. This difference image isolates the wire. A Canny edge detection algorithm is then applied to a binary version of this image. A Hough algorithm then finds the best-fit position for the edge-enhanced images.

Once the edges of the wire have been found, the original image is then cropped and rotated so that the long edges of the wire are vertical. A horizontal edge detection filter then isolates the etched, horizontal lines. A Hough algorithm marks these lines in the image, which are then represented by a series of points along the center of the wire. In this way, each horizontal line then has one point at its start and one at its end. Once these reference points are located in each stereo image, they are matched across the images. Their corresponding positions in each image are input into a Direct Linear Transform algorithm (DLT). The DLT uses a previously calibrated relationship between the 2D space of the

images with the 3D space of the surrogate bone. The DLT algorithm provides the output of the fine edge detection stage: the wire's axis in 3D space relative to the bone. The only remaining degree of freedom to define is where the tip of the wire sits inside the bone, which is hidden from view.

Figure 2 - A flowchart describing the sequence of algorithms used to generate a virtual fluoro image.

The address assessment stage uses a normalized, cross-correlation algorithm to determine the position of the wire tip within the bone. The algorithm takes the section of wire seen by a camera and compares it to a template of the complete wire address. The location of the markings on the wire, its address, is determined by the position of maximum agreement between the template and visible wire section. This information, coupled with the wire's axis relative to the bone that was determined in the previous stage, is sufficient to calculate the position of the tip within the bone.

The accuracy of the simulator was determined by placing the K-wire at known locations in the workspace and comparing the calculated tip location to the known tip location.

RESULTS AND DISCUSSION

The proposed simulator for this work has been successfully tested with orthopaedic surgical residents at three training institutions. The system displays the virtual fluoro images after a 2 second lag and users indicate that they trust the veracity of the result. As can be seen in Table 1, the accuracy of the simulator in controlled tests varies from approximately 1.66 to 3.03 mm. Occasionally in field tests, obviously wrong position estimates are produced, with errors of several centimeters. We believe these are the result of software errors and a more accurate estimate is generally produced on a second request in the same position. A previously developed simulator reported on by Thomas et al. showed similar accuracy values ranging from 1.5 to 3.6 mm of error[2]. In that simulator, the virtual images were generated through the use of a costly device that generated an electromagnetic field. As the image processing algorithms continue to develop, it is expected that the error and run time of the proposed simulator will only decrease with time. Furthermore, given that the simulated experience depends more on the internal and relative consistency than on absolute consistency, it is unlikely that absolute accuracies greater than 1 mm would have a large impact on training effectiveness.

INTRODUCTION

Abnormal motion patterns between constituent bony elements of a joint have been etiologically linked to arthropathies in general and to the occurrence of back pain, in particular [1]. Current methods of quantification of inter-vertebral motion is associated with exposure to ionizing radiation, and are mostly restricted to two dimensional analysis [2]. The technique reported here is being developed with the long-term goal of using it to detect and quantify complex motion of spine segments. The proposed technique uses (i) a series of images acquired using a dynamic MRI sequence that can scan objects in motion, (ii) a 3D segmentation software to create virtual models of solid body objects, and (iii) an animation software that re-creates and permits quantification of displacements between 3D models in six degrees of freedom of motion.

METHODS

MRI compatible solid-body objects (two, 4 cm cubes of solid wood) were constructed with cylindrically hollowed-out centers. The adjacent edges of two sides of these cubes were marked at 0.5 cm increments so that one cube could be manually translated relative to the other over a range 2 cm on either side of a neutral position (zero displacement between the mid-line of the cubes). Customized 3D models of the solid bodies were segmented using the 3D segmentation software AVIZO (Hillsboro, OR) from transverse scans obtained using a T_1 weighted sequence (TR=810 ms, TE=30 ms) in the neutral position prior to initiating the trials. The solid bodies were placed in a 0.3 Tesla open-MRI (Esaote G-scan Brio, Genoa, Italy) coil after the imaging volume of the coil was calibrated with a custom built calibration grid. A camera-view was created in Autodesk MAYA animation software (San Rafael, CA) using the information from the coil volume calibration. The objects were scanned at different displacements between 0.5 to 2 cm in a random order (n=32 trials; each respective displacement having 8 trials) (Table 1) between the solid bodies, across several scanning sessions on multiple days. A dynamic 2D HYCE S® sequence was used to scan the static displaced positions (slice thickness=7 mm). The series of 2D HYCE S DICOM images of the solid-body objects were then processed in AVIZO and converted into JPEG files. The camera-views were used to import the scanned images and the 3D models of the solid-bodies into MAYA. Next, the virtual 3D models were manually positioned (rotoscoped) [3] to align and fit into the images captured during the trials. The rotoscoping process was assisted by using the margins and hollowed core of the solid bodies as anatomical cues. This process was repeated for all trial image frames. A joint co-ordinate system between the solid-body elements was created using a semi-automated process in MAYA. The animation software quantified the inter-body translation in one plane, as performed in the experiment. The rotoscoping and quantification processes for all images were preformed twice at two different week-long sessions separated by a week. Obtained data from the two sessions (S1 and S2) was analyzed for reliability (correlation coefficient) (Figure 1) and variability (coefficient of variation, CV) (Table 1) by a single observer.

RESULTS AND DISCUSSION

The technique exhibited a high degree of reliability between the measurements from the two sessions (r=0.978; Figure 1), and low variability as observed from the CV's ranging between 5-9% (Table 1). A paired T-test comparing the measurement of each displacement from the two sessions did not show any significant difference (p≥0.21).

Figure 1: Correlation between quantified displacements from two measuring sessions (n=32 for each session).

Our work shows that quantification of solid-body displacements can be achieved with use of the 2D HYCE S® dynamic sequence. Accordingly, the use of the reported technique can be used to quantify motion in dynamically moving elements in human joints. While our observed reliability was very high, it is probable that higher levels of accuracy are obtainable using higher field magnets, using motion control devices that could move solid-bodies through pre-determined displacements with greater precision and/or with the use of improved multi-planar dynamic sequences. The animation software is capable of quantifying 3-dimensional angular and linear displacements, and we are currently exploring modalities of imaging and quantifying multi-planar spine motion using the same technique. Additionally, we are currently investigating the accuracy of this technique.

CONCLUSIONS

Our results provide basic proof-of-concept for a reliable non-ionizing radiation based inter-body motion quantification technique that can be safely used to identify and characterize pathological behavior between elements in bony articulations. This technique can also be applied for biomechanical analysis of complex joint system such as the human spine.

INTRODUCTION

Full 3D motion-capture systems (e.g. Motion Analysis, Vicon) can cost well over $100,000. However, for classroom demonstrations and undergraduate research, a full system may not be needed. If joint angles are desired, electric goniometers can be employed, but are intrusive and also expensive. Furthermore, it is hard to find angles for some joints (e.g. hip) with a goniometer.

We present and validate, via a pilot experiment, a motion capture system and method for planar motion for less than $500 (not including software). The hardware is available off the shelf and the software runs in Matlab. The system was tested while capturing knee and ankle angles of a participant walking on a treadmill. A pilot validation of the method was performed by comparing the angle found with the camera system to that found by an electric goniometer.

METHODS

Six green markers were affixed to locations on the right leg of a participant: proximal and distal medial thigh, proximal and distal medial shank, lateral calcaneus and the base of the fifth metatarsal. For later calibration, the ankle was set perpendicular to the ground and the knee was set to 180° and a still image was captured. The knee and ankle angle found in this image are used as the 0° values.

As a proof of concept, the system was set up to capture knee and ankle angles in the sagittal plane. A participant walked on a treadmill (Quinton TM65, Milwaukee, WI) at a comfortable walking pace of 2 mph for 30 s. The right sagittal plane (See Fig. 1) was filmed with digital video camera (Canon r500) at a high resolution of 1920x1080 at 60 fps.

The first frame of video is used to initialize the program. Here, the six markers are manually identified for their position and color. The program iterates one frame at a time, to identify the marker positions. First, markers are found by color-thresholding the image using previously identified marker color. Next, a *k-means clustering* routine is run on the image to identify the six largest clusters, using the previous image as a starting point for their location. Each cluster is then associated with the appropriate marker by calculating which previous marker it was closest to. All marker centroid coordinates are saved and the data is fed forward to the next frame and repeated through all frames.
Figure 1: Vector overlay of limb segments on typical screenshot of video. A black sheet was placed behind the treadmill to increase contrast.

The pairs of markers on each limb segment are used to calculate a vector describing the limb's direction (see line overlays on Fig. 1). The angle between limbs in then found using the dot product operation. Since the markers are not aligned with the limbs themselves, the angles found in the calibration are subtracted off to find the angle

between limbs rather than the angle between markers.

Gait cycles are automatically identified from the joint angle data. We define the cycle beginning *near* heel strike (specifically when the shank and ankle are 90° after the heel strike). For each stride, the time is normalized to 100% and data is resampled using a cubic-spline interpolation. For each point in the cycle, the mean (μ) and standard deviation (σ) is calculated.

To validate the optical method for finding joint angles, a test was performed to compare the angle found by video to an angle determined by an electric goniometer (Biometrics Ltd, Ladysmith, VA). Four markers and the electric goniometer were affixed to an analog goniometer. Data capture began and the analog goniometer was moved from 70° to 180° in 10° increments. This test was repeated at distances from the camera lens of 70 cm to 370 cm.
Figure 2: Gait cycle created from video analysis on pilot participant. For the ankle angle, positive values indicate dorsiflexion, negative are plantar flexion. For knee angle, negative values indicate extension, positive are flexion.

RESULTS AND DISCUSSION
The original video was overlayed with the identified markers and limb-segment vectors for visual inspection of the automated method. A

typical screenshot is shown in Fig. 1.

The average knee and ankle angles of one participant over 20 strides are shown in Fig. 2. By visual inspection, the data look similar to normative gait data for ankle and knee presented in Kadaba [1].

For the validation test, a typical result – taken from the 250 cm test – is shown in Fig. 3. Using the electric goniometer as the "true" measure, the difference between the measurements was calculated. The standard deviation was at most 0.571°.
Figure 3: Comparison of angle determined by video and by electric goniometer in pilot test (250cm from camera lens)

CONCLUSIONS
The system gives reasonably accurate ($\pm0.58°$) joint angles when compared to data captured from an electric goniometer. Based on this validation pilot, the error is certainly small enough for classroom use and potentially research as well. The joint angles measured for the pilot participant matches reasonably well to published results. Based on these promising early results, the system will be used further for testing on larger participant pools.

Between day reliability of markerless versus traditional marker based motion capture during a stepdown task

[1]Kristin Morgan, [1]Mao Ye, [1]Ruigang Yang and [1]Brian Noehren

[1]University of Kentucky, Lexington, KY, USA

INTRODUCTION

Marker based motion capture analysis enables researchers to measure dynamic motion to assess movement abnormalities. However, this technology is cumbersome to use, requires a large space, is expensive to purchase and requires significant expertise to operate limiting its ability to be translated to a clinical setting or be used in a natural environment (e.g. playing field). Clinicians could benefit from a system that allows them to evaluate changes in joint biomechanics in their office or on the playing field to be able to better tailor rehabilitation programs and assess their outcomes.

Markerless motion capture analysis has the ability to address this need. Markerless motion capture has been shown to measure joint kinematics with similar levels of accuracy as motion capture system [1]. The next step in markerless motion capture analysis is to assess the day-to-day reliability of this system and its post processing algorithm. This is particularly critical to evaluate as clinicians are interested in being able to assess day to day changes due to the patient and not the variability in the system.

Thus this study investigated the day-to-day reliability of the Microsoft Kinect markerless motion capture system [1]. To assess this, we evaluated individuals during a stepdown task over two different days using both the markerless (Kinect) and marker-based systems. The objective of this research was to determine if a markerless motion capture system could measure joint angles with the same level of precision and reliability as the marker based motion capture system.

METHODS

Five participants (4 males, 1 female; height 1.8±0.1m; mass 75.8±10.4kg; age 25.2±2.8yrs) were recruited to perform the study protocol. The study had the participants conduct a series of five single-leg stepdown tasks on a small box three inches high on two different days with a minimum of 24 hours between each session. Twenty-eight reflective markers were placed on the participants' lower extremity to track their movement via the 10-camera motion capture system (Motion Analysis Corp, Santa Rosa, USA) that were sampled at 200Hz [2].

A single Kinect camera was used to record the participants at the same time as the marker based system during the stepdown task [3]. Color images and depth maps were extracted from the Microsoft Kinect image data and an iterative closest point (ICP) algorithm was used to align the initial scan of the participant with the extracted images [4]. Joint angles were obtained from these extracted images using MeshLab [5] and a custom Matlab code (MathWorks Inc., Natick, MA).

Peak joint angles were obtained from the motion capture and Kinect generated waveforms of the hip and knee in the sagittal, frontal and transverse planes. The between day reliability of the motion capture and Kinect measured peak joint angles was assessed using intraclass correlation (ICC).

RESULTS AND DISCUSSION

The between day reliability of both the markerless and marker based techniques was comparable for many of the measurements (Table 1). The Kinect displayed high day-to-day reliability in the sagittal (0.95) and frontal (0.93) plane at the hip (Table 1).

The between day knee and hip ICC values for the Kinect though were lower (0.67 knee 0.53 hip) Lastly, the ICC for the Kinect was 0.53 and 0.49 in the transverse plane for the hip and knee, respectively.

Differences in day-to-day mean peak joint angles for the Kinect were approximately 1° for hip and knee in the sagittal and frontal planes. Furthermore, the Kinect measured peak joint angles that were within 5° of the marker based motion capture system in all three planes for the hip and in the sagittal and frontal planes for the knee. Analysis of the markerless system waveforms showed similar patterns to the marker based system and between the two days (Fig. 1).

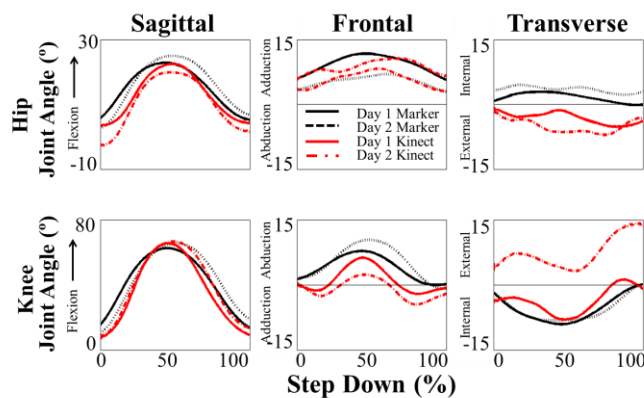

Figure 1. Comparison of the day-to-day hip and knee waveforms between the marker based (red) and markerless (black) systems for one participant. Day 1 waveforms are represented by the solid lines while day 2 waveforms are represented by the dashed lines.

CONCLUSIONS

These findings indicate that the markerless system possesses the day-to-day reliability to assess joint kinematics with similar precision as the marker based system in the sagittal plane. The markerless

system also displayed high reliability in the frontal plane at the hip.

The day-to-day reliability of the markerless system was weaker in the transverse plane at both the hip and knee. Future assessments will include adjusting how anatomical landmarks are denoted on the initial registration of the markerless motion capture system. Additionally, improvements tracking transverse plane motion may be found in using a higher resolution markerless camera.

These results highlight the potential ability of the markerless system as an application in clinical settings to measure and document changes in motion due to rehabilitation. Further we have shown reliability in a task that is common for clinicians to assess when evaluating a patient with lower extremity dysfunction, increasing the systems external validity. Further work is needed though assessing the system during high speed movements and during more complicated tasks that patients commonly engage in such as a side cut run task.

INTRODUCTION

Understanding the three-dimensional (3D) trajectory of ball flight and its relationship to environmental (wind, humidity, temperature) and human factors (kinematics and EMG) is essential to optimizing elite athlete performance. Unfortunately, existing technology is often too expensive ($15,000-$100,000), has limited accuracy, and/or lacks the versatility required to track diverse objects (e.g., soccer ball vs. football vs. baseball). The purpose of this study was to develop and validate an affordable post-processing method that uses computer-vision to track the 3D trajectory of a ball.

METHODS

A golf ball was selected as the initial object for algorithm development. One camera (Panasonic HC-V100, 1080p, 24 Hz), oriented perpendicular to the *x-axis* (Figure 1), produced data relevant to the projectile's motion along the *x* and *z-axis* (longitudinal and vertical position). A second similar camera, oriented parallel to the *x-axis*, produced data relevant to the projectile's motion along the *y-axis* (lateral position). To create a "sight triangle" which was subsequently used to evaluate the projectile's movement in the *y-direction,* a set of calibration lines (40x10 mm) was affixed to the ground 0.762 m apart in the expected direction of projectile motion (*x-axis*) to calibrate the video data in the *x-z plane*. A second equidistant set (in the *x-direction*) was placed 0.305 m apart in the *y-direction* for calibration of the camera directed down the *x-axis*.

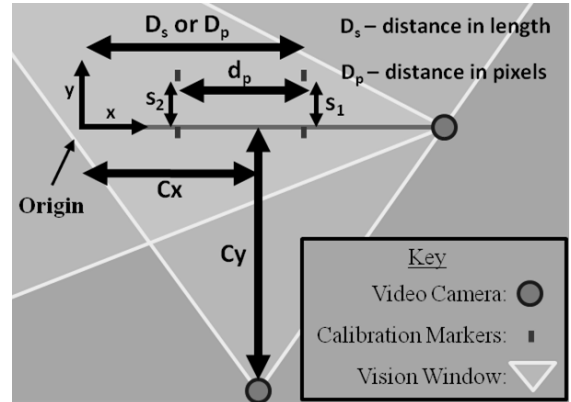
An *uncompensated* 2D motion trajectory of the golf ball's flight was calculated for each camera by measuring position with a pixel to distance ratio (Tracker software) [1]. Data from the two cameras were time-synched through identification of the ball to ground impact.


Figure 1 - Data Collection Set-Up/Explanation of Variables

To accommodate for the distortion arising from out-of-plane motion for each camera, coordinate data were adjusted using the following methodology.

The *y-position* was adjusted using equations 1-3:

$$y_i' = \frac{s_1}{s_1 - y_{c(i)}} * y_i \qquad \{Eq. 1\}$$

$$y_{c(i)} = \frac{\frac{D_p * D_s}{s_1} - x_{p(i)}}{\left(\frac{\frac{d_p * d_s}{s_1}}{s_1 - s_2}\right)} \qquad \{Eq. 2\}$$

$$x_{p(i)} = \frac{D_p}{D_s} * x_i \qquad \{Eq. 3\}$$

where y_i is the uncompensated *y-position*, s_1 and s_2 are the distance between the two calibration markers in pixels from the view of the parallel camera (see Figure 1), $y_{c(i)}$ is the correcting *y-factor,* D_s is the distance from the origin of the reference frame to the furthest set of calibration markers, D_p is the distance D_s in pixels from the view of the parallel camera, x_i is the uncompensated *x-position*, $x_{p(i)}$ is the x_i position in pixels, d_s is the distance between the two sets of calibration markers, d_p is the distance d_s in pixels from the view of the parallel camera, and y_i' is the compensated *y-position*.

Next, y_i' was used to calculate the compensated z and *x-positions*, z_i' and x_i' respectively. These compensated positions were calculated using equations 4 and 5:

$$z_i' = \frac{z_i - h}{C_y} * \left(C_y + y_i'\right) + h \qquad \text{\{Eq. 4\}}$$

$$x_i' = C_x - \left(C_y + y_i'\right) * \frac{C_x - x_i}{C_y} \qquad \text{\{Eq. 5\}}$$

where h was the viewing height of the camera, C_y was the distance from the perpendicular camera to the *x-z plane* (see Figure 1), C_x was the longitudinal distance the perpendicular camera was from the coordinate origin, and z_i is the uncompensated *z-position*.

Algorithm validation was performed using a "*gold standard*" 3D motion analysis system (3 Qualisys Oqus 300 series cameras, 200 Hz, calibration residuals < 1mm). A golf ball (42.67 mm in diameter), covered with retro-reflective tape, was simultaneously tracked during flight through a 3x3x3 m capture volume by the 2D Panasonic cameras and the 3D motion capture technology. Ten repetitions were performed (Table 1).

RESULTS AND DISCUSSION

The *uncompensated* coordinate data resulted in an average percent deviation from the *gold standard* 3D trajectory of 10.37 ± 3.88%. After applying the presented geometrical adjustment technique, the average percent deviation of the *compensated* from the *gold standard* trajectory was reduced to 4.20 ± 1.35%. These findings demonstrate that the compensated technique was over 240% more accurate than the uncompensated approach at golf ball trajectory tracking.

The error presented relates to the average overall error in the system with respect to the distance traveled by the projectile. Calibration markers must be accurately positioned and the cameras needs to be directed to clearly view the *x-z* and *y-z planes* to obtain the most accurate position measurements.

Figure 2 - Example result displaying the *Gold Standard, Uncompensated,* and *Compensated* trajectories. (Trial 05)

The low frame rate (24 Hz) of the 2D cameras used in the current study resulted projectile blurring in a number of frames. In these instances the center of the blurred projectile was approximated and assessed as the data point. Cameras recording at a higher frequency would be expected to reduce the amount of error resulting from video processing and time-based compiling.

In summary, this work developed and validated an affordable (estimated at $400), accurate (<5% average error) technology for tracking 3D ball flight. Current work is aimed at validating range and versatility of use with other projectiles (e.g., a football).

THE EFFECT OF FORCEPLATE DATA ERROR ON JOINT TORQUES DURING RUNNING

[1]Anne Schmitz and [2]Jaclyn Norberg

[1]Gannon University, Erie, PA, USA; email: schmitz005@gannon.edu
[2]Salem State University, Salem, MA, USA; email: Jnorberg@salemstate.edu

INTRODUCTION

Joint torques have been used to elucidate muscle function in injured subjects. For example, people with a reconstructed anterior cruciate ligament have been shown to exhibit a decreased knee extensor moment, which has been interpreted as avoidance of the quadriceps muscles [1]. Errors in these torque calculations can arise from many sources: segmental parameters, marker movement, ground reaction force data, and joint center location [2]. These errors can range from 6-232% of the torque magnitude where the proximal joints are more adversely affected than distal joints [2]. Although the effects of these errors on joint torques are well documented, walking has been the focus [2-8].

Running has gained much interest over the last decade as a form of exercise. This has also led to a large prevalence of running injuries as up to 70% of runners get an overuse injury [9]. Therefore, the evaluation of joint torques during running has gained much clinical interest to investigate the causes of these injuries. For example, patellofemoral pain patients have been shown to exhibit a decreased peak knee extensor moment but greater hamstring co-activation during running when compared to healthy controls, which may result in greater patellofemoral contact forces and pain [10]. Although [11] have shown that sagittal plane hip, knee, and ankle torques can vary by 7-14% during running due to errors in the center of pressure measurement, it is unclear how non-sagittal angles are affected. Since forceplate data has been shown to have the largest effect on joint torques [6], the purpose of this study was to determine how errors in force and center of pressure measurements propagate to three-dimensional hip, knee, and ankle joint torques during running.

METHODS

One subject (mass 53.2 kg, height 1.63 m, age 31 years) ran across a runway at 4.35 m/s. Data was collected from two Bertec forceplates sampling at 1000 Hz while trajectories of 61 retroreflective markers were also collected at 200 Hz using an 11 camera MotionAnalysis system.

A Monte Carlo analysis was performed using sixty simulations with Visual 3D (C-motion, Germantown, MD, USA) as the dynamics engine. In each simulation, the forceplate data was first perturbed by adding an offset of $0 \pm 1N$ to each direction of the ground reaction force (GRF) data and 0 ± 3.5 mm to each direction of the center of pressure (COP) data [12]. The perturbation levels were chosen at random, assuming a normal distribution. Next, the marker trajectories were filtered at 10 Hz and perturbed forceplate data at 26 Hz using a lowpass, zero-lag, fourth order Butterworth filter. The cutoff frequencies were determined from a residual analysis of the data [13]. Then, joint torques of the hip, knee, and ankle were calculated. The distal segment was referenced to the proximal segment and the torque resolved into the proximal segment coordinate system. Joint torques were also calculated for the unperturbed data.

Custom Matlab code (MathWorksInc., Natick, MA) was used to extract joint torques during the stance phase of running, where stance was defined as when the vertical GRF was greater than 10 N. Next, the peak joint torques were calculated as: maximum transverse plane hip torque, maximum knee torque in all planes, maximum non-sagittal ankle torques, minimum non-transverse hip plane torques, and minimum sagittal plane ankle torque. Then, the maximum differences between the peak torques calculated from the perturbed simulations and the unperturbed original data were calculated. Pearson's product moment correlation coefficients were also calculated to quantify the relationship between each perturbed variable and the peak joint torques. The correlations provide an estimate of Sobol indices [14] and thus a way to rank the effects of each

variable on peak joint torque (i.e. greater correlation means greater sensitivity to that variable). To justify the use of Pearson's coefficients, the normality of the peak joint torques was verified using the Lilliefors test.

RESULTS AND DISCUSSION
During walking, joint torque uncertainty has been shown to be larger for proximal joints compared to the distal joints [2]. Our results show this also extends to running. The maximum error induced by forceplate error was 4.8 (4%), 3.6 (3%), and 0.9 (3%) Nm for the sagittal, frontal, and transverse plane peak hip torques, respectively. These errors decreased at the knee, which were 2.5 (2%), 1.7 (7%), and 0.1 (1%) Nm for the sagittal, frontal, and transverse plane. These errors decreased even further at the ankle with errors of 0.5 (<1%), 0.4 (1%), and 0.1 (2%) Nm for the sagittal, frontal, and transverse plane. This may occur due to the bottom-up approach used to calculate joint torques. For example, the ankle torque is calculated using a free body diagram of the foot. Then, this ankle torque is applied to the distal end of the tibia and used in conjunction with the tibia's mass and kinematics to calculate the torque at the proximal end (i.e. knee joint torque). Hence, this may lead to the propagation of torque errors from distal to proximal joints.

Errors in joint torques were due more to inaccuracies in the GRF magnitude than the COP measurements (Table 1), which agrees with a previous sensitivity study of torques during walking

[6]. The torque the GRF produces about any joint can be calculated as GRF magnitude times its moment arm about the joint center. It is likely that joint torques were more sensitive to GRF magnitude than location because the GRF magnitude is much greater than the moment arm value, thus dominating this term.

CONCLUSIONS
Forceplate errors had a larger effect on proximal joint torques than on the distal joints, with torque errors ranging from 0.1 – 4.8 Nm (<1%-4%). Therefore, forceplate accuracy may be an important aspect to report in studies investigating more subtle torque differences (<4%) between clinical populations. The main contributors to torque error were inaccuracies in the GRF magnitudes, as opposed to the location of the center of pressure.

INTRODUCTION

Many biomechanics researchers aim to move out of the lab and quantitatively evaluate function in natural environments for a variety of movements. While many focus on this goal for humans, techniques may initially be developed for mice because they use numerous behaviors, and small variations in movement reflect differences in functional capability. Also, mice are used as experimental models to identify mechanistic targets for treating persons with neuromuscular disorders; therefore, distinguishing the continuum of pathological movement patterns from normal would advance the understanding of locomotion control and enable development of more effective treatments for human disability.

Spinal cord injury (SCI) in mice produces variable patterns of disability similar to humans, and resulting motor deficits are well characterized [1]. Animals of all functional ability are evaluated using the Basso Mouse Scale (BMS), a 10-point semi-quantitative, observation-based, locomotor rating scale [1]. The BMS is limited to visually detectable behaviors during a 4-min trial. For animals capable of stepping, marker-based motion capture has been used to assess limb kinematics and motor function following SCI. Limitations to this approach include accuracy due to skin movement artifact [2], and the biological relevance of straight line, steady-state locomotion to unconstrained movements [3].

This research aims to automatically classify motor function in rodents with SCI using markerless motion tracking data. This approach would address many limitations in current methods used to characterize rodent motor function.

METHODS

Markerless tracking methods were used to reconstruct each mouse 3D volume throughout a 2-min trial [4]. Animals moved freely in a 2' diameter environment while 10 synchronized cameras recorded at 100 Hz. Every animal's 3D shape was reconstructed with and without a tail from each set of 10 video images using background subtraction and shape-from-silhouette techniques (Fig. 1) [4].

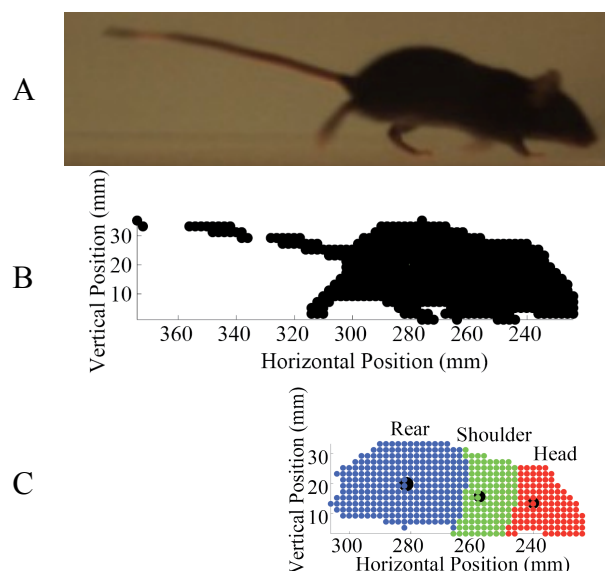

Figure 1: (A) Video frame, (B) 3D reconstructed mouse volume, (C) Volume with tail removed, then divided into 3 segments. Black dots are CoV positions.

Thirty-two animals with a wide spectrum of motor capabilities were tested 1-3 times each throughout recovery following SCI. Sixty trials were used to develop the two-step motor function classification algorithm consisting of movement segmentation and parameter identification. The algorithm's predictive capability was evaluated using the BMS.

First, center of volume (CoV) position and speed were used to segment the continuous 2-min trials into periods containing five different movements: directed and exploratory locomotion, meandering, standing, and rearing [4]. Directed locomotion was defined as CoV displacement faster than 60mm/s, and longer than 200mm. Animals must have directed locomotion and standing to be classified.

Next, parameters describing CoV positions of three segments roughly representing the head, shoulders, and rear were calculated by dividing the mouse volume into 3 clusters (Fig. 1). The animal was divided into equal front and rear clusters at the CoV mean, perpendicular to the volume's first principle component. A head and shoulder were segmented at the center of the front cluster, perpendicular to the same first principle component. Median, minimum, maximum, 25% and 75% percentile values were calculated to describe an animal during directed locomotion and standing. The 160 parameters included: CoV speed (10), locomotion path straightness (10), three eigenvalues of the volume PCA (30), absolute and relative CoV height of each segment (60), distance between each segment CoV (30), and body straightness defined as angles between vectors connecting the three CoV (20).

A stepwise linear regression was performed to identify parameters best predicting the BMS score. A post hoc analysis ensured that linear modeling assumptions were satisfied and that the model did not contain parameters with multicolinearity.

RESULTS AND DISCUSSION

A model with 4 parameters from directed locomotion, and 1 from standing predicted the BMS score with an r^2=0.89 (Fig. 2). Errors in the predicted BMS score have a slight bias toward overestimating the lower functioning animals, and underestimating higher ones. Parameters included:
- directed locomotion – straightness of path, median
- directed locomotion – head height, 25th percentile
- directed locomotion – rear height, 75th percentile
- directed locomotion – height difference between the shoulder and rear, 25th percentile
- standing – body straightness in the animal's sagittal plane, 75th percentile

These parameters indicate that mice with varying motor capabilities had different movement patterns and distinct body positions during directed locomotion and standing. The higher functioning animals had straighter locomotion paths, lower head CoV positions, higher rear CoV positions, and the shoulder CoV height was lower than the rear CoV. Also, when standing higher functioning animals had a larger back arch than lower functioning animals (i.e. the head is lifted upward).

Figure 2: Measured and predicted BMS scores

CONCLUSIONS

The method and classification parameters identified here represent a fundamental shift in behavioral and kinematic analysis of animal locomotion. The increased precision, sensitivity, and repeatability address many limitations of current research methods, while including continuous data and more behaviors when classifying function. This 2-step framework could also be applied to human functional assessments in order to include a wider variety of unconstrained movements.

INTRODUCTION

Recent advances in multi-photon laser scanning microscopy allow for the three-dimensional (3D) imaging of live cells embedded in native tissue. When coupled with controlled mechanical testing systems, the multiscale problem of how mechanics are transferred between the tissue and cellular scales can be investigated [1]. This is accomplished by comparing the geometry of cells in a state in which the tissue boundaries are unloaded to the geometry of cells in some loaded tissue state. The nature of this load transfer is crucial to understanding the mechanical environment of cells, and their biological response resulting from mechanical stimuli.

Analysis of these 3D image data is challenging in both the image segmentation and characterization of the deformation. Historically, image segmentation has been performed using simple threshold-based methods [2]; however, these often fail when objects are in close proximity. To characterize the deformation, objects were typically approximated as ellipsoids and changes in the ellipsoid axes lengths were taken to reflect strains. This approach has two major drawbacks: 1) it cannot distinguish rigid body rotation from shear strain, and 2) it degrades as the object's true shape diverges from ellipsoidal. To address these limitations, new software was developed that provides robust image segmentation and more complete deformation analysis.

METHODS

Custom software for 3D image segmentation and kinematics (deformation) analysis, pyCellAnalyst, was developed in Python employing the Insight and Visualization Toolkits (Kitware Inc.) An array of image segmentation strategies are implemented in pyCellAnalyst including thresholding (statistics-,

entropy-, and intensity-based) and active contour models. Likewise, numerous smoothing/denoising filters are also provided. This extensive functionality allows for segmentation of images acquired with different modalities where the object of interest can appear in either the foreground or the background. Cells in close proximity can typically be resolved as single objects with the proper selection of tool(s). A support vectors machine algorithm is provided as a fallback measure for resolving clustered objects.

Three methods are included for kinematics analysis.

1) The traditional ellipsoidal approximation measures can still be acquired allowing users to compare with past analyses. This ellipsoidal approximation is calculated from the reconstructed object's principal moments of inertia.

2) In addition to this, the complete deformation gradient can also be calculated using an iterative closest point algorithm included in *VTK* and the reconstructed objects in reference and deformed frames. The complete Green-Lagrange strain tensor is then calculated from this deformation gradient.

3) Finally, a non-uniform deformable image registration can be performed using a diffeomorphic demons registration algorithm provided in *ITK* [3]. This returns the displacement field that maps the reference state object to the deformed state object. Additionally, a finite element mesh is automatically generated with TETGEN and the displacement fields are interpolated to the surface nodes of this mesh to serve as boundary conditions for a finite element analysis of the cellular deformation. All necessary information for such an analysis is

saved in a Python *pickle* binary file. A utility to perform a finite element simulation employing this information to do finite element analysis in the open-source software, FEBio, is provided.

The software can be imported into any Python script as a module, and its functionality can be applied as needed. Additionally, a graphical user interface (GUI) has been developed to ease usage (Figure 1).

RESULTS AND DISCUSSION

The software exhibited robust segmentation performance for datasets acquired with different modalities (second harmonic generation, confocal, and dual photon fluorescence). Furthermore, it was capable of reconstructing cells in very close proximity. The novel tools for deformation analysis showed good performance in verification/validation studies. The iterative closest point algorithm was able to calculate strains for objects with known large deformations and rotations with little error. Likewise, the deformable image registration calculated correct displacement fields for image pairs of known deformation.

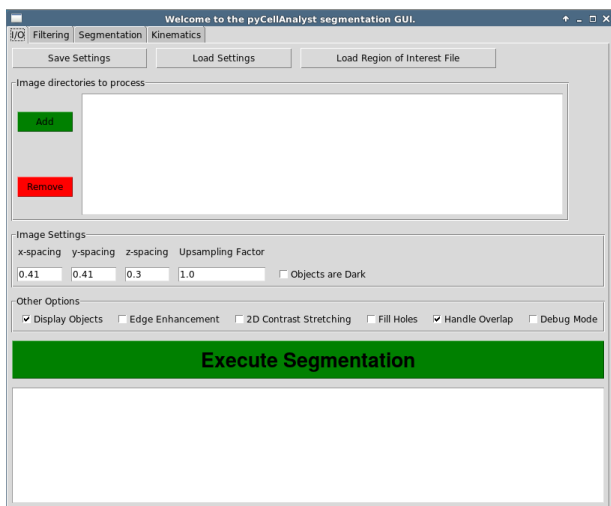

Figure 1: The graphical user interface utility for pyCellAnalyst. Note the four tabs to present all tools in an organized, easy-to-follow manner.

CONCLUSIONS

pyCellAnalyst supplies the user with powerful tools for 3D image segmentation and kinematics analysis.

It is capable of resolving cells in close proximity into individual objects, allowing users to consider most cells in the field of view rather than simply the ideal, isolated ones. For kinematics analysis, it can return the traditional ellipsoidal approximation based measures used in many studies, but additionally offers the ability to calculate the complete Green-Lagrange strain tensor assuming uniformity across the cell. Furthermore, by employing the deformable image registration tools the user can also calculate the non-uniform displacement field that best maps the cell between reference and deformed states. This information can be used to drive finite element models, providing a powerful avenue for analysis of the complete stress-strain state of the cell (Figure 2). A utility to do this with the popular open-source finite element software, FEBio, is included.

Figure 2: An example of a finite element analysis driven by the displacement field calculated by deformable image registration.

The software are open-source and freely available at github.com/siboles/pyCellAnalyst, distributed under the MIT license.

UPPER EXTREMITY INJURIES IN LOW-SPEED MOTOR VEHICLE ACCIDENTS WITHOUT AIR BAG DEPLOYMENT

[1,3] Kevin K. Toosi and [2,3] Pamela A. Chrissis

[1] The University of Pittsburgh, Pittsburgh, PA, USA
[2] Carnegie Mellon University, Pittsburgh, PA, USA
[3] Pittsburgh Biomechanics, LLC, Pittsburgh, PA, USA
email: kktoosi@pghbiomechanics.com, web: www.pghbiomechanics.com

INTRODUCTION

Research studies have demonstrated an increased risk of upper extremity injuries due the deployment of air bags, including fracture of the radius and ulna [1-3]. According to the National Automotive Sampling System (NASS), only 5.33% of injuries affecting the upper limbs result from low-speed vehicle impacts without air bag deployment [4]. While the upper extremity injuries are not commonly seen in low-speed collisions, forensic biomechanical engineers are frequently tasked to evaluate injuries involving upper limbs, such as rotator cuff pathologies, tear of the glenoid labrum, and carpal tunnel syndrome, that have been claimed as a result of low-speed motor vehicle accidents. The purpose of this study was to examine the real-world vehicle collisions, in order to have a better understanding of whether those claimed injuries could be attributed to the accident.

METHODS

Data were obtained from the NASS database [4] using the following criteria: vehicle body type (automobile), vehicle air bag deployment (not deployed), and occupant body region (upper limbs). This investigation resulted in 3192 automobile accidents, which all occurred over the time period from 2004 until 2011, with a higher concentration of reports found between 2004 and 2008. Only 170 applicable cases were matched the definition of low-speed impacts, i.e., vehicle barrier speed of less than 20 miles per hour (mph). From these specifications, various variables were selected for further analysis; these categories included number of vehicles, occupant injured, type of injury, and cause of injury.

RESULTS AND DISCUSSION

In the 170 cases observed, it was found that the impacts occurred by a single vehicle itself, the collision of two vehicles, or the collision of three vehicles. In the case of single vehicle accidents, 30 cases of the total were involved or approximately 17.8%. There were 117 cases, or 68.8%, of the total that occurred with a collision of two low speed vehicles. Finally, it was observed that 23 cases involved the collisions of three vehicles that amounted to 13.6% of the total number of cases observed. Following this classification of the cases, further analysis into the vehicle occupants' injuries took place. It was observed that out of all 170 cases, there were a total of 189 instances of injuries affecting the vehicle drivers, the vehicle passengers, or both. A total of 74 vehicle 1 drivers reported injury, which was 39.2% of the 189 instances occurring with primary vehicle drivers. Along with drivers, there were 29 instances, 15.3%, of primary vehicle passenger injuries reported in the database. There were reports of 62 secondary vehicle drivers injured, amounting to 32.8% of the total instances; additionally, 19 secondary vehicle passengers reported upper extremity injuries, which was 10.0%. Lastly, in the 23 cases involving three vehicles, 5 drivers of the tertiary vehicles reported injuries, 2.6%, and there were no reports of any passengers in the third vehicle being injured. From these observations, it appears that the majority of upper extremity injuries are incurred by those drivers of primary and secondary vehicles followed by those passengers in the primary vehicle.

Amongst the various injured occupants, several different areas throughout the upper extremities. The following categories were used to classify the

injuries reported in the cases: carpal-metacarpal joint sprain, finger fracture, wrist joint sprain, wrist joint fracture, radius fracture, elbow joint sprain, shoulder joint sprain, upper extremity muscle laceration, upper extremity muscle sprain, upper extremity skin abrasion, upper extremity skin contusion, upper extremity skin laceration, and upper extremity 2nd or 3rd degree burn. The most prominent injury resulting from a low speed vehicle collision was an upper extremity skin contusion with 104 instances from the 170 cases, or 61.18%. The next three highest injuries were upper extremity skin laceration with 23 instances (13.5%), upper extremity skin abrasion with 17 instances (10.0%), and shoulder joint sprain with 14 instances (8.2%). The remaining upper extremity injuries all occurred with a frequency of 3 instances of less: upper extremity muscle strain with 3 instances (1.76%), carpal-metacarpal joint sprain and wrist joint sprain each with 2 instances (1.18%), and finger fracture, wrist fracture, radius fracture, elbow joint sprain, upper extremity muscle laceration, and upper extremity 2nd or 3rd degree burn each with 1 instance (0.59%) throughout the applicable cases. Although many types of upper extremity injuries occur in low speed collisions, it appears that it is much more likely for certain injuries to occur, i.e. upper extremity skin contusions, lacerations, abrasions, and muscle joint sprains.

The above injuries resulted from several sources either inside of the vehicle itself or occasionally outside of it. The top cause of injury amongst the 170 cases observed was the seat belt webbing and/or buckle; 61 cases were reported equating to 35.9% of the total. The steering wheel rim was the second highest cause of injury in vehicle occupants with 20 instances or 11.8%. There were 13 instances, 7.65%, of a left side interior surface, excluding hardware or armrest, causing upper extremity injuries amongst occupants. These three injury types were the top categories observed throughout the data; the remaining injuries occurred with fewer than 10 instances. Either flying glass or the left B-pillar was the cause of injury in 9 instances each, contributing to 5.29% of the total. Closely following with 8 instances, the seat and/or back support caused injuries in 0.71% of the cases. The remaining sources contributed upper extremity

injuries in 5 or less observed instances: Steering wheel (combination of codes 004 and 005) with 5 instances (2.94%), right instrument panel and right-side interior surface excluding armrest and hardware each were found to cause 4 injuries (2.35%), the first row center console, left instrument panel and below, left rear upper quadrant, right instrument panel and below, and windshield each contributed to 3 instances (1.76%) of injuries, the left A(A1/A2)-pillar, left instrument panel, right rear upper quadrant, roof or convertible top, ground, other occupants, or other objects amounted to 2 instances each (1.18%), and lastly add on equipment, child safety seat, fire in vehicle, left armrest/hardware in forward upper quadrant, left armrest/hardware in rear upper quadrant, right B-pillar, right lower instrument panel, and steering wheel hub/spoke with 1 instance (0.59%) each. It can be noted that many of the left side injuries were mainly inflicted on the driver while most of the right side injuries occurred in passengers. Also, all steering wheel injuries resulted in injuries to the drivers of the vehicles.

CONCLUSIONS

The results of this study demonstrate that only 2.94% of the upper limb injuries occurring in low-speed motor vehicle collisions without air bag deployment were of moderate level while the rest were reported as minor upper extremity injuries; none of the observed injuries were categorized as major injuries. Therefore, it can be concluded that injuries such as acute traumatic tear of the rotator cuff, tear of the glenoid labrum, and acute carpal tunnel syndrome cannot be reasonably attributed to the low-speed vehicle accidents.

PRE-SHOT JITTER DURING SELF-PACED FIRING USING SMALL ARMS WEAPON SYSTEMS

Courtney A. Webster, Frank Morelli, Jennifer M. Neugebauer

U.S. Army Research Laboratory, Human Research and Engineering Directorate
Dismounted Warrior Branch
Aberdeen Proving Ground, MD, USA
Email: courtney.a.webster2.ctr@mail.mil

INTRODUCTION

Marksmanship is an essential skill for military personnel, and is a complex task that combines postural control, static load bearing, and fine motor control. Although training and practice can improve shooting performance, even expert marksmen exhibit subtle motion when acquiring or dwelling on a target. These small fluctuations in weapon aim can result in large shot errors and missed targets. Here, we use the term "jitter" to describe these fluctuations which may result from a number of factors including postural instability[1], physiological muscle tremor[2] and natural oscillations of the extended arms[3,4].

Another potential contributor to jitter may be the anticipation of recoil energy sustained from a particular weapon system. Recoil describes the backward momentum of a weapon following trigger pull. Factors influencing recoil include ammunition charge quantity, burn rate, weapon size and weight, and muzzle device design. Anticipatory perception of (and response to) recoil likely depends on shooting experience, individual differences in musculature, and tolerances for pressure and pain.

The U.S. Army Research Laboratory (ARL) has a vested interest in understanding all aspects of shooting performance in order to design technologies, interventions, or training regimens to optimize Soldier marksmanship. Human and weapon dynamics, recoil forces and accelerations, and shooting performance were quantified during militarily-relevant firing scenarios using three weapon conditions. Here, we report on pre-shot jitter during self-paced, single shots as recorded by tri-axial activity monitors. Jitter measures were analyzed to determine: 1) whether muzzle device affects jitter and its correlation to shooting accuracy within each weapon condition, and 2) whether jitter differs for weapons of different calibers.

METHODS

Eight (8) male service members were recruited to participate in a marksmanship performance study conducted at the U.S. Army Marksmanship Unit (USAMU) Pool International Range Complex at Fort Benning in Columbus, GA. Subjects included volunteers from the U.S. Army 3rd Infantry Division and U.S. Army and Air Force Special Operations Forces. Four subjects (Q group) had completed a specialized training course qualifying them for the role of squad designated marksman (SDM) while the remaining four had not yet completed the course (NQ group). This distinction in shooting experience was used as a factor in the statistical analyses.

Subjects were instrumented with tri-axial wireless activity monitors (AM; Model GT3X+ ActiGraph Corp., Pensacola, FL) on segments of the shooting and support arms. Two additional AMs were secured to the buttstock and barrel of the weapon. Subjects fired each of three weapon conditions (listed from smallest to largest recoil): a standard M4 carbine firing 5.56 mm rounds (C556), an M4 carbine retrofitted to fire 6.8 mm rounds (C68), and a compact M110 rifle variant which fired 7.62 mm NATO rounds (C762). The C556 and C68 systems were fired with each of three muzzle device conditions including the standard-issue A2 "birdcage" flash hider (BC), a muzzle brake (MB; SureFire LLC, Fountain Valley, CA), and the muzzle brake with a suppressor adapter (SUP). Operationally, the C762 weapon is not typically fired without either a muzzle brake or a suppressor. Therefore, the C762 condition was fired with only the MB and SUP muzzle conditions. Targets were presented at a range of 50 m. Subjects fired 7

practice rounds with each system followed by 10 rounds at a self-selected pace, during which accelerations and shot accuracy were recorded.

Periods of pre-shot jitter were identified manually through visual inspection of the acceleration profiles. Jitter measures included mean resultant acceleration, the peak deviation from this mean (Peak), the difference between maximal and minimal acceleration magnitude (Range), the time-on-target, and the correlation of Range to shot accuracy. Pre-shot jitter measures from the barrel-mounted AM are presented here. Acceleration values are in units of gravity (g). To evaluate weapon or muzzle device effects, ANOVA analyses were conducted on linear mixed models which included experience (NQ, Q) and either condition (C556, C68, C762) or muzzle device (BC, MB, SUP) as fixed factors with a random effect of subject. Level of significance was set to 0.05.

RESULTS AND DISCUSSION

Between Muzzle Device Conditions - The data set was first blocked by weapon condition to analyze the effect of muzzle device when using a specific weapon system. Analyses revealed a significant interaction effect of muzzle device and experience for the C68 condition for Peak (X^2 (2, N = 236) = 12.73, $p < 0.002$) and Range (X^2 (2, N = 236) = 19.18, $p < 0.0001$) measures. Specifically, within the NQ group, the MB resulted in lower Peak and Range scores (0.041 ± 0.016 g and 0.074 ± 0.029 g, respectively) than either the BC or SUP options. Peak and Range scores were greater with the BC (0.058 ± 0.028 g and 0.100 ± 0.043 g) than with the SUP (0.051 ± 0.020 g and 0.089 ± 0.034 g).

Between Weapon Conditions - A second analysis was performed using the data set blocked by muzzle device condition which allowed us to examine differences between weapon conditions when the same muzzle device was used. Significant main and/or interaction effects were observed for the Range measure within each device option (Figure 1). Generally, Range measures varied between weapon conditions for the NQ group. Only for the SUP condition did the Q group exhibit differences in Range between weapons (C556 and C762).

Figure 1. Jitter Range measures for each group, weapon, and muzzle device condition. Symbols denote statistically significant differences: * = $p < 0.0001$; † = $p < 0.001$; ‡ = $0.01 < p < 0.04$.

CONCLUSIONS

The Range jitter measure provides an estimate of the magnitude of postural correction during weapon aiming. Larger Range measures indicate poorer weapon stability. Results suggest that weapon type may affect jitter magnitude during aiming, and that the effect is more pronounced for those with less shooting experience. Additional analyses will investigate jitter from the body-mounted AMs and the relationship between these jitter magnitudes and shooting accuracy.

INTRODUCTION

Extraocular muscles (EOMs) enlargement affects the biomechanics of eye movement and is a key factor of several orbital diseases [1]. Identification of EOM enlargement is important for clinical diagnosis and treatment, however, accurate and efficient quantification of EOM anatomy is challenge. We present a fully automatic method to segment and reconstruct 3D model of the EOMs. We design a novel algorithm which uses superpixels (i.e. clusters of pixels) as the basic units for segmentation. After obtaining the segmented EOM boundaries, we reconstruct 3D models of the EOMs. Our proposed method on automatically reconstructing patient-specific EOM models can be applied in clinical diagnosis and surgical planning.

METHODS

A few existing algorithms provided computer-assisted semi-automatic [2, 3, 4] methods to segment EOM boundaries, which are more efficient than manual segmentation. All of these approaches apply segmentation on discrete image pixels, which may not be the most natural representation of visual scenes. We suggest it would be more natural and efficient to process the EOM image with perceptually meaningful image patches that contains many pixels sharing similar image features. We represent local structures by using small patches obtained from superpixel over-segmentation [5] as the basic primitives for subsequent image processing. Each superpixel groups nearby pixels into one which have similar intensities and are more likely to belong to the same structure. Figure 1(b) illustrates the superpixels of the MR image in Figure 1(a). The orbital wall and the rectus muscles were manually outlined, each of which includes several superpixels. The number of superpixels in one image obtained affects the accuracy and computational efficiency of the following segmentation procedure. The number of superpixels was optimized to be 1800 based on applying model selection theory on several training image sets, which is used as a fixed constant during later segmentation.

(a)   (b)

Figure 1: (a) MR Image of EOM; (b) Superpixel of MRI image in Fig. 1(a) with manually outlined structure boundaries.

We then constructed a region adjacency graph (RAG) for each image based on the neighborhood relationship among superpixels. Each superpixel was defined as a node in the RAG. Each node was connected to all its neighbor nodes through edges. The weight w_{ij} of the edge connecting two nodes n_i and n_j is defined as:

$$w_{ij} = \exp(\frac{-\left\|I_i - I_j\right\|^2}{\sigma^2})$$

We applied the normalized cuts algorithm to the constructed RAG to partition the graph into two similar subgraphs. Then for each of the two parts, it recursively carries out the same procedure (Figure 2(a)) until all the labels were classified (Figure 2(b)). Applying the superpixel based normalized cut other than pixel level method is more accurate since the edge's weight between regions is larger than that between pixels. Moreover, the size of the

affinity matrix and the complexity of the RAG for image representation are significantly reduced, which makes the approach computationally more efficient.

(a)   (b)

Figure 2: (a) RAG segmetnation through normalized cut; (b) Labeled segmentation resutls after recursive segmentation using normalized cuts.

The Laplacian of Gaussian filter and the label connected component methods were then applied to determine the connected contours of the orbital wall (Figure 3(a)), EOMs and the optical never. The center of each contour was calculated. By using k-nearest algorithm (k=2), regions of the optical nerve and the orbital wall can be identified from the contours in image center. The orbital region was automatically extracted using convex hull with shape prior knowledge and defined as region of interest (ROI) (Figure 3(b)). By doing this, the EOMs with incomplete boundaries (lateral and medial rectus muscles in this example) can be segmented correctly from the background (Figure 3(c)). Finally, image region and hole filling algorithms were used to complete the EOM segmentation (Figure 3(c)). Once we have the segmented boundaries, we reconstructed the 3D extraocular muscle models using standard approaches, such as template based fitting [4].

RESULTS AND DISCUSSION

We applied our proposed method to two sets of orbital T2-weighted MR images of both eyes acquired from two normal subjects. All images used were digitized with 256×256 pixels and 16 bits gray-level of resolution at voxel size of 0.3 mm×0.3mm×2.0mm. We evaluated accuracy of our approach using the Boundary-based Directional Cut Discrepancy method by measuring the mean

distance between our segmentation with manual segmentation. The average error was 2.75±1.93 (mm). We plan to segment more data sets and perform more quantitative evaluation.

INVESTIGATING THE MECHANISM OF NEONATAL BRACHIAL PLEXUS PALSY USING BIOMECHANICAL TESTING

INTRODUCTION

Despite considerable research and improvements in obstetrical care, permanent Neonatal Brachial Plexus Palsy (NBPP) continues to occur in 1.1-2.2 out of 10,000 births and remains a regular challenge for the affected families and treating physicians [1]. The brachial plexus (BP) is a network of nerves that originate in the neck and run through the shoulder to the arm [2]. Stretching of the BP or avulsion of the roots can occur during birth when the infant's shoulder impacts with the bony pelvis of the mother due to maternal (endogenous) forces as well as clinician-applied (exogenous) forces [2,3]. The effects of these forces on the BP are directly related to: magnitude, loading rate, surrounding tissue properties, and how the applied force is transmitted to the BP. Since *in vivo* measurements of the endogenous and exogenous forces, fetal shoulder deformation, and the response of the BP are difficult to assess during delivery, computational and physical models are used to simulate these events. However, a complete lack of biomechanical properties and data on the neonate BP limits the correct assessment of the risk of injury using these models. Thus, the goal of this study is to determine the biomechanical properties of the BP using a neonatal porcine model (piglets).

MATERIALS AND METHODS

Twenty fresh neonatal (3-5 days old) piglet BP cord segments were harvested and immediately preserved in 1% BSA (bovine serum albumin) until testing. A digital microscope was used to obtain images of harvested BP segments before stretch (5X; Digital Microscope, Elmwood Park, NJ). A 2mm scale (Leitz,Ernst-Leitz-Wetzlar GmbH, Germany) at the same magnification measured the segment diameter.

The BP segments were divided into two groups based on tensile loading rate. Group A (n=10) specimens were subjected to a stretch rate of 0.01 mm/s (quasistatic) and those in Group B (n=10) were subjected to a stretch rate of 10 mm/s (dynamic). Maximum stress, strain, and modulus of elasticity were calculated from the obtained load-displacement data during tensile testing. An ADMET material testing machine (eXpert 7600, ADMET Inc., Norwood, MA) was used to stretch the nerve (Fig. 1). Each BP segment was anchored by specially designed and fabricated clamps (Fig. 1). The design of the clamp allows for clamping of each segment firmly between the padded plexiglass and flat surface of the cylinder. The padded side facing the segment helped minimize the stress concentration at the clamping site [4,5,6]. The two clamps were initially set at a distance of 10-20 mm (depending on the initial length of the BP segment) and the segments were clamped with no initial tension prior to stretch. Stretch rates were controlled by built-in GuageSafe software (ADMET Inc., Norwood, MA). The actuator was triggered, which stretched the BP segments at their assigned rates (0.01 mm/s or 10 mm/s) until complete failure. During this test, the load and displacement data was acquired at a sampling rate of 25 Hz for quasistatic and 1000 Hz for dynamic stretch rates. After completion of the experiment, the failure site was recorded and the clamps were checked for the presence of BP tissue. No tissue in the clamps implied that the tissue had completely slipped, and the results of those experiments were disregarded. Load data and the cross sectional area was used to calculate nominal stress. Displacement data was used to calculate the tensile strain that results from the applied tension. The load-displacement and stress-strain curves were plotted and the maximum and failure load, maximum and failure stress, strain at the point of maximum

failure and stress, and modulus of elasticity (the slope of the stress-strain curve after toe region and below the proportional limit, E) were determined.

**Figure 1**: Biomechanical Testing Machine and Clamps

Figure 3: Preliminary Testing of BP Cord Segment at 0.01 mm/sec

Table 1: Mechanical Data of BP Segments

Rate	Failure Stress (MPa)	E (MPa)
Quasistatic (0.01 mm/sec)	11.7	48.5
Dynamic (10 mm/sec)	18.8	108.2

RESULTS

Stress at the proportional limit and apparent elastic modulus were used as indicators of strength, elasticity, and stiffness. Nerve rupture typically occurred immediately after reaching the proportional limit as shown in Fig. 3. Table 1 contains experimental data for brachial plexus segments tested at both quasistatic and dynamic rates. The average values for the modulus of elasticity are greater for the dynamic rate data than the quasistatic rate data.

CONCLUSION

At a quasistatic strain rate, a lower modulus of elasticity and failure stress was observed and a higher stress and modulus of elasticity was observed at the dynamic rate. This is because the nerve tissue acts in a viscoelastic manner and becomes stiffer at a faster strain rate. Overall, the experimental data provides an accurate approximation to the biomechanical properties of the BP nerve tissue. The dynamics and quasistatic rates are good representations of the various forces acting on the infant during birth. The quasistatic rate could represent the maternal forces of the mother pushing during labor. The dynamic rate could represent sudden impact of the infant's shoulder with the mother's pelvis or a sudden clinician-applied force. The data obtained from studying the BP nerve at these two rates helps to better understand the biomechanical properties of the BP and assess the associated injury mechanisms associated with NBPP. This information can be used to develop a biofidelic computational model that accurately illustrates the predisposing risk factors for BP injury.
