INTRODUCTION

Crouch is a common gait abnormality in cerebral palsy that is characterized by excessive knee flexion during stance. Distal femoral extension osteotomy (DFEO) and patellar tendon advancement (PTA) procedures [1] are promising approaches to treat impairments underlying crouch. DFEO compensates for knee flexion contractures by creating an extension deformity of the distal femur. PTA corrects knee extensor insufficiency and tightens the quadriceps by advancing the patellar tendon (PT) insertion distally on the tibia. The combined procedures improve knee kinematics during gait more than traditional techniques or either procedure in isolation [2]. However, the degree of improvement remains variable and the procedures have not been standardized across institutions. Further, it is uncertain if additional procedures (e.g. hamstring lengthening) should be performed simultaneously. To address these issues, we are using dynamic musculoskeletal models to assess how surgical decisions made in DFEO and PTA procedures influence knee mechanics, muscle lengths, and articular cartilage loading in gait.

Figure 1: Model with 12 DOF knee joint.

METHODS

Knee Model: We constructed a multi-body knee model with 6 DOF tibiofemoral and patellofemoral joints [3] (Fig. 1). This model was created using bony and cartilage geometries and ligament attachment sites obtained from MR images of a healthy adult female (61 kg, 1.65 m). The knee was incorporated into a lower extremity musculoskeletal model with 43 muscle-tendons acting about the hip, knee, and ankle [4]. This new construct was shown to accurately reproduce passive and active *in vivo* knee kinematics, as measured by dynamic MRI [3].

DFEO Surgical Simulation: The knee model was modified to include a 30º knee flexion contracture. The reference strain of the posterior capsule ligaments was set to restrict knee extension to 30º when a 5 Nm extension torque was applied. A DFEO was then virtually performed by removing an anterior wedge of the distal femur geometry. The distal fragment was rotated to close the gap (Fig. 2), and translated to maintain the knee axis in the same anterior-posterior (AP) location [1]. A passive forward simulation was then run to determine the new resting knee posture. This process was repeated for a series of wedge apex locations. For each apex, we characterized the change in femur length, and medial hamstrings and vastii lengths.
Figure 2: A) Creation of the DFEO wedge. Sensitivity analyses were conducted by moving the wedge apex in the AP and superior-inferior directions. B) Altered orientation of distal femur after removal of 30º anterior wedge from A, and after forward simulation.

PTA Surgical Simulation: PTA was simulated by varying the patellar tendon length such that the reference patellar position varied between 3 cm superior (alta) and 2 cm inferior (baja) to nominal. For each patellar position, we simulated the knee mechanics through a normal gait cycle. To do this, an enhanced static optimization method was used to simultaneously predict muscle and ligament forces, secondary knee kinematics, and cartilage contact pressure necessary to generate normal gait kinematics. Maximum quadriceps and PT forces during stance and mean patellar contact pressures in stance were compared between conditions.

RESULTS

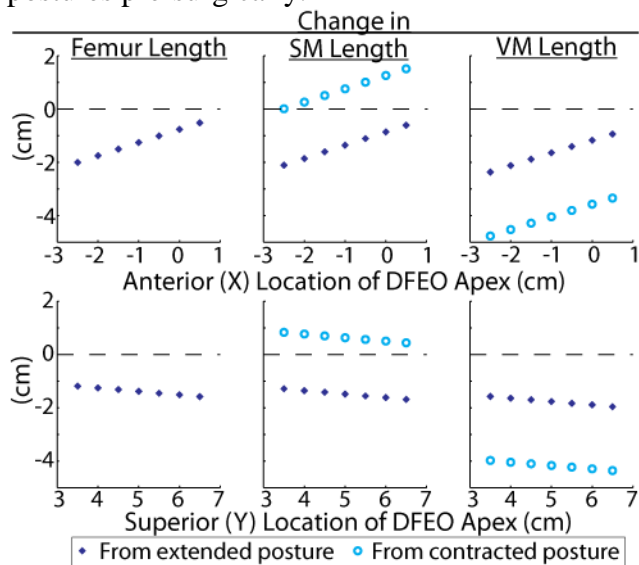
DFEO Surgical Simulation: Varying the AP location of the apex of the DFEO wedge had a larger effect on femur and muscle lengths than varying the superior-inferior position (Fig. 3). Varying the apex AP location by 1 cm led to a 0.45 cm change in femur length. The osteotomy tended to increase semimembranosus (SM) lengths compared to their state in a contracted posture, though they were shorter than lengths that would occur in a fully extended knee. Vastus medialis (VM) lengths were substantially reduced compared to that seen in both contracted and extended postures pre-surgically.


Figure 3: Change in femur, SM, and VM lengths between the original model and the model with DFEO performed. Muscle lengths are referenced to the model in an extended posture and with a 30º knee flexion contracture. Nominal Y location for the DFEO wedge was 4 cm, and X location was -1 cm (Fig 2).

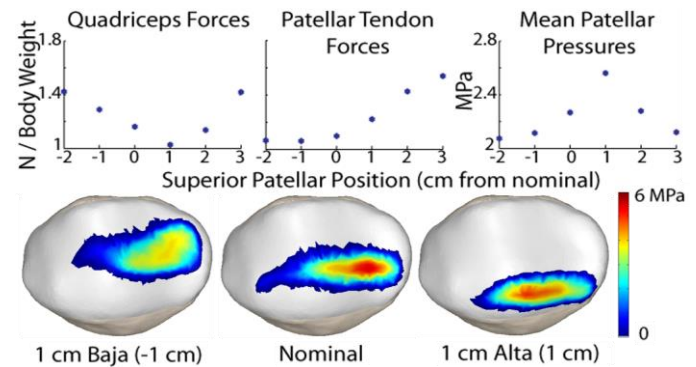
PTA Surgical Simulation: Varying the patellar position substantially altered the quadriceps and PT forces and patellar pressures during walking (Fig. 4). A small amount of alta required the lowest quadriceps forces needed during gait, but induced larger PT forces and mean patellar contact pressures. Alta also migrated the patella contact to the inferior edge of the patella. The patella baja positions had a tendency to increase quadriceps force needed during walking, and drive contact to the superior edge of the patellar facets.


Figure 4: Maximum quadriceps (sum of all components) and PT forces during stance and mean patellar pressure at the maximum stance phase knee flexion angle. Negative numbers on the x-axes represent baja, whereas positive numbers represent alta. Patellar pressure distributions are shown below.

CONCLUSIONS

Our DFEO simulations suggest that the procedure has the potential to induce substantial shortening of the femur and quadriceps, with the greatest effect occurring when a cuneiform wedge of bone is removed (i.e. –X apex locations). In contrast, the hamstrings are most lengthened when the apex is near the posterior edge of the bone (X=0.05 cm), and a triangular wedge is removed. The latter observation is a concern surgically where there is a concern of introducing increased tension in the posterior compartment structures. The PTA simulations demonstrate that advancing the patella alters both the knee extensor mechanism, and cartilage loading. PTA procedures are often performed in a way that induces patella baja, which the model suggests may induce higher quadriceps load and superior patellar pressure if upright gait is achieved post-surgically. The greater quadriceps loading seems to result from a diminished effective moment arm of the extensor mechanism with baja. We conclude that the insights gained through this type of study can enhance the understanding and planning of complex surgeries used to treat crouch.

ACHILLES TENDON DEFORMATIONS AND THE AGE-RELATED REDUCTION IN PLANTARFLEXOR PERFORMANCE DURING WALKING

Jason R. Franz[1,2] and Darryl G. Thelen[1]

INTRODUCTION

Plantarflexor performance (i.e., net ankle joint kinetics) during the push-off phase of walking decreases precipitously in old age [1-2]. Although potentially important, few studies of walking have investigated the role of age-related changes in the behavior of the Achilles tendon (AT) [3]. The free AT governs the transmission of gastrocnemius and soleus muscle forces, and consists of distinct bundles of tendon fascicles arising from each of these muscles: superficial fascicles arise from the medial gastrocnemius and deep fascicles arise from the soleus [4]. We recently proposed that sliding between AT fascicle bundles may facilitate relatively independent gastrocnemius and soleus muscle fiber behavior, and thus muscle-tendon coordination tuned for effective force or power generation in walking [5]. Aging may reduce the capacity for sliding between tendon fascicle bundles [6], thereby potentially contributing to diminished plantarflexor performance commonly observed in old adults.

We coupled dynamic ultrasound imaging, quantitative motion capture, and inverse dynamic analyses to investigate age-related changes in free AT deformations *in vivo* during walking and their relation to plantarflexor mechanical performance. We first hypothesized that superficial-deep variations in free AT deformations would be smaller in old than young adults. Second, we hypothesized that these more uniform AT deformations in old adults would be accompanied by proportional reductions in net ankle joint kinetics compared to young adults.

METHODS

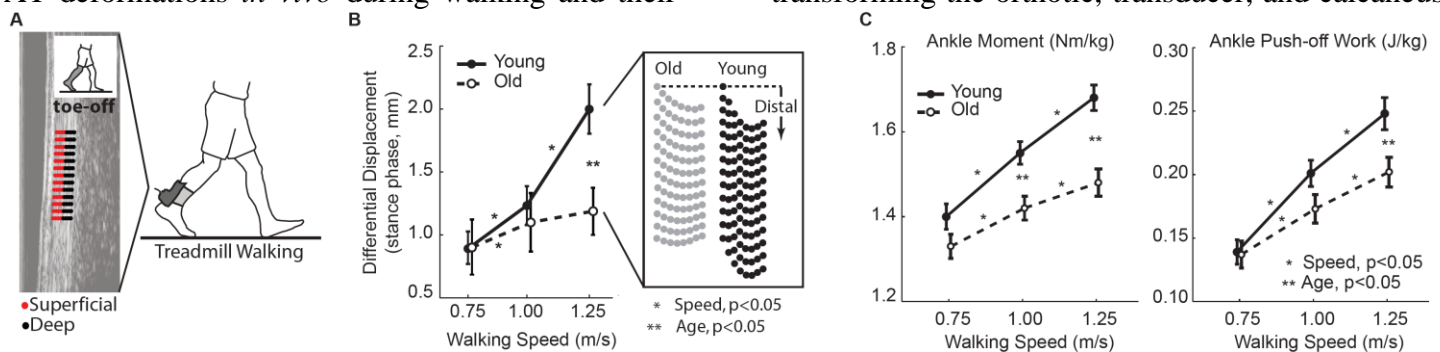
9 healthy young (mean age, 23.9 years) and 8 healthy old (69.9 years) adults walked at three speeds (0.75, 1.00, and 1.25 m/s) on a force-sensing treadmill. Subjects completed one 2 min walking trial at each speed in random order. A linear array transducer secured via a custom orthotic recorded ultrasound radiofrequency data from the free AT approximately 6 cm superior to the calcaneal insertion (Fig. 1A). A custom 2D speckle tracking algorithm [5] tracked superficial and deep tissue displacements within the free AT. We used motion capture to record lower extremity kinematics and the position and orientation of the ultrasound transducer. We estimated superficial and deep AT elongation (i.e., change in length) relative to the calcaneal insertion by transforming the orthotic, transducer, and calcaneus


Figure 1. (A) We tracked superficial and deep tissue displacements within the free AT using a 2D speckle tracking algorithm. (B) Group mean (SE) differential (i.e., deep-superficial) free AT displacements and representative deformations. (C) Group mean (SE) peak ankle moment and positive ankle work during push-off.

kinematics into a common reference frame. Finally, we calculated peak ankle moment and power, and positive ankle work performed during push-off via inverse dynamics. A repeated measures ANOVA tested for significant main effects of and interactions between age and speed on each outcome measure. We also computed bivariate correlations between tendon deformations and net ankle joint kinetics.

RESULTS AND DISCUSSION

We observed significant depth-dependent variations in free AT deformations, wherein the superficial tendon displaced significantly less and elongated significantly more during stance than the deep tendon at all speeds for both old and young adults. The difference in displacements and elongations between superficial and deep AT regions did not differ between old and young adults at the slower two walking speeds (p's>0.63) (Fig. 2). However, a significant age × speed interaction revealed that only young adults exhibited a progressive increase in relative motion between the superficial and deep AT with faster walking speed (p<0.01). Consequently, depth-dependent variations in free AT deformations were 41% smaller in old vs. young adults at 1.25 m/s (p=0.01) (Fig 1B). Compared to young adults, old adults averaged 8% and 12% smaller peak ankle moments at 1.00 m/s (p<0.01) and 1.25 m/s (p<0.01), and performed 19% less positive ankle push-off work at 1.25 m/s (p=0.02) (age × speed, p<0.01) (Fig. 1C). More uniform tendon deformations in old adults most strongly predicted reduced peak ankle moment ($R^2 = 0.40$), but also significant correlated with reduced peak power generation ($R^2 = 0.15$) and positive ankle work during push-off ($R^2 = 0.19$) (p's<0.01) (Fig. 2).

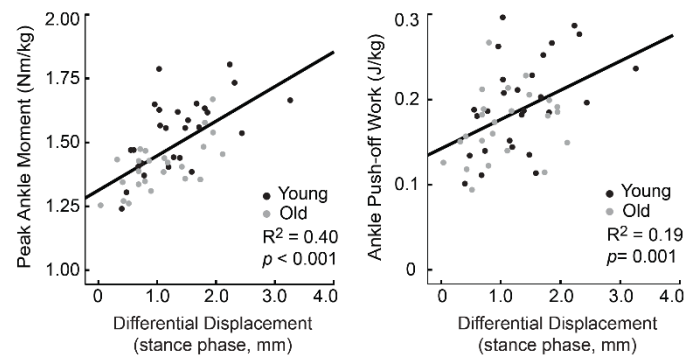
One interpretation of our findings is that a reduced capacity for sliding in old tendons [6] may act to couple gastrocnemius and soleus muscle-tendon behavior, thereby reducing net plantarflexor performance. This coupling would be undesirable for at least two reasons. First, the triceps surae muscles perform different biomechanical functions during walking, with the prevailing opinion that the gastrocnemius contributes more to forward propulsion and the soleus to vertical support. Thus, a loss of independent actuation of the gastrocnemius


Figure 2. Bivariate correlations between free AT differential (i.e., deep-superficial) displacements and peak ankle moment and positive work during push-off for all subjects and walking speeds.

and soleus muscles may reduce old adults' ability to optimally modulate relative levels of propulsion and support during push-off. Second, the gastrocnemius and soleus muscles exhibit markedly different muscle fiber kinematics during walking [7] which may be facilitated by differences in tendon elasticity. A reduced capacity for sliding in old tendons may alter series elasticity and thus muscle fiber operating lengths and muscle-tendon mechanical output.

CONCLUSIONS

Advanced age brings more uniform free AT deformations that predict reduced plantarflexor performance in old adults during the push-off phase of walking. Together, our findings: 1) demonstrate a potential role for non-uniform AT deformations in governing gastrocnemius and soleus muscle-tendon function, and 2) allude to altered tendon behavior that may contribute to the age-related reduction in plantarflexor performance during walking.

INTRODUCTION

Despite regaining joint stability, patients who undergo ACL-reconstructive (ACL-r) surgery often exhibit radiographic signs of osteoarthritis (OA) within 10 years [1]. It is theorized that abnormal knee mechanics may persist after ACL-r, leading to altered tissue loading that initiates cartilage degeneration [2]. However, it remains challenging to test this theory as morphological changes with OA are often not detectable for many years.

In the early stages of OA, there are changes in the cartilage composition, such as the degradation of collagen and proteoglycan and an increase of water content. Quantitative MR imaging of T2 relaxation time has been used to indirectly assess these compositional changes, though the traditional T2 relaxation parameter is nonspecific and influenced by multiple factors [3]. More recently, multi-component driven equilibrium single shot observation of T1 and T2, termed mcDESPOT, has been introduced to distinguish the contributions of the fast relaxing T2 signal, which is correlated with water tightly bound to proteoglycan, and the slow relaxing T2 signal assigned to the bulk water [4]. Thus, quantitative MR imaging is an attractive modality to identify early signs of cartilage degeneration following ACL-r before the onset of cartilage volume loss and radiographic OA.

In this abstract, we describe our use of static, dynamic and quantitative MR imaging to investigate links between altered mechanics and early cartilage degeneration in reconstructed knees. We hypothesize that ACL-r knees exhibit normal morphology but abnormal cartilage contact patterns after surgery. We also show initial evidence that links spatial locations of abnormal contact and quantitative MR measures of cartilage degeneration.

METHODS

Eight subjects with a primary unilateral, isolated ACL-reconstruction (4 F, 25.8 ± 4.9 yrs, 86.3 ± 18.2 kg, 2.3 ± 0.6 yrs since surgery, 5 patellar tendon grafts, 3 hamstrings grafts, 1 partial lateral meniscectomy) and nine healthy controls (2F, 22.7 ± 3.1 yrs, 79.3 ± 8.9 kg) were tested after obtaining informed consent according to an IRB-approved protocol. Control subjects had no history of knee pain, injury or surgery and no history of inflammatory or crystalline induced arthritis.

Subjects underwent a bilateral static MR protocol consisting of a fat-suppressed 3D SPGR sequence (0.37x0.37x0.90 mm resolution) and a 3D FSE Cube sequence (0.31 mm isotropic resolution). Distal femur, and proximal tibia bone geometries were segmented from the SPGR images. Articular cartilage surfaces were segmented from the FSE Cube images. Cartilage thickness maps of the tibia plateau were generated by determining the distance from the articular cartilage surface to bone surface.

Dynamic MR imaging was used to measure knee kinematics and cartilage contact during an active flexion-extension task. Subjects were positioned supine with their lower leg secured on a MR-compatible loading device. Cyclic knee flexion and extension was performed at 0.5 Hz for 5 min while SPGR-VIPR images were continuously collected [5]. Model-based tracking was used to determine femoral and tibial bone position and orientation at each frame of the motion cycle. Regions of cartilage contact were assessed by computing the proximity between tibia and femoral cartilage surfaces, with negative proximity indicative of contact. Contact maps were generated by determining the closest proximity of each tibial cartilage mesh face through the motion cycle.

A mcDESPOT sequence (0.6x0.6x3.0 mm resolution) was performed unilaterally on the reconstructed knee of the subjects and a healthy knee of the controls. Fraction maps for the fast relaxing water component (F_{pg}) were calculated as the ratio of water bound to proteoglycan to the total amount of water in a voxel.

Bounding boxes surrounding the medial and lateral plateaus were subdivided into 20 regions of interest (ROIs). Average contact and cartilage thickness were computed for each ROI. A one-way ANOVA tested the effect of surgery on thickness and contact between the ACL-r knees and the control subject knees. A repeated measures ANOVA was used to compare the ACL-r knees and their contralateral knees. If a significant difference was found ($p<0.05$), a post-hoc Tukey test was performed to identify the location of group differences ($p<0.05$). A correction was made for an uneven N between ACL-r and control subjects.

RESULTS AND DISCUSSION

As hypothesized, there were no significant differences in ACL-r tibial cartilage thickness when compared to the contralateral knee or control knees. However, cartilage contact patterns in the reconstructed knees were significantly different (Fig. 1). In particular, ACL-r knees exhibited greater contact in the posteromedial aspect of the medial plateau and the posterior aspect of the lateral plateau. Initial evaluations of the F_{pg} maps also

reveals potential evidence of reduced proteoglycan content in similar regions of the ACL-r tibia plateaus (Fig. 1).

To our knowledge, this is the first study to show that abnormal tibiofemoral cartilage contact patterns can be detected in reconstructed knees with dynamic MRI. Prior studies using biplanar fluoroscopy have identified altered contact during gait [6], suggesting that the changes seen in the simpler flexion-extension task may be representative of functional tasks. The absence of changes in cartilage thickness in this population is consistent with prior studies suggesting that long time periods are needed to detect changes in cartilage morphology following ACL-r [7]. However, it is notable that quantitative MR does detect potential evidence of altered cartilage composition within 1-2 years of reconstruction [3]. Further study is needed to see if the decline in fraction of rapidly relaxing water component is consistently evident in reconstructed knees and is associated with cartilage loss over time.

ASSESSMENT OF THE CONTRIBUTIONS OF ELASTIC ENERGY IN THE HUMAN PLANTAR APONEUROSIS

Justin C. Wager and John H. Challis

Biomechanics Lab, The Pennsylvania State University, University Park, PA, USA
email: jcw296@psu.edu

INTRODUCTION

The arch of the human foot has received considerable attention for its potential to store and release elastic energy (EE) and possibly influence the metabolic cost of running [1]. While *in situ* testing has demonstrated that the spring-like function of the arch exists under simple loading conditions, it remains unclear whether this function exists during the more complex task of human locomotion. The aim of this study was to investigate one of the main elastic tissues in the arch (the plantar aponeurosis; PA) to examine its ability to store EE and contribute to the movement of the foot. A second aim was to investigate the influence of the initial foot contact pattern (IFCP) on the function of the PA during the stance phase of running.

METHODS

A 10 degree of freedom rigid body model of the human lower leg and foot was created that consisted of five segments (tibia, calcaneus, talus, midfoot, combined toes). A non-linear spring (tuned to match *in situ* data [2]) connecting the calcaneus to the great toe was added to represent the PA. This model was then scaled to match the anthropometry of eight men and women and driven using kinematics of running barefoot at 3.1 m/s under two IFCP conditions: rearfoot initial contact (RF; foot strike angle, mean $\pm$ SD: 12.3 $\pm$ 2.7°) and non-rearfoot initial contact (NRF; foot strike angle: -1.4 $\pm$ 4.0°). PA strain was computed using the length of the PA during stance. Initial and peak strains were used to determine the average strain rate from foot contact to peak PA strain. The joint moments were determined using inverse dynamics. To investigate the contribution of the PA to the movement of the foot, the joint moments arising from the PA force were calculated using the PA moment arms over the course of the stance phase. PA joint power (P_{PA}) at the talonavicular (TN) joint and metatarsophalangeal (MTP) joint was determined from the PA moments and the joint angular velocities; positive PA joint work (W_{PA}) was computed as the time integral of P_{PA}. EE_{PA} stored was calculated as the integral of the spring's non-linear force-strain relation. PA strain rate as well as peak measures of strain, force, P_{PA} and EE_{PA} were compared between the conditions using paired t-tests ($\alpha = 0.05$).

RESULTS AND DISCUSSION

Average strain rate of the PA from foot contact to peak strain was significantly higher in the NRF condition compared with the RF condition. This is due to both a lower initial strain ($p < 0.001$) as well as less time to peak strain ($p < 0.001$) in the NRF condition. Peak values of PA strain, force, EE_{PA}, P_{PA}, and W_{PA} were not significantly different between conditions (Table 1). The temporal profiles of PA strain for the two conditions illustrate both the increased strain rate in early stance as well as the lack of differences at peak strain and beyond (Figure 1).

Table 1: Means ($\pm$ standard deviation) of peak values for the IFCP conditions. Subscript PA-TN denotes PA joint power or work at the TN joint.

	RF	NRF	*p*
PA strain	0.062 $\pm$ 0.013	0.063 $\pm$ 0.014	0.09
PA strain rate (s^{-1})	0.18 $\pm$ 0.05	0.31 $\pm$ 0.06	<0.001
PA force (BW)	1.22 $\pm$ 0.44	1.20 $\pm$ 0.41	0.07
EE_{PA} (J)	3.0 $\pm$ 1.5	3.1 $\pm$ 1.7	0.07
P_{PA-TN} (W·kg^{-1})	1.56 $\pm$ 0.87	1.54 $\pm$ 0.88	0.70
W_{PA-TN} (J·kg^{-1})	0.10 $\pm$ 0.05	0.09 $\pm$ 0.05	0.31
Figure 2: Group means for PA strain for the NRF (dashed red) and RF (solid blue) conditions. Shaded regions are ± 1 S.D.

As no significant differences were found from peak strain to toe-off, the two conditions were collapsed into one data set to examine the function of the PA during pushoff. Peak PA strain (0.063 ± 0.013 at $58.8 \pm 3.7\%$ of stance) was slightly higher than and occurred slightly earlier than peak PA strain during walking [3]. Peak PA force (1.21 ± 0.43 BW) was also slightly higher than that found during *in situ* simulations of walking [2]. Peak EE stored in the PA (3.1 ± 1.6 J) was similar to the decrease in EE storage obtained upon sectioning of the PA during simple loading of cadaveric specimens [1].

The contributions of the PA to foot dynamics were the largest at the talonavicular (TN) joint. Of the peak TN joint moment, the PA accounted for $19.4 \pm 11.0\%$ (23.1 ± 5.1 N·m). In addition, the PA produced power at the TN joint (peak: 1.54 ± 0.88 W·kg^{-1} at 77% of stance) and performed positive work at the TN joint from 55% of stance to toe-off (Figure 2). However, the magnitudes of the joint power and joint work are small compared to power and work at other joints during running [4].

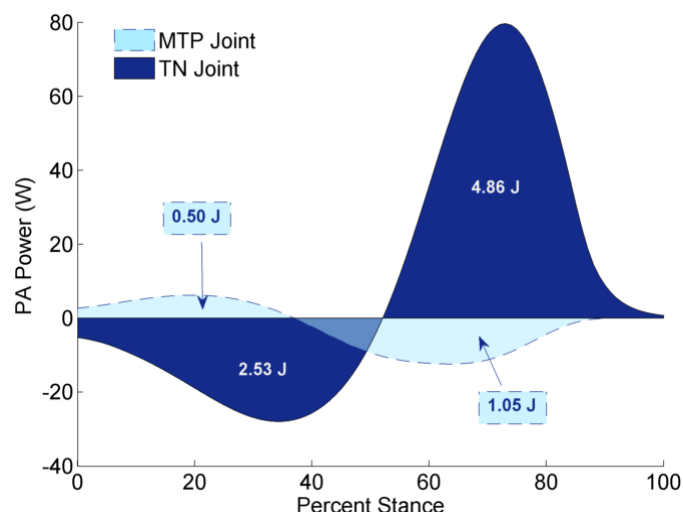
At the MTP joint, the PA accounted for $18.8 \pm 14.8\%$ (1.3 ± 0.7 N·m) of the peak joint moment. PA joint power at the MTP joint followed a pattern of power generation early in stance before power absorption from 37% of stance to toe-off, which is consistent with the pattern of MTP joint power previously found during running [5].


Figure 1: Mean PA joint power & joint work at the TN and MTP joints for one representative subject.

CONCLUSIONS

It has been speculated that the spring-like function of the arch of the foot stores and releases EE, reducing the energetic cost of running [1]. The present study examined this speculation within the scope of the PA, using a multi-segment rigid body foot model driven by experimental running data. The results support the storage and release of EE in the PA, with magnitudes of energy storage that agree with the results of *in situ* testing. This storage and release of EE was not different between IFCP conditions (RF and NRF). During pushoff, the PA produced power at the TN joint of the foot, which suggests that the PA can contribute to the shortening of the arch during late stance. However, the magnitude of the TN joint power generated by the PA is small compared to the power generated at more proximal joints during running [4]. This study demonstrates that the PA does store EE during running gait, but that the return of this energy does not make a large contribution to the energetics of running gait.

THE INFLUENCE OF SOLID ANKLE-FOOT-ORTHOSES ON FORWARD PROPULSION AND DYNAMIC BALANCE IN HEALTHY ADULTS DURING WALKING

Arian Vistamehr[1], Steven A. Kautz[2, 3] and Richard R. Neptune[1]

INTRODUCTION

Solid polypropylene ankle-foot-orthoses (AFOs) are frequently prescribed to assist with gait impairments in post-stroke hemiparetic subjects (e.g., [1]). These AFOs hold the ankle in a near neutral position to assist in foot clearance during swing while bracing the ankle during stance. While most studies have reported increased walking speed and improved toe clearance when walking with an AFO (e.g., [1]), the effects of solid AFOs on other aspects of walking are unclear.

Improving mobility is a common rehabilitation goal. Mobility demands, such as changing walking speed and direction, are accomplished by accelerating or decelerating the body while maintaining dynamic balance. Previous studies have shown that the ankle plantarflexors are primary contributors to regulating forward propulsion (e.g., [2]) and dynamic balance [3]. However, with AFOs limiting ankle motion and plantarflexor output during stance, execution of these walking subtasks may be compromised.

The purpose of this study was to assess the influence of a commonly prescribed solid polypropylene AFO on forward propulsion and dynamic balance in healthy subjects across a range of walking conditions including steady-state, accelerated and decelerated walking. Assessing the influence of AFOs on healthy subjects' walking mechanics will provide a baseline for comparison with hemiparetic subjects, which collectively can provide clinicians with quantitative rationale as to whether solid AFOs improve paretic leg impairments and overall walking mobility.

METHODS

Ten healthy young subjects (age = 27.3 ± 2.7) walked on an instrumented treadmill in randomized trials of steady-state (0.6 m/s and 1.2 m/s), accelerated (0-1.8 m/s at 0.06 m/s^2) and decelerated (1.8-0 m/s at -0.06 m/s^2) walking. Subjects walked with and without wearing a unilateral solid AFO (Fig. 1) on a randomly assigned leg. Kinematic and ground reaction force (GRF) data were collected at 120Hz and 2000Hz, respectively. An inverse dynamics model was used to calculate the center-of-mass position and velocity for all body segments.

Dynamic balance was assessed using the range of whole-body angular momentum (H) in each plane, which was calculated as the difference between the maximum and minimum value of H over the entire gait cycle as described in [4]. Propulsion was assessed using the propulsive and braking GRF impulses, which were calculated using the time integral of the positive and negative anterior-posterior GRFs, respectively.

The range of H was compared between the AFO and no AFO (NAFO) conditions at each walking speed using a paired t-test. Braking and propulsive impulses were compared using a one-factor (AFO condition) repeated measures ANOVA ($\alpha = 0.05$) with three levels (AFO leg, contralateral leg, and average of both legs during the NAFO condition).

RESULTS AND DISCUSSION

The propulsive impulses decreased in the AFO leg compared to the contralateral leg and no AFO condition at steady-state moderate, accelerated and decelerated walking conditions (Fig. 2). With no change in the propulsive impulse at the slow steady-

state walking speed, the present results suggest that a solid AFO may hinder forward propulsion to a greater extent during non-steady-state walking.

Walking with an AFO resulted in a greater range of H in the frontal plane for all the walking conditions and in the sagittal plane during the steady-state moderate (Fig. 3), accelerated and decelerated walking conditions [4]. Whole-body angular momentum has previously been found to be highly regulated during walking and that successful regulation of H is needed in older adults to prevent a fall following a trip [5]. Thus, poor regulation of H during walking results in higher magnitudes of H, which may indicate a decreased ability to control dynamic balance.

In summary, common clinically prescribed solid polypropylene AFOs adversely influenced the generation of forward propulsion and dynamic balance in healthy adults during steady-state and non-steady-state walking. These results suggest that AFOs limit the successful execution of these important mobility tasks, especially when changing walking speed is important, and that the prescription of AFOs should be carefully considered. In cases where an AFO is needed to compensate for gait impairments such as foot drop, perhaps more advanced AFO designs that promote ankle plantarflexion or functional electrical stimulation systems (e.g., The WalkAide System, Austin, TX, USA) that promote dorsiflexion can improve rehabilitation outcomes.

THE INFLUENCE OF PASSIVE-DYNAMIC ANKLE-FOOT ORTHOSIS BENDING AXIS ON GAIT PERFORMANCE IN INDIVIDUALS WITH LOWER-LIMB IMPAIRMENTS

INTRODUCTION

Passive-dynamic ankle-foot orthoses (PD-AFOs) are commonly prescribed to augment impaired ankle muscle function by providing elastic energy storage and return and improve gait performance. Previous studies have examined the benefits of PD-AFOs over traditional designs [e.g., 1] and the influence of PD-AFO mechanical properties, such as stiffness, on pathological gait [e.g., 2]. However, the design and prescription process remain largely qualitative and modifications to other PD-AFO design characteristics may be advantageous.

One PD-AFO design includes a molded footplate, a cuff worn below the knee and a strut rigidly connecting the two (Fig. 1a). During gait, deflection occurs along the length of the strut, with the greatest deflection occurring at a central bending axis. A previous study indicated that a correlation may exist between AFO instantaneous center of rotation (representing the axis of a hingeless AFO as determined by AFO deformation) and ankle joint mechanics [3]. Thus, PD-AFO bending axis is a design characteristic that may influence gait performance, yet it has been largely uninvestigated. However, previous work has demonstrated that misalignment of articulated AFOs with the natural ankle joint may increase resistance torque [4] and cuff movement [5] which may cause discomfort.

The overall goal of this study was to investigate the influence of altering the bending axis location on gait performance. We hypothesize that subjects will prefer a bending axis closer to the natural ankle joint, and this preference will correspond to improvements in biomechanical gait measures.

METHODS

Thirteen subjects who had experienced unilateral lower extremity trauma and were clinically prescribed a PD-AFO by their orthopedic surgeon were enrolled in this study. A previously developed framework [6] was used to fabricate selective laser sintered (SLS) PD-AFO struts with bending stiffnesses matching each subject's prescribed PD-AFO. A second SLS strut incorporated a 2.5cm radius circular extrusion located at 30% of the inner bolthole-to-bolthole distance from the strut center. Strut orientation was used to manipulate the device bending axis (Fig. 1 b or d).

In the experimental data collection protocol, subjects completed overground walking trials at self-selected speed while electromyographic (EMG), kinetic and kinematic data were collected. Subjects completed testing in three different PD-AFO bending axis conditions (Fig. 1): proximal (high), central (nominal) and distal (low), and indicated the order of their bending axis preference once testing was completed.

Figure 1: PD-AFO with the a) prescribed strut, b) proximal (high) bending axis, c) central (nominal) bending axis, and d) distal (low) bending axis.

Integrated EMG (iEMG), joint work and ground reaction force (GRF) impulses were calculated as the time integrals of EMG, joint powers and GRFs, respectively. Biomechanical measures were computed in six gait regions: 1) first double-leg support, 2) early single-leg support, 3) late single-leg support, 4) second double-leg support, 5) early

swing, and 6) late swing. Three way (limb, bending axis, subject preference) repeated measures ANOVAs were conducted to test for significant differences. Significant main and interaction effects were adjusted using a Huynh-Feldt correction and examined using post-hoc pairwise comparisons with a Bonferonni correction (unadjusted $p < 0.05$).

RESULTS AND DISCUSSION

Contrary to what was hypothesized, the majority of subjects (seven) preferred the nominal bending axis, with two subjects preferring the high and four preferring the low condition. Altering PD-AFO bending axis had few effects on peak joint kinematics and kinetics. In region 1, peak ankle plantarflexion was greater in the low compared to nominal condition ($p=0.018$) in both limbs.

Some differences were observed in joint work, primarily at the hip (Fig. 2). In region 1, positive hip work was greater in the nominal compared to high condition in both limbs ($p=0.027$). In region 2, positive ankle work was greater in the low compared to nominal condition in both limbs ($p=0.003$). Negative hip work was also altered by bending axis in region 4 (limb*bending axis*preference; $p=0.004$).

Bending axis had little effect on GRF impulses. In region 3, the vertical GRF impulse was greater in the nominal compared to both low ($p=0.043$) and high ($p=0.002$) conditions in both limbs.

Bending axis altered vastus medialis (VAS), medial gastrocnemius (GAS) and rectus femoris (RF) activity (iEMG). In region 1 and region 4, bending axis altered VAS activity (limb*bending axis* preference; region 1: $p=0.015$, 4: $p=0.002$). Bending axis also altered GAS activity in regions 1, 4 and 5 (bending axis*preference; region 1: $p=0.046$, 4: $p=0.028$, 5: $p=0.034$) and RF activity in region 5 (bending axis*preference: $p=0.028$).

Although several changes were observed, they were generally small and not likely of functional relevance. This suggests that one bending axis does not significantly improve gait and factors such as preference and comfort may play a more important role in prescription. As differences found were often based on preference, future work should examine the relationship between etiology and preference.

Understanding this relationship and the influence of bending axis on gait performance may allow for improved PD-AFO prescription guidelines and rehabilitation outcomes.

INTRODUCTION

The selection of the correct orthosis to improve the gait pattern of children with cerebral palsy (CP) is a complex task for orthopaedic physicians, since it should match the condition of spasticity and weakness of the muscles of each patient [1, 2]. The prescription of an orthosis for a patient is currently based on the physician's experience and is not specific in terms of the mechanical and/or geometrical properties the orthosis should have [1]. Therefore, we aim to assess the effect of ankle bending stiffness of a posterior leaf spring ankle-foot orthosis (AFO), on the gait pattern of one hemiplegic child with spastic CP, which could provide some suggestions about how this characteristic feature of orthosis affects a child's gait pattern.

METHODS

Subject

One child (11.6 years, 29.8kg), diagnosed with spastic unilateral CP on the left side, and evaluated in the clinical gait analysis laboratory from the Instituto de Ortopedia Infantil Roosevelt (IOIR) in Bogotá, Colombia, participated in this study. The following inclusion criteria were used: independent gait without assistive devices, GMFCS I and II; cognitive ability to understand and follow instructions taking part of the experimentation protocol. The exclusion criteria were: orthopaedic lower limbs surgery in the past year; applied Botulinum toxin in the last six months; rigid equinus; symptoms of dystonia and other conditions that may affect balance and/or gait pattern.

Subject assent and parental consent was approved by the Institutional Review Board of the IOIR.

AFOs with different stiffness

An orthopaedic technician of IOIR fabricated three different posterior leaf spring AFOs for the child. Orthoses were fabricated from 3.0 mm thick polypropylene, extending distally under the toes and proximally on the posterior surface of the leg to about 3-5cm below the knee. All were fabricated with a fixed 90° plantar flexion. Different bending stiffness were achieved in their fabrication by increasing the width of the back part and the width of the reinforcement placed in the back (Fig. 1a).

a.   b.

Figure 1a: Posterior view of the posterior leaf spring AFOs fabricated for the subject, from left to right in order of bending stiffness (low to high).
Figure 1b. BRUCE design suggested by Bregman *et al* [3].

Characterization of the ankle bending stiffness

A device was constructed based on the BRUCE design [3] (Fig. 1b) to determine the ankle bending stiffness of the AFO over a functional range of deflections in the sagittal plane. Inverse dynamics were used to obtain the moment exerted by the AFO for different angles, based on the geometry of the device, the vertical displacement velocity (1mm/s) and the vertical force registered by the Instron machine (5586). **Error! Reference source not found.** describes stiffness obtained for the three different orthoses manufactured for the subject.

Table 1. Ankle bending stiffness [N·m/°] (n=5)

Orthosis	Mean	St. Deviation
Low stiffness	0.0318	0.0082
Medium stiffness	0.0931	0.0209
High stiffness	0.1311	0.0082

Experimental design

A single-subject A-B-C-D experimental design was used, in which a baseline phase (A) was followed by three different intervention conditions (B, C and D). In each intervention phase, the child tested one of the three different fabricated AFOs (with high, medium and low stiffness) in randomized order.

Three-dimensional kinematic data were collected using the BTS Motion System. Markers were placed over the skeletal landmarks according to Davis *et al* standard clinical protocol. Kinetic data were collected using two force plates (AMTI). For each test, the subject was instructed to walk along a 10 m laboratory walkway at his/her self-selected comfortable walking speed. Two trials per phase were finally selected and averaged, for the analysis. All the kinematic information was processed and normalized in biomechanical indexes (MAP).

RESULTS AND DISCUSSION

Kinematic results showed that the principal effect of the ankle bending stiffness is the resulting amount of ankle mobility during the stance phase. Fig. 2 shows the change in MAP of the reviewed subject of some gait characteristics of both sides (L: Left, R: Right), when walking barefoot (BF) and with low (LOW), medium (MED) and high (HIGH) ankle bending stiffness AFO.

Not all the MAP indexes show an improvement when increasing the ankle bending stiffness of the orthosis. Although, some such as the Knee Flx/Ext (L) and the Hip Int/Ext (L) show an improvement, some others such the Ankle Dor/Pla (L) show a deterioration of the gait pattern when increasing this characteristic. This happened during the analysis of both sides. In addition, none of the indexes of gait pathology include in their calculation process the subject's kinetic information obtained during the

gait analysis; hence there is no evidence of those results in the values obtained by this indexes.
Figure 2: MAP indexes for each condition.

CONCLUSIONS

Ankle bending stiffness of posterior leaf spring AFOs is a feature that produces an immediate effect over the gait pattern of hemiplegic child, creating changes in the kinematic and kinetic data of the patient. The results obtained with the MAP indexes, showed that an overall evaluation of changes in the gait pattern cannot be made just using the indexes of gait pathology, since they do not include in their definition the kinetic data from which physicians gather important information about the physiological characteristics of the patient's muscles.

In clinical practice it is convenient to find the optimal AFO for a specific patient, by testing different AFOs with different stiffness. In this process physicians should study not only the kinematic but also the kinetic data obtained from the patient testing all the orthosis, and determine which orthosis addresses best the particular patient's gait pathology. The final selection should be consistent with the results the physician is expecting, taking into account that there is a trade-off in the correction.

ADAPTIVE GAIN FOR PROPORTIONAL MYOELECTRIC CONTROL OF A ROBOTIC ANKLE EXOSKELETON DURING HUMAN WALKING

Jeffrey R. Koller, Daniel A. Jacobs, Daniel P. Ferris, C. David Remy

University of Michigan, Ann Arbor, USA

jrkoller@umich.edu, jacobsda@umich.edu, ferrisdp@umich.edu, cdremy@umich.edu

INTRODUCTION

There exists a large disconnect between the natural fluid motion of unconstrained human walking and the unnatural, rigid motion of human walking with a robotic exoskeleton. This unnatural movement of walking in a robotic exoskeleton is largely due to poor controller design and can make the motion energetically inefficient for the user [1]. Our research group has been developing techniques to use neural signals from the wearer to directly control exoskeleton actuation timing and amplitude. By using neural signals to control the device we are attempting to alleviate the issues that come with relying on intrinsic mechanical measurements for exoskeleton control.

In our work, we use electromyography (EMG) to directly control walking robotic exoskeletons. In the past, these controllers created a control signal for actuation by using a *constant* mapping gain to map the EMG linear envelope to an actuation voltage. This constant mapping gain was hand tuned by the researcher. The researcher would tune the gain such that it mapped the peak EMG linear envelope during walking to the saturation voltage of the actuators. We call this max-to-max mapping the calibration mapping gain. The researcher would then scale the calibration mapping gain by 2.0 to encourage a reduction in the user's own muscle recruitment [2]. Because of this scaling, subjects were forced to adapt to walking with a peak muscle recruitment 50% lower than their normal walking muscle recruitment in order to achieve an unsaturated control signal. This technique has resulted in large reductions in metabolic cost; however, the constant mapping gain could be a limiting factor of the controller.

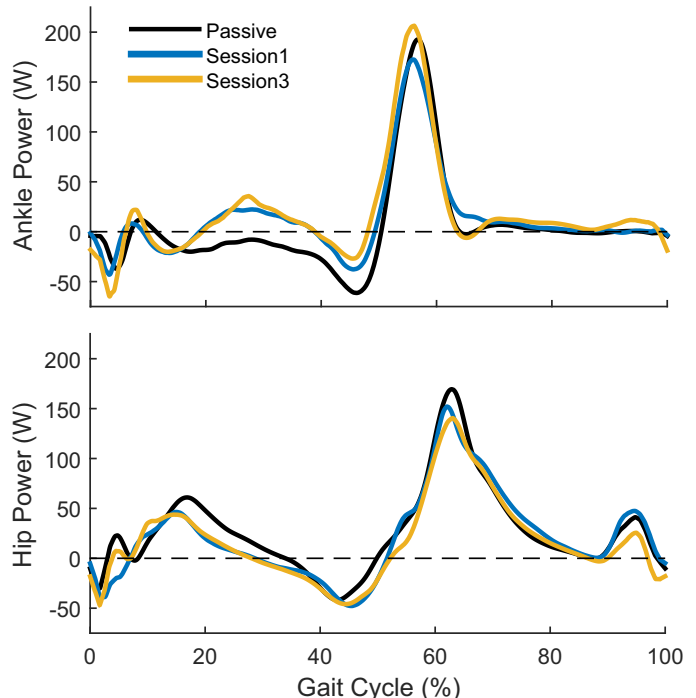
The constant gain constrained the way the user walked in previous ankle exoskeleton studies from


Figure 1: Subjects chose to use more ankle power at the ankle in order to reduce their effort at the hip. Data representing Session 1 and Session 3 were collections that occurred at the end of the powered walking portion of the corresponding testing days.

our lab. The 2.0 scaling of the calibration gain led to a muscle recruitment of the user that may not reflect their preferred manner to walk with the exoskeleton. To overcome this limitation, we developed an EMG based control scheme that frees this mapping gain to *dynamically* adapt to the user as the user adapts to the device. This allows the wearer to use whatever muscle recruitment level they see fit while still receiving maximum unsaturated actuation from the device. By doing so, our adaptive controller refrains from constraining the user to specific dynamics at the ankle. This controller allows us to study what amount of ankle power is preferred by subjects during walking with a robotic exoskeleton. We hypothesized that

subjects would learn to co-adapt with the device in order to achieve a metabolic reduction.

METHODS

For this study, we designed and built a simple one degree of freedom robotic ankle exoskeleton (2.09 kg). The exoskeleton used artificial pneumatic muscles to assist with plantar flexion and was controlled by an off board real-time processor. We used EMG from the user's soleus to control actuation.

Our controller processed the raw EMG to get the signal's linear envelope and then conducted a real-time max search of the linear envelope on a stride by stride basis. The detected maximum of each stride was added to a moving average of the previous fifty strides. Our controller then calculated the mapping gain necessary for this moving average to map to a desired maximum actuator voltage. The controller then updated the mapping gain after every stride. In other words, the exoskeleton always operated at its maximal power output while subjects were able to alter the amount of their own soleus recruitment; thereby adjusting the amount of total ankle power.

We tested three subjects (male, $19.3 \pm .7$ years, 70.8 ± 3.7 kg, 182.0 ± 6.6 cm; means $\pm$ s.e.m.) during treadmill walking at $1.2 \mathrm{~m~s}^{-1}$. All subjects walked in the device continuously for 50 minutes on three separate training days. Each training day was identical and consisted of 10 minutes of unpowered (passive) walking, 30 minutes of powered (active) walking, followed by 10 minutes of unpowered walking. We collected electromyography, metabolic, kinematic, and kinetic data across all sessions. All joint kinematics and dynamics were processed in OpenSim.

RESULTS AND DISCUSSION

We found that by the end of the third session, our adaptive controller had choosen gains that were a 1.76 ± 0.24 (mean $\pm$ s.e.m.) scaling of the would be calibration mapping gain. Previous studies used a constant scaling factor of 2.0. The scaling results show that subjects opted to

Table 1: Results percent change relative to passive conditions (mean $\pm$ s.e.m.)

Measurement	Session 1	Session 3
Peak Ankle Power	-15.8±8.0%	4.9±8.9%
Peak Hip Power	-8.5±9.3%	-12.2±1.0%
Metabolic Cost	-19.0±6.7%	-24.6±1.8%

use higher peak soleus activity than what was enforced in previous studies with a static mapping gain.

Additionally, subjects chose to increase their peak ankle power across training days when using the adaptive controller. This increase in ankle power was coupled with a decrease in hip power (Figure 1 & Table 1). Because our adaptive controller did not constrain subjects to walk in any specified manner, this trade off between ankle and hip dynamics was discovered by subjects voluntarily. This trade off seen between ankle and hip dynamics is supported by the work of Lewis et al. [3]. We believe subjects adapted to these joint dynamics for their energetic benefits due to the metabolic reduction seen across training days. The energetic benefits from actuating the ankle as opposed to the hip has been shown in simulation by Kuo [4] and supports our findings.

Our results suggest that subjects voluntarily increased effort at the ankle in order to reduce effort at the hip. This finding opens an interesting discussion as to what is the best way of providing assistance to the human gait. Should we be employing similar strategies to intrinsically controlled exoskeletons or prosthesis as opposed to replicating 'normal' joint dynamics?

IMPLEMENTING A VIRTUAL GAIT ASSISTANCE DEVICE WITHIN A MUSCULOSKELETAL SIMULATION FRAMEWORK

Tunc Akbas and James Sulzer, Ph.D

The University of Texas at Austin, Austin, TX, USA

email: tuncakbas@utexas.edu

INTRODUCTION

Exoskeletons are promising tools for gait assistance in those with neurological impairments [1]. Our goal is to develop exoskeletal assistance for post-stroke Stiff-Knee gait (SKG). We have developed a lightweight, transparent knee flexion actuator intended to assist knee flexion torque during pre-swing in those with SKG after stroke [2]. We initially hypothesized that knee flexion torque assistance would reduce the need for compensatory kinematics such as hip circumduction. However, our results showed that circumduction increased during assistance in people with SKG compared to healthy controls [3]. We concluded that abnormal coordination patterns following stroke, independent from biomechanics, were responsible for this finding.

The suspected abnormal coordination patterns could be involved in any number of superficial or deep musculature, some of which were not detectable using surface electromyography (sEMG). Musculoskeletal simulation packages such as OpenSim have become a powerful complement to experimental approaches, with the ability to estimate muscle activations that may be difficult to directly measure. As such, our goal is to simulate the activation dynamics resulting from exoskeletal assistance in those with SKG to uncover these abnormal coordination patterns. Here we introduce the challenges involved in this novel neuro-muscular simulation of exoskeletal gait assistance.

METHODS

The active knee brace (Figure 1a) was used by nine stroke patients with SKG and five healthy controls on an instrumented treadmill using a motion capture system to monitor lower body kinematics. The hip and knee flexion torque assistance was provided during the preswing phase. We encountered a number of challenges while integrating this data into OpenSim, including adjustment of motion capture data, application of the external device, and accounting for unmeasured handrail forces and torques. We used the reduced residual algorithm (RRA) [4], and inverse dynamics approaches to assure dynamic consistency and obtain the joint moments, respectively.

OpenSim assumes a full-body marker set where all markers are fixed to the human model. However, our experimental data only constituted a lower body marker set, with left thigh and knee markers on the actuator. Patients also wore ankle-foot orthoses (AFOs) that reduced ankle mobility. To account for these factors, we condensed the weight of the torso to the pelvis and reduced the marker weightings on the orthosis to account for the non-rigid connection to the body. For patients with SKG, we fixed the ankle joint of the impaired side perpendicular to the shank to accurately model the aforementioned kinematic constraint.

The assistive device, which provides a torque couple for hip and knee flexion, is modeled as external force couples at the femur (thigh) and tibia (shank). These couples are applied in opposite directions to provide hip flexion and knee flexion torques (Fig. 1) and set with equal distance from the center of mass of the corresponding bodies (Fig. 1c). The simulated torque assistance is calculated using Eq. 1 and added as an external force to the RRA algorithm (Eq. 2).

$$\tau_{device} = \sum_{i=1}^{4} F_i \times d \tag{1}$$

$$\sum_{i=1}^{11} ma = F_{GRF} + \tau_{device} + F_{residual} \tag{2}$$

Where τ_{device} is the experimental torque measure from the device, F_{GRF} is the ground reaction force vector, $F_{residual}$ is residual forces and moments, F_i is the decomposed force couples of the device and d is the distance of these force couples from the center of mass of the corresponding bodies.
Figure 1: **a.** Free body diagram of the device **b.** Implementation of the device in OpenSim **c.** Free body diagram of the modeled external forces

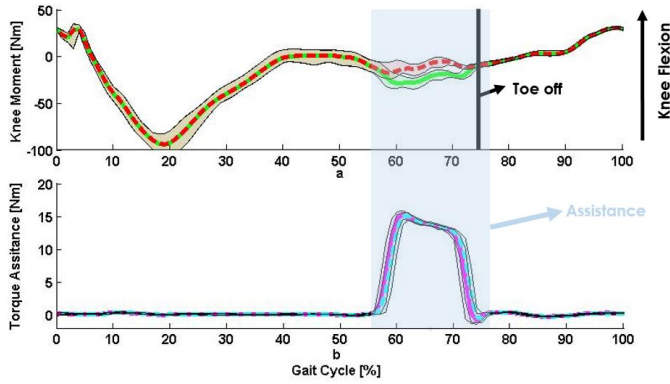
We validated the model by comparing the simulated torque at the knee with and without modeled assistance to the measured torque at the brace (Fig. 2). The maximum average RMS error was below 0.002 Nm.


Figure 2: **a.** Averaged knee joint moments obtained from RRA analysis with (dashed line) and without (solid line) the introduction of the device **b.** Modeled assistance (dashed line) and the assistive torque measured by the experiments (solid line)

Another challenge was accounting for unmeasured unilateral handrail use of stroke patients that would reduce the accuracy of the model. In recent studies it has been shown that handrail forces in the vertical direction can be successfully estimated using residual forces [5]. But the residuals may have originated from various sources such as inaccessible movement artifacts in the upper body or inconsistencies between marker data and force plate readings. Therefore, we subtracted the difference between the forces and torques generated by the body kinematics and ground reaction forces to account for handrail support. We then applied these forces and torques on the pelvis segment to model the handrail support. The following equations were used to obtain the differences between forces and torques:

$$F_{total} = \sum_{i=1}^{11} ma \, , \; F_{diff} = F_{total} - F_{GRF} \tag{3}$$

$$\tau_{diff} = \sum_{i=1}^{11} \frac{d\bar{H}}{dt} - \hat{r} \times F_{GRF} \tag{4}$$

$$\sum_{i=1}^{11} ma = F_{GRF} + \tau_{device} + F_{residual} + \tau_{diff} + F_{diff} \tag{5}$$

Where i is the index of the corresponding body in the OpenSim model, F_{diff} and τ_{diff} are force and torque differences between the body kinematics driven equations and ground reaction forces, $\bar{H}$ is the angular momentum and $\hat{r}$ is the position vector from the contact point to center of mass (CoM) location.

RESULTS AND DISCUSSION

To verify the dynamic consistency of our simulations we compared the average residuals of the initial model (absence of modeled device and handrail force feedback) and modified model of a stroke patient. All of the residuals were decreased by considerable amount (Table 1) except the residual moment around x-axis (M_x), which is negligible (0.85 Nm). Using these methods on a larger data set, we intend on delineating the neuro-muscular mechanisms of abnormal muscle coordination in people with SKG. We believe neuromuscular simulation could be a valuable tool in development of exoskeletons for those with post-stroke SKG and similar neuromuscular impairments.

SURVEYING THE INTEREST OF INDIVIDUALS WITH UPPER LIMB LOSS IN NOVEL PROSTHETIC CONTROL TECHNIQUES

Susannah M. Engdahl, Breanne P. Christie, Brian Kelly, Alicia Davis, Cynthia A. Chestek, Deanna H. Gates

University of Michigan, Ann Arbor, MI, USA
email: sengdahl@umich.edu web: http://rehab-biomech-lab.kines.umich.edu/

INTRODUCTION

Acquiring reliable control signals for upper limb prostheses is a challenge that obstructs further development of advanced devices. Recent research has focused on ways to collect control data by interfacing directly with the nervous system. These efforts fall into three categories: targeted muscle reinnervation (surgically moving nerves to residual muscles in the missing limb to create additional control sites) [1], peripheral nerve interfaces (electrodes implanted in the residual limb to record signals directly from the peripheral nervous system) [2], and cortical interfaces (electrode arrays implanted in the brain to record action potentials directly from motor neurons) [3]. Given the surgically invasive nature of these techniques, it is important to understand whether individuals with upper limb loss are willing to try them. The goal of this work was to evaluate the general interest in surgically invasive and noninvasive prosthetic control techniques.

METHODS

An anonymous online survey was made available to individuals over age 18 with a major upper limb amputation. The survey contained closed and open-ended questions regarding interest in four prosthetic control techniques: myoelectric control, targeted muscle reinnervation, peripheral nerve interfaces, and cortical interfaces. Participants viewed a simple drawing and a brief explanation of each technique, along with a description of any associated medical procedures and potential risks. Participants were then asked to rate their likelihood of using the technique at each of six theoretical performance levels, which were roughly ordered from basic to advanced (Fig. 1). Participants were also asked to rate the overall importance of each feature, in order to gauge their general interest in the features. All responses were collected on a 5-point Likert scale.

A two-way repeated measures analysis of variance with Greenhouse-Geisser corrections was used to examine the effect of technique type and performance level on participants' interest in each technique. Pairwise comparisons were performed using Fisher's Least Significant Difference method.

RESULTS AND DISCUSSION

A total of 104 responses were collected. The mean age was 47 ± 15 years and 67% were male. Most participants (92%) had unilateral limb loss, which primarily occurred at the transradial and transhumeral levels. Trauma was the most common reason for limb loss.

When the responses were collapsed across all six performance levels, participants expressed the most interest in myoelectric control and the least interest in cortical interfaces. Out of all 104 participants, 83% responded positively to the myoelectric control. Only 39% responded positively to the cortical interfaces, while targeted muscle reinnervation and peripheral nerve interfaces were roughly equivalent (63% and 68%, respectively).

We anticipated that participants would be more likely to try each prosthetic control technique if it offered higher levels of functionality. However, the initial responses did not follow this expected trend – participants generally responded less positively to more advanced performance levels (Fig. 1). A similar trend was present in participants' theoretical interest in each performance level (Fig. 1). To address this concern, we altered the wording to be explicitly cumulative. Thirty-five participants used the original "discrete" wording of the performance levels (Fig. 1A) and 69 used the subsequent

"cumulative" wording (Fig. 1B). Changes in the wording did not substantially affect our findings: there were significant differences in participants' interest in different performance levels for both the discrete (p = 0.008) and cumulative (p = 0.031) wording. This fact strengths our findings, suggesting that participants truly viewed the advanced features as less important.

Written comments from the participants revealed that common concerns regarding myoelectric control included weight, difficulty of use, cost and durability. The inherent risk of surgery with the other interfaces was difficult for many participants to accept. However, some respondents reported that the potential benefits would justify the surgical risks and recovery time.

The results of this work will be instrumental in the development of advanced devices that are appealing to individuals with upper limb loss. Larger studies investigating the relationship between demographic factors and interest in novel prosthetic control techniques are still needed to fully inform the design of future devices.

QUICK, LOW-COST, SENSITIVE MOTOR ASSESSMENT
USING MARKERLESS MOTION CAPTURE

[1,2]Steven K. Charles, [2]Paula Johnson, and [1]Clay Kincaid

[1] Mechanical Engineering and [2]Neuroscience, Brigham Young University, Provo, UT

INTRODUCTION

There is a nationally recognized need for more sensitive motor assessments to evaluate and diagnose motor impairments following traumatic brain injury (TBI). Conventional motor assessments rely on subjective observations and often fail to detect subtle impairments common in TBI. The purpose of our research is to 1) develop a quantitative motor assessment (QMA) that is quick, low-cost, and highly sensitive, and 2) establish a normative database to allow comparison of a patient's motor assessment relative to a healthy norm.

To this end, we developed a system to administer traditional motor tests using low-cost markerless motion capture. Our system consists of an $80 Leap Motion sensor and custom software (Figure 1). This system automates traditional motor tests and measures the position of finger tips with a resolution of 0.01mm and a sampling frequency of 100Hz. We have seeded a normative database by administering this QMA to 50 control subjects.

Figure 1: Test setup. For most tests (A), subjects pointed to objects on a screen while a Leap Motion sensor (C) captured their movements. In the balance test (B), subjects' head sway was extracted from the motion of dowels attached to a helmet.

METHODS

Fifty healthy, right-handed subjects (age range 18-30 years; 23 females, 27 males) completed five QMA tests (described below). To allow for comparison with traditional assessments, we included 3 traditional tests as well: Halstead-Reitan Finger Tapping Test, grip strength, and the Beery Visual Motor Integration Test. Tests were performed in random order. Positions and velocities of the finger tips and palm were recorded at 100 Hz. Movements were performed by both hands. The entire assessment required 1 hour 45 minutes.

Each subject performed the following QMA tests:
Finger Oscillation Test
- Participants were instructed to make oscillatory finger movements as fast as possible for 10s
- Subjects received visual feedback of their finger location on a graphical user interface (GUI) (Figure 2A) and needed to oscillate their finger above and below a band to achieve a tap
- Subjects needed 5 trials within 5 oscillations of each other (10 trials max)
- 30-90s rests between trials

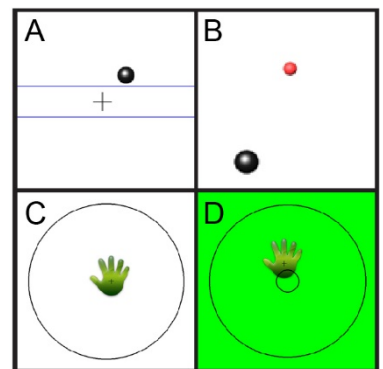
Visually Guided Movement
- Subjects moved the tip of their index finger, represented as a red dot, as quickly as possible to targets appearing in random order (Figure 2B)
- The next target appeared after the finger had rested on the target for 500ms.


Figure 2: Graphical User Interface for QMA tests: finger oscillation (A), visually guided movements (B), postural tremor (C), and reaction time (C-D).

- Two trials, each with 12 paths executed 5 times in random order were completed

Postural Tremor
- Participants were instructed to hold their hand over the motion capture sensor with palm down and fingers spread (Figure 2C)
- Two trials of 30s each for each hand

Reaction Time
- Participants held their hand over the sensor (Figure 2C)
- Subjects were instructed to remove their hand as quickly as possible as soon as the background color changed from white to green (Figure 2D)

Balance
- Participants stood with feet together and hands across the chest for 30s (Figure 1B)
- Five different trials were completed, each in a different pose
  - Hard surface eyes open
  - Hard surface eyes closed
  - Soft surface eyes open
  - Soft surface eyes closed
  - Tandem stance, preferred foot in front

The data from each test were analyzed to extract test-specific measures (Table 1). Together these measures form a normative database against which patients' QMA results can be compared to evaluate the degree of their impairment.

RESULTS AND DISCUSSION

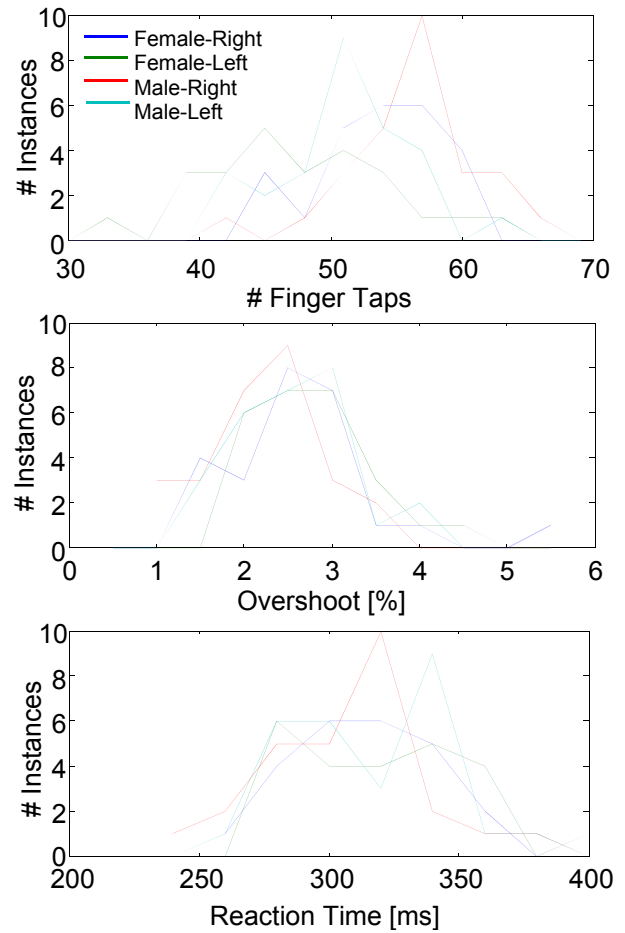
Being normative data from young, healthy subjects, the QMA results were generally stereotyped, with few differences between men and women or dominant and non-dominant hands (Figure 3).
Novel markerless motion capture technology allows for collection of an abundance of quantitative movement information. Using this technology and the associated normative databases will allow for quick, low-cost, and highly sensitive motor assessment in clinical settings, which we expect will result in improved diagnosis, prognosis, and rehabilitation following TBI. Because of the gaming industry, markerless technology is bound to continue to improve, creating more sensitive instruments.
This QMA and its normative database will be available. We invite others to take advantage of it and contribute to the database.


Figure 3: Histograms of QMA measures for the finger oscillation (top), visually guided movement (middle), and reaction time (bottom) tests.

QMA Test	Behavioral Attributes	Measures
Finger Oscillation	Strength, movement efficiency	Number and regularity (approximate entropy) of taps
Visually Guided Movements	Visuomotor control, kinetic tremor	Dysmetria, duration, smoothness, power spectrum area
Postural Tremor	Tremor, chorea, strength, impersistence	Area under power spectrum between 4 and 12 Hz
Reaction Time	Processing time	Reaction time
Balance	Postural stability	Mean path, max. excursion of the crown of the head

Table 1: Each QMA test was designed to assess particular behavioral attributes that were defined and quantified as measures.

PORTABLE MYOELECTRIC BRACE USE IN CHRONIC, POST STROKE HEMIPARESIS

INTRODUCTION

Stroke frequently causes debilitating upper extremity (UE) motor impairments that are retained well beyond rehabilitation discharge. Several UE motor rehabilitative approaches have been developed, with most adhering to the P.R.A.C.T.I.C.E. principles[1]. Yet, many promising UE rehabilitative strategies[2–4] are only efficacious in individuals already exhibiting high levels of active, paretic UE movement; only a small portion of the growing stroke survivor population.

Reduced UE impairment and increased function were reported among survivors with moderate UE impairment participating in repetitive task-specific practice (RTP) that integrated a portable, electromyography (EMG) triggered, brace ("Myomo")[5–7]. We wished to compare the efficacy of this regimen with the use of RTP only (the standard of care in most outpatient environments) while concurrently characterizing the motor behavior of stroke survivors exhibiting moderate UE impairment.

METHODS

Subjects: Twelve subjects gave written consent to participate (4 males; age=53.5+5.35 years; mean time post-stroke=61.7 months; 11 Caucasians, 1 African-American; 6 left-sided strokes; 10 ischemic strokes; 1 basal ganglia stroke; 3 strokes in the left-middle cerebral artery; 1 in the frontal lobe; 2 in the parietal lobe; 5 in unspecified locations). They were randomized into two groups: 7 subjects were administered RTP+Myomo, and 5 RTP-only.

Apparatus: The Myomo e100 (Fig. 1) is an FDA approved, lightweight (~2lbs), myoelectric brace that uses surface EMG signals from the biceps and triceps brachii from active paretic UE movement attempts to assist the active muscle with movement

of the paretic UE[7]. A treating therapist can adjust the system parameters to alter the amount of mechanical assistance provided.

Figure 1. Myoelectric brace used in the study.

Intervention: Both groups (RTP+Myomo and RTP-only) participated in individualized, 45-minute therapy sessions occurring 3 days/week over an 8-week period. As described previously[7], the intervention's design and therapy session content involved progressive difficulty in tasks. In all cases, the latter tasks were selected collaboratively with the patient, caregiver, and therapist. With or without the Myomo, chosen tasks were functional/goal directed, integrating the paretic UE into whole-arm tasks that were salient to the subject. Therapy included both bilateral and unilateral UE tasks, and included components of muscle control, coordination, strength, endurance, and proprioception.

Behavioral data: We administered the Stroke Impact Scale (SIS); a 64-item self-report measure. For this study, we focused on changes in the paretic UE (SIS arm and hand scales), ability to perform activities of daily living, and recovery scales.

Kinematic data: An 11-camera motion capture system (Motion Analysis Corporation Raptor-12 system, Santa Rosa, CA, USA) tracked 3D-motion of subjects' paretic and less affected UEs during the experimental tasks. Twenty-six reflective markers were placed on the upper body (Fig. 2). Each subject performed 5 repetitions of two reaching

tasks with the paretic and non-paretic UE. For the 'reach-out' task, a cylinder-shaped object was placed in front of the subject on the table, aligned with the subject's sternum at 2/3 of paretic UE length. For the 'reach-up' task, the same object was elevated by 24 cm. Subjects were instructed to reach for the object as if they were reaching for a glass of water, without specific instructions on movement speed. Joint angles were calculated based on a standard UE model and conventions for the shoulder joint.[8] Main outcome measures were shoulder flexion (range), elbow extension (range) and hand velocity (peak).

Statistics: Mann Whitney U tests compared all behavioral and kinematic changes between intervention groups.
Figure 2. Kinematic model of subject in the starting position

RESULTS AND DISCUSSION

Subjects administered RTP+Myomo tended to exhibit larger improvements on all scales than subjects administered RTP-only. This difference between groups reached significance for SIS recovery (U=4, p=0.032, point probability=0.015), and came close to significance for SIS ADL (U=6, p=0.061, point probability=0.001).

None of the subjects were able to grasp and lift the object with their paretic limb. Therefore, kinematic analyses focused on the reaching part of the movement, which ended when the hand touched the object. When subjects were unable to touch the object, we analyzed the full attempt. Most patients demonstrated improved capability to move the object after completing the intervention. The change in hand velocity from pre-test to post-test in the 'reach-up' task was significantly larger in the RTP-only group compared to the RTP+Myomo group (U=3, p=0.018, point probability=0.04). None of the other changes in kinematic variables from pre-test

to post-test were significantly different between groups (all p>0.53).

A trend towards a significant correlation was observed between the change in the SIS arm subscale and the change in range of elbow extension during the reach up task. However, Spearman's correlation coefficient was negative (rho=-0.57, p=0.054), which indicates that subjects with larger elbow range of motion while reaching up tended to report lower arm function SIS scores. None of the changes in other kinematic variables significantly correlated with any of the changes in SIS subscales (all p≥0.12)

CONCLUSIONS

RTP integrating myoelectric bracing might be more beneficial than RTP only in improving subjects' perceptions of their overall recovery. This approach does not convey superior benefits to RTP only in terms of UE kinematics, and no significant correlations were observed between changes in self-reported outcomes and reaching kinematics. Our findings suggest that clinicians may be able to reduce the debilitating impact of moderate UE impairment using RTP+Myomo.

IMPROVING FINGER MOVEMENT REPERTOIRE IN STROKE

Rajiv Ranganathan

Michigan State University, East Lansing, MI, USA
email: rrangana@msu.edu, web: https://sites.google.com/site/motrelab/

INTRODUCTION

Stroke often results in an impairment of hand function, which severely impairs activities of daily living [1]. One common deficit that is observed after stroke is a loss of finger independence [2], which is associated with reduced hand dexterity. The purpose of the current study was to examine if we could use a body-machine interface to increase the repertoire of finger movements in stroke survivors. Specifically, we examined if we could elicit different patterns of finger movements by manipulating which finger motions contributed to task performance.

METHODS

Participants were 8 chronic stroke survivors (mean 7 years after stroke) who had mild to moderate deficits in hand function as quantified by the Chedoke-McMaster test of hand function. Participants wore an instrumented glove (Cyberglove, Cyberglove Systems, San Jose, CA) which measured finger kinematics of the affected hand. The motions at the MCP joint of the index, middle, ring and little fingers were mapped to the horizontal motion of a cursor on a screen [3]. The task of the participants was to move the cursor between two targets shown on the screen (Fig. 1).
Figure 1: Finger kinematics were mapped on to the horizontal position of a cursor (shown in red). The task was to move the cursor between two targets.

The critical manipulation in the experiment was to alter the mapping between the finger motions and the motion of the cursor. Initially, all fingers were given uniform weights so that the typical power grasp motion (where all fingers jointly perform flexion and extension with no finger individuation) could be used to perform the task. However, after the first 25 trials, the weights were gradually altered over the next 25 trials so that this motion was shifted to the null space (i.e. performing the same power grasp motion now resulted in little to no motion of the cursor). At this point, participants had to reorganize their finger coordination, and find an alternative coordination pattern to continue moving the cursor to the remaining 50 targets. Each session took about 1 hour and participants performed the task for 5 sessions spread over 2.5 weeks. Here, we focus only on the first (Pre) and last session of practice (Post).

We used the path length (i.e. the distance traveled by the cursor in going from one target to another) as a measure of task performance. In order to examine the reorganization in the coordination pattern, we used principal component analysis (PCA) on the finger kinematics. Specifically, we examined the change in the first principal component (which accounts for the most variance) using a dot product.

RESULTS AND DISCUSSION

Task performance (as measured by the path length) showed significant increases as the weights changed, indicating that participants were engaged in exploration of different coordination patterns while attempting to move the cursor between the two targets. The amount of this exploration was significantly reduced at the last session of practice, indicating that participants were now able to switch to a different coordination pattern more quickly (Fig. 2).
Figure 2: Path length of the cursor (summed over 10 trials) during the experiment. Trials 1-25 indicate the uniform weights for each finger, 26-50 indicate the gradual transition to the new weights, and 51-100 indicate the performance with the new weights. A lower value indicates fewer reversals in cursor direction when moving between targets.

In terms of the coordination patterns (as measured by the PCA), we found significant changes in the dominant coordination mode (i.e. PC1) as participants transitioned from the old weights to the new weights. The average change was about 20 degrees, both initially in practice as well as the final session of practice (Fig. 3).
Figure 3: Change in the first principal component during the experiment both in the first and last session of practice. There was a significant increase in the angle when the weights were changed indicating reorganization of coordination patterns.

These results show that stroke participants are able to reorganize their finger coordination patterns when provided with appropriate feedback in a game-like environment. Specifically, participants were able to move out of the dominant non-individuated pattern that is normally seen in stroke, and were able to not only learn but also retain these new coordination patterns to solve the task.

CONCLUSIONS

The results here suggest that the paradigm described here has potential for the rehabilitation of hand function in participants with mild to moderate deficits. Given that the changes here are implicit (i.e. no explicit instruction was given regarding the finger coordination pattern), this paradigm could be combined with game-like environments and virtual reality [4] to improve hand movement repertoire and facilitate rehabilitation in stroke.

SCAPULAR KINEMATIC IS ALTERED AFTER ELECTROMYOGRAPHY BIOFEEDBACK TRAINING

[1] Jun G. San Juan, [1]Samantha R. Gunderson, [1]Kai Kane-Ronning and [1] David N. Suprak

[1] Western Washington University, Bellingham, WA, USA
email: jun.sanjuan@wwu.edu

INTRODUCTION

Electromyography (EMG) biofeedback training has become a more useful tool with rehabilitation of subacromial impingement syndrome. Biofeedback affords patients a better sense of different muscle activations involved in the movement of the shoulder girdle [1]. It is important to address scapular kinematics in the healthy population, because those who have daily routines involving large amounts of lifting at shoulder level or higher are at a heightened risk of developing subacromial impingement syndrome (SAIS) [2]. Understanding the effects of scapular stabilization exercises in order to prevent subacromial impingement syndrome to these population is beneficial. As a result, the aim of this study was to investigate the effects of scapular stabilization exercises with EMG biofeedback training in scapular kinematics.

METHODS

Nineteen healthy subjects (14 males, 5 females) volunteered for the study. The mean age was 22.9 ± 3.1 y/o, mean height of 1.76 ± 0.1 m and mean mass of 75.1 ± 11.0 kg. To measure muscle activation, a Noraxon Telemyo DTS (Gain 500, CMRR > 100dB, input impedance > 100Mohm) was utilized and sampled at 1500 Hz. The EMG data were normalized using maximum voluntary isometric contraction (MVIC) for all the muscles tested. Bi-polar surface electrodes were placed parallel to the muscle fibers of the upper and lower trapezius, serratus anterior, and lumbar paraspinals of the dominant arm with an inter-electrode distance of 2.0 cm (Figure 1). The EMG data were displayed on a stationary overhead projector connected to a PC-type of computer using MR3.4 MyoMuscle software (Figure 1). A Polhemus Fastrak magnetic tracking device was used to measure 3-dimensional scapular kinematics. The receivers were attached to the spine of the scapula using a customized scapular jig, sternum (inferior to the jugular notch), and distal humerus (Figure 1). A Polhemus sensor pen was utilized to digitize the spinous process of C7, T1, T7, and T8, the sternal notch, the sternoclavicular joint, and lateral and medial epicondyles of the humerus to set-up the coordinate system following the standard set by the International Society of Biomechanics [3].
Figure 1: EMG and Magnetic tracking device set-up.

A customized LabVIEW program was utilized to collect and analyze scapular kinematics. The kinematics data were sampled at 40 Hz. After a standardized warm-up protocol, subjects underwent scapular kinematic testing before and after biofeedback training that consisted of three humeral elevation trials in the scapular plane. Subjects were afforded to practice humeral elevation trial before the data collection commenced. Then EMG biofeedback begun with scapular stabilization exercises (I, W, T, Y) performed at 1 set of 10 repetitions (Figure 2). Subjects were told to actively try and reduce the muscle activation shown on the screen for the upper trapezius during the exercises. A two-way repeated measures ANOVA was utilized to compare scapular kinematics before and after the EMG biofeedback scapular stabilization exercises.

The independent variables were humeral elevation (30°, 60°, 90° & 110°) and time (Pre and Post biofeedback training). The dependent variable was scapular kinematics. Alpha level was set to 0.05.

Figure 2: Scapular stabilization exercises (I, W, T, Y)

RESULTS AND DISCUSSION

There was a statistically significant difference at all humeral elevation angles during scapular external rotation ($p < 0.004$) between times (Figure 3). After the exercises, the scapula was in a more externally rotated orientation with a mean difference of 6.8 degrees. There were no significant differences found for scapular upward rotation and posterior tilt at all humeral elevation angles between times.

We hypothesize a significant change in scapular kinematics after EMG biofeedback training. The current study's result was able to observed changes in scapular kinematics after the scapular stabilization exercises. Scapular kinematics is altered by EMG biofeedback training. However, only external rotation was significantly affected by the exercises. We did not see any significant differences in upward/downward rotation and anterior/posterior tilt of the scapula. According to the literature, increase in subacromial space can be attained by an increase in upward rotation, external rotation and posterior tilt of the scapula during humeral elevation. It can decrease the chance of

SAIS. The change in external rotation observed in the current study can be attributed to the exercises implemented, which targeted the serratus anterior. The action of the serratus anterior muscle is to prevent scapular "winging" or excessive internal rotation of the scapula. The exercises used in this current study combined with EMG biofeedback has a valuable effect in preventing shoulder pain.

CONCLUSIONS

Scapular stabilization exercises together with EMG biofeedback can help change scapular kinematics in healthy individuals. A more externally rotated scapula might result in an increase in subacromial space that can be beneficial in decreasing the development of subacromial impingement syndrome. Workers that necessitate large amount of lifting above their shoulder and overhead athletes (e.g. pitchers, tennis players) will benefit from these type of exercises for shoulder injury prevention.

USING SENSORS TO IMPROVE SPORT SAFETY

[1] Stefan M. Duma and [1] Steven Rowson

[1] Virginia Tech, Department of Biomedical Engineering and Mechanics
Blacksburg, VA, USA
email: Headbiomed@vt.edu, web: www.vt.edu/helmet

INTRODUCTION

In the fall of 2003, Virginia Tech became the first collegiate football team to utilize wireless helmet mounted accelerometer systems [1]. Throughout the next decade, over 2,000,000 head impact data points were collected on football teams across the country using the same Head Impact Telemetry (HIT) technology (Simbex) [2]. This abstract provides a very brief discussion of this research area and introduces the future Sensor STAR system that will help guide the widespread implementation of sensors in all sports.

FOOTBALL HELEMET SENSORS

The original HIT system consists of six accelerometers that are mounted in the crown of the football helmet. The individual sensors are used to calculate linear and rotational head acceleration values for each head impact. These data are relayed in real time to a sideline controller that can then alert the medical staff if there is a high impact. These alerts are not diagnostic, but simply a page to a beeper to alert the physicians of a high impact. Over the past decade, multiple systems have been developed by Simbex and used throughout all ages of football (Figure 1) [3].

The sensor data has proven dramatically valuable and has resulted in two specific sport safety improvements. First, the data on youth football was used to provide guidelines for safer practice structures that were adopted nationally by Pop Warner [4,5]. Second, these data were used to develop advanced concussion risk functions and subsequently the Virginia Tech helmet rating program that has resulted in improved helmet design [6,7,8,9]

SENSOR STAR

Over the past several years, there has been an explosion of new head impact measuring systems. Many of these will allow for data collection in non-helmeted sports and in particular will allow for data collection in female sports (Figure 2). In order to evaluate the effectiveness of these new sensors, we have introduced the Sensor STAR program. This program will utilized a three step process to access the accuracy of the sensor systems.

The first step of the process will be to mount the sensors onto a dummy head form and subject the system to a range of impact severities and impact directions. The new sensor data will be compared to the reference data measured at the center of gravity of the head form. It is important to note that we are looking for reasonably accurate systems and not perfect systems, as those may never exist for wide-spread volunteer use. For example, a sensor with a 10% error would measure 45g or 55g for an impact with a 50g reference value. There is no meaningful difference between these three impact values.

Once a sensor has passed the first step, the second level includes evaluation on volunteers during low level impact events, such as heading soccer balls. This evaluation will evaluate the sensors ability to trigger and count impacts correctly. This is particularly important as the head impact counts are being used to modify league rules, and the need to be reasonably accurate prior to rule changes. The last level of evaluation will utilize high impacts on human surrogates to evaluate the sensor's ability to accommodate surface interaction conditions. The Sensor STAR information will be provided on-live via our ratings web page: www.vt.edu/helmet

Figure 2: New sensor technologies will allow for widespread data collection on female and youth athletes in non-helmeted sports. A female subject is shown with Triax Technologies headband sensor.

QUANTIFYING FIELD-BASED WARFIGHTER PERFORMANCE VIA A BODY-WORN ARRAY OF WIRELESS INERTIAL SENSORS

[1] Scott G. McLean, [1]Stephen M. Cain, [2] Ryan S. McGinnis, [1] Steven P. Davidson, [1] Rachel V. Vitali and [1] Noel C. Perkins

[1] The University of Michigan, Ann Arbor, MI, USA, [2] MC10 Inc., Cambridge, MA, USA
email: smcain@umich.edu

INTRODUCTION

Warfighter performance is inherently challenging to monitor, quantify and ultimately interpret. These challenges originate from the varied and complex tasks that warfighters perform, the underlying variability in human task performance, the environments in which they operate, and a limited knowledge of the measures that truly characterize task performance success/failure. Adding to these challenges are the confounding effects on physical performance due to equipment (e.g., load, bulk and stiffness), task training, and explicit performance degradation. Our ongoing research in this rapidly growing area aims to address these challenges by engineering and evaluating a complete performance approach to quantify and report warfighter performance in naturalistic outdoor environments.
Figure 1: Body-won sensor array for the warfighter

Continued efforts rest on advancing our ongoing research utilizing body-worn arrays of miniature inertial measurement units (IMUs) that synchronously measure and transmit data defining the spatial mechanics of major body segments and their interactions with external equipment. Our current array utilizes up to ten IMU nodes attached to the task-relevant segments/equipment of interest. The IMU data encode the thumbprint of task performance. For example, during walking or running gait, performance metrics include timing events (e.g., ground contact), gait speed, and explicit segmental dynamics. To date, we have developed an integrated functional IMU array and companion (Matlab™ based) computational algorithms for analysis of select warfighter tasks. Currently the end user is required to have significant expertise in human biomechanics, experimental methods, and software development/manipulation to implement the integrated system in a functional setting. Current efforts aim to mitigate these limitations and extend system capabilities by engineering and evaluating a fully automated measurement system. Our ultimate goal is to deliver an integrated hardware/software system that enables easy and reliable assessment and comparison of warfighter performance. Specifically, we will generate a complete measurement system that discriminates warfighter performance using IMU data within naturalistic (and often random) movement environments encountered by the warfighter.

METHODS
We have collected data on a large number of young healthy subjects, both for the purposes of the IMU-based system validation and to subsequently assess the effects of load-carriage within a simulated warfighter environment [1, 2]. For the purposes of validation, we compared a number of IMU-derived body and segmental kinematical measures during a variety of (e.g., walking, running, jumping, rifle aiming) movement tasks to those obtained via "gold-standard" motion capture techniques. Mocap derived data were generated using or well established methods [3]. Load-carriage effects were evaluated with the validated IMU-system for subjects moving within an outdoor obstacle course. The course was consistent with those adopted

within the military, containing a series of running, jumping, crawling, climbing and rifle aiming tasks. Specifically, subjects completed the course with and without additional (20.5kg) load.

Throughout the testing protocol, subjects had eight wireless IMUs (Opal, APDM, Inc.) secured to specific body segments (feet, shanks, thighs, sacrum, and torso). Each IMU contains a 3-axis accelerometer, angular rate gyro, and magnetometer; a proprietary Kalman filter estimates the directions of gravity and magnetic north relative to sensor-fixed axes. Subjects initial perform calibration movements to determine segment-to-sensor alignments for post-processing purposes.

RESULTS AND DISCUSSION

Results from our extensive efforts to date have yielded four major findings; namely: 1) IMU-derived kinematical measures of human movement accurately replicate those determined from standard motion capture; 2) these kinematical measures distinguish performance in a spectrum of highly relevant warfighter tasks; 3) our chosen performance measures are sensitive to extreme load carriage (e.g., loaded versus unloaded), warfighter fitness and/or task induced performance degradation (e.g., fatigued versus non-fatigued); and 4) IMU technology and the embedded algorithms readily translate to and be largely immune to the inherently random nature of outdoor environments. More specifically, our validation experiments have revealed excellent agreement between IMU and mocap measurements of linear acceleration and angular velocity as well as quantities derived therefrom, including linear velocity and angular orientation. Less accurate, in general, are position estimates, particularly for unconstrained tasks, which is consistent with the raw data being measured by a sensor, as position would be an integrated parameter from the raw velocity and acceleration signals. A key outcome of our obstacle course work, which is particularly relevant to the already encumbered warfighter, is that a rich and highly applicable dataset can be generated with a minimum number of sensors. For example, walking and running performance can be successfully

quantified and compared across (e.g., load and or performance degradation) conditions using relatively straightforward IMU-derived gait parameters (e.g., stride period, length, and speed; duration of single/double support phases and swing phases). Similarly, jumping, climbing and landing performance can be successfully quantified and compared using sacral IMU-derived measures of vertical acceleration and velocity as well as jump height.

CONCLUSIONS

Our research provides an innovative and critical vertical step in field-based warfighter performance assessment techniques. Specifically, we have shown that meaningful and readily comparable and translatable performance outcomes can be obtained from a small number of body-worn miniature IMU sensors. By extending beyond the confines of the traditional laboratory setting, this approach will ultimately enable warfighter performance to be successfully monitored and optimized within a variety of complex and often random environments. Moving forward, we will extend our approach to more effectively characterize critical movement metrics that can consistently distinguish levels of performance success. Additionally, we will automate the assessment approach so that it can be used by the non-expert evaluator. Through these steps, we expect this integrated technology will readily translate to a variety of clinical settings.

CLINICAL INTERVENTIONS FOR GAIT ABNORMALITIES: MODE OF FEEDBACK AND LOWER EXTREMITY MECHANICAL EFFECTS

[1] D. S. Blaise Williams III

[1] VCU RUN LAB, Virginia Commonwealth University, Richmond, VA USA
email: dswilliams@vcu.edu, web: https://khs.vcu.edu/about/vcu-run-lab/

INTRODUCTION

The yearly incidence of injuries across all runners varies between 24% to 71% (Fields, 2011). Of these injuries, the majority involves the lower extremity with 70-80% occurring from the knee distally (van Gent, 2007). These high injury rates for runners result from multiple reported causes including, poor training, abnormal structure, weakness, inflexibility and poor motor control. It is likely that these differences in running-related injuries are due to a combination of these factors. While the comprehensive understanding of the etiology of running-related injuries is incomplete, it is generally accepted that running injuries are related to three main factors: overexposure, lower extremity structure, and lower extremity biomechanics. Exposure or training can be easily monitored or changed while structure is much more difficult to change or account for. Biomechanical changes are attainable but often difficult to learn or slow to change.

Gait training has been an integral part of physical therapy practice since the beginning of the profession. However, interventions related to gait are often subjective or based on predetermined norms. Because there are likely multiple biomechanical factors involved in lower extremity injury, there are consequently multiple approaches available to address these factors. Recently, evidence has emerged investigating the mechanical effects of modification of gait. Specifically, gait can be modified with 3 main types of feedback: auditory, visual and motor feedback. The purpose of this presentation is to demonstrate the acute biomechanical effects (particularly on ground reaction forces, stride frequency, strike position and strike pattern) of various types of feedback. Further discussion will be added regarding clinical application.

METHODS

All subjects will undergo running assessment via 3D motion analysis. Data will be presented based on various feedback interventions. During the gait assessment, retroreflective markers (at least three per segment) will be placed bilaterally on the segments of the rearfoot, shank, thigh and pelvis. A standing calibration trial will be collected. The subject will then be asked to run on a specialized treadmill instrumented with a force platform and surrounded by an 8-camera, motion analysis system. The subjects will run at a constant speed (3.35 m/s). Kinematic data will be sampled at 240 Hz, and force data will be collected at 1200 Hz. Thirty seconds of data will be collected for pre- and post-conditions. Kinematic and kinetic data will be time-synchronized. The three-dimensional coordinates of each marker are reconstructed using a direct linear transformation method. The reconstruction errors in a volume of approximately 1m X 1m X 2m are typically on the order of 0.5 mm. The 3-dimensional coordinates will be filtered using a 2nd order recursive Butterworth filter with a 12 Hz cutoff frequency.

The following modes of feedback will be employed for pre- and post- comparison: step rate via metronome and cuing, hip drop via video and cuing, strike position via video and cuing, strike pattern via video and cuing, trunk lean via video and cuing, soft landing via cuing. Additionally, mechanical outcomes following acute bouts of stretching, strengthening and repetitive motion will be examined. Mechanical variables of loading rate, peak vertical GRF, strike position, strike pattern and vertical stiffness will be evaluated. Lower extremity

stiffness will be determined during running by dividing vertical ground reaction force by vertical displacement of the body's center of mass (Farley & Gonzalez, 1996). Based on the results of these laboratory tests, similar clinical interventions will be used and outcomes evaluated in runners with injuries or performance deficits.

RESULTS AND DISCUSSION

There were distinct differences in outcomes post intervention across most variables. Feedback with metronome was successful for immediate change in stride frequency, strike position and strike pattern. With cuing, there were immediate changes but the changes were not as distinct and were not consistent after 1 minute. These will be demonstrated in clinical settings utilizing free apps and basic clinical feedback methods.

Differences were realized in hip drop with visual cuing and verbal cuing. Visual cuing resulted in slower changes that deteriorated when feedback was removed. Cuing resulted in immediate changes that were longer lasting but deviated further from baseline. Strike position and strike pattern were less consistent in their response to both video and cuing. Clinical examples that result in short term and long term changes in pain will be demonstrated.

Trunk lean feedback, whether through video or cuing resulted in varying mechanical outcomes and subjects were less able to successfully change trunk lean. Soft landing via cuing was successful but not symmetrical. Lower extremity stiffness was greater pre cuing for soft landing 14.15Nm/kg compared to post 10.11Nm/kg which represents a 27% decrease in stiffness. Clinical examples of trunk lean and soft landing will be presented.

Mechanical outcomes following acute bouts of stretching resulted in reductions in lower extremity stiffness and loading rates. After acute bouts of strengthening exercises, there were no differences in mechanics. With repetitive motion, there were changes in stiffness and stride rate.

CONCLUSIONS

In general, runners are able to quickly and easily respond to most feedback methods in the clinic. Based on mechanical outcomes, stride rate and soft landing cues appear to be the most effective and easily realized. The fact that runners are able to change running mechanics does not indicate they have adapted to a particular running style. The current study was not designed to develop permanent adaptations and therefore does not suggest that these or other runners are able to maintain these gait patterns. In fact, depending on the type of feedback, it may not be maintained over a single training session. This suggests that caution should be exercised when training runners with new or different mechanics as the intended changes may not be realized (4).

It appears that runners are able to quickly alter their gait patterns based on a number of different feedback modes. While auditory feedback for stride frequency seems to be most successful, verbal cuing has reasonable success for many variables. Visual feedback, particularly for trunk lean is least effective in achieving changes. More practice may be necessary to further train runners in specific gait parameters. Future studies are still needed to determine if runners permanently adapt to changes in their running mechanics and whether these changes alter any risk for running-related injuries.

ASSESSING LOAD AND LOAD SYMMETRY OUTSIDE THE LAB

[1]Robin M Queen, PhD, FACSM

[1] Duke University Medical Center, Michael W. Krzyzewski Human Performance Lab, Durham, NC, USA
email: robin.queen@duke.edu, web: http: http://klab.surgery.duke.edu/

INTRODUCTION
Biomechanical assessment has been traditionally completed in a controlled laboratory setting. With advances in technology it is now possible to assess movement in athletes and patients outside of the lab and therefore to more closely recreate normal movement during a variety of activities in both athletic as well as patient populations. Previous work has demonstrated that both movement and loading asymmetry is present in a variety of populations from orthopaedic patients following surgical intervention to athletes as they return to completion following an injury. While previous studies have demonstrated that these movement and loading deficits are present in a variety of populations all of this work has been completed in a controlled laboratory environment.

Following both total hip replacement (Queen, Clin Biomech 2015), and total ankle replacement surgery (Queen, JBJS 2014), Queen Clin Biomech, 2014) both movement and loading asymmetry have been reported to persist for up to 24 months. These asymmetries have been associated with incomplete recovery and it has been proposed that additional post-operative interventions might be needed in order to improve long-term outcomes and restore both loading and movement symmetry. In addition, Paterno, et al as well as other have reported a similar asymmetrical movement pattern that persists following anterior cruciate ligament (ACL) reconstruction (Paterno, CJSM 2007, Dai, AJSM 2012, Butler, Sports Health, 2014). This asymmetrical pattern in post-operative ACL patients has been associated with an increased risk for a secondary injury and therefore an area of focus for rehabilitation as well as injury prevention programs (Paterno, CJSM 2007).

Previous studies have examined changes in loading patterns outside of the lab setting on a variety of athletic surfaces (Queen, BJSM 2008, Orendurff, AJSM 2008). However the collection of this information was not without limitations and at times the set-up and collection of this data can be difficult due to the need for data logging and or a close proximity to the computer. Based on these and other limitations a method of collecting data that can provide real-time feedback without needing to be in the laboratory setting will be essential as we begin to explore how various injuries and pathologic conditions impact activities of daily living in a variety of settings.

METHODS
The purpose of the symposium and this presentation are to stimulate discussion within the biomechanics community and raise awareness about the variety of techniques that can be used for the collection of biomechanical data in a variety of non-laboratory based settings. The collection of plantar loading data has been possible for years using in-shoe pressure systems such as Pedar-X (Novel Electronics, St. Paul, MN) as well as the F-Scan (Tekscan, South Boston, MA). However, the collection and interpretations of this data can be time consuming and have limited applications for immediate feedback to the subject. The current options for the collection of in-shoe pressure data will allow the researcher to collect the data either through data logging, which does not provide immediate feedback to the researcher or the subject or the researcher is required to have the subject move in close proximity to a computer in order to use Bluetooth to obtain the plantar loading data. While these collection methods have provided invaluable information about how the foot is being loaded during a variety of conditions and in a variety of settings, this method does not allow for the flexibility that is needed for the assessment of movement in a "real-life" setting.

The PedoPed (Novel Electronics, St. Paul, MN) is a new device that is designed to deliver on many of the current needs for the assessment of loading in a variety of environments. The PedoPed is a single sensor insole (up to 300Hz) that fits within most

shoes (US Women's 5.5 – Men's 15). The PedoPed does not require a separate transmitter or battery to be worn by the subject. The PedoPed uses Bluetooth technology to link to an iDevice app for data collection. The application allows for the real-time visualization of the vertical force for each foot in two graphical forms. Data collected from the PedoPed can be stored on the iDevice and then downloaded through iTunes for additional analysis.

Figure1: Screen-shot of PedoPed App during 3 mile run data collection.

The preparation and subject set-up take no more than 5 minutes from the time the insole is placed in the shoe until the first trial is collected. All that is required to begin is an accurate body weight (converted to newtons). Once the load information is entered into the iDevice app the subject is asked to stand on one foot and then the other (fingertip touch for stability) in a sequence in order to calibrate the system. Once this is completed and then the insoles are zeroed, data collection can begin.

Throughout the presentation a variety of scenarios for the use of the PedoPed device in a variety of settings from a controlled laboratory environment to running and walking on a nature trail will be described. These examples, including running (Figure 1), biofeedback (Figure 2), and orthopedic rehabilitation (Figure 3), will demonstrate the versatility of the PedoPed as well as its uses for both the collection of research data as well as the ability to set thresholds and provide immediate biofeedback (Figure 2) to the patient independent of the testing location.

RESULTS AND DISCUSSION
A 67 year old female, 5 years post-op from a right TKA was asked to complete a 1 mile walk in a location of her choosing while wearing the PedoPed

Figure 2: Real-time biofeedback during a squat in a patient with an asymmetric loading pattern.

insoles. The total set-up time was 7 minutes and the subject chose to walk on the sidewalks around town. The calibration was completed with a single fingertip touch to improve balance and stability prior to data collection. Data was collected for 30 second every 2 minutes throughout the walk.
Figure 3: Collection of walking data at 0.9 miles with 5yr post-op R-TKA patient

This data (Figure 3) would indicate that this subject has a significant asymmetry with an overload of her non-operative limb.

Through the use of technology like PedoPed and other, researchers and clinicians will be able to monitor movement in any environment in order to replicate specific activities and conditions. The ability to collect in any environment will allow for the design and implementation of interventions to improve long-term health, decrease injury risk factors and hopefully allow individuals to maintain an active and healthy lifestyle.

INTRODUCTION

Developing virtual knee models for clinical and scientific simulations of the patellofemoral joint requires evaluating their predictive capacity, to represent physiological joint kinematics-kinetics and contact mechanics, in order to establish model credibility [1]. With comprehensive testing, specimen-specific models can be developed to represent not only individualized anatomy, but also tissue mechanical properties. In addition, with joint level mechanical testing data, the accuracy of the model can be confirmed.

Recently, the Open Knee(s) project has been launched to mitigate various uncertainties in modeling and simulation of the knee joints with the aim to build completely specimen-specific (geometry and material) three-dimensional finite element representations from different populations with varying gender, age and grades of osteoarthritis [1]. Within this project's framework, specimen-specific patellofemoral joint mechanics have been measured such that specimen-specific evaluation of model performance can be conducted in an elaborate manner. The goal of this document is to provide the specific details of the patellofemoral testing within the framework of the Open Knee(s) project.

METHODS

Six knee specimens were obtained (Table 1). All specimens were absent of knee injury, surgeries or inflammatory arthritis. A specimen preparation protocol allowed placement of optoelectronic measurement sensors (Optotrak, Northern Digital Inc., Waterloo, Ontario, Canada) and registration markers (to relate mechanics data to imaging) on the tibia, femur, and patella.

Table 1: Specimen Characteristics

Specimen #	Gender	Age	Height	Weight	BMI
oks001	Male	71	1.83 m	77.1 kg	23.1 kg/m^2
oks002	Female	67	1.55 m	45.3 kg	18.9 kg/m^2
oks003	Female	25	1.73 m	68.0 kg	22.8 kg/m^2
oks004	Female	46	1.58 m	54.4 kg	21.9 kg/m^2
oks006	Female	71	1.52 m	49.4 kg	21.3 kg/m^2
oks007	Male	71	1.7 m	65.8 kg	22.7 kg/m^2

Anatomical landmarks and MRI-opaque registration spheres were digitized relative to the optoelectronic sensors, respectively, on the tibia, femur and patella and standardized joint coordinate systems (JCS) were created and defined for the tibiofemoral and patellofemoral joints [2]. The specimen was then secured to the robotic Universal Musculoskeletal Simulator [3], capable of six degrees-of-freedom and real-time force feedback using simVITRO™ software (Cleveland Clinic, Cleveland OH). The tibia was secured to two 6 DOF force-torque sensors (SI-1900-80, ATI Industrial Automation, Apex, NC) embedded in a custom stage rigidly attached to the robot. These sensors were used to measure force vectors applied to the tibia by the femur and provide feedback needed to drive the robot. A quadriceps loading system was developed utilizing a Baldor (Fort Smith, AR) model BSM80N-275AE servomotor and a harmonic drive system (CSG-40-50, Hauppauge, NY). The quadriceps tendon was held by a custom wire mesh grip (DCD Design and Manufacturing Ltd., Richmond BC, Canada) and frozen with liquid nitrogen. Quadriceps loading was applied under force feedback control synchronized with the robot to achieve a desired joint loading state.

A Tekscan (Boston, MA) sensor (5051, 1,200 psi range) was inserted in the patellofemoral joint to measure contact mechanics.

Patellofemoral mechanics were characterized under quadriceps loading at tibiofemoral flexion angles of 0°, 15°, 30°, 45°, and 60°. At each flexion angle the tibiofemoral joint was set to a position approximating passive flexion (20 N quadriceps, 20 N tibiofemoral compression, and all other off-axis loads minimized). Then, quadriceps loads were applied at 20, 100, 200, 300, 400, 500, and 600 N. At each loading state, the patellofemoral contact mechanics, patellofemoral kinematics, tibiofemoral kinematics, and tibial loads were measured.

RESULTS AND DISCUSSION
Figure 1: Patellofemoral contact mechanics for oks007 specimen. a) pressure distribution at 60° flexion and at 600 N quadriceps force, b-d) contact force, area, and peak pressure at all flexion angles and loading conditions, respectively.

For the purpose of this abstract, one specimen's results were highlighted. Patellofemoral contact mechanics for a single specimen (oks007) are shown in Figure 1. The pressure distribution at 60° flexion with a 600 N of quadriceps load a dual contact area is shown in Figure 1a. The contact force and area increased with both flexion and quadriceps loading and the peak contact pressure monotonically increased with quadriceps loading (Figures 1b-d), but not with flexion. The highest contact pressure recorded for this specimen was at 45 degrees of flexion. Table 2 illustrates the variability of peak contact pressure across specimens at this same loading condition.

Table 2: Peak contact pressure for each specimen at 45 degrees of flexion and 600 N of quadriceps load.

Peak Contact Pressure (MPa)					
oks001	oks002	oks003	oks004	oks006	oks007
1.76	2.90	2.90	2.22	3.37	2.61

In order to build virtual knee models with accurate specimen-specific joint mechanics, the model predicted joint kinematics-kinetics and contact mechanics should be similar to the experimental measurements for the corresponding specimen. This document outlined the specific details on how patellofemoral testing was completed within the framework of the Open Knee(s) project to provide the opportunity for specimen-specific evaluation. Anatomical images and tissue properties were also collected for the same specimens as part of the Open Knee(s) initiative, aiming to build geometric and mechanically consistent specimen-specific models.

When specimen-specific patellofemoral joint mechanics data are not available, data from the literature can be utilized. However, it is evident that contact mechanics vary largely amongst specimens and such comparisons may suffer from uncertainties associated with anatomical and mechanical variations between specimens (Table 2).

Open Knee(s) project targets to complement the reported data by testing four additional specimens, to further diversify the population of patellofemoral joint data. The next steps involve development of specimen-specific knee models to evaluate against the contact mechanics data collected in this study, for each respective specimen. These models can then be used by any and all interested investigators to further elucidate patellofemoral pathologies and potential treatment options for patients.

AN ACL DENERVATION MODEL FOR DETERMINATION OF THE EFFECTS OF SENSORY AFFERENTS ON JOINT FUNCTION

[1]Christopher Nagelli, [2]James L. Cook, [2]Keiichi Kuroki, [2]Chantelle Bozynski, [1]Timothy Hewett

INTRODUCTION

Anterior cruciate ligament (ACL) injuries are extremely common. Patients sustaining ACL injury also incur damage to other joint tissues with resultant dysfunction. Surgical ACL reconstruction (ACLR) is performed to regain knee stability and allow return to function in a timely manner. Autografts and allografts used for ACLR must undergo cellular repopulation, revascularization, and re-innvervation for joint function to return to normal. The most common complications after ACL injury and ACLR include continued dysfunction, re-tear, and secondary osteoarthritis (OA).[1] These complications may be inter-related and may stem from the inability to fully restore ACL, and whole-joint, integrity and function. Importantly, 50-100% of ACLR patients experience early onset OA with radiographic evidence seen as early as 5 years after ACL injury.[2] These sequelae indicate that current management strategies for ACL injuries are suboptimal and have profound clinical implications regarding long-term prognosis and related healthcare costs.

Several mechanisms for development of OA secondary to ACL injury have been reported, including altered tibiofemoral biomechanics after injury, chondrocyte death due to initial trauma, and neuromuscular control deficits.[3,4] Recent evidence indicates that an absence of sensory information may play a critical role in the development of OA.[5] To investigate this potential mechanism, we developed a novel large animal model to assess the relative contributions of sensory afferents in the ACL and the joint to knee function and early development of OA. We hypothesized that ACL sensory denervation would manifest in knee joint dysfunction and development of early OA.

METHODS

With IACUC approval, purpose-bred, adult research dogs (n=9 dogs, 18 knees) underwent aseptic arthroscopic surgery to create 6 treatment cohorts (**Table 1**). An immunotoxin was used to induce sensory denervation. OX7-saporin has been reported to successfully denervate 80% of the sensory nerve fibers projecting to the knee.[5] Once injected, this immunotoxin was taken up by a nerve through endocytosis and transported back to the cell body where it deactivated the ribosomes, killing the nerve. For this study, OX7-saporin (50ug) was injected into the ACL for the ACL insufficient (denervated) group and into the knee joint for the Joint insufficient (whole-joint denervation) group. Partial transection of the ACL was performed to provide a positive control of known mechanical dysfunction (ACL deficient group) and sham procedures were performed in the contralateral knees (**Table 1**).

Table 1: Project Cohort Description

Study Group	Control	Representative
ACL denervation (n=3)	ACL saline (n=3)	ACL Insufficient
ACL transection (n=3)	ACL sham transection (n=3)	ACL Deficient
Joint denervation (n=3)	Joint Saline (n=3)	Joint Insufficient

After intervention, dogs were enrolled in a regimented exercise program in which they were leash-walked for 20 minutes/day 5 days/week. Gait analysis was performed at weeks 1, 4, 8, and 12 using a pressure-sensitive walkway. Clinically relevant functional assessments of the knees were performed by a board-certified veterinary surgeon,

blinded to treatment, at weeks 4, 8, and 12. At week 12, the animals were humanely euthanatized for arthroscopic, gross, and histologic assessments. Two different raters assessed the histological results in blinded fashion.

RESULTS AND DISCUSSION

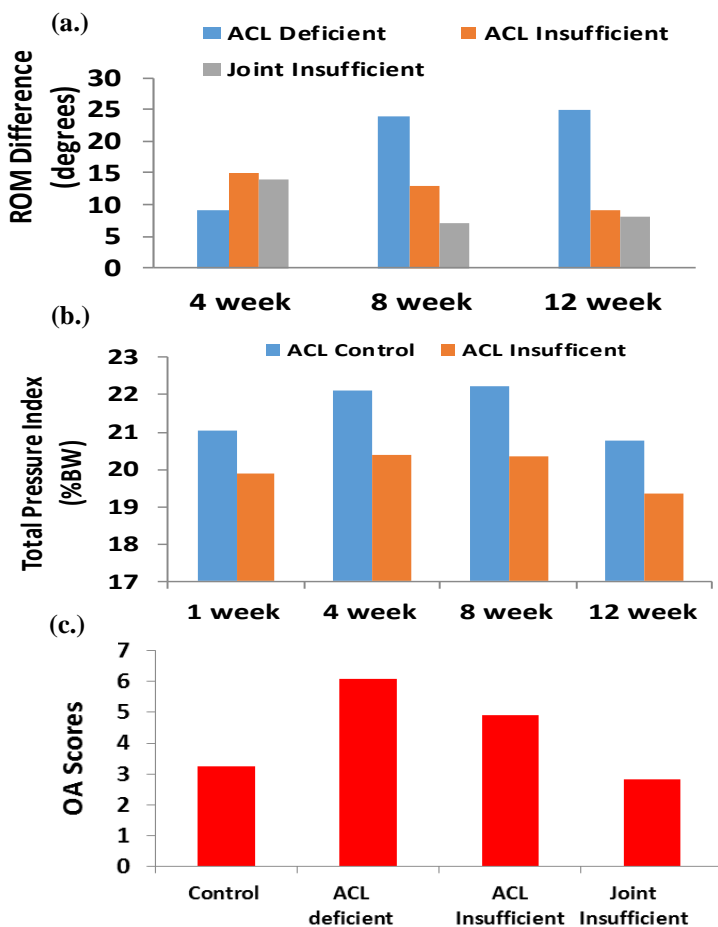
The ACL insufficient group demonstrated joint dysfunction as evidenced by reduced limb loading and comfortable range of motion compared to the contralateral control limb. Interestingly, knee dysfunction and ACL pathology scores associated with ACL denervation were relatively more severe than that associated with whole-joint denervation, but less severe than ACL deficiency. These results indicate that sensory dysfunction of the ACL has effects on knee joint health and function, which has profound implications for management of ACL injuries.


Figure 1: A change in overall joint function (1a and 1b) and tissue health (1c) was observed between the study groups.

Early onset OA secondary to ACL injury is likely a multi-factorial process. Aberrant biomechanics, arthrogenic muscle inhibition, and trauma to the subchondral bone have been strongly associated with the degradation of articular cartilage seen in OA. The present findings indicate that it is necessary to elucidate the effects of ACL afferents on osteoarthritic changes in the knee after ACL injury as the neurologic function of the ligament appears to play important roles in this disease process. This novel model may provide a platform to: (1) investigate the neural mechanisms of osteoarthritis and (2) understand the consequences of selective sensory ablation on joint function. The current study has limitations. In addition to the small number of dogs included in each cohort, the relatively short duration of the study limits the conclusions that can be made from these observations. The effects of the toxin OX7-saporin on sensory afferents in the dog have not been validated, but are part of our ongoing analyses.

CONCLUSION

To the investigators' knowledge, this is the first study to investigate the effects of local sensory denervation of the ACL on knee joint function and health. Further development and use of this novel model holds importance as the ACL is a major sensory structure for knee joint function. After ACL injury, there is disruption in the sensory-motor connection to the knee, which ACL reconstruction does not immediately re-establish. The results of our study indicate denervation of the ACL may lead to joint dysfunction and subsequent osteoarthritic changes. These findings have implications for management of patients with ACL injuries, including rehabilitation programs that focus on re-establishment of sensory-motor function, which may ameliorate rapid development of OA knee.

PEDIATRIC OBESITY AND WALKING DURATION AFFECT MEDIAL & LATERAL TIBIOFEMORAL COMPARTMENT CONTACT FORCES

Zachary F. Lerner, Wayne J. Board, and Raymond C. Browning

Colorado State University, Fort Collins, CO, USA
email: Zach.Lerner@ColoState.edu web: http://pal.colostate.edu

INTRODUCTION

Obese children can improve their health outcomes by engaging in sufficient walking and running physical activity. However, since obese children have greater muscle force requirements relative to lean-mass during locomotion [1], continuous bouts of walking or running may elicit fatigue, which may alter joint loading and increase injury risk. Altered tibiofemoral loading during daily physical activity in obese children is theorized to contribute to their well-documented increased risk of orthopedic disorders of the knee (e.g. growth plate suppression and joint malalignment); conditions thought to lead to a cycle of weight gain [2,3]. However, it is unknown how tibiofemoral loading is altered by pediatric obesity during walking and this limits our ability to evaluate the risk-benefit ratio of physical activity on the musculoskeletal system. *This study sought to determine the effects of pediatric obesity and walking duration on the magnitudes, distribution, and loading rates of medial and lateral tibiofemoral contact forces.*

METHODS

We collected experimental biomechanics data during treadmill walking at 1 m•s^{-1} for 20 minutes in 10 obese (BMI$_Z$ > 95%) and 10 healthy-weight (5% < BMI$_Z$ < 85%) 8-12 year-olds. Age, sex, and leg length were similar between groups.

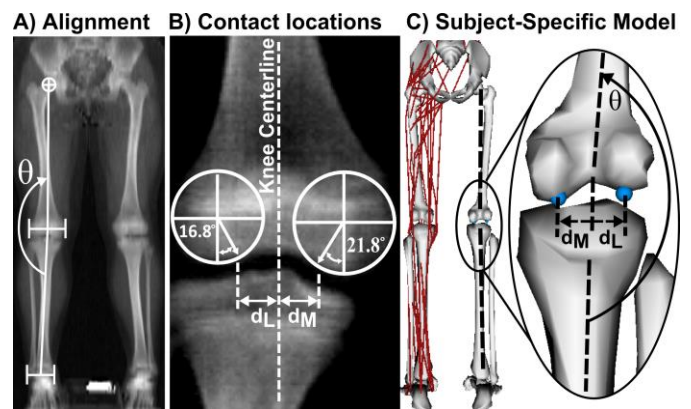
We used dual x-ray absorptiometry to capture whole body and higher-resolution knee radiographs for each child (Fig. 1A, B). We defined a medial tibial epiphysis region of interest (ROI) and measured the areal bone mineral density (BMD) (Fig. 2A). In a prior model development and methodology validation study, we introduced a knee mechanism into a full-body OpenSim gait model that was capable of incorporating subject-specific tibiofemoral alignment and centers-of-pressure, and accurately resolving medial & lateral compartment contact forces [4] (Fig. 1C). In the present study, we created subject-specific musculoskeletal models by specifying leg alignment and compartment centers-of-pressure by analyzing the radiographs for each child using established methods [5]. In OpenSim, we used weighted static optimization to estimate the muscle forces that reproduced the measured walking motions, and calculated the contact force in each compartment using Joint Reaction [4].


Figure 1: Measurement (A,B) and specification (C) of alignment (θ) & medial and lateral compartment contact locations (d$_M$/d$_L$) [5] for each subject-specific model.

RESULTS AND DISCUSSION

Obesity and walking duration affected tibiofemoral loading (Fig. 2-4). In the obese vs. healthy-weight children, peak contact forces (N) during stance were 2.1 times greater in the medial compartment (*p*<0.001) (Fig. 2B), but similar in the lateral compartment (*p*=0.406). Normalized to the BMD in the medial tibial epiphysis ROI, peak medial forces (N•kg^{-1}•cm^2) were 1.77 times larger in the obese vs. healthy-weight individuals (Fig. 2C).
Figure 2: Medial tibial epiphysis ROI (A), and absolute (B) and BMD normalized (C) medial compartment contact forces in the obese (solid) and healthy-weight (dashed) children. * denotes a significant difference.
Figure 3: The linear relationship (r^2=0.79) between % medial load (%ML) and body fat % (BF%); %ML = 1.3•BF% + 28.3.

At the start time-point (1st minute after 5 minute acclimation period), the average medial load share during stance was 85% in the obese children vs. 63% in the healthy-weight children. At the end time-point (20th minute), the average medial load share was 90% in the obese children vs. 72% in the healthy-weight children (Fig. 4).
Figure 4: Media load share in obese and healthy-weight children at the start and end time-points.

Medial compartment loading rates were 1.78 times greater in the obese vs. healthy-weight participants and increased 17% in both groups at the end vs. the beginning time-point (*p*=0.001).

CONCLUSIONS

During adolescence there is a disassociation between longitudinal bone growth and mineral accrual, affecting bone microarchitecture. Our finding of elevated medial compartment force relative to the underlying BMD supports the theory that altered loads in obese children during walking may contribute to their increased risk of developing orthopedic disorders of the knee. The strong relationship between medial load share and body fat % (Fig. 3) also supports the previously reported positive association between pediatric obesity and knee pain/pathology. Walking duration affected loading in both groups, yet the baseline values were greater in the obese children. Thus, longer activity durations may increase the risk of musculoskeletal injury more in obese vs. healthy-weight children, so shorter durations may be advisable.

INTRODUCTION

Malalignment, high body mass index, and soft tissue injuries have all been associated with knee osteoarthritis (OA). Patients with knee OA most typically suffer from varus malalignment, which overloads the medial compartment. Medial knee compartment contact forces can be reduced by the use of valgus bracing[1,2] and lateral knee compartment forces can be reduced by the use of varus bracing[1]. The effect of lateral and medial foot wedges with and without valgus knee bracing upon compressive joint loading is unknown. Total knee contact force was measured on an individual wearing medial and lateral foot wedged insoles with and without a knee brace. The test subject has been fitted with an instrumented knee replacement (e-tibia) that measures total knee contact force *in vivo*. We hypothesize: (**H1**) lateral wedged foot insoles will decrease medial compartment forces, while medial wedged foot insoles will decrease lateral compartment forces, and (**H2**) that wedged foot orthoses will further decrease total knee contact forces compared with knee bracing alone.

METHODS

A pilot study was conducted on a single-subject (female, 69 years old, 81 kg) who had an e-tibia total knee replacement (TKR). Composed of a polyethylene insert, tibial tray, and telemetry system, the e-tibia measured three forces (F_x, F_y, F_z) and three moments (M_x, M_y, M_z) through 12 load cell strain gages integrated within the TKR[3]. The subject walked at her self-selected speed on a level walkway while simultaneously measuring e-tibia contact loading and 3D inverse dynamics (12 Eagle cameras, Motion Analysis Corp, Santa Rosa, CA; 2 Bertec, Columbus, Ohio; and 2 AMTI, Bilarica, MA force plates). The test subject walked with a knee brace (Unloader Select, Ossur Americas, Foothill Ranch, CA) adjusted to 4° valgus and in the unbraced condition representing baseline (control). In addition, the test subject was fitted with 5° medial and lateral wedged full length foot insoles which were assessed with and without the knee brace. Inverse dynamics and e-tibia data were simultaneously collected from the subject with four trials per condition. Total contact forces from the e-tibia were stratified into medial and lateral compartment forces using subject-specific regression equations.

RESULTS AND DISCUSSION

Medial (solid) and lateral (dashed) compartment contact forces were measured by the e-tibia (Fig. 1). The unbraced condition (control) shown in purple demonstrated the largest peak forces in both the medial and lateral compartments of the knee. The Unloader Select knee brace (4° valgus correction) shown in green significantly reduced peak contact forces in the medial compartment (~20%). Medial wedges alone shown in dark blue significantly reduced the 1st peak contact force in the medial compartment but not the 2nd. The lateral wedges alone shown in yellow significantly reduced the 2nd peak contact force but not the 1st. Neither wedge alone had a substantial impact on lateral compartment forces. The medial and lateral wedges in conjunction with knee bracing are shown in light blue and red and were both effective at reducing medial compartment contact forces.

A valgus knee brace alone or with wedged foot insoles was able to significantly reduce peak contact forces within the medial compartment of the knee (Fig. 1). Wedged foot orthoses alone were able to reduce medial peak contact forces preferentially. Neither wedged insole was effective at reducing lateral compartment forces supporting partial acceptance of hypothesis 1. The addition of either medial or lateral wedged foot insoles to knee bracing did not further reduce peak contact forces. This suggests the mechanism for reducing contact forces is through load sharing via the brace hinge.[4] Wedge insoles employ a different strategy, which is to shift the load through altering foot alignment. Given that the addition of wedged insoles did not further reduce contact forces compared knee bracing alone hypothesis 2 is rejected.

CONCLUSIONS

Wedged foot orthoses were able to preferentially reduce the 1st or 2nd peak of the medial compartment knee contact force. Knee braces alone were capable of reducing both the 1st and 2nd peak of the contact force and the addition of medial or laterally wedged foot insoles did not provide additional benefit to braces alone.

CAN OSTEOARTHRITIS RADIOGRAPHIC SEVERITY AND PAIN BE EXPLAINED BY JOINT MECHANICS?

[1] Elizabeth A Hassan and [1] Kevin J Deluzio

[1] Dept. of Mechanical Engineering, Queen's University, Kingston, ON, Canada
email: elizabeth.hassan@queensu.ca

INTRODUCTION

Intuitively, it would make sense for radiographic signs of osteoarthritis severity to be closely related to pain and joint mechanics during gait. However, quantifying this relationship has proven to be analytically challenging, particularly in patients with mild or moderate severe osteoarthritis. The previous literature is not conclusive on the topic, Astephen *et al* [1] linked pain to stride characteristics, but not to mechanics, but was able to link knee adduction moment to radiographic severity, and Zifchock *et al* [2] found that pain did not correlate with knee adduction moment, but did correlate with radiographic indicators of severity. In contrast, Henriksen *et al* [3] linked increased pain to decreased peak knee adduction moment. This abstract proposes that links between pain, radiographic severity and mechanics can be quantified using Partial Least Squares, and that this technique offers some interpretation advantages over more traditional tools such as multiple linear regression.

Partial Least Squares (PLS) [4] is a generalized form of principal component analysis (PCA). An advantage of PLS over PCA and multiple linear regression is that it is possible to analyze multiple, continuous response (Y) variables simultaneously. This advantage is particularly useful in cases with multiple correlated predictors and responses.

METHODS

To evaluate the performance of PLS as an analysis and interpretation tool for biomechanical data, it was tested on an already published data set. The data set includes hip, knee and ankle kinematic and kinetic data from 37 subjects with mild to moderate osteoarthritis; the details of the data collection are summarized in Astephen *et al* [1]. The analysis procedure was as follows:

Preprocessing:
Calculate PC scores for 3 components on each variable
$$[PC_1^{Knee\ Ax}\ PC_2^{Knee\ Ax}\ PC_3^{Knee\ Ax}]=PCA(Knee\ Flexion\ Angle\ Ax_{37x101})$$
$$[PC_1^{Knee\ Ay}\ PC_2^{Knee\ Ay}\ PC_3^{Knee\ Ay}]=PCA(Knee\ Adduction\ Angle\ Ay_{37x101})\ etc...$$

X is composed of all PC Scores for all variables
$$X=[PC_1^{Knee\ Ax}\ PC_2^{Knee\ Ax}\ PC_3^{Knee\ Ax}\ PC_1^{Knee\ Ay}...]_{37x45}$$

Y is composed of outcome measures, VAS and pain
$$Y=[VAS\ Pain]$$

Variable Selection:
Calculate the PLS model, reject least important variable, repeat until 5 variables remain in X

PLS:
Calculate scores for 2 Latent Variables
$$[T_1\ T_2]=PLS(X,Y)$$

MLR:
Predict Y based on T_1 and T_2
$$Y_{VAS}=a_0+a_1T_1+a_2T_2$$
$$Y_{pain}=b_0+b_1T_1+b_2T_2$$

The PCA analysis was conducted using MATLAB code written by our lab group. Three principal components were extracted for the flexion and abduction-adduction angles, and all moments at the hip, knee and ankle. The PLS analysis was conducted using MATLAB code written by the author, based on the algorithm outlined in Abdi [5]. The number of columns in X was reduced to a more parsimonious set of 5 variables using the criteria described in Andersen and Bro [6]. Multiple linear regression (MLR) on the PLS latent vector scores was conducted with built in MATLAB functions.

RESULTS AND DISCUSSION

The response (Y) variables were radiographic VAS (Visual Analog Scale, average of grade from two surgeons, mean 4.4, range 1.1 to 8.3) and the pain

subscale from the WOMAC Score (mean 7.2, range 0 to 18). The Kellgren-Lawrence (KL) Score for these patients ranged from 1 to 4.

The predictor variables selection process extracted kinematic and kinetic variables as shown in Figure 1, along with the regression weights calculated as part of the PLS process. The knee moment variables were of similar importance to the prediction of VAS and pain, but in the opposite direction. Hip adduction moment PC2 score (corresponding to the first peak) was an important predictor for pain, but was not an important factor in predicting radiographic severity. The ankle toe in-toe out moment PC1 (corresponding to magnitude) was important for predicting radiographic severity, but not pain. However, severity and pain are not associated with each other, and the relationship between mechanics and pain and the relationship between mechanics and radiographic severity are different. Multiple linear regression revealed that mechanics better explained radiographic severity than pain, with R^2 values of 0.3 for VAS, 0.2 for pain.

The importance of knee adduction moment is consistent with the previous literature relating radiographic severity and this feature. Henriksen *et al* [2] noted the relationship between this variable and pain, but Henriksen analyzed the peak knee adduction moment, and the PC2 extracted by this analysis appears to also related to the curve shape, as shown in Figure 2.

CONCLUSIONS

The results of the PLS analysis suggests that mechanics can be linked to both radiographic severity and pain in moderate OA patients. The Astephen *et al* 2011 paper was not able to link pain to joint mechanics, but the current analysis was able to using the same data, which indicates that multivariate methods may be required to quantify the pain-radiographic severity-mechanics relationship.

ACTIVE AND PASSIVE KNEE STABILITY IN PATIENTS WITH SEVERE OA

[1] Gregory Freisinger, [1] Erin Hutter, [1] Jackie Lewis, [1] Rachel Baker, [1] Jeffrey Granger, [2] Matthew Beal, [1] Xueliang Pan, [1] Laura Schmitt, [1] Robert Siston and [1] Ajit Chaudhari

INTRODUCTION

Osteoarthritis (OA) is the largest single cause of disability in the United States, and the knee joint is most frequently affected [1]. Increased knee laxity has been reported in knee OA patients compared to controls [2], and additional active knee stability, by increased muscle activation or co-contraction of antagonist muscles, has been hypothesized to assist in knee stabilization [3]. Muscle guarding may reduce the magnitude of measured laxity, and it is currently unknown how large of an effect this plays in identifying a relationship to active stability.

The primary purpose of this study was to identify the association between passive knee laxity, measured when each participant is under general anesthesia, and contributors to active knee stability in participants with severe OA. We hypothesized that increased passive knee laxity would be associated with increased quadriceps muscle activity and co-contraction indices during gait.

METHODS

Twenty individuals (22 total knees: 7 male / 15 female, age=59.0 $\pm$ 7.3 y, ht=1.68 $\pm$ 0.11 m, mass=93.5 $\pm$ 15.3 kg, BMI=33.3 $\pm$ 4.5 kg/m^2) completed this study after providing IRB approved consent. Participants had predominantly medial compartment tibiofemoral OA and were awaiting total knee arthroplasty (TKA). Prior to surgery, each participant completed gait analysis in Ohio State's Movement Analysis and Performance Lab. Participants walked along a 10 m path at a self-selected speed (0.98 $\pm$ 0.26 m/s). Marker data were collected at 150 Hz utilizing 10 motion-capture cameras (MX-F40; Vicon; Oxford, UK). A modified point-cluster technique marker set was used in conjunction with a functional hip joint center to calculate lower extremity kinematics.

Wireless surface electromyography (EMG) (Telemyo DTS; Noraxon USA, Inc; Scottsdale, AZ) was recorded at 1500 Hz for specific lower extremity muscles that cross the knee joint on the involved limb. Three separate, unweighted tasks were used as submaximal reference activities to normalize EMG signals. Seated uni-lateral knee extension was used to normalize the rectus femoris (RF), vastus medialis (VM), and vastus lateralis (VL). Standing uni-lateral knee flexion was used to normalize semimembranosus (SM) and biceps femoris (BF). Standing bi-lateral ankle plantarflexion was used to normalize medial and lateral gastrocnemius (MG & LG). The highest 500ms running average of EMG for each muscle was used for normalization.

The average quadriceps activation (avgQUAD) and average co-contraction indices (avgCCI) were used as active stability measures for their potential to stabilize the knee joint during gait. avgQUAD was found by calculating the mean of RF, VM, and VL muscle activity and avgCCIs were calculated using Equation 1 [4] for the following antagonist muscle pairs: quadriceps and hamstring (QH); quadriceps and gastrocnemii (QG); VM and SM (MQH); VL and BF (LQH); VM and MG (MQG); and LV and LG (LQG).

$$avgCCI = \frac{1}{n}\sum_{i=1}^{n}\left(\frac{lower\ EMG_i}{higher\ EMG_i} \times (lower\ EMG_i + higher\ EMG_i)\right)$$

Equation 1. Average co-contraction index (avgCCI) was calculated using the relatively lower and higher EMG signals for antagonistic muscles.

avgQUAD and avgCCIs were calculated over the weight acceptance phase of gait (WA), which was defined as the time period from initial heel contact to peak knee flexion. Four trials of gait were used to calculate ensemble averages for the muscle activations during WA. Selected muscle activation values from specific participants were dropped from further analysis due to poor signal quality, so the number of participants used are shown in Table 1.

Passive varus-valgus knee laxity was measured intra-operatively using a custom navigation system and knee stability device [5] in the osteoarthritic knee before TKA. Laxity was calculated as the difference in varus-valgus knee angle when the knee was loaded with 10 Nm of varus and valgus moment, respectively. Each participant's overall varus-valgus laxity was the average value found during three trials in the operating room.

Non-parametric statistics were chosen after an initial inspection of the data revealed 4 of the 7 EMG variables were not normally distributed (Anderson-Darling test; $p<0.05$). Spearman's rank order correlations were calculated for varus-valgus laxity and EMG variables of interest. A p-value <0.05 was used to indicate statistical significance.

RESULTS AND DISCUSSION

No association was observed between passive varus-valgus laxity and any active stability measure during the WA phase of gait. The distribution of passive varus-valgus laxity, avgQUAD activation and avgCCIs are reported in Table 1.

Quadriceps force can create a moment to counteract varus-valgus rotation, as a result of the bicondylar nature of the knee joint and attachment point of the quadriceps on the tibia; however this was not related to varus-valgus laxity in this cohort. While no CCI was related to laxity, LQH was significantly larger than MQH (Mann-Whitney U test, p=0.005). This may be a neuromuscular strategy to stabilize the adduction moment during weight acceptance, and prevent the lateral side of the femur from lifting off the tibia [3].

Table 1. Variables of interest and Spearman's rank order correlation to varus-valgus laxity

	n	Mean ± SD / Median [IQR]	rho	P-value
VV Laxity, °	22	4.7 ± 2.4	1	n/a
avgQUAD, %	22	90.4 [46.3]	-0.171	0.446
QH avgCCI	19	1.15 [0.65]	0.070	0.775
QG avgCCI	21	0.26 [0.28]	-0.136	0.556
MQH avgCCI	22	0.57 [0.61]	0.067	0.786
LQH avgCCI	19	1.51 [0.74]	0.103	0.647
MQG avgCCI	22	0.24 [0.22]	-0.094	0.687
LQG avgCCI	21	0.30 [0.36]	-0.132	0.559

Footnotes: Interquartile range (IQR); varus-valgus (VV); average (avg); co-contraction index (CCI); quadriceps/hamstrings (QH); quadriceps/gastrocnemii (QG); medial (M); lateral (L).

CONCLUSIONS

The primary purpose of this study was to identify the relationship between passive knee laxity and contributors to active knee stability in participants with severe OA. Contrary to our hypothesis, we found no associations between passive varus-valgus laxity and average quadriceps activity or any of the co-contraction indices during gait. Stability of the knee joint necessitates a complex control strategy; further study is needed to understand the contributions of passive and active structures in osteoarthritic populations.

INFLUENCE OF TENDON STIFFNESS ON MUSCLE-TENDON INTERACTION DYNAMICS DURING CYCLIC CONTRACTIONS

[1] Jonathan A. Doering and [1] Gregory S. Sawicki

[1]UNC-NC State Joint Department of Biomedical Engineering, Raleigh, NC, USA
email: jadoerin@ncsu.edu

INTRODUCTION

Series elastic elements (SEE) (e.g., tendon and aponeurosis) are critical for efficient contractions during cyclic, steady locomotion tasks (e.g., walking, hopping, running), as they can store and return significant mechanical energy, reducing mechanical work required by muscle (CE) [1]. In many clinical conditions, the SEE stiffness is altered, becoming either more or less stiff [2]. In addition, the SEE of muscle-tendon units (MTU) tend to get relatively longer when moving from proximal to distal lower-limb joints. The goal of this study was to examine how changes in MTU architecture via altered SEE stiffness impact the 'tuned' interaction between CE and SEE during cyclic locomotion. We hypothesized that there would be an optimal, intermediate SEE stiffness that generated high MTU forces, isometric strut-like CE behavior, and facilitated large amounts of elastic energy storage and return in the SEE (i.e., 'tuned' MTU dynamics).

Figure 1. Lumped ankle plantarflexor MTU model of vertical hopping. A bodymass in gravity with fixed mechanical advantage (L_{in}/L_{out}) simulates ankle MTU dynamics during cyclic contractions. Simulations were performed with series elastic stiffness, k_{SEE} at baseline (180kN/m), $k_{SEE}/3$ (54kN/m) and $k_{SEE}*3$ (540kN/m).

METHODS

We employed a MTU model containing a muscle contractile element (CE) with a parallel elastic element (PEE) and a series elastic element (SEE) that acted in opposition to a point mass experiencing constant gravitational forces, simulating MTU dynamics of the lumped ankle plantarflexors during cyclic contractions [3] (Fig. 1). Force was generated in the modeled CE by a Hill-type muscle with classic force-length and –velocity relationships, with stimulation modeled as a square wave pulse with a duty of 10% relative to the cycle period. The PEE and SEE followed non-linear force-displacement relationships taken from recent literature, and the SEE compliance was parametrized by specifying the stiffness, k_{SEE}, in the linear region. To address the role of SEE stiffness on MTU interaction dynamics we compared MTUs with k_{SEE} in a compliant (=60kN/m), baseline (=180kN/m) and stiff (=540kN/m) setting. Then we performed two simulation protocols on each case: (1) a 'passive pluck' of the modeled MTU where the passive components oscillated against the load (i.e. no stimulation, to establish the natural frequency) and (2) a dynamic contraction, where the MTU was actively driven with neural stimulus at the passive natural frequency from baseline condition (=~2.2Hz) and 10% duty factor. Finally, to address the hypothesis, we extracted and compared force, length change and mechanical power dynamics of the MTU, CE and SEE from each simulation case.

RESULTS

The passive resonant frequencies, ϖ_0, computed based on a period of oscillation from 'passive plucks' for $k_{SEE}/3$, k_{SEE}, and $k_{SEE}*3$ were 1.64, 2.20, and 2.36 Hz, respectively. Results from the dynamic contractions driven at $\varpi_{DRIVE} = 2.2$Hz and 10% duty (i.e., stimulation period = 450ms; duration=45ms)

demonstrated that in the compliant $k_{SEE}/3$ condition (i.e., $\varpi_{DRIVE} > \varpi_0$) (Fig. 2, left), the MTU produced less force, underwent more excursion at lower velocity, and produced less mechanical power than the baseline k_{SEE} condition (Fig. 2, middle). With a compliant SEE, the CE underwent significant length changes, shortening in the first half of the contraction and performed more mechanical work than baseline. In the stiff $k_{SEE}*3$ condition (i.e., $\varpi_{DRIVE} < \varpi_0$) (Fig. 2, right) the MTU produced similar force but at higher rate and with more passive contribution, underwent less excursion at lower velocity and produced less mechanical power than baseline. With a stiff SEE, the CE underwent significant length changes, lengthening in the first half of the contraction and performed more mechanical work than baseline.

CONCLUSIONS

These results strongly support our hypothesis that there is a 'sweet spot' in SEE stiffness that leads to 'tuned' MTU interaction with high forces and the majority of the MTU mechanical power cycled in elastic tissues. If the SEE is too compliant, the CE undergoes internal shortening, performs significant mechanical work suffers reduced force production force output suffers due to force-length relationship of muscle. If the SEE is too stiff, the CE is passively stretched, and can produces high forces at high rate, but at dangerously long lengths. These results suggest an underlying fundamental principle; that for optimal function, neural drive of an MTU should match its architecture such that it is driven near its passive natural frequency.

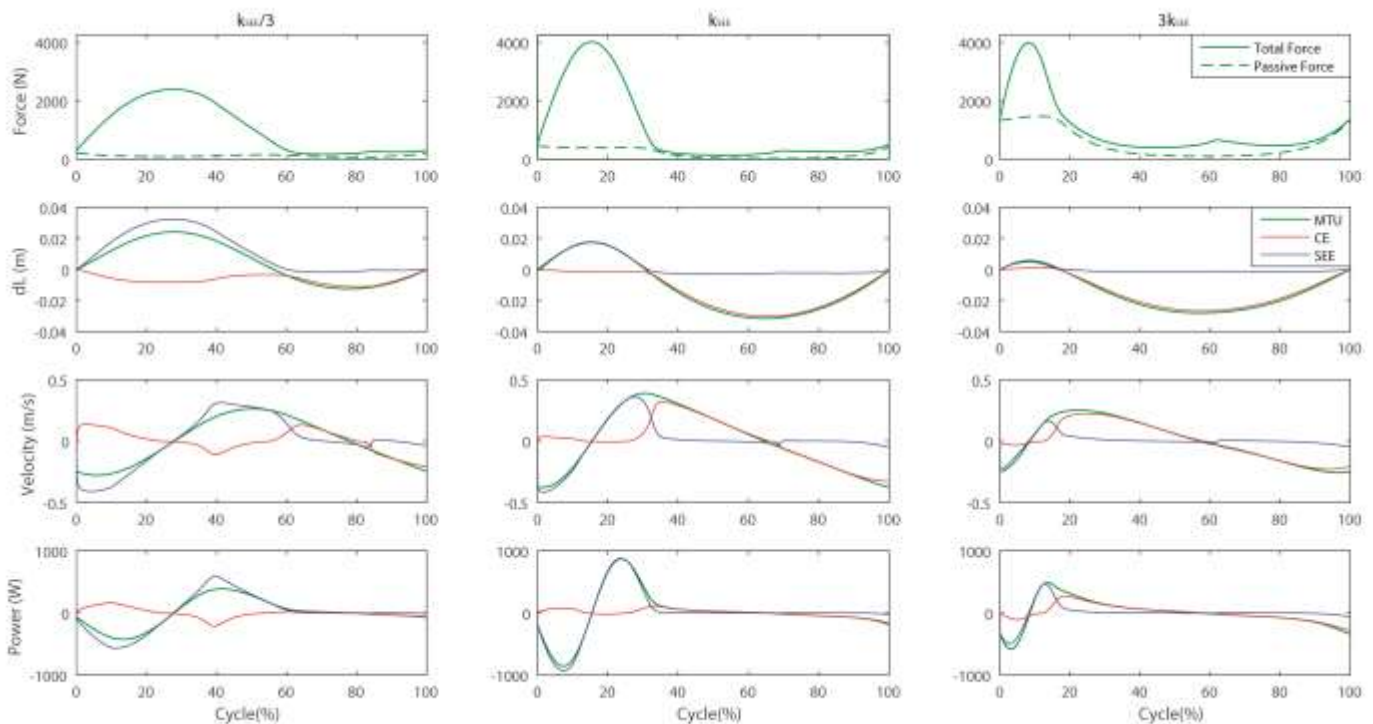

Figure 2. Simulated ankle plantarflexor contraction dynamics for MTUs of varying compliance in steady locomotion cycles. Force, length change, velocity and mechanical power (top to bottom) for MTU (green), CE (red) and SEE (blue) during contraction cycles with k_{SEE} going from compliant ($k_{SEE}/3$=60kN/m) to baseline (k_{SEE}=180kN/m) to stiff (k_{SEE}=540kN/m) (left to right). Baseline shows optimal 'tuning' for efficient contractions dominated by elastic energy storage and return in SEE.

3D FINITE-ELEMENT MODELING OF THE SOFT PALATE REVEALS SYNERGIC ACTIONS OF SPEECH MUSCLES

[1] Joshua M. Inouye, [2] Jamie L. Perry, [1] Kant L. Lin, and [1] Silvia S. Blemker

[2] East Carolina University, Greenville, NC, USA
email: ssblemker@virginia.edu

INTRODUCTION

The velopharyngeal (VP) mechanism is a complex deformable system consisting of several muscles and complicated soft tissue geometry within the soft palate. Understanding the mechanics of this system is essential for developing effective treatments for speech disorders and improving surgeries for cleft palate patients. However, the mechanics of the soft palate are complex. Several muscles interact with one another to move the soft palate during speech, and the physics of the interactions between these muscles are poorly understood. The goal of this work is to develop a multi-muscle model of the soft palate and use model to examine how the various muscles of the soft palate contribute to the movement of the soft palate during speech.

METHODS

We created a 3D finite element model of the VP mechanism based on MRI scans of a 20-year-old Japanese male subject with normal VP anatomy. The model components included the soft palate, the posterior pharyngeal wall (PPW), the levator veli palatini muscle (L), the musculus uvulae (U), and the palatopharyngeus muscle (P) (Figure 1).

Simulations were based on the muscle and soft tissue mechanical properties from the literature [1,2]. The soft tissue was modeled as an isotropic, hyperelastic Mooney-Rivlin material with elastic modulus of 25kPa and muscle was modeled as a transversely isotropic material. Muscle fiber trajectories for the muscle material were determined using computational fluid dynamics [3]. We used Sefea[TM] (Strain-Enriched FEA, AMPS Technologies) finite element solver with explicit strain energy function specification and automatic meshing of 4-node enhanced tetrahedral elements to run the simulations [4]. In these half-symmetry simulations, we activated all combinations of the three simulated palate muscles. We measured soft palate elevation, closure force, and contact length (Figure 2a) for each combination at muscle activation levels ranging from inactive to fully active, smoothing the variables to remove numerical noise.
Figure 1: We used MR images to create a 3D finite-element model of the velopharyngeal mechanism with three muscles (cyan).

RESULTS

The different combinations of muscle activations show markedly different deformations (Figure 2b). Deformations in dynamic speech MRI data [5] compared favorably with model deformations for L activation (Figure 2c). L and LU activation reached similar soft palate elevations as the MRI data (Figure 2d). Experimental speech data for closure force [6] compared most favorably with L and LU activation (Figure 2d). L, LU, LP, and LUP activation combinations were able to produce contact length ranges measured in a previous MRI study [7] (Figure 2d).

DISCUSSION

The different deformations created by muscle activations show both synergistic and antagonistic actions. For example, L and P synergize to retract

the velum towards the PPW. However, their effects on soft palate elevation are antagonistic. Proper action of L (the largest palate muscle) is necessary but not sufficient to reproduce data comparing favorably with experimental data in normal speech (Figure 2d). These deformation patterns and future modeling studies will help in surgical planning for cleft palate patients (where the musculature must be surgically reconstructed) and aid in clinical assessment of dysfunctional motor control during speech. More broadly, these simulations demonstrate the applicability of muscle biomechanical analysis to studies of speech function.

AGENT-BASED MODEL OF INFLAMMATION AND REGENERATION FOLLOWING CONTRACTION-INDUCED MUSCLE INJURY

Kyle S Martin, Kelley M Virgilio, Shayn M Peirce and Silvia S Blemker
The University of Virginia, Charlottesville, VA, USA
email: ksm5ha@virginia.edu

INTRODUCTION

Skeletal muscle has an extraordinary ability to regenerate and recover from injury. After the initial insult (such as a contusion, toxin, laceration, contraction-induced injury, etc.), muscle tissue regenerates through a sterile inflammatory response [1]. This response involves the spatially dynamic recruitment and activation of numerous cells, including neutrophils, macrophages, satellite stem cells, muscle fibers, and fibroblasts [1]. The timing and magnitude of response is dependent on the type and severity of injury. For instance, muscle regeneration and speed of recovery is different between a single lengthening contraction with large strain vs. multiple contractions with a small strain [2]. Additionally, the timing of recruitment of inflammatory cells have been shown to be dependent the number of muscle contractions.

In this study, we wish to probe the differences in the inflammation and muscle regeneration responses across varying levels of strain-induced injury. We have developed a novel multi-scale modeling platform that couples micromechanical finite element modeling with cellular level agent-based modeling in order to explore injury-related inflammation and muscle regeneration.

METHODS

The flow of our modeling framework can be summarized in six steps. Step 1: we utilized an agent-based model to create a cross-section of a muscle fascicle (muscle fibers and ECM) [3]. Step 2: we created a micromechanical model reflecting the same cross-sectional geometry [4, 5]. Step 3: we applied boundary conditions to the micromechanical model based on a macro-scale simulation of an eccentric contraction (similar to [5]). Step 4: the predicted strains were mapped onto our agent based model. Areas of strain above a threshold of 15% were considered damaged and

simulated as necrotic tissue. Step 5: we simulated inflammation and regeneration at the cellular level using our agent based model. In agent based modeling (ABM), agents are given rules or behaviors to follow. In our model, each cell was considered an agent. Over 50 rules were defined in the ABM, many of which are stochastic in nature. A subsample of these rules is provided in Table 1. We tracked the interactions between and among satellite stem cells, neutrophils, pro- and anti-inflammatory macrophages (labeled M1 and M2 in Table 1 and Fig 1), muscle fibers, and fibroblasts. Our primary output focused on inflammatory cell populations through 10 days of regeneration.

RESULTS

The simulations were able to generate inflammation responses similar to published literature [1,6]. In particular, the timing and peak populations of the simulated neutrophils and M1 macrophages were generally consistent with muscle injury studies [1,6]. However, muscle injuries often result in a M2 macrophage population peak around day 4-7, and ours peaked around day 3. However, the predicted M2 population remained elevated for the entire 10-day simulation period, which has been seen in the literature [1,6].

DISCUSSION

The presented results illustrate the potential of predicting the inflammatory and regenerative response from injury. While our current data includes one strain profile and threshold of damage, which resulted in ~20% damage, future work will include predicting the response from low, medium, and high levels of strain. We wish to explore changes in inflammation and recovery from different damage profiles, something that has been seen previously [2]. Furthermore, the model has application to prediction of the behavior of many cell types and muscle fiber metrics that are also

highly applicable to the regenerative response of muscle, including fibroblast and satellite stem cell populations, necrotic/damaged area, and average fiber cross sectional area (CSA).

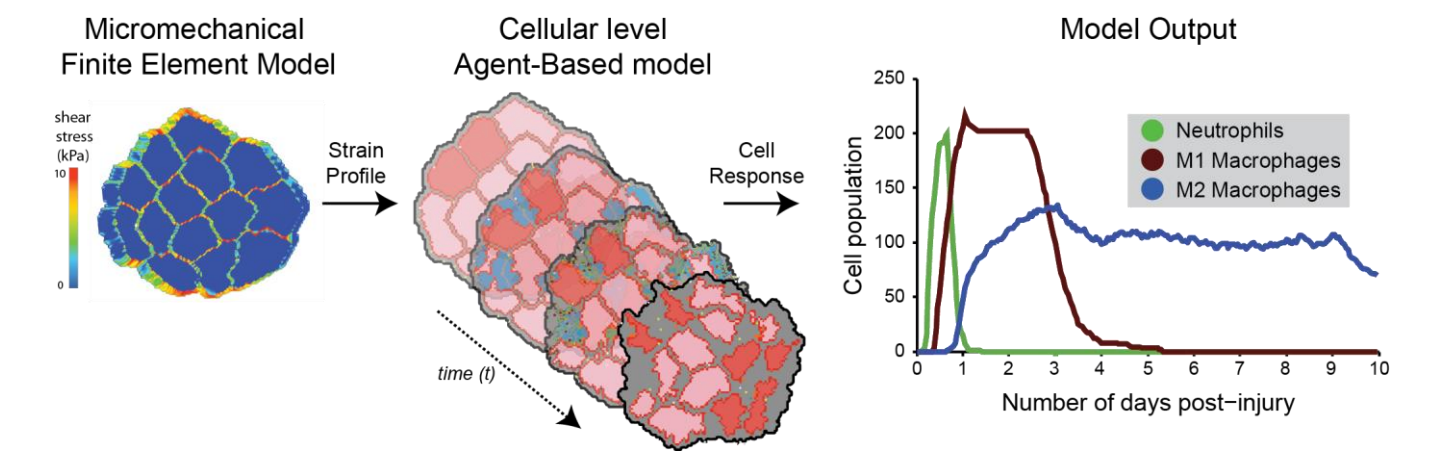

Figure 1: Multiscale computational model simulates how changes in strain affect dynamic muscle remodeling and inflammation. (From left) Screen shot of a simulated muscle fascicle cross-section showing how the micromechanical finite element model predicts shear stress throughout the muscle cross-section. A strain profile was outputted to the agent-based model (middle); where strain levels exceeding a threshold proscribed the locations of muscle fiber damage. Muscle fibers that are damaged become necrotic and produce damage-related proteins that invoke inflammation in the model. Populations of different inflammatory cells are tracked over the course of 10 days (right).

Table 1. Example rules implemented in the ABM	
Behavior	*Rule*
Fibroblast secretion of IGF-1 as function of strain	8.8×10^{-5} pg/cell/hr
Fibroblast apoptosis in response to TNF-alpha, where baseline apoptosis rate equals one cell every 15 days	If $0.2 < $ TNF $ < 20$ ng/ml: apoptosis rate = baseline apoptosis rate + (2.5 * (log TNF-alpha) + 2.75) * 100 - 100
Change in muscle fiber cross-sectional area as a function of protein synthesis and degradation.	$$dCSA/dt = \beta S - \beta D * CSA$$ βS : protein synthesis coefficient (μm2/hr) βD protein degradation coefficient (1/hr). CSA: Cross sectional area
Neutrophils apoptose after phagocytosis of necrotic tissue, and each phagocytosis event makes it more likely to apoptose	Neutrophil: If random 3 + 3 <= # of phagocytosis events then become apoptotic
Macrophages switch phenotype when they engulf apoptotic neutrophils: if a macrophage engulfs 2 apoptotic neutrophils it has a chance of polarizing from M1 to M2.	M1 Macrophage: If random (6 - # of neutrophils engulfed) < 1 then become M2 Macrophage
Activated satellite cells sense growth factor and secrete chemokines that attract macrophages.	If Hepatic Growth Factor > 10 ng/ml then satellite cells produce MCP-1 at a rate of 0.15 ng/hr/cell

EFFECTS OF Q-ANGLE AND TIBIAL SLOPE ON ANTERIOR CRUCIATE LIGAMENT FORCE: A FINITE ELEMENT STUDY

INTRODUCTION

Many factors contribute to the resultant forces in the anterior cruciate ligament (ACL). Rapid generation of ACL force has the capability to induce ruptures that can lead to significant osteoarthritis and reduction in sport activity. Substantial research has contributed to understanding the effects of subject-specific geometry and its relation to force propagation in the ACL. Important geometric parameters of the knee joint include the Q-angle, and coronal, lateral, and medial tibial slopes. The goal of this study was to evaluate the effect of patient-specific Q-angles and coronal/lateral/medial tibial slopes on ACL force during flexion through the use of subject specific validated finite element models of the knee joint.

METHODS

MRI and CT images were obtained from three subjects with no history of knee injury. The Q-angle, and coronal, lateral, and medial tibial slopes were calculated using ImageJ (NIH, Bethesda, Maryland) and Mimics v15.0 (Materialise, Leuven, Belgium). Q-angle was calculated by the angle formed by the intersection of the center of the patella, the center of the femoral shaft, and the center of the tibial tuberosity [1]. The tibial slope was determined by identifying the outer-most points of the lateral and medial sides of the tibial plateau, and bisecting that line with a line generated from multiple points along the center of the tibial shaft [2]. Subject-specific finite element models were developed from three sets of MRI and CT images. 3D geometries of hard and soft tissues were digitized using Mimics v15.0 (Materialise, Leuven, Belgium). Geometries were converted into solid 8-node hexahedral elements for the patella, ligaments (ACL, MCL, LCL, and PCL), and menisci. The geometries of the femur, fibula, and tibia were constructed with an outer layer of wedge C3D6

elements for cortical bone and tetrahedral C3D4 elements for cancellous bone. Cartilage utilized tetrahedral C3D4 elements. Meshes were imported into ABAQUS 6.11-2 (SIMULIA, Providence, RI, USA). Capsules, muscles, tendons, and remaining ligaments were simulated using uniaxial truss elements.

Figure 1 – ABAQUS Knee Joint Model

The material properties of the ACL, PCL, and MCL were modeled with hyper-elastic properties. Material properties of all other tissues were modeled as linear elastic with different moduli assigned to the corresponding tissue. The femur, fibula, and tibia were defined as non-deformable rigid bodies. All uniaxial truss elements were defined as incompressible. The resultant models were validated against cadaveric testing on 18 fresh frozen legs undertaken at our lab [3]. Model validation was achieved by subjecting cadaveric specimens to loading conditions to simulate tibial rotation, anterior shear, and valgus/varus moments during knee flexion. Simulations consisted of a 100N anterior shear force in static loading conditions at 0, 10, 20, and 30 degrees of flexion.

RESULTS

Geometric Angle (Deg)	MODEL 1	MODEL 2	MODEL 3
Coronal Tibial Slope	1.41	5.03	4.76
Lateral Tibial Slope	5.18	5.62	4.10
Medial Tibial Slope	0.85	1.22	1.60
Q-Angle	18.99	14.27	18.00

Table 1 – Q-Angle and tibial slope comparison between models

The Q-Angle ranged from 14.3 to 19.0 degrees and the range of the slopes for the three models are listed in Table 1.
Figure 2 – ACL force prediction as a function of flexion angle as compared with ex-vivo data [3].

ACL force varied amongst the three models, as shown in Figure 2. Model 3 demonstrated a 25% increase in force at lower flexion angles (i.e., 10 degrees of flexion).

DISCUSSION

As supported by these preliminary results, variability in model-specific geometric factors and relative positioning (knee joint flexion angle) contribute to ACL force. Tibial geometry (coronal, lateral, and medial tibial slope) and Q-angle contributed to up to a 25% change in ACL force in the 0-10 degree flexion range. Variability in geometry has been previously implicated in changes of joint kinematics and kinetics. This study provides a solid framework upon which to build future studies with sensitivity analysis, greater sample sizes, and more comprehensive geometric and kinematic variability.

ACKNOWLEDGEMENTS

EFFECT OF DEEP MEDIAL COLLATERAL LIGAMENTS ON MENISCUS MOTION

[1]Trent M. Guess, [1]Swithin Razu and [1]Hamidreza Jahandar

[1]The University of Missouri, Columbia, MO, USA
email: guesstr@health.missouri.edu, web: www.mizzoumotioncenter.com

INTRODUCTION

The extent of meniscus motion on the tibia plateau and the role of peripheral attachments in limiting this motion are not completely understood. Anatomical studies of the deep medial collateral ligament (dMCL) have separated it into two functional units, the meniscofemoral and meniscotibial divisions, with stout attachments to the meniscus described [1]. But, based on their cadaver study, Stein et. al. concluded that the medial collateral ligament did not affect the stability of the medial meniscus [2]. In the current study, subject specific computational models coupled with subject specific leg motion are used to predict meniscus excursion on the tibial plateau. The effect of the dMCL meniscal attachments on medial meniscus motion is also explored.

METHODS

Two adult females (Subject 1: age 20 years, height 159.5 cm, mass 59.0 kg, Subject 2: age 29 years, height 170 cm, mass 70.3 kg) free of any lower extremity problems participated in this study after providing written informed consent approved by the institution's human subjects review board. Magnetic resonance images (MRI) were acquired of each subject's right leg and the images converted to geometries of bone, cartilage and menisci. Ligament insertions and origins were also determined. Leg motion during passive movement of the knee (laxity test) was recorded using a VICON motion capture system. During these laxity tests, an orthopaedic surgeon manipulated the knee of each subject through its complete range of flexion-extension, abduction-adduction and internal-external rotations while taking care to minimize any applied forces.

Computational models were developed in the multibody dynamic analysis program ADAMS (MSC Software Corporation, Santa Ana, CA).
Figure 1: Medial and lateral view of subject 2 multibody knee model.

Deformable contacts were defined between tibial and femoral cartilages. The ligaments were attached to the bones according to the identified origin and insertion sites. The anterior cruciate ligament and posterior cruciate ligament were both separated into two bundles. The lateral collateral ligament was separated into three bundles and the medial collateral ligament was separated into five bundles, three superficial (sMCL) and two deep bundles (dMCL). The three bundles of the sMCL wrapped around the tibia. Each ligament bundle was modeled as a tension only nonlinear spring using a piecewise function that described its force-length relationship [3]. The menisci were modeled as previously described [4]. Briefly, the menisci geometries were sectioned into multiple wedge shaped rigid bodies connected by 6 x 6 stiffness matrices. The medial and lateral menisci were sectioned at 10° intervals radiating from the geometric center of each meniscus. For the two subjects, the medial meniscus was divided into 20 rigid bodies and the lateral meniscus was divided into 25 rigid bodies. Mass properties were assigned to each meniscus element based on its volume and a density of 1,100 kg/m^3. Deformable contacts were defined between each meniscus element and tibial cartilage and femoral cartilage geometries. The menisci were connected

to the tibia via four horn attachments and the anterior intermeniscal ligament was also included. The two bundles of the dMCL were connected to the medial menisci via three-axis springs.

Localizers that appeared in both the MRI and motion capture system were worn by each subject and used to place the knee model relative to the motion capture markers. Motion constraints that followed motion capture marker trajectories were used in the initial simulation. The motion constraints were connected to the femur and tibia via three-axis springs. These initial laxity simulations were used for fine adjustment of the femur and tibia position and to determine the zero-load lengths of each ligament bundle. After adjustments, relative motion between the tibia and femur using Grood and Suntay [5] local coordinates was recorded during simulation. For the final laxity simulations, the femur was held fixed and the recorded tibia motion was applied to the bone through a 6-axis spring. The laxity simulations included multiple flexion-extension cycles ranging from 0 to 140°. Additional simulations included internal-external knee rotation (range of 40°) added to the laxity motion and simulations with the dMCL attachments to the menisci removed.

RESULTS AND DISCUSSION

During the laxity simulation both knees exhibited the screw home mechanism, rotating externally from 25° flexion to full extension. In addition, the max force required to move the tibia through the laxity motion was less than 30 N for both knees and maximum torque less than 0.7 N-m. Anterior-posterior menisci excursion on the tibia plateau during laxity simulations are provided in Table 1. The medial and lateral menisci translated posteriorly with flexion. Lateral excursion is greater than medial excursion for both knees and the excursion distance is within that measured by Yao et. al. during passive extension and flexion (lateral meniscus 8.2 ± 3.2 mm, medial meniscus 3.3 ± 1.5 mm, n=10) [6]. For the laxity simulations with added internal-external rotation, the excursion distance increased for both the lateral and medial menisci (Table 2). Removing the dMCL meniscal attachments increased anterior-posterior excursion

of the medial meniscus. Additionally, the increase in motion occurred during internal rotation (Fig. 1).

Table 1: Anterior-posterior excursion of the middle meniscus element during laxity simulation.

	Laxity	
	Lateral	Medial
Sub 1	6.9 mm	4.2 mm
Sub 2	9.8 mm	3.5 mm

Table 2: Anterior-posterior excursion of the middle meniscus element during the laxity with internal-external rotation simulation.

Laxity with Internal External Knee Rotation

MUSCLE ARCHITECTURE ANALYSIS USING COMPUTATIONAL FLUID DYNAMICS

[1] Joshua M. Inouye, [1] Geoffrey G. Handsfield, and [1] Silvia S. Blemker

[1] University of Virginia, Charlottesville, VA, USA
email: ssblemker@virginia.edu

INTRODUCTION

The trajectories of skeletal muscle fascicles are critical to their function, and many skeletal muscles across the body have fascicles with highly complex trajectories. Architectural descriptions of muscles account for fascicle trajectories by reporting parameters such as fascicle length, physiological cross-sectional area, and pennation angle. These parameters are typically reported as constants [1], yet it has been shown that some muscles have large distributions of these parameters [2]. Cadaveric studies of muscle architecture can be time-consuming and do not represent young healthy or patient-specific populations, and MRI diffusion tensor imaging (DTI) studies of muscle architecture can suffer from noisy data acquisition [3]. We present a method to calculate architecture parameters from arbitrarily complex muscles automatically using computational fluid dynamics (CFD). This method can be used to map and examine the three-dimensional architecture of a given muscle, and it can also be used as input to 3D finite-element models of muscle [4].

METHODS

Our method of generating fascicle trajectories using CFD analysis consists of three key steps. Step 1 is to create an image-based solid model of the muscle in Autodesk Inventor® (Autodesk Inc.). Step 2 is to export the solid model to Autodesk Simulation CFD® (Autodesk Inc.) and set up the simulation. We set the inlet pressure to 1Pa and the outlet pressure to 0Pa at the regions of fascicle origin and termination. The other surfaces are set to slip boundary conditions (Figure 1a). The fluid is set to be incompressible with a viscosity of 1Pa-s and density of 1g/cm^3. This resulted in very low Reynolds numbers (<1) and good convergence.

Incompressible, laminar, viscous, and steady-state flow are prescribed. These conditions along with the boundary conditions help satisfy the observations about fascicle trajectories in muscle [3]: i) they are coaxially aligned and do not cross each other (viscous flow) ii) they do not branch (incompressible flow) iii) they will not reverse their directions abruptly (laminar flow) and iv) they must connect between attachment points (boundary conditions).

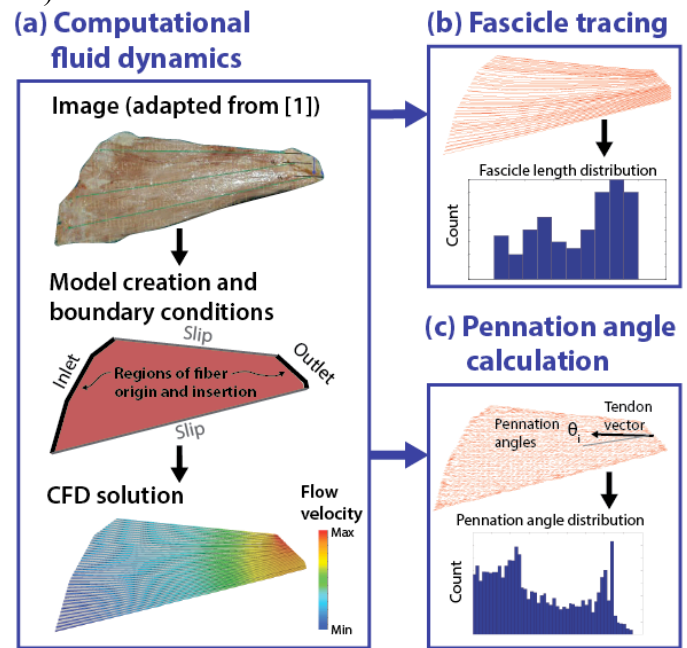
Step 3 is to export the flow direction vectors from the CFD mesh into Matlab (Mathworks Inc.) to perform fascicle and pennation angle analysis. The fascicles are traced and their length distributions are computed (Figure 1b). In addition, pennation angle distributions are calculated using a tendon vector specification from the distal tendon, as in [1] (Figure 1c).


Figure 1: (a) We create image-based models and use CFD to determine muscle architecture parameter distributions for (b) fascicle lengths and (c) pennation angles.

We performed the process on a 2-D image of the adductor brevis [1] and a 3-D MRI-based model of the biceps femoris longhead [5]. We compared the adductor brevis calculations with a previous cadaver study [1].

RESULTS

The mean fascicle length for the 2D adductor brevis model (raw, unadjusted for sarcomere length) was 12.9cm (Figure 2a). This can be compared to the published raw fascicle length average measurements of 11.1cm with standard deviation of 1.53cm across 21 cadavers (10.3 ± 1.42cm optimal fascicle length and 2.91 micron average sarcomere length). The pennation angle distribution ranged from 0 to 17 degrees, with an average of 6.9 degrees (Figure 2a). The cadaver study measured 6.1 degrees mean and 3.1 degrees standard deviation averaged across cadavers.

The CFD solution for the 3D biceps femoris longhead model computed realistic fascicle trajectories and enabled automatic calculations of the fascicle length and 3D pennation angle distributions (Figure 2b).

DISCUSSION

We have proposed a method using computational fluid dynamics to automatically compute muscle architecture parameters and their distributions within the muscle. The method leverages the power of CFD solvers and also enables efficient fascicle mapping for finite-element studies of muscle. The advantages of this method over other methods include ease of implementation and objective, efficient calculation of 3D muscle architecture parameters. Flow guiding surfaces can be incorporated so that complex observed features such as twisting or MRI-DTI data can be incorporated. One limitation of this method is that the fascicles are measured implicitly from the geometry of the muscle and not directly measured. However, the close correlation of the direct cadaver measurements with our computational measurements for the adductor brevis provides preliminary validation of the method. This method has great potential to enhance and empower *in vivo* architecture studies (e.g., using MRI) on arbitrarily complex muscle geometries.

INDIVIDUAL DIFFERENCES IN REQUIRED COEFFICIENT OF FRICTION AFFECT SLIP RISK DURING LEVEL WALKING

[1] Kurt Beschorner, [1] Devon Albert, [1]Mark S. Redfern

[1] The University of Pittsburgh, Pittsburgh, PA, USA
email: beschorn@pitt.edu, web: http://www.engineering.pitt.edu/KurtBeschorner/

INTRODUCTION

Slip and fall accidents are a major source of occupational and public health injuries. Previous studies have demonstrated that slipping risk can be predicted from the difference between the available coefficient of friction (ACOF) and the required coefficient of friction (RCOF) using a logistic regression equation [1]. This logistic regression equation predicts that slipping risk is most sensitive to RCOF when the RCOF and ACOF are approximately equal and that increased RCOF is associated with a higher risk of slipping. Several studies have used RCOF as a measure of individual slip risk [2, 3] under the assumption that subtle changes in RCOF alter slipping risk. Surprisingly, however, the link between individual RCOF and slip risk has not been confirmed experimentally.

The purpose of this study is to determine if individual differences in RCOF are predictive of slip risk. The shoe-floor-contaminant conditions were selected such that the shoe-floor ACOF was approximately equal to RCOF for gait.

METHODS

Thirty healthy and young subjects (13 female, 17 male) between the ages of 20 and 35 years were recruited to participate. Participants signed informed consent and the study was approved by the University of Pittsburgh Internal Review Board.

Each participant performed a series of baseline walking trials to characterize their RCOF and two unexpected slipping trials. Boots with three different outsole materials were used in this study. Subjects wore tight-fitting clothing, a safety harness and reflective markers including one placed on the heel of the boot to track slip distance. After being randomly assigned to an initial pair of boots, subjects completed between five and eight baseline walking trials, were unexpectedly slipped, changed into a different pair of boots with a different outsole material, completed 10-23 additional baseline walking trials and then were unexpectedly slipped again. A 50% glycerol/50% water solution was applied to a vinyl floor during the unexpected slips. The three boots had an identical upper region, identical tread pattern but different materials. The three materials included a hard material (Shore A: 85), a moderate hardness material (Shore A: 76) and a soft material (Shore A: 64). ACOF values were measured as the ratio of shear forces to normal forces recorded by a force plate while a slip tester applied a normal force of 250 N, a sliding speed of 0.3 m/s and a shoe-floor angle of 7°. ACOF values for the three shoes were: 0.149 (hard), 0.168 (moderate hardness) and 0.179 (soft).

RCOF was calculated and averaged for the five baseline walking trials preceding each slip. The RCOF was defined as the peak ratio of resultant shear to normal force for the intervals when the normal force exceeded 100 N, the ratio was increasing with time, and the anterior/posterior force was in the anterior direction [4]. The resultant sliding distance of the heel marker between heel contact and slip stop (defined by the first minimum in slip velocity after the maximum velocity or when the foot sliding off of the force plate) was used to characterize a slip. A slip distance exceeding 10 mm was considered a slip, while smaller slip distance were considered a non-slip.

ANOVA methods were used to determine if the boot outsole material, the slip order or their interaction (independent variables) affected the RCOF (dependent variable). The effect of RCOF on slipping risk was examined using a logistic

regression model with slip outcome as the dependent variable and RCOF as the prediction variable.

RESULTS AND DISCUSSION

RCOF did not vary significantly across the different boot materials or between the first and second slip. The interaction between outsole material and slip order was also not significant. The minimum RCOF was 0.135, the maximum RCOF was 0.272 and the mean RCOF was 0.201 (standard deviation: 0.026). The lack of difference in RCOF across the boots suggests that the modest change in available COF across the boots did not have an impact on the amount of RCOF required for gait. The average RCOF values reported in this study (0.201) was similar to what has been reported in other studies for level walking (0.18) [1].

Twenty-nine percent of the trials resulted in a slip. Increased RCOF led to an increase in slipping risk ($p<0.05$) (Figure 1). This model suggests that the risk of slipping for the subject with the highest RCOF value (0.272) was 79% whereas the risk of slipping was just 7% for the subject with the lowest RCOF value (0.135). The slip risk for mean RCOF value (0.201) was 34%. These findings suggest that RCOF is a valid measure of an individual's slip risk and that persons with a high individual RCOF have an increased risk of slipping whereas individuals with a low RCOF have a reduced risk of slipping.

The findings of this study confirm the relevance of previous research that utilized RCOF as an individual measure of slip risk [2,3]. This supports the conclusions from previous research that quadriceps fatigue increases slip risk [2] and that anticipating a slippery surface reduces slipping risk [3]. Furthermore, the results of this study can be used as justification for future research studies that may use RCOF as a measure of slip risk when it is impractical to unexpectedly slip subjects.

This study is limited in its ability to generalize the developed slip risk model. The slip risk model that was developed in this study is specific to just the shoe-floor-contaminant conditions that were considered. A different relationship between RCOF

and slip risk is expected for other shoe-floor-contaminant combinations, particularly when the ACOF is much larger or smaller than the RCOF. The trend observed in this study (i.e., that slip risk increases with RCOF) is expected to be similar in other studies where ACOF was approximately equal to RCOF.
Figure 1: Effect of RCOF on slip outcomes and the predicted slip risk. Each data point represents the outcome of an individual slip. The solid line represents the logistic regression prediction model.

CONCLUSIONS

This study confirmed that RCOF values have a significant impact on slipping risk when the available COF is similar to the RCOF. The RCOF magnitudes that were observed in this study ranged from 0.135 to 0.272, which corresponded to a predicted slipping risk ranging from 7% to 79%. Thus, individual differences in RCOF can have a dramatic impact on their slipping risk.

INTRODUCTION

Falls due to slipping are a serious occupational concern. Slipping is estimated to cause 40-50% of all fall-related injuries [1]. Epidemiological data suggest that individuals who are older or obese fall more frequently than younger, non-obese adults [2]. The problem of slip-related falls may be exacerbated by a high prevalence of obesity and an aging workforce in the United States. The purpose of this study was to investigate the effects of obesity and age on slip severity and fall frequency following a laboratory-induced slip. Results from this study can help to identify obesity and/or age as risk factors for falling from slipping, and may aid in the development of fall-prevention strategies

METHODS

Seventy-two adults completed the study including: 26 young (18-29 years) non-obese (BMI 17.7-24.9 kg/m^2); 25 young obese (BMI 29.1–40.4 kg/m^2); 10 older (50-66 years) non-obese (BMI 19.5-26.3 kg/m^2); and 11 older obese (BMI 30.1–45.1 kg/m^2) individuals. During each experimental session, participants wore a harness and walked at a comfortable, but purposeful, pace along a 10m walkway. After 10-20 walking trials, a thin layer of vegetable oil was applied to the surface of a force platform to induce a slip of the dominant foot.

Positions of selected anatomical landmarks were sampled at 100 Hz using a six-camera motion analysis system (Vicon Motion Systems, Centennial, CO) and low-pass filtered at 7 Hz (second-order, zero-phase-lag Butterworth filter). Ground reaction forces under the slipping foot and force applied to the harness were sampled at 1000 Hz using a force platform (Bertec Corporation, Columbus, OH) and a uniaxial load cell (Cooper Instruments and Systems, Warrenton, VA), respectively. Both were low-pass filtered at 20 Hz.

Slip outcomes were classified as falls, recoveries, or harness-assisted based on methods similar to Brady et al. [3] and Yang and Pai [5]. Gait speed, step length, and four measures of slip severity (slip duration, slip distance, peak slip velocity, and mean slip velocity) were calculated for each slip classified as either a fall or recovery. Slip severity thresholds, separating most falls from most recoveries, were iteratively determined. The effects of obesity and age group on gait speed and step length were analyzed using two-way analyses of variance. Slip severity measures were analyzed using three-way analyses of covariance, with independent variables of obesity group, age group, and gender, and with gait speed as a covariate. Slip outcome was analyzed using a logistic regression model with independent variables of obesity group, age group, gender, and gait speed. Statistical analyses were performed using JMP 10 (SAS Institute Inc., Cary, NC) with a significance level of $p \leq 0.05$.

RESULTS AND DISCUSSION

Slip outcome differed between obesity groups (p=0.005; Table 1) in that 33.3% of obese participants fell after slipping, while only 8.3% of non-obese participants fell. The odds ratio for obesity group indicated that obese participants were 8.24 [95% C.I.: 1.81, 57.10] times more likely to fall than non-obese participants when adjusting for age group, gender, and gait speed. Slip outcome did not differ between age groups (p=0.937) or genders (p=0.399; Table 1).

Table 1: Slip outcomes among groups

	Fall	Recovery	Harness-Assisted	Total
Total	15	48	9	72
Obese	12	21	3	36
Non-obese	3	27	6	36
Older	5	12	4	21
Young	10	36	5	51
Male	5	24	4	33
Female	10	24	5	39

Mean slip velocity was 8.3% higher ($p=0.022$) among obese participants, but slip duration ($p=0.974$), slip distance ($p=0.121$), and peak slip velocity ($p=0.065$) did not differ between obesity groups (Table 2). Age group did not affect any slip severity measures. Slip distance ($p=0.005$), peak slip velocity ($p<0.001$), and mean slip velocity ($p<0.001$) increased with gait speed, but gait speed did not affect slip duration ($p=0.148$). Gait speed and step length did not differ between obesity (speed $p=0.486$, step length $p=0.886$) or age groups (speed $p=0.245$, step length $p=0.593$; Table 2).

In general, participants who fell experienced more severe slips. The majority of falls occurred at slip distances beyond 50 cm, slip durations longer than 0.3 s, peak slip velocities above 2.5 m/s, and mean slip velocities above 1.0 m/s. More specifically, a slip distance of 56.5 cm separated 85.4% of recoveries from 86.7% of falls, a slip duration of 0.35 s separated 54.2% of recoveries from 86.7% of falls, a peak slip velocity of 2.57 m/s separated 91.7% of recoveries from 80.0% of falls, and a mean slip velocity of 1.19 m/s separated 79.2% of recoveries from 86.7% of falls.

CONCLUSIONS

Laboratory-induced slips resulted in more severe slips and a higher fall rate among individuals who are obese. However, no obesity × age interaction effects were found for slip outcome or slip severity. These results suggest that the higher fall rates reported among obese individuals may be due, at least in part, to a greater rate of falling after slipping while walking. Slip severity thresholds that separated the majority of falls from recoveries were also reported, and may have practical value in the design of fall-resistant flooring.

OBESITY INCREASES FALL RATE FOLLOWING A LABORATORY-INDUCED TRIP

INTRODUCTION

Tripping accounts for an estimated 53% of falls among adults aged 65 and older [1]. A common strategy to prevent a fall after tripping is to step to extend the base of support anteriorly, and thereby provide vertical and posterior ground reaction forces that can help arrest the forward momentum of the trunk [2]. As such, stepping characteristics and trunk kinematics are critically important during trip recovery.

Obese adults exhibit a higher rate of falls than those who are normal-weight [3], but the reason for this higher rate is unclear. The purpose of this study was to investigate: 1) obesity- and age-related differences in trip recovery, and 2) differences between successful and failed recoveries. Dependent variables included measures of fall rate, stepping characteristics, and trunk kinematics.

METHODS

Participants included 10 young (age 18-30 years) normal-weight (body mass index, BMI, of 18-24.9 kg/m^2) adults, 10 young obese adults (BMI over 30 kg/m^2), 10 older (age 60-70 years) normal-weight adults, and 10 older obese adults. Participants were tripped near mid-swing using a 7-cm-high obstacle while walking at a speed of 1.4-1.6 m/s. Forces applied to a safety harness were sampled from a load cell (Cooper Instruments and Systems, Warrenton, VA) at 1000 Hz and low-pass filtered at 20 Hz (eighth-order, zero-phase-shift Butterworth filter). Kinematic data using a modified Helen Hayes marker set were collected at 100 Hz with a 6-camera motion analysis system (MX-T10, Vicon Motion Systems Inc., L.A, CA) and low-pass filtered at 5 Hz (8th-order, zero-phase-shift Butterworth filter).

Harness load was used to classify trip recovery outcome as either a recovery (peak load less than 30% body weight), a harness-assisted recovery (peak load 30-50% body weight), or a fall (peak load exceeded 50% of body weight). Trials classified as harness assisted were removed from further analysis.

Logistic regression analyses were used to investigate the effects of obesity and age on fall rate and stepping strategy (elevating or lowering). A three-way analysis of variance was used to investigate the effects of obesity, age, and trip recovery outcome on recovery step time and length, and peak trunk angle and angular velocity. All statistical analyses were performed using JMP 10 (SAS Institute Inc., Cary, NC) with a significance level of $p \leq 0.05$.

RESULTS AND DISCUSSION

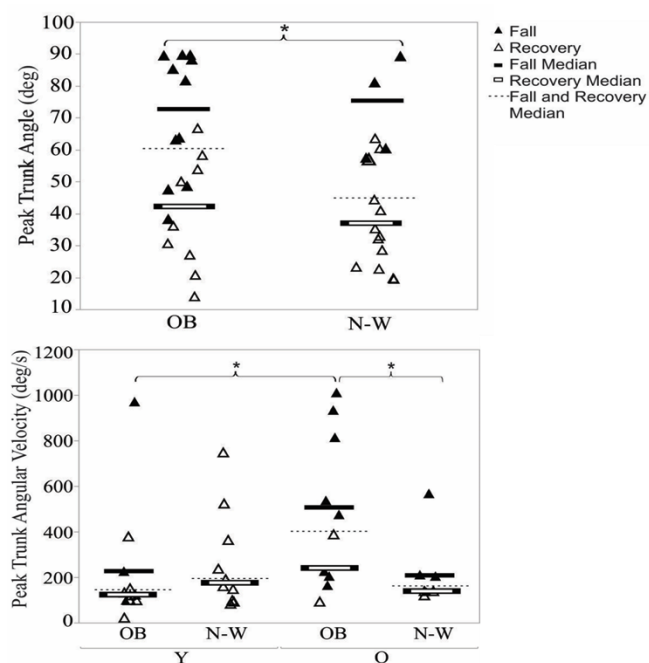
Obesity affected several aspects of trip recovery. Fall rate was 52% among obese adults and 22% among normal-weight adults, with an odds ratio indicating obese adults were 8.79 (C.I.: 4.62, 394.8; p=0.026) times more likely to fall when adjusting for age and gender. Stepping strategy (p=0.151), recovery step time (p=0.499), and recovery step length (p=0.854) did not differ between obesity groups. Peak trunk angle was 13 degrees higher among obese adults (p=0.046) (Figure 1). Peak trunk angular velocity was affected by an obesity level x age interaction (p=0.038; Figure 1). Peak trunk angular velocity was 216 degrees/s higher among obese older adults compared to normal-weight older adults (p=0.012), and 245 degree/s higher among obese older adults compared to obese young adults (p=0.005).


Figure 1: Peak trunk angle (top) and peak trunk angular velocity (bottom) separated by obesity group, and obesity and age group. Brackets indicate significant differences between groups. Note: OB=obese, N-W=normal-weight, Y=young, O=older.

Comparing dependent variables between falls and recoveries also revealed several differences. A lowering strategy was used during 73% of falls and 25% of recoveries with odds ratios indicating users of a lowering strategy were 8.25 (C.I.: 2.03; 40.18; p=0.003) times more likely to fall. Recovery step time and length did not differ between falls and recoveries (p=0.541 and p=0.758). Peak trunk angle was 32 degrees higher during falls (p<0.001), and peak trunk angular velocity was 287 degrees/second higher during falls (p=0.027).

The higher rate of falls among obese adults may have resulted from differing trunk kinematics, and three intrinsic factors associated with obesity could be responsible for these differences. First, an anterior shift of the trunk COM among obese adults [4] could increase the gravitational moment that rotates the body forward after tripping, Second, greater trunk mass would increase trunk momentum that needs to be decelerated through trunk and lower extremity muscle exertions [5]. Third, reduced relative strength

among obese adults could reduce the ability to decelerate trunk momentum.

Although recovery step time and length were not affected by obesity or trip recovery outcome, the success of trip recovery was dependent upon the choice of stepping strategy. Other studies have reported a higher prevalence of a lowering strategy among obese adult fallers [6]. For older adults it has been shown that practicing balance recovery from a simulated trip improves recovery kinematics following an actual trip [7]. This training may be effective in promoting more frequent use of the elevating strategy during mid-swing trips, and may help improve the success of trip recovery.

In conclusion, obese adults exhibited a higher fall rate after tripping. This higher fall rate was not due to altered stepping characteristics, but appeared to be related to trunk kinematics. These results suggest the higher rate of falls among obese adults reported elsewhere may be due to impaired trip recovery, and support the use of interventions to improve trip recovery capability to help prevent falls among obese adults.

VIBRATION TRAINING COULD REDUCE RISK OF FALLS AMONG YOUNG ADULTS WITH OBESITY

Jose Munoz, JaeEun Kim, Maria Sanchez and Feng Yang

The University of Texas at El Paso, TX, USA
E-mail: fyang@utep.edu

INTRODUCTION

Obesity is a major health concern all over the world. One of the major concerns related to obesity is that it leads to increased risk of falls. It has been reported that individuals with obesity have a higher likelihood of falls in comparison to their non-obese counterparts. High risk of falls among individuals with obesity has been associated with several factors, such as muscle weakness, postural instability, and abnormal body mass distribution [1]. As falls are considered the most common cause of injuries in obese community, it is pressingly needed to develop an effective training paradigm which can reduce those aforementioned risk factors of falls.

Though training programs based on weight loss and strength training have been applied to reduce the risk of falls among individuals with obesity [2], they may not be suitable for the entire obese community. For example, a significant portion of individuals with obesity is unable or unwilling to comply with or manage conventional training regimens requiring high intensity and long duration. Therefore, alternative training approaches requiring less intensive physical activities involved to prevent falls targeting persons with obesity are highly demanded.

Controlled whole-body vibration training (CWBV) has recently emerged as a relatively novel modality to train older adults to reduce their fall risk [3]. It has been proven that a short-term (6-10 weeks) CWBV training course enhances neuromuscular performance and reduces risk of falls among older adults [4]. The transmission of mechanical vibrations and oscillations to the human body can lead to physiological and neuromuscular changes on numerous levels [5]. Some common risk factors of falls shared by older adults and individuals with

obesity suggest that CWBV could be a promising approach to prevent falls in the stroke community. However, no study has investigated the potential effect of CWBV training on reducing falls among populations with obesity. Therefore, the primary purpose of this study was to systematically examine the overall effectiveness and feasibility of CWBV training in reducing risk of falls among individuals with obesity. We were particularly interested in studying the impact of a 6-week CWBV training on reducing body fat percentage, improving muscle strength, and enhancing dynamic gait stability.

METHODS

Five young adults (age: 26.2 ± 9.04 years; body height: 172.16 ± 4.43 cm; body mass: 100.18 ± 6.28 kg; 2 females) with obesity were recruited to participate in this preliminary study. Obesity level was determined based on both the body mass index (BMI ≥ 30 kg/m^2) and the body fat percentage ($\geq 30\%$). All subjects gave informed consent for participating in this study.

This study adopted a pretest-posttest design. All subjects received CWBV training 3 days a week for 6 weeks. The training was delivered by a vibration platform (Orthometrix, NY) in an intermittent way: each 1-min vibration was followed by a 1-min rest for 10 minutes when they stood on the platform. The vibration frequency was 25 Hz and the amplitude 7.8 mm. Immediately prior to (or pre-training) and following (or post-training) the 6-week CWBV training, each subject was evaluated for their risk of falls quantified in terms of the muscle strength, body fat percentage, and dynamic stability during walking.

Subjects' knee joint extensor strength capacity was assessed under isometric condition on the right side

via an isokinetic dynamometer (Biodex, NY). The body fat percentage was measured by a bioelectric impedance analysis (BIA) machine (RJL-101, MI). To evaluate the dynamic gait stability, each subject was required to walk on a 12-m walkway at their preferred gait speed. Their full body kinematics was collected from 28 retro-reflective markers placed on the subjects' body and floors by using an 8-camera motion capture system (Vicon, UK).

The body center of mass (COM) kinematics was computed using gender-dependent segmental inertial parameters [6] from the filtered markers paths. The two components of the COM motion state, i.e. its position and velocity were calculated relative to the rear of base of support (i.e. the leading heel) and normalized by foot length and $\sqrt{g \times bh}$, respectively, where g is the gravitational acceleration and bh the body height. The timing for two events in the gait cycle: touchdown (TD) of the leading foot and liftoff (LO) of the trailing foot, was identified from feet kinematics. The stability was calculated at both time instants as the shortest distance from the COM motion state to the limits of stability against backward balance loss [7].

Paired t-tests were used to compare all risk factors between the two evaluation sessions (i.e. pre-training vs. post-training) in order to determine the possible effect of the CWBV training. All statistics were performed using SPSS 19.0 (IBM, NY), and a significance level of 0.05 was used.

RESULTS AND DISCUSSION

The 6-week CWBV training significantly improved the maximum isometric knee extensor strength among the obese adults in this study. Specifically, the maximum knee extensor strength increased to 1.83 ± 0.23 Nm/kg in the post-training evaluation from 1.66 ± 0.28 Nm/kg in the pre-training evaluation ($p < 0.05$). Similarly, the dynamic gait stability was improved as the result of the vibration training. In detail, the stability values were 0.61 ± 0.02 and 0.32 ± 0.06 respectively for TD and LO before the training. The stability at TD and LO became 0.70 ± 0.05 ($p < 0.01$) and 0.40 ± 0.03 ($p < 0.05$), respectively post the training.

Interestingly, the body fat percentage did not show difference between two evaluations (37.45 ± 7.40 vs 37.45 ± 7.65, $p > 0.05$). One explanation for this could be that the 6-week CWBV training actually does not affect body composition. Alternatively, the small sample size or the accuracy level of the BIA machine employed in this study could also contribute to the similar body fat percentage between tests. The stability examined in this study was the one against backward falling. Therefore, it remains unknown how CWBV training affect the stability against balance loss in other directions. These warrant our further investigation.

CONCLUSIONS

A 6-week CWBV training course can increase muscle strength and improve dynamic gait stability control among young obese adults. As these two factors closely relate to falls, CWBV training could serve as a promising training method to reduce fall risk among individuals with obesity. However, it may not change the body composition at least in the sample studied in this experiment. Still, the finding from this study sheds light on the feasibility of applying CWBV training to reduce falls among individuals with obesity.

AN EVALUATION OF FALL BIOMECHANICS THAT MAY UNDERLIE THE INCIDENCE OF WRIST AND HIP FRACTURES IN OLDER ADULT WOMEN

INTRODUCTION

After the age of 75 years (yrs), the incidence of wrist fractures in women declines [1], while the incidence of hip fracture begins to rise [2]. Differences in fall biomechanics with aging have been hypothesized to account for these concurrent trends. Possible fall biomechanics proposed include:

M1. An age-related inhibition of protective arm movements during a fall that results in less impact to the hand/wrist, in turn reducing the risk of wrist fracture, but increasing the risk of hip fracture.

M2. An interaction between age and direction-specific fall risk that predisposes the oldest women to more posterior and lateral falls, but fewer anterior falls. This interaction likely reduces the incidence of wrist fracture and increases the risk of hip fracture [3].

The purpose of this study was to evaluate fall biomechanics in women age ≥65 yrs through i) laboratory assessments of fall recovery and ii) the prospective tracking of falls over 1 yr in the free-living environment. We compared women age 65-75 yrs to women age >75 yrs given the dramatically altered incidences in fractures at the wrist and hip between these age groups [1,2]. We hypothesized that, based on laboratory assessments, women age >75 yrs would have diminished protective arm movements (M1) and would demonstrate recovery responses that reflect greater risk of falling posteriorly and laterally (M2). We also hypothesized that, over 1-yr follow-up, women age >75 yrs would demonstrate fewer fall impacts to the hands (M1) and would exhibit a higher incidence of posterior and lateral falls (M2).

METHODS

We recruited an age-stratified sample of 125 ambulatory, community-dwelling women. There were 58 women age 65-75 yrs (mean ± s.d. age=69.7±3.3 yrs, BMI=28.5±5.3 kg/m^2), and 67 women age >75 yrs (age=82.6±4.2 yrs, BMI=26.2±4.5 kg/m^2).

Laboratory Assessments of Fall Recovery
A subset of participants (65-75 yrs: n=49; >75 yrs: n=50) completed assessments to determine anterior (AMST) and posterior (PMST) multiple-stepping thresholds. These thresholds were determined using a progressive series of treadmill-induced postural disturbances that induced anterior or posterior falls [4]. Participants were asked to recover balance with a single step, and thresholds represent the disturbance magnitudes that elicited more than one step or a fall into a safety harness over the course of four attempts. AMST, PMST, and the ratio of the two thresholds (AMST/PMST) were evaluated to determine direction-specific fall risk (M2).

The stepping-threshold assessment of 67 participants (65-75 yrs: n=32; >75 yrs: n=35) were recorded with motion capture technology. For failed attempts to recover in a single step, the following variables were calculated:
- The largest anterior (AMST) or posterior (PMST) distance ($d_{wrist-pelvis}$) between a wrist marker and the pelvic center 500 ms after the disturbance onset (M1). Positive values indicate a wrist positioned in the direction of the fall relative to the pelvis.
- The lateral distance between the whole-body center of mass (COM) and the stepping-foot toe (AMST) or heel (PMST) marker at foot contact [5,6]. (M2)

Free-Living Environment Assessments of Fall Risk
Falls were recorded by all participants using semimonthly questionnaires. The questionnaires included fall orientation and anatomical figures in order to ascertain, respectively, the direction of the fall (M2) and impact locations (M1).

RESULTS AND DISCUSSION

Laboratory Assessments of Fall Recovery
The older group demonstrated smaller protective arm movements compared to the younger group when falling anteriorly (p=0.003), but not posteriorly (Table 1). We did note that 25% of younger participants demonstrated negative $d_{wrist-pelvis}$ during a posterior fall, which may reflect a strategy aimed at fall recovery, not impact preparation [7]. In contrast, only 6% of older participants demonstrated negative $d_{wrist-pelvis}$. Negative $d_{wrist-pelvis}$ values were not observed in either group for anterior falls.

The ability to recover from anterior and posterior falls, as quantified by multiple-stepping thresholds, was impaired with older age (Table 1). Group differences in AMST/PMST ratio approached significance (p = 0.058, effect size = 0.52). A post-hoc linear regression analysis determined a significant relationship between age and this ratio (AMST/PMST = 0.849 + 0.013·age, p=0.01). Such results suggest that older age impairs posterior fall-recovery more than anterior fall-recovery.

In response to an anterior fall, the lateral distance between the COM and stepping-foot toe was wider for the >75 yr group (p=0.03) (Table 1). This finding suggests that, with advanced age, anterior fall-recovery mechanics are altered in a way that may increase lateral fall risk. This effect of age was not observed during posterior falls.

Free-Living Environment Assessments of Fall Risk
There was a trend for women age >75 yrs to be more likely to fall posteriorly (37% vs. 28%, p=0.25) (Table 1). For those individuals who experienced a fall, older age did not decrease the odds of having an impact to the hand (OR [95% CI] = 0.83 [0.36-1.93]). Furthermore, older age did not increase the odds of having a hip impact with no impact to the hand (OR = 1.13 [0.47-2.73]).

CONCLUSIONS
These results suggest that, in response to an anterior fall, a reduction in protective arm movements in older women may explain a late-age decline in wrist fractures (M1). Furthermore, late age may involve a change in anterior fall recovery that predisposes women to a lateral fall, in turn increasing the risk of hip fracture (M2). An apparent age-related impairment of posterior fall-recovery and an increase in posterior fall incidence may also increase the risk of hip fracture with older age (M2).

AUTOMATION OF STRIDE-SPECIFIC BELT VELOCITIES ON INSTRUMENTED TREADMILLS FOR GAIT REHABILITATION AND TRAINING

Jacob W. Hinkel-Lipsker and Michael E. Hahn

University of Oregon, Eugene, OR, USA
email: jhinkell@uoregon.edu, web: http://bssc.uoregon.edu

INTRODUCTION

Split-belt treadmill training has been shown to be effective in normalizing gait symmetry by inducing a motor adaptation to an asymmetry in belt velocity [1]. This method of training has shown positive outcomes in clinical populations such as those who suffer from stroke [2], and has been used to investigate the effects of introducing a novel gait to healthy populations [3]. Gait training methods that have utilized changes in belt velocity from step-to-step between training blocks require the treadmill operator to quickly adjust belt velocities through the controlling device [3]. This form of manual control can become a source of error and even impossible if the belt velocity changes are frequent (eg. stride-by-stride). Further, timing of velocity changes is of crucial importance to insure that the adjustment happens during the desired phase of gait.

As research into treadmill gait rehabilitation progresses, the need has arisen for automated treadmill operation. While some virtual reality interfaces have utilized kinematic data for user-driven control schemes [4], there is currently a lack of operator-driven schemes that can be pre-set to change speeds given a specified gait event. Therefore, a scheme was implemented to automate an operator-driven control system for split-belt treadmill walking. The purpose of this study was to detail the process of automated treadmill control and test its performance during a trial of random asymmetrical split-belt training.

METHODS

A random training protocol, which represents the most challenging practice difficulty according to contextual interference theory [5], was implemented. This practice method involved the non-dominant limb being driven at the user's self-selected walking speed (SSWS) while the dominant limb was randomly changed within an upper and lower velocity limit of ± 0.5 m/s of SSWS for every step. These velocities were randomized prior to the trial in order to decrease computation time. One subject (185 cm, 84 kg, SSWS = 1.57 m/s) walked for 100 strides on the treadmill. Ground reaction force (GRF) data were collected by the force plate embedded under the dominant leg treadmill belt at 1200 Hz and were used to calculate swing phase time (ms) for each step of the dominant leg.

A Bertec split-belt instrumented treadmill (Bertec, Columbus, OH) was used for this study due to its ability to be remotely controlled through TCP/IP protocol. The control scheme was as follows: analog force plate data (volts) were streamed (T1) to an Arduino Mega 2560 at 25 Hz (T2), which then interfaced with a Windows 7 machine (2.7 GHz, 8 GB RAM) using a USB serial connection (T3). These data were streamed into MATLAB (Mathworks Inc.) using the Data Acquisition Toolbox (T4). As the analog data is streamed, this custom-written program detects swing phase for the dominant foot and issues a command at the first sample where GRF > 0 volts to change speeds (T5) from the pre-set speed randomization file to a TCP/IP controller via USB (T6), which interfaces with the treadmill motor to drive the belt. The acceleration of the belt (T7) during each velocity was set at 20 m/s^2 (Figure 1).

For this control scheme to function as intended, the treadmill belt needed to be fully accelerated during swing phase, prior to the next foot contact. To assess performance, the total time (TT) for the scheme to process and perform its commands was calculated as the sum of the seven time points previously specified. Assuming T1, T3, T5, and T6

were nearly instantaneous, only T2, T4, and T7 were used to calculate TT. T2 was calculated to be 40 ms, which would represent the longest possible time for the Arduino board to capture a GRF > 0 signal while sampling at 25 Hz. T4 was calculated using a MATLAB function to compute the time between signal input and output. T7 was calculated as the change in velocity for each step divided by the 20 m/s^2 acceleration of the treadmill belt. A factor of safety (FOS) was calculated by dividing TT for each step by the minimum swing phase time over the 100 strides.
Figure 1: Treadmill control scheme with time points for calculation of total time. Analog force plate data are sampled by an Arduino A/D board, then streamed in real-time into custom written MATLAB software. Once swing phase is detected, a command for a pre-set velocity change is sent to a TCP/IP controller, which controls the motor to drive the treadmill belts.

RESULTS AND DISCUSSION

Minimum swing phase time was calculated to be 300 ms. At a maximum belt velocity change of 0.43 m/s, TT was calculated to be 66 ms, resulting in a FOS of 5. A polynomial fit of the relationship between velocity change and TT (R^2 = 0.93), indicates that sampling rate and device processing time were not large factors in calculating TT (Figure 2).

These results indicate that, with a maximum TT of 66 ms, this control scheme is sufficient to accommodate treadmill belt velocity changes within

the ± 0.5 m/s limit imposed on this study. This approach would function well for given patient populations with much shorter swing phases, such as hemiplegic stroke patients [6]. Further, given the polynomial equation calculated, this control scheme can accommodate a treadmill velocity change ranging from -1.77 m/s to + 1.47 m/s.

This control scheme can be implemented for future split-belt treadmill studies that require automated belt velocity changes. It can also be combined with user-driven kinematic parameters in virtual reality interfaces to detect gait events and implement operator-controlled gait rehabilitation or training programs.

$$y = 10.843x^3 + 101.02x^2 - 1.5738x + 45.089$$
Figure 2: Total time as a function of belt velocity change. Total time increased as treadmill velocities reached their upper and lower limits (R^2 = 0.93).

GAIT RETRAINING TO IMPROVE STANCE TIME ASYMMETRY REDUCES KNEE EXTERNAL ADDUCTION MOMENTS: A CASE STUDY OF A UNILATERAL TRANSTIBIAL AMPUTEE

INTRODUCTION

Individuals with a unilateral transtibial amputation (TTA) are at increased risk of developing osteoarthritis (OA) in their intact limb knee [1]. During walking, these individuals load their intact limb for longer than their amputated limb and this asymmetric loading may result in joint pain [2]. Furthermore, greater knee external adduction moments (KEAM) have been reported in the intact versus amputated limb of these individuals [3].

Real-time feedback has previously been used to decrease asymmetry during a single treadmill walking session in individuals with a unilateral TTA [4]. It remains unclear whether a treadmill-based gait retraining program with a faded feedback design can improve symmetry in individuals with a unilateral TTA, and whether such changes translate to a reduced KEAM in the intact limb during overground walking.

The objective of this case study was to evaluate the effect of gait retraining using real-time feedback on stance time asymmetry and intact limb KEAM during overground walking in an individual with a unilateral TTA. It was hypothesized that following retraining, stance time asymmetry would decrease, resulting in reduced intact limb KEAM.

METHODS

This case study involved a 40 year old female (67.9kg; 1.67m) with a left traumatic TTA. The participant had high functional capability, and reported no discomfort during walking. Following screening to ensure the participant met the inclusion criterion of $\geq$ 5% stance time asymmetry, a pre-training gait assessment was completed, followed by gait retraining, and finally a post-training assessment. During assessments, 7 trials were collected in which the participant walked along a 30-m runway at 1.1m.s^{-1} ±5%, contacting a force plate (AMTI, Watertown, MA) at its center, with the intact limb. Kinematic data were obtained using a 10-camera Vicon (Oxford, UK) system and full-body markers.

Twelve gait retraining sessions were conducted on an instrumented treadmill (AMTI, Watertown, MA) over a 7 week period. A harness was worn throughout retraining sessions to prevent injury if a fall occurred. A custom program (C-motion, Germantown, MD) calculated and displayed real-time stance time asymmetries for each gait cycle. This was displayed on a large screen positioned in front of the treadmill (Fig. 1).
Figure 1: Demonstration of real-time stance time asymmetry feedback. Colored bars indicate the magnitude and side of the stance time asymmetry.

Duration of retraining sessions increased from 10 to 30 minutes over 12 sessions. Feedback was provided for the entirety of the first 6 sessions. The amount of feedback was reduced in each of the final 6 sessions in a faded feedback design, to encourage internalization of the new walking pattern [5].

RESULTS

Following gait retraining, stance time asymmetry was reduced by 32% (Fig. 2), and this corresponded with a 14% decrease in KEAM (Fig. 3). Post retraining there was a 2% increase in peak vertical

GRF, an 8% reduction in peak medial GRF, and a 3° increase in peak knee adduction angle (Table 1).
Figure 2: Mean (SD) stance time asymmetry during walking pre and post gait retraining.
Figure 3: Mean (SD) KEAM in the intact limb during walking pre and post gait retraining.

DISCUSSION

The gait retraining program reduced stance time asymmetry in a participant with unilateral TTA. Intact limb KEAM was also reduced, likely as a result of the reduced peak medial GRF, despite the fact that the real-time feedback exclusively provided stance time asymmetry information. It is important to highlight that the changes in stance time asymmetry and intact limb KEAM observed in this case study occurred in a participant with a high baseline level of symmetry. It is plausible that the magnitude of change from pre to post training would be greater in a more asymmetric participant.

Additional research is required to determine the success of this program in a larger population, and the ability of the participant to maintain changes without exposure to real-time feedback. As such, a follow-up assessment is planned after a period in which the participant undertakes focused walk training without feedback. If a more symmetric gait pattern can be maintained, the long-term risk of knee OA in the intact limb of individuals with a unilateral TTA may be reduced.

CONCLUSIONS

Based on this case study, gait retraining using visual real-time feedback is promising for improving stance time symmetry and reducing KEAM in individuals with a unilateral transtibial amputation.

DEVELOPMENT OF A VISUAL BIOFEEDBACK SYSTEM FOR CENTER OF PRESSURE MODIFICATION DURING GAIT

INTRODUCTION

Visual biofeedback has been utilized for mobility modification in various impaired populations for a considerable amount of time [1-4]. With the advent of new technologies capable of both collecting and portraying physiological information in real time, new techniques for mobility modification are now available. Center of pressure (COP) , defined as the centroid of all external forces acting on the plantar surface of the foot, it is a direct combination of kinetic and kinematic variables making it an intriguing function to investigate within mobility modification [5]. In order to evaluate this claim, we have developed a system to visually show COP trajectory in the transverse plane of the foot along with target locations for heel strike and toe off location. **The overall goal of this project is to modify COP during gait as a method to alter functional mobility in healthy adults in order to further understand and develop rehabilitation techniques and strategies.**

We hypothesize that:
1.) All healthy walkers will be able to volitionally modify and maintain an altered COP trajectory when provided visual biofeedback and
2.) Shifting the COP trajectory medially and laterally will decrease/ increase frontal plane ankle moments, respectively, while anterior and posterior shifts will increase and decrease sagittal plane ankle moments, respectively .

METHODS

In this feasibility study, one adult subject walked at 1.25 m/s on a split belt instrumented treadmill (Bertec, Columbus, OH) while motion capture (Vicon Nexus, Denver, CO) data of the lower extremities was collected.

Utilizing a software development kit capable of connecting motion capture and ground reaction force data with computation software (MathWorks, Natick, MA) we provided a visual/graphical representation of the COP trajectory in real-time to the walking subject through the use of a custom Matlab code. Using the subject's normal/neutral COP trajectory as the basis, we graphically provided a target toe off location which was shifted medially, laterally, posteriorly and anteriorly along the length of the foot.

In the extended study with no fewer than 12 healthy subjects, we will also use electromyography (EMG) to understand specific ankle muscle compensations (tibialis anterior, gastrocnemius and soleus) caused by the modified COP. Finally, using indirect calorimetry, the metabolic energy expenditure required to maintain each modified COP trajectory will be collected.
Figure 1: Graphical depiction of output from custom Matlab code. Purple represents neutral toe off location alongside four potential shifted targets (**red**, **green**, **purple**, and **light grey** target locations for shifts laterally, medially, posteriorly and anteriorly, respectively).

RESULTS AND DISCUSSION

This proof of concept study demonstrated the general ability of an individual to modify their toe off location along the foot's x-axis (medial/lateral) shown in **Figure 2**. These results represent the average COP trajectory over 20 consecutive steps for one healthy adult male walking at 1.25 m/s.
Figure 2: Transverse plane view of COP trajectory while provided no biofeedback/neutral walking (**Blue**), toe off shifted 10% of foot width medially (**Green**) and toe off shifted 20% of foot width laterally (**Red**). Axes normalized to foot width and foot length, respectively.

Mechanics data shown below in **Figure 3** provided some key insight into the underlying effects caused by modifying the COP trajectory. The most prominent alterations occurred with the 20% lateral shift of the toe off while the 10% medial shift generated largely similar mechanical outcomes in both the sagittal and frontal planes.

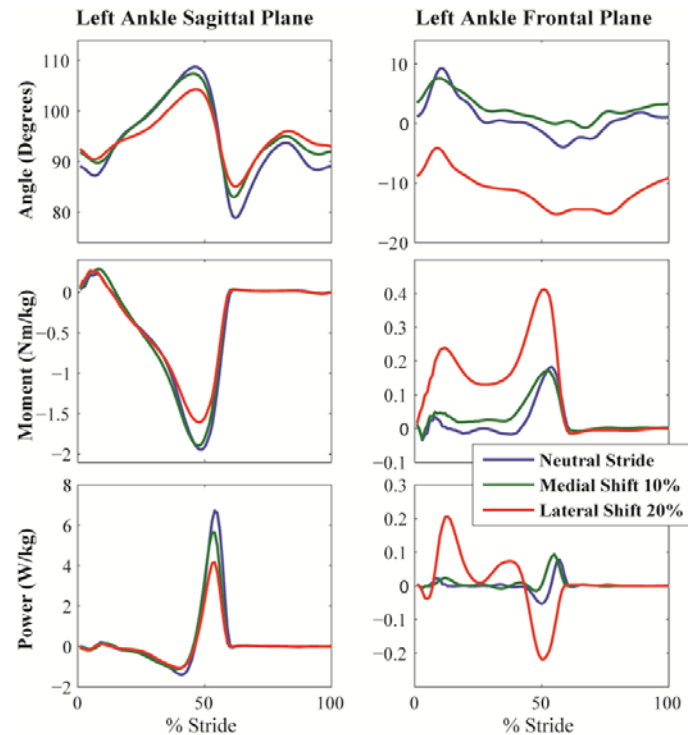
The lateral shift had implications in the sagittal plane (decreased dorsiflexion angle contributing to a reduction in moment magnitude during stance phase and, thus, reduced peak power during push-off). Frontal plane kinematics showed an approximately 10 degree offset throughout the entire gait cycle towards ankle inversion that had substantial effects on the frontal plane moment (~150% increase). Power generation, while visibly affected, had peak magnitudes of only ~3% of those seen in the sagittal plane.


Figure 3: Sagittal and frontal plane mechanics for the left ankle joint while provided no biofeedback/neutral walking (**Blue**), toe off shifted 10% of foot width medially (**Green**) and toe off shifted 20% of foot width laterally (**Red**).

Ultimately, this pilot study and data has demonstrated the capacity of healthy walkers to modify their COP trajectory via our biofeedback application. We will continue validating the approach through further data collection including evaluation of compensations at more proximal joints (i.e. knee and hip) and also new parameters including EMG and metabolic expenditure.

MODIFYING ANKLE JOINT NEUROMECHANICS USING AN ANKLE FOOT ORTHOSIS WITH VIBROTACTILE FEEDBACK DURING HUMAN WALKING

Audrey E. Westbrook and Gregory S. Sawicki

North Carolina State University, Raleigh, NC, USA
email: aewestbr@ncsu.edu, greg_sawicki@ncsu.edu

INTRODUCTION

Two common walking-related problems in impaired populations are the inability to propel the body forward during push-off at end of stance and/or clear the foot during forward leg swing (foot drop). A key factor contributing to these symptoms may be inadequate ankle joint control in the weakened limb. A potential solution to improve ankle joint control is through the use of biofeedback. For example, studies have investigated the capability of biofeedback in older adults with propulsive deficits, finding that this population has "considerable and underutilized propulsive reserve available" [1], making real-time biofeedback a promising method of rehabilitation. We have developed an ankle foot orthosis (AFO) with built-in vibrotactile biofeedback to provide dynamic feedback and encourage activation of ankle muscles during walking. The goal of this project was to test the effectiveness of this device in healthy subjects by asking the user to modify ankle kinematics by altering control of their own muscles based on biofeedback cues.

METHODS

A custom fabricated, unilateral carbon fiber/fiber glass composite AFO was created for eight healthy participants (age = 23.63 ± 3.29 years; mass = 74.72 ± 10.82 kg; height = $1.75 \pm .08$ m). The device uses a microcontroller with inputs from an encoder and pressure sensors to control biofeedback through the use of a buzzer and a vibration motor (Fig. 2a). Time series data between each step is shown in Figs. 2b,c. Each participant was asked to walk in four 7 minute conditions: (1) No AFO, (2) AFO – No Feedback, (3) AFO encouraging increased plantarflexion (i.e. improve push-off), and (4) AFO encouraging increased dorsiflexion (i.e. prevent foot-drop). An instrumented treadmill was used to record ground reaction forces (Bertec,

Columbus, OH) while a motion capture system (Vicon, Oxford, UK) was used to determine joint kinematics. A combination of the two was used in an inverse dynamic analysis to compute joint powers using Visual 3D software (C-Motion Inc., Germantown, MD). EMG was collected through surface electrodes (SX230 Biometrics Ltd.) processed and integrated while a portable indirect calorimetery system (Oxycon Mobile, Yorba Lina, CA) was used to measure inspired O_2 and expired CO_2 and compute metabolic power. Data was averaged over 10 steps and ANOVA with a Bonferroni adjustment was used to compare differences between No AFO and AFO with the different forms of biofeedback.

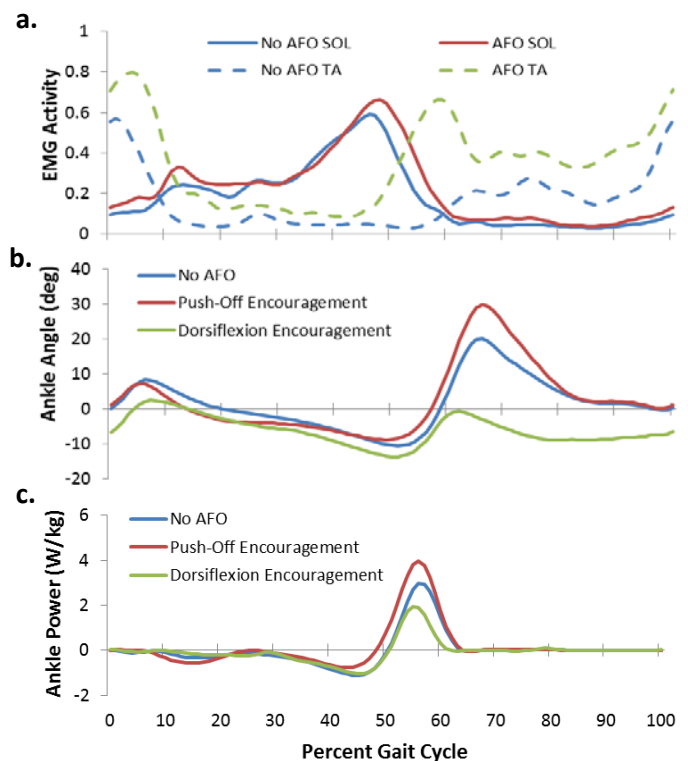
RESULTS AND DISCUSSION


Figure 1: (a) Soleus (solid) and Tibialis Anterior (dotted) EMG ; (b) ankle angle ; (c) ankle power. Data are group means.

For the increase dorsiflexion/prevent foot drop biofeedback framework, users exhibited increased tibialis anterior muscle activity (Fig. 1a) and dorsiflexion of the ankle (Fig. 1b) during the swing phase of gait. However compensations such as decreased ankle power (Fig. 1c) and increased hip power were observed during swing, contributing to increases in metabolic cost while walking with the AFO turned on (Table 1). These results lead us to believe that this type of rehabilitation will be best for users with foot drop not accompanied by other neuromuscular impairments by strengthening their tibialis anterior muscle and increasing ankle dorsiflexion. However, for those who suffer from foot-drop and propulsion deficits (e.g., post-stroke), intensely focusing on using ankle dorsiflexors to keep a lifted toe would negatively impact propulsion performance. In these cases, strategies that focus more on knee flexion to achieve toe clearance, might be better.

In the second framework, increase plantarflexion/improve ankle propulsion deficiencies, increases in propulsive ankle power (Fig. 1c) and soleus muscle activity (Fig. 1a) were observed, as well as decreases in peak hip power (Table 1), indicating that users could recruit unused reserves of ankle 'push-off' power for limb advancement by trading off with power at the hip. Slight increases in metabolic cost were observed, however this was expected as enforced gait patterns can elicit higher metabolic energy cost [2]. If an impaired population, such as those with hemiparesis following stroke can attempt to replicate these results, we are hopeful that gait symmetry and walking economy could be restored, leading to improved quality of life.

CONCLUSIONS

This study lays the groundwork for future testing on a vibrotactile biofeedback AFO to prevent foot drop and assist push-off in impaired populations. This targeted, on-line biofeedback approach, could positively impact rehabilitation practices if impaired populations can recruit muscle activity that they are not using on a daily basis.

Individuals with Incomplete Spinal Cord Injury Change Locomotor Stability After Exposure to a Viscous Force Field

INTRODUCTION

All strategies for stabilizing gait are not equal. Individuals with neurologic impairments rely heavily on general stabilization strategies that are present every step to resist and respond to any potential perturbation. General stabilization strategies (e.g. taking wide steps and increasing percent time in double support) decrease the necessity of sensing and responding to specific perturbations but inherently limit maximum walking speed, increase the metabolic cost of transport, and decrease maneuverability. Training individuals to utilize specific stabilization strategies (e.g. corrective steps, anticipatory postural adjustments) that are present only when needed could improve gait stability, speed, efficiency and adaptability. However, inducing individuals to practice task-specific stabilization strategies is very difficult, because general stabilization strategies can act as a physiological "crutch" that reduce the requirement to perform specific corrective actions when practicing walking in a balance-challenging environment.

The purpose of this study was to induce a temporary after-effect of reduced reliance on general stabilization strategies during gait in ambulatory individuals with incomplete spinal cord injury by exposing them to a brief period of walking with external lateral stability.

METHODS

Two ambulatory subjects with chronic, AIS (American Spinal Injury Association Impairment Scale) D, incomplete spinal cord injury, completed 600 steps of treadmill walking at their preferred speed. The first 200 steps established a **Baseline** measure of how subjects walked with no external assistance. The next 200 steps occurred in the presence of an added **Viscous lateral force field**. After these 200 steps, the force field was turned off and the subject continued to walk for another 200 steps to measure any **After Effects**. The forces were applied via a cable/pulley system attached to the subjects' hips and driven by two brushless AC linear motors (Baldor, USA). Force control was maintained using feedback from load cells placed in series between the subject and the motors. The Viscous lateral force field consisted of a 66 N baseline force, applied bilaterally to the subject, and an additional variable force proportional to the subject's lateral center of mass velocity. The effect of the viscous field was to resist subjects' lateral motion. Motion capture cameras were used to measure mediolateral pelvis kinematics and foot placement variability.

RESULTS AND DISCUSSION

As shown in Figures 1 and 2, during the **After-Effects** period, subjects demonstrated an increase in mediolateral center of mass excursion variability (~70-220%), step width variability (~100% - 350% increase), and minimum lateral margin of stability variability (~40% - 350% increase) when compared with **Baseline** walking. Step width mean and margin of stability mean both tended to decrease (~10% - 50%), double-support time decreased (~4-30%), and no consistent trend was found for center of mass excursion mean. These results suggest decreased reliance on general stabilization strategies during the **After-Effects** period as compared to **Baseline.**
Figure 1: Extrapolated center of mass (XCOM), left base of support (LBOS), and right base of support (RBOS) data for two subjects walking during baseline, exposure to a viscous lateral force field, and after-effects immediately after removing the force field. Data shown is for the last 20 steps of the baseline and viscous field trials, and the first 20 steps during the after-effects period.

CONCLUSIONS

A temporary period of reduced reliance on general stabilization strategies during gait can be induced in individuals with incomplete spinal cord injury by exposing them to a brief period of walking with external lateral stabilization. We believe that external stabilization can be used to prime the motor system for acquiring specific stabilization strategies during targeted gait rehabilitation interventions, by temporarily decreasing an individual's reliance on the physiological "crutch" of general stabilization strategies

ACKNOWLEDGEMENTS

INTRODUCTION

Identifying priority research areas has a variety of positive effects. In addition to focusing individual researchers' attention on issues that are important and urgent, it requires an honest assessment of the state and direction of one's field of research, creates community-wide communication around a common theme, and invites collaboration and cross-fertilization.

The Grand Challenge to Predict In Vivo Knee Loads was announced in 2009 and has had a positive impact on the biomechanics community. The associated competitions have benchmarked current methods, encouraged innovation, raised awareness, and increased conversation in the lower-limb biomechanics community [1, 2].

However, upper limb biomechanists face a different set of important and urgent issues. There are fundamental differences between lower- and upper-biomechanics on a variety of levels, including function, loading, control, and pathology. In addition, methods employed in upper-limb biomechanics research are generally less standardized than lower-limb methods, making comparisons and community-wide communication more difficult. The upper-limb biomechanics community would greatly benefit from efforts to identify its own set of priority areas and grand challenges. Although identifying such priority areas and grand challenges is beyond the scope of a single symposium (let alone coming to agreement), this symposium can serve to start a community-wide discussion of priority areas and potential grand challenges (for the purposes of this symposium, a priority area is defined as a research area of exceptional importance, whereas a grand challenge is defined as a specific, tightly defined problem that addresses an aspect of a priority area and draws attention to it, often through an organized competition).

SYMPOSIUM FORMAT

The symposium will begin with a short presentation by each author in which he/she presents his/her opinion of priority areas in upper-limb biomechanics, and suggestions for potential grand challenges. After these presentations, the audience will be divided into groups and encouraged to discuss the presentations and develop their own priority areas and grand challenges, which each group will briefly present to the entire audience. The symposium will end with a moderated debate involving the authors and the audience.

PRESENTATIONS

Charles: The gap between researchers and clinicians is a significant obstacle to the progress of upper-limb biomechanics research. This gap is arguably larger for upper limb movements than for lower-limb movements, perhaps in part because standardization is more pervasive for the lower limb (gait is more easily standardized than upper limb function) and because the lower-limb research community has more researchers who bridge that gap (e.g. researchers in exercise science, who often pursue applied research, make up a large part of the lower-limb biomechanics research community but rarely

research upper limb biomechanics). There appears to be relatively little discussion (or even common ground) between researchers in upper-limb biomechanics and motor control and clinicians such as occupational therapists and surgeons. Greater communication between researchers and clinicians would greatly benefit patients with movement disorders by informing researchers of clinically relevant problems and by assisting clinicians in adopting more quantitative tools for evaluation and diagnosis. One potential first step may be to take advantage of recently developed motion capture systems that are low-cost, quick-and-easy (markerless), *and* high-resolution (e.g. Leap Motion sensor). Gathering and sharing upper-limb movement data from large numbers of subjects would allow us to establish quantitative norms of upper limb movements (intra- and inter-subject variability as well as means). Although such an endeavor is difficult because upper limb function is highly variable, it could enable identification of subtle movement abnormalities believed to cause the movement impairment syndromes so common in clinical practice (60% of patients seen by physical therapists, for example [3]).

Li: Biomechanics is an applied science that bridges basic research and clinical applications, effectively translating research findings to benefit patients. Research in musculoskeletal biomechanics has led to significant advances in clinical practice in orthopedic surgery and rehabilitation, including implant design, joint replacements, medical devices, surgical techniques, orthotics and prosthetics, and performance evaluation. However, biomechanics for the hand is somewhat underdeveloped in comparison to other musculoskeletal areas. Yet, the hand offers a unique research opportunity for biomechanics research because of its anatomical complexity, functional versatility, and pathological vulnerability. My research for over 15 years has focused on hand biomechanics and motor control with a clinical application to carpal tunnel syndrome. I will share my experiences of disease-centered research development and discuss the challenges and opportunities of biomechanics research related to several main hand disorders.

Murray: In biomechanics, the upper limb is often considered somewhat of a niche area. In addition to the complexity of the system and the difficulty in stereotyping the most common way humans use their arms and hand (compared to gait, for example), this viewpoint is a challenge to progress and momentum in the field of upper-limb biomechanics. Researchers interested in the upper limb need to continue to demonstrate how advances in this area add and advance a common knowledge base that should be of interest to a wide community, not to just those who focus their efforts in this area.

Similarly, upper limb researchers often face difficulties in translating their research to the clinic. Without a specialized journal or society that brings researchers and clinicians together (such as the Gait and Clinical Movement Analysis Society), researchers interested in the upper limb often have difficulty finding clinicians who are familiar with upper-limb biomechanics research. This can limit the clinical collaborations and can make distribution of research findings challenging; sometimes findings are considered too clinical for a scientific journal and too research-oriented for a journal with clinical interests.

Finally, in the lower limb, joint replacements are considered to be one of the most successful medical devices of our time. In contrast, joint replacements in the upper limb have had relatively limited success; degenerative pain in the wrist and thumb is most commonly treated by simply removing the bones associated with the degeneration, without any replacement.

Perreault: Understanding the proximal-distal differences in the neural control of upper limb biomechanics is a priority area. Different levels of the nervous system are engaged in different proportions as we consider proximal and distal joints in the human arm. We do not presently have a good understanding of how these differences contribute to our ability to complete various motor tasks, or how these abilities are altered by injury. This is arguably a much greater issue for the upper limb than it is for the lower limb.

Also, efforts to identify neural control strategies need to incorporate task and biomechanical constraints. Many studies attempt to infer neural control strategies from recorded muscle activations but fail

to consider how those activations are constrained by the biomechanics of the limb and the task being performed. This issue is relevant to both upper and lower limbs, though solutions may be more feasible for the upper limb.

Valero-Cuevas: We should re-evaluate the current cortico-centric view of the neural control of the upper extremity and hand. For over a century, researchers have agreed that our anatomy and brains exhibit dramatic, specific, and useful adaptations for control of the upper extremity and hand. But if we roll back evolutionary time, it is not at all clear what were the evolutionary pressures that drove such drastic neural adaptations. For example, the advantages of monosynaptic corticospinal projections are often taken to be self-evident for biomechanical function—but it is equally evident that the larger proportion of oligosynaptic corticospinal and rubrospinal projections serve humans and other dexterous vertebrates well. Similarly, time delays argue against cortical circuits being the dominant drivers of time-critical biomechanical dexterity. Roger Lemon has argued that these adaptations cannot be the sine qua non of dexterity [4], yet this caveat has largely gone unheeded. Therefore, let us explore a hierarchical and distributed neuromechanical architecture that leverages, yet does not supersede, phylogenetically older structures shared by humans and other dexterous vertebrates.

Vidt: There is a movement toward developing models for individualized medicine, but more work is needed before this can become a plausible solution for the upper-limb. There are several aspects of shoulder biomechanics notably absent or simplified in current models [5]. These exclusions necessitate further model development and should be considered as priority areas for the upper limb research community. For example, muscle scaling and humeral head translation are needed to more accurately represent different individuals, and these

parameters become increasingly important in the context of orthopaedic injury (e.g. rotator cuff tears, subacromial impingement). Muscle force and the relative positions of the bony structures are essential determinants of the magnitude and direction of joint contact forces. To bridge the gap between biomechanics and the clinic, it is important to quantify how these measures change following injury and the extent to which they affect joint loading and contribute to subsequent joint damage during typical upper limb movements.

A potential grand challenge would include model prediction of glenohumeral joint contact forces measured using instrumented shoulder implants. Being able to accurately predict *in vivo* loads would require a model that effectively captures the muscular changes associated with injury, as well as the intrinsic bony kinematics. The challenge would be in the same spirit as that of the lower limb, but due to the anatomical and functional differences of the shoulder, it would require a markedly different approach.

INTRODUCTION

The standing long jump is an athletic event that has been frequently studied to analyze and improve athletic mechanics and performance. Analysis of the biomechanics of the standing long jump can be complex due to requisite coordination of the upper and lower body movements. The net muscle torques at anatomic joints can be calculated using inverse dynamics on kinematic and kinetic data obtained from a motion capture system. The conventional calculation of joint torques involves modeling the body as a series of rigid segments connected by joints and iteratively solving the Newton-Euler equations of motion for each segment in the model. Measurement and modeling errors compound as the solution to one segment is used to solve for the solution to the next. For systems involving more than a few segments, the errors can become larger than physiologically possible [1]. Including the ground reaction forces measured by force plates can be used to increase accuracy but results in an over-determined set of equations. This over-determinacy is often resolved by arbitrarily ignoring the equations from or applying residual forces and a torque to the top-most segment.

The objective of the present study was to investigate various strategies for performing inverse dynamics for the standing long jump including neglecting the equations of motion for different segments to yield determinate conventional solutions and by simultaneously solving all of the equations using a least squares static optimization solution method [2].

METHODS

Six adult males (mean ± standard deviation, mass: 90.3 ± 12.0 kg and height: 182.0 ± 6.3 cm) each completed a series of eight standing long jumps.

The positions of reflective markers placed on their bodies were recorded by an eight-camera motion capture system (Vicon Motion Systems Ltd., Los Angeles, CA) and the ground reaction forces and center of pressure locations were recorded by two in-ground force plates (Advanced Mechanical Technology Inc., Watertown, MA). The locations of the reflective markers were selected to allow for the creation of a two-dimensional, seven segment (foot, shank, thigh, pelvis, trunk/head, upper arm, and forearm/hand) link model. The volunteers were given the opportunity to warm up and familiarize themselves with the standing long jump motion through practice jumps. For the recorded trials, the participants were instructed to stand with one foot on each force plate and perform standing long jumps for best distance.

The planar Newton-Euler equations of motion were derived for all seven segments. The joint torques at the ankle, knee, hip, lower back, shoulder, and elbow were calculated using a conventional "bottom-up" inverse dynamics procedure by applying the measured ground reaction force data and neglecting the equations of motion for the forearm/hand segment. The same joint torques were calculated using a conventional "top-down" inverse dynamics procedure by applying the known zero external loading at the hand and neglecting the equations of motion for the foot. Conventional solutions neglecting the equations for each of the other segments were obtained by simultaneously completing the "bottom-up" and "top-down" procedures until the eliminated segment was reached. In addition, a static optimization procedure was used to obtain the joint torques by including the measured ground reaction force data and simultaneously solving the equations of motion for all seven segments in a least squares sense similar to the procedure proposed by Kuo [2].

A one-way single variable ANOVA blocking on the six participants was created in SAS JMP 10.0 (SAS Institute, Cary, NC, USA) and used to calculate the mean joint torque with 95% confidence intervals at each frame for each inverse dynamics method.

RESULTS AND DISCUSSION

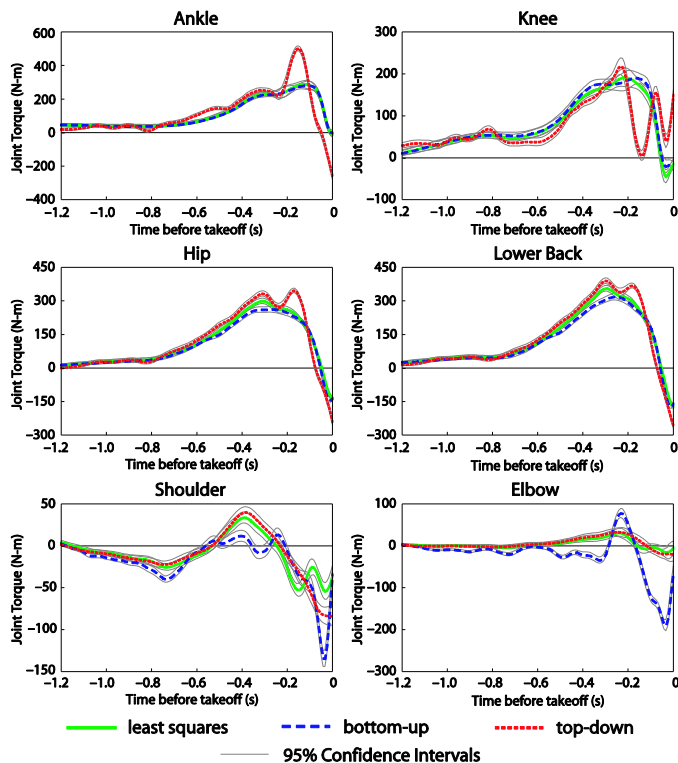
The joint torques for the conventional "bottom-up" and "top-down" inverse dynamics and the least-squares static optimization procedures for the last 1.2 s before take-off are shown in Figure 1.


Figure 1: Comparison of joint torques for "bottom-up" and "top-down" conventional solutions and least squares solution (+ extension/plantarflexion).

The hip and lower back torques demonstrated the greatest agreement for the three methods, with overlapping confidence intervals through the jump. The least squares solution almost entirely coincided with the "bottom-up" solution at the ankle and with the "top-down" solution at the elbow. The conventional joint torques calculated for the two joints furthest from the known applied force (shoulder and elbow for the "bottom-up" solution, knee and ankle for the "top-down" solution) substantially differed from the least squares

solution. The propagation of error for the inverse dynamics solutions crossing more than three or four segments was considerable.

The effects of discarding equations for segments other than the forearm/hand and foot segments were explored by using the "bottom-up" solution "up" to the segment of interest and the "top-down" solution "down" to the segment. Neglecting the equations for the trunk yielded joint torques over the full-body model that were most similar to the least squares analysis, which suggests that greater accuracy in conventional full body inverse dynamics may be obtained by ignoring the equations of motion for the trunk segment.

CONCLUSION

Conventional methods of inverse dynamics result in well-established errors in the calculated joint torques that increase considerably as the number of segments increases. Including known or measured external forces at the ground and/or at the hand can increase accuracy but results in an over-determined system of equations. The present study explored various strategies for resolving this over-determinacy including leaving out the equations of motion for various segments and solving all of the equations simultaneously using a least squares static optimization procedure. The calculated torques for joints more than three or four segments away from a known external force demonstrated questionable reliability as they substantially diverged from the other two solution methods. The results from this study suggest that the reliability in the calculated torques for a full body model can be enhanced considerably by discarding the equations of motion for the trunk segment through a combined "bottom-up" and "top-down" conventional inverse dynamics solution or by solving all of the equations simultaneously using a least squares static optimization procedure.

SYNTHESIS OF SUBJECT-SPECIFIC TASK-LEVEL MOTIONS
FOR PREDICTIVE SIMULATIONS OF BALANCE RECOVERY

INTRODUCTION

Among older adults in the U.S., falls are the leading cause of nonfatal injuries, with 2.5 million treated in 2013 alone [1], at a direct healthcare cost of 30-billion dollars annually [2]. The number of fall events continues to rise each year, providing a rationale to study balance control and how it relates to a fall event. Through this approach prophylactic exercise prescriptions can be developed, to reduce the number of preventable falls. Experiments have identified many aspects of falls; however, simulations can complement experiments to help uncover mechanisms of coordinated and uncoordinated movements for predicting balance recovery. Synthesis of subject-specific movements requires accurate musculoskeletal modeling, complex dynamic simulation, and robust control system design. Human movement involves closed-loop control and a combination of biomechanics and robotics approaches offers great potential for improving fall-related interventions; in addition, it will accelerate the study of human movement control and subject-specific outcome prediction.

METHODS

Motion capture and electromyography (EMG) data (Gluteus Maximus, Gluteus Medius, Rectus Femoris, Vastus Medialis & Lateralis, Biceps Femoris, Semitendinosus, and Medial Gastrocnemius) of balance recovery were collected from a healthy female (height 1.72 m; mass 68 kg) and male (height 1.79 m; mass 84.5 kg) using a Computer Assisted Rehabilitation Environment (CAREN) system (Fig. 1). The CAREN base was randomly (1 to 3 sec into trial) translated (6 cm) anterior or posterior at maximum viable speed (40 cm/s), while each subject stood on one foot lifting the contralateral foot (>10 cm) above the surface.

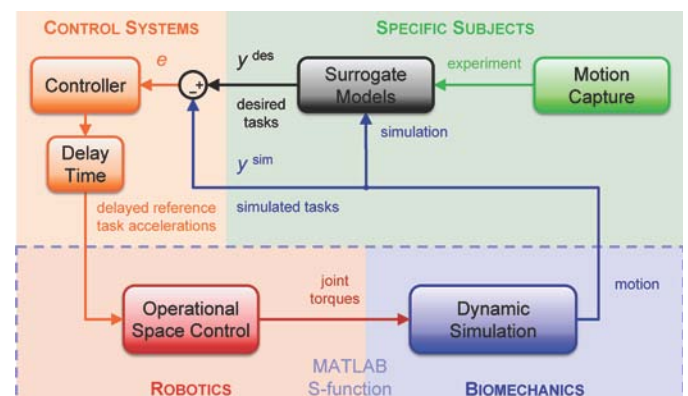
Subject-specific dynamic simulations with supporting contacts were created from a three-dimensional, full-body musculoskeletal model with 17 degrees of freedom and 92 muscle–tendon actuators using OpenSim [3] and a custom MATLAB S-function [4]. The simulated motion was combined with surrogate models of experimental motion capture data to begin forming the closed-loop control (Fig. 1; Fig. 2 top right). Separate quadratic response surfaces were developed for each desired subtask (e.g., swing foot position) as a function of a primary task (e.g., center of mass position) to approximate subject-specific task-level movement coordination allowing synthesis of a range of motions (e.g., prediction of post-treatment outcome from pre-treatment motion).
Figure 1: Subject-specific surrogate models created from experimental motion capture data and used for desired task-level coordination during simulations.


Figure 2: Overview of task-level simulation using OpenSim and MATLAB.

Differences between simulated and desired tasks were used to compute task errors (Fig. 2 top left). Differences between simulated and experimental tasks were minimized by tuning proportional-integral-derivative (PID) controller gains in the feedback loop to a specific subject. Desired task accelerations were delayed (60 ms) to represent time lags for neuromechanical processes.

Task accelerations were used to synthesize whole-body motions using prioritized, multi-task approaches for a support-consistent formulation maintaining the foot-ground contact [5, 6] (Fig. 2 bottom left). Each task force is comprised of the task acceleration multiplied with its task space inertia matrix, plus velocity and gravity compensation terms. Composite joint torques to simultaneously control all tasks are found by multiplying task forces by their respective reduced Jacobians and dynamically-consistent, priority-level-determined, null space matrices for each task.

Joint torques from the prioritized operational space motion control were used for a musculoskeletal dynamic simulation with supporting contacts (Fig. bottom right). Static optimization minimized the sum of muscle activations squared subject to bounds (0 to 1) and constraints on net muscle moments, the product of muscles forces and their moment arms, equaling the total joint torques for the tasks.

The synthesized motions were compared with the experimental ones from each subject. In addition, the model's muscle activations were compared with processed experimental EMG from each subject.

RESULTS AND DISCUSSION

The synthesized motions and muscle activations reproduced the balance recovery experiments. The simulated whole-body center of mass displacements were, on average, within 0.7 cm (female) and 1.3 cm (male) of experimental ones (Fig. 3a male subject). Model muscle activations (Fig. 3b bottom row) matched experimental EMG (Fig. 3b top row) in timing of peak muscle excitations. Differences between simulated and experimental balance recovery were similar in both anterior and posterior translation directions of the CAREN base.

The combination of biomechanics and robotics approaches for closed-loop control simulations allowed synthesis of subject-specific task-level motions. The surrogate response surfaces allowed synthesis of new, coordinated motions without additional experimental motion capture data. The optimal PID gains allowed control over simulated tasks for each subject. The operational space control allowed multiple prioritized tasks to balance on a single supporting limb in contact with the ground. The four areas of the closed loop (Fig. 2: specific subjects, control systems, robotics, and biomechanics) offer numerous directions for future work to advance the study of human balance control and subject-specific outcome predictions.

SIMULATION-BASED DESIGN OF DEVICES TO AUGMENT HUMAN MOVEMENT

John R Rogers

United States Military Academy, West Point, NY, USA
email: john.rogers@usma.edu

INTRODUCTION

Musculoskeletal dynamic simulation can aid the design of devices that augment human movement. These devices can be used for rehabilitation or for enhancing athletic performance; in the latter role the device relieves some of the metabolic work done by muscles acting over a joint. The design of powered devices requires knowledge of the speed and torque at the joint over time. In-vivo measurement of these quantities is inherently difficult, but they can be predicted by simulation. The objective of this study is to intelligently design wearable robotic devices, including selection of motors, springs, etc.

Exoskeleton systems that transmit force to the human body have been developed for rehabilitation [1], for load carrying [2], and for enhancing strength and endurance [3]. The simulation-based design method described in this paper is applied to a prototype hip actuator, the purpose of which is to help a person run fast. The device is light, of few parts, and is capable of delivering a significant fraction of hip power. Hamner et al. [4, 5] and Dorn [6] describe simulations of human running. The author has not found any physics-based musculoskeletal simulations of humans with exoskeletons in the literature.

This study demonstrates simulation-based selection of springs and electric motors for a hip actuator to assist running. The author's vision is to utilize external power to enable an average runner to maintain his or her sprint pace for a mile.

METHODS

Simulation is based on a human body model that accounts for the sizes and masses of body segments, muscle-to-bone attachment points, and muscle dynamics. OpenSim is software for simulating musculoskeletal dynamics of human and animal movement. OpenSim executes inverse kinematics, inverse dynamics, residual reduction, and computed muscle control algorithms. Simulation results include joint moments, joint angular velocities, and joint power, and metabolic rate [7]. The human body model used in this work contains 92 musculotendon actuators of the lower extremities and torso [4, 5]. The hip actuator is also included in the model.

The action of the hip actuator prototype is reciprocating: a flexion moment applied by the device to the right leg is accompanied by an equal and opposite moment (extension moment) applied to the left leg. The mechanism does not restrict hip abduction and adduction, thus it minimizes interference with the natural motion of running. The controls and battery are in a backpack.
Figure 1: Hip actuator torque (red) is timed to maximize the contribution to hip flexion moment.

Extension and flexion moments exerted ny the hip actuator are synchronized to the runner's gait. The torque profile is shown in Fig. 1 on the same plot with hip joint moments from an OpenSim analysis of over-ground running at four speeds up to 9m/s [6]. A four minute mile is run at 6.7 m/s for comparison. The torque profile must accommodate the reciprocating action: force on the right leg must be equal and opposite to the reaction force on the left leg. The peak magnitude of the torque profile shown is 120 Nm; such a torque would require a peak force of 300 N (68lb) applied to the leg proximal to the knee. Gain control is used to reduce

the magnitude of the torque applied. The phase of the control signal is aligned with the positive and negative peaks of the hip muscle moment to maximize the contribution of the system.

The angular position of the system is equal to the angular position of one leg relative to the other, Fig. 2A, and the motor speed is the system speed multiplied by the motor gear ratio, Fig. 2B.
Figure 2a: Hip flexion angles for right and left legs over one gait cycle. **Figure 2b:** Motor speed.

A motor is selected to satisfy the speed and torque profiles, iteratively analyzing the current-, voltage- and power-versus-time profiles with candidate motors.

RESULTS AND DISCUSSION

The motor input power profile for one gait cycle is shown in Fig.3. This figure is for running at 4 m/s. The RMS power is 170 W; the peak is 320 W.
Figure 3: Motor input power over one gait cycle.

CONCLUSIONS

This paper presents a method of incorporating mechanical devices in OpenSim for the purpose of design.

An important limitation of this analysis is the assumption that gait kinematics are the same with the device as they are without the device. This

approach can answer the question "if a runner runs the same way with the device as he runs without it, will there be a metabolic savings?" If the runner adapts his or her gait to accommodate wearing the system, this analysis does not account for the change.

The next step in this project is to run the OpenSim metabolic analysis with and without the hip actuator, the hypothesis being that metabolic rate will be less with the device. OpenSim will be also used to identify potential negative effects on non-hip muscles, and bone-bone contact forces. Once the prototype is assembled and subjected to pilot testing, the author will seek approval for a trial from the Institutional Review Board for human subject testing.

Simulation-based prediction of the effects of machines on human metabolics and muscle force is helpful to understand the impact of such devices on the user. An OpenSim analysis can output joint angular velocities and joint torques, the principle quantities necessary for the design of wearable robotic systems.

SIMULATED SOFT-TISSUE OSCILLATION INCREASES STABILITY IN PASSIVE-DYNAMIC WALKERS

Samuel E. Masters and John H. Challis

Biomechanics Lab, The Pennsylvania State University, University Park, PA, USA
email: sem361@psu.edu

INTRODUCTION

The majority of human body mass is comprised of soft tissue that oscillates during human locomotion. As a result, models of human locomotion that ignore soft tissue vibration may affect the measurement accuracy of gait kinematics and kinetics. Models of human locomotion that contain a soft-tissue component can be used to study the potential role of soft-tissue oscillation. Passive-dynamic walkers (PDWs) are simple human ambulation models that can be used to study the underlying dynamics of walking gait. A bipedal, point-mass walker with masses located at the hip and both feet can ambulate on an incline solely due to gravity [1]. A PDW model can be modified to study the dynamics of biologically-inspired systems (e.g., energy storage and release in a muscle-tendon unit, or arm swing). A simple PDW with a soft-tissue component was modeled to study the effects of soft-tissue oscillation on human gait dynamics.

The objectives of the study were: (1) quantify the effects of soft-tissue oscillation on the stability of human walking gait; and (2) to measure the kinematic differences between a bipedal walker with and without a soft-tissue component.

METHODS

A two-dimensional PDW was modeled to study the effects of soft-tissue oscillation on gait dynamics. The control passive-dynamic walker (CPDW) contained a point mass at the hip and each foot. The legs were massless and rigid. The oscillating passive-dynamic walker (OPDW) was identical to the CPDW except for the addition of spring-mass-damper system attached to the hip mass to simulate soft-tissue oscillation (Fig. 1).
Figure 1: Diagram of a passive oscillating mass walker. (a) The initial position of a step cycle. (b) An intermediate position of a step cycle.

Stable gait cycles were found by systematically incrementing the spring-damper (S-D) parameters until the walker failed to ambulate. The damping values analyzed were between 0 and 12 N.s.m^{-1} in increments of 0.25 N.s.m^{-1}, and the spring stiffness value was incremented by 0.1 N.m^{-1}. The conditions for foot-ground contact were such that each step was mathematically dependent upon the angular position of the stance leg exclusively [1]. Therefore, the stance leg state trajectory was analyzed in order to assess stability.

The gait stability of the control and oscillating PDWs were measured by Floquet multipliers (FMs), basin of attraction (BOA), and step-time variability (STV). The S-D parameters that resulted in period-1 gait were analyzed for stability. A period-1 gait cycle is such that each cycle is kinematically identical, therefore, the PDW could ambulate indefinitely if unperturbed. The FMs and BOA were analyzed by perturbing the initial state of the stance leg and analyzing the subsequent gait cycles.

To test PDW robustness to an isolated perturbation in the terrain, the slope was perturbed and the subsequent steps were recorded. The perturbation was systematically increased and

decreased until the PDW failed to ambulate. The slope perturbation range (SPR) was the range of slope perturbation values that the walker could ambulate without failing in the subsequent steps. To further test robustness, the CPDW and the OPDW for varying S-D parameters were simulated for 200 steps on uneven terrain. The slope was randomly varied and the standard deviation of the step time was calculated for the CPDW and an OPDW with varying S-D parameters.

RESULTS AND DISCUSSION

The OPDW gait dynamics were sensitive to the S-D parameters. The S-D parameters could be tuned such that the OPDW exhibited stable period-1, period-n (n>1), or chaotic gait cycles.

A FM with a magnitude less than one constitutes a system that is stable step-to-step. The S-D parameters could be tuned such that the step-to-step stability of the OPDW was greater than that of the CPDW (Tab. 1). The range of slope values for which an OPDW with S-D parameters of 62.4 $N.m^{-1}$ and 3.5 $N.s.m^{-1}$ could ambulate was 112.9% greater than that of the CPDW. The most stable FM value for this OPDW occurred at a mid-range slope value, which corresponded to a relatively moderate walking speed.

Table 1: Floquet multiplier values for the CPDW and varying spring-damper parameters for the OPDW.

	Control	----------Oscillating----------		
c ($N.s.m^{-1}$)	0	3.5	10.0	12.0
k ($N.m^{-1}$)	0	25.8	32.3	39.1
Floquet Multiplier	0.5883	0.3545	0.3644	0.3651

The phase space of the BOA plane was the Poincare section of the initial state for each step. The S-D parameters for the OPDW with the largest BOA were 1.1 $N.m^{-1}$-2.5 $N.s.m^{-1}$. The area was 111.6% larger than that for the CPDW.

The S-D parameters that resulted in the largest SPR were 53.7 $N.m^{-1}$ and 3.5 $N.s.m^{-1}$. The SPR for this OPDW was 0.0167 radians, which was 131.9% larger than the SPR of the CPDW. The standard deviation of the step time for the CPDW on varying terrain was 0.12810 seconds. The standard deviation of the step time for the OPDW on the same randomly varied terrain was 0.07017 seconds, which is 45.2% less than the CPDW.

The S-D parameters for the oscillating mass could be tuned such that PDW exhibited an increase in step-to-step stability, global stability, and robustness to changes in the terrain. In fully rigid body models of human ambulation, stability is largely attained by muscle actuation. The extent to which the neuromuscular system controls stability may be overestimated. Soft-tissue vibration passively increases stability, which would decrease the necessity of the neuromuscular system to aid stability.

It has been illustrated that varying the S-D parameters will drastically change the gait dynamics of a bipedal walker. Stability in human walking gait has been shown to be different amongst different age groups and body types. Differing levels of stability amongst humans may be attributed, in part, to inter-human soft tissue composition variability. Adipose tissue, which is less stiff than other soft tissues, will passively affect the walking kinetics and kinematics of human gait differently than other types of soft tissue (e.g., muscle tissue, skin tissue, and tendon tissue).

CONCLUSIONS

Passive-dynamic walkers can be utilized to obtain insights into human locomotion. These simple PDW models were extended to study the effects of soft-tissue oscillation on walking gait dynamics. Importantly the walking gait of the PDW model with an oscillating component was much more stable than the fully rigid model. This suggests damped soft-tissue oscillations may, in addition to their other roles, make gait more stable.

GENERATING PREDICTIVE SIMULATIONS OF MUSCULOSKELETAL MOVEMENT USING OPTIMAL CONTROL, MATLAB AND OPENSIM

[1] Leng-Feng Lee and [2] Brian R. Umberger

[1] Stony Brook University, New York, USA
[2] University of Massachusetts Amherst, Amherst, MA, USA
email: lengfenglee@gmail.com, umberger@kin.umass.edu

INTRODUCTION

Computer simulation and optimization are powerful tools for studying the biomechanics of movement. Dynamic optimizations can be categorized as either data-tracking or predictive problems. The open-source software OpenSim [3] provides tools for generating tracking simulations but not predictive simulations. However, OpenSim includes a robust application programming interface (API) that permits extending its capabilities with scripting languages such as MATLAB [e.g., 2]. In the work presented here, we combine the computational tools provided by MATLAB with the musculoskeletal modeling capabilities of OpenSim to create a framework for generating predictive simulations of musculoskeletal movement based on direct collocation (DC) optimal control techniques [1,4].

METHODS

The optimal control problem can be stated as: find the state and control trajectories that minimize an objective function, subject to constraints represented by the system dynamical equations, bound constraints on the controls, and arbitrary task constraints [4]. With DC, both the states and controls are discretized in time and treated as unknowns, and the original optimal control problem is transformed into a large-scale, nonlinear programming problem [1]. In our approach (Fig. 1), we use MATLAB to set-up and solve the optimization problem using the fmincon solver (interior-point algorithm) and to communicate with OpenSim via the API. OpenSim is used to calculate the derivatives of the state variables, given a set of discretized states and controls, as well as to return any other quantities of interest (e.g., muscle or contact forces). In evaluating the system dynamical

equation constraints, we used a backward Euler discretization.

For demonstration purposes, we used a simple 1 degree of freedom (DOF) model consisting of a block acted upon by two muscles (6 states, 2 controls), that was modified from the "Tug of War" example provided with OpenSim. Task constraints were defined such that the block should move from a starting position of -0.08 m to a position of 0.08 m and back to the original position in 1.0 s. The objective function to be minimized was the sum of squared muscle activation integrals.

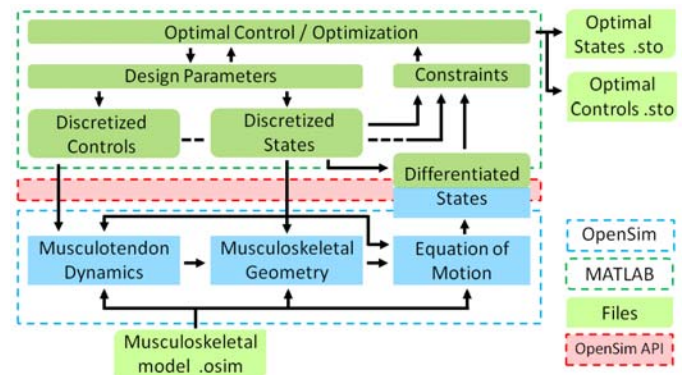
We evaluated the solutions by comparing them at different mesh densities between 25-201 nodes, and by comparing them with forward simulations based on the resulting initial conditions and controls from DC. To evaluate the scalability of the Matlab-OpenSim DC approach, we also present preliminary result for a predictive human walking simulation using a two-dimensional (2-D) model with 12 DOF and 18 muscles (60 states, 18 controls).


Figure 1: MATLAB-OpenSim interface for solving optimal control problems using DC.

RESULTS AND DISCUSSION

For the 1-DOF model, all node densities resulted in approximately sinusoidal motions that satisfied the constraints (tolerance = 1e-6) even when the initial guess (blue lines in Fig. 2) was far from the final result (black and green lines in Fig. 2).

With increasing node density, the minimum objective function value (related to the activation integrals in Fig. 2b) decreased considerably until 101 nodes, with little further reduction at 201 nodes.

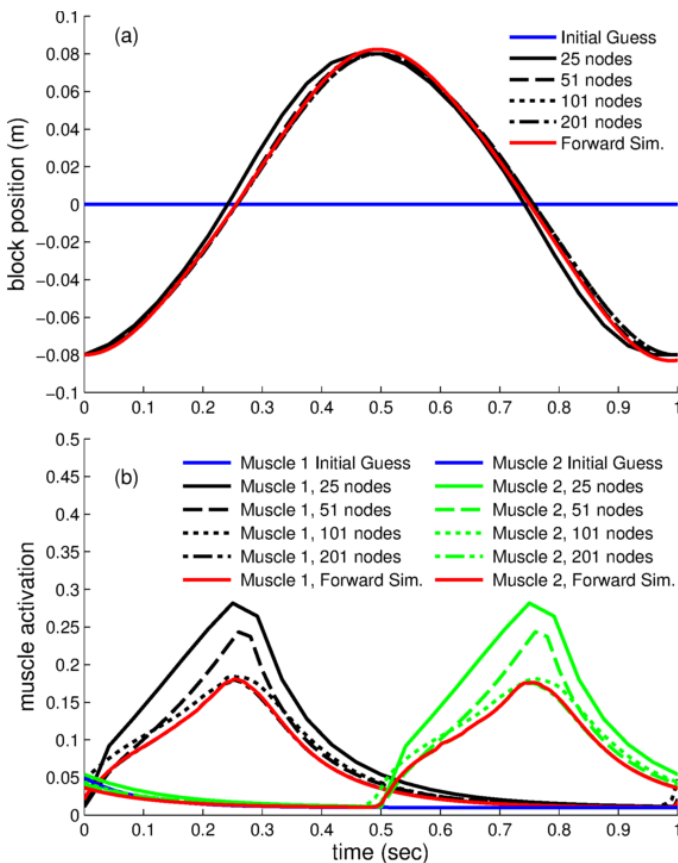
The forward simulation based on the 201 node solution (red lines in Fig. 2) was nearly identical to the DC result, with a maximum discrepancy of 2.8 mm in the block position at the end of the 1.0 s simulation.


Figure 2: (a) Optimized block position and (b) optimized muscle activations for different numbers of nodes, and for the forward solution. The 201 node activations (dash-dot lines) are hidden behind the forward simulation results (red lines).
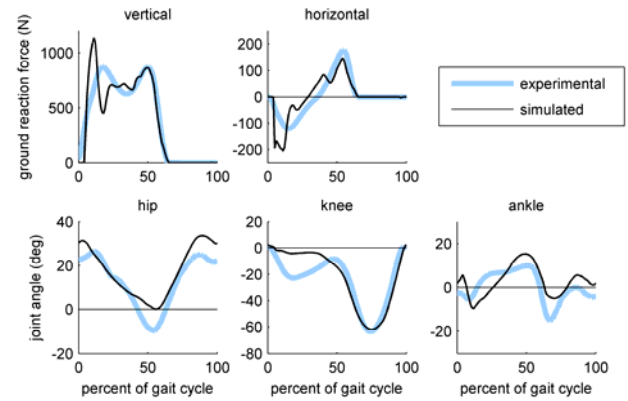

Figure 3: Results for the predictive 2-D walking simulation. Experimental data were not tracked.

The results for the 2-D walking simulation (Fig. 3), while still preliminary, were also encouraging, with ground reaction forces and joint angles that were in reasonable agreement with experimental data. However, convergence to an acceptable tolerance was slow (>100 hr) using the fmincon solver.

CONCLUSIONS

The MATLAB-OpenSim interface provides a powerful and flexible approach for generating predictive musculoskeletal movement simulations using the DC optimal control approach. We are currently investigating replacing fmincon with the IPOPT and/or SNOPT solvers [4], which should substantially reduce the computational time needed to generate the simulations.

INFLUENCE OF STIFFNESS OF AN ANKLE-FOOT ORTHOSIS ON GAIT
A PREDICTIVE SIMULATION STUDY

Anne Koelewijn and Antonie J. van den Bogert

Cleveland State University, Cleveland, OH
email: a.koelewijn@csuohio.edu, web: http://hmc.csuohio.edu

INTRODUCTION

An ankle-foot orthosis (AFO) is often prescribed to patients with instability or weakness in the lower leg to assist plantarflexion or dorsiflexion [1]. A limited number of studies focuses on the optimal stiffness of the AFO. It is known that excessive AFO stiffness introduces buckling in the knee [1]. It would be desirable to have the ability to predict the effect of an AFO on the gait of a specific patient. This would make customized prescriptions possible and reduce the need for trial and error. Bregman et al. used a simplified gait model and found that patient energy cost might be reduced by choosing the correct stiffness [2]. However, this model did not have muscles.

In the present study, a dynamic musculoskeletal model will be used to predict the effect of the stiffness of the AFO on gait parameters. We hypothesize that less muscular effort is required in the lower leg with an increased stiffness in the AFO due to the higher moment generated in the AFO.

METHODS

Predictive simulations of gait were performed with a sagittal plane model having nine degrees of freedom and 16 muscles. An open loop optimal control problem was formulated to find a gait cycle that minimizes a weighted sum of muscular effort and deviation from normal gait kinematics. The model and solution method were identical to [3], but a full gait cycle was simulated. Also, tracking was not performed on the ankle where the AFO was applied, since this could make the muscles "fight" the orthosis.

The optimal control problem was solved for an able-bodied system with and without an AFO. The AFO was modelled as a rotational spring that was applied to one of the ankle joints. The stiffness of the AFO ranges from 50 to 400 Nm/rad, similar to the range of stiffnesses that were tested in [2].

RESULTS AND DISCUSSION

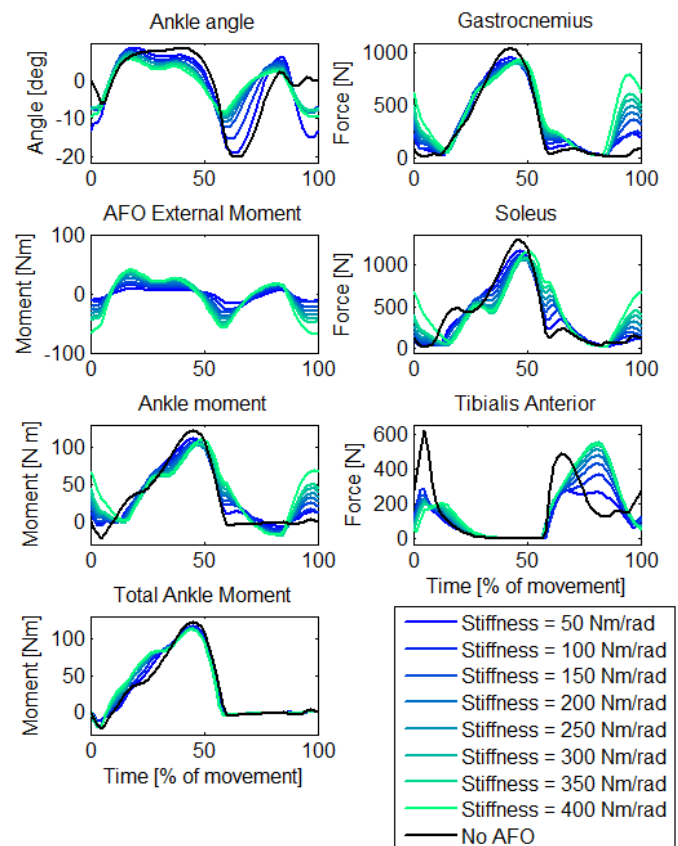
Figure 1 shows the ankle moment and muscle forces in the lower leg of the predictive simulations. The color of the line gets lighter with an increased stiffness. The black line shows the result without an AFO.


Figure 1: Results of the predictive simulations of gait with and without an AFO.

Figure 1 shows that the AFO decreases the force required in the Tibialis Anterior during initial stance significantly. However, there is little benefit of having a higher stiffness, since the decrease is much

higher between the no-AFO simulation and any simulation with AFO. Also, the stiffness does not have an effect on the size of the peak Gastrocnemius and Soleus force during stance. Both are lower than in gait without AFO, but there is no significant effect of the stiffness.

It was found that this is due to the timing of the moments that are generated by the AFO. During push-off, the ankle angle is almost zero, so the AFO is not able to provide much assistance during this phase. However, during the stance phase, when the ankle angle is larger, the total ankle moment increases with AFO stiffness.

The AFO stiffness has a significant effect on the Tibialis Anterior force during the swing phase. The muscle is counteracting the AFO to provide sufficient toe-clearance, for which a dorsiflexion angle is required. This suggests that a too large stiffness is not beneficial, since it increases the necessary force in the Tibialis Anterior.

There is also a significant effect of the stiffness of the AFO on the Gastrocnemius and Soleus during the initial and final phase of the swing phase. It was found that this was due to the tracking of the vertical ground reaction force, which requires a nonzero ankle angle during the swing phase, yielding a moment in the AFO. The Soleus and Gastrocnemius were activated to reduce the total ankle moment to 0. Further research is necessary to find if this behavior is also present in reality, or if it is an artifact of the cost function that was used in the optimal control problem.

Studies on impaired patients walking with and without an AFO confirm our finding that there is no decrease in peak muscle force in the Gastrocnemius and Soleus muscle [4]. Balmaseda et al., in a study on healthy subjects, reported a reduction of the mean stance phase duration of 4.83% with an AFO compared to without an AFO [5]. This reduction is confirmed by this study, which also yielded a reduction in the stance phase of approximately 5%.

CONCLUSIONS

The hypothesis that an increase in AFO stiffness yields a decrease in muscular effort was not confirmed. It was found that there was only little effect of the stiffness of the AFO on the peak force in the Gastrocnemius and Soleus.

Future studies should include a verification of these results using a subject study, for example to see if humans also increase their force in the Gastrocnemius and Soleus during the swing phase. If it is found that this is an artifact of the optimal control problem, such results can be used to further improve the formulation of suitable cost functions.

Biomechanical, Clinical, and Functional Changes with Achilles Tendon Pathology

[1] Jennifer A. Zellers, [1]Daniel H. Cortes, and [1]Karin Gravare Silbernagel

[1] The University of Delaware, Newark, DE, USA
email: jzellers@udel.edu

INTRODUCTION

Achilles tendon injury is associated with pain, functional impairment and an inability to return to prior level of function in activities of daily living as well as sport activity. Early viscoelastic recovery of the tendon has been suggested to correlate with functional gains following Achilles tendon rupture [1]. Prior studies have been limited by an inability to adequately measure tendon viscoelastic properties non-invasively. A novel, non-invasive ultrasound elastography technique using continuous shear wave elastography (cSWE) has been developed to measure viscoelastic properties of the tendon [2,3]. This technique has been validated and applied to a healthy population, however, application of this technique to Achilles tendon dysfunction has only been described in one subject [2,3]. This study evaluated tendon viscoelastic properties via cSWE and functional capacity of three subjects with Achilles tendon dysfunction.

METHODS

Three subjects with varying tendon pathologies were included in this case series. This study was approved by the University of Delaware Institutional Review Board.

Subjects were examined by a licensed physical therapist to confirm Achilles tendon injury. Tendon geometry was obtained via B-mode ultrasound imaging to measure tendon length from the calcaneal notch to the soleus insertion and gastrocnemius myotendinous junction. Viscoelastic properties of the tendons were measured using cSWE. Data was collected at eleven frequencies (323, 340, 358, 379, 403, 430, 461, 496, 538, 586, 645 Hz) due to the variation in wave propagation of healing tissue. Six frequencies which produced a complete sine wave in the visualized region were used in the calculation of shear and viscous moduli.

Subjects completed functional testing including the heel-rise test for ankle plantar flexor muscular endurance. This test has been found to correlate with tendon length and functional outcomes [4]. Subjects completed questionnaires regarding self-reported symptoms and function including the Victorian Institute of Sport – Achilles Questionnaire (VISA-A), the Achilles Tendon Total Rupture Score (ATRS), and the Foot and Ankle Outcome Score (FAOS).

RESULTS AND DISCUSSION

Case 1 is a 72 year-old male, presenting with chronic, tendinopathic changes. Case 2 is a 56 year-old male, presenting with Achilles tendinopathy. Case 3 is a 25 year-old female, presenting seven weeks status-post acute Achilles tendon rupture currently undergoing conservative treatment.
Figure 1: Viscoelastic map of shear modulus superimposed on B-mode ultrasound image for the symptomatic tendon in each of the three cases.

Achilles tendon length, viscoelastic properties, heel-rise test total work and maximum heel-rise height, VISA-A and ATRS scores are included in Table 1. Viscoelastic maps were constructed for each of the subjects (Fig. 1). None of the subjects were able to complete a unilateral heel-rise on their affected side. FAOS scores are shown in Figure 2.
Figure 2: Results of the FAOS for each case in pain, symptom, activity of daily living (ADL), sport and recreation, and quality of life (QOL) subscales.

CONCLUSIONS

Each of the three subjects included in this case series were diagnosed with Achilles tendon injury. Two demonstrated varying severity of Achilles tendinopathy and one was status-post acute Achilles tendon rupture. All subjects demonstrated differences in shear and viscous moduli compared to their asymptomatic side. All subjects also demonstrated decreased functional performance as evidenced by the inability to perform a single heel

rise and by subject self-report using the VISA-A, ATRS and FAOS.

This is the first study to identify differences in Achilles tendon viscoelastic properties using the cSWE technique and associate them with clinical outcomes in an unhealthy population. Additional studies with larger subject numbers are required to identify whether there are correlations between viscoelastic properties and functional outcomes and whether these properties change over time with healing.

VARIATION IN THE HUMAN ACHILLES TENDON MOMENT ARM DURING WALKING

Kristen Rasske[1], Darryl G. Thelen[1], and Jason R. Franz[1,2]

INTRODUCTION

The Achilles tendon (AT) moment arm is an important biomechanical measure that converts gastrocnemius and soleus muscle forces into a joint moment at the ankle, ultimately contributing to the generation of mechanical power during walking. However, existing measurements of the AT moment arm are limited to isolated ankle exercises, which are then assumed to apply during walking [1-4]. For example, current modeling approaches presume a kinematic AT moment arm that increases with plantarflexion over the range of motion observed in walking. Yet, recent evidence suggests that the relation between AT moment arm and ankle joint rotation is load dependent and varies significantly from rest with increasing muscle activity [2]. Thus, the AT moment arm may vary in a complex manner during gait, reflecting considerable and compound changes in joint angle and muscle forces.

Our purpose was to couple ultrasound imaging and quantitative motion capture to dynamically estimate the AT moment arm *in vivo* during walking. We hypothesized that the AT moment arm varies considerably during walking, but not as a strict kinematic function of ankle joint angle.

METHODS

Ten healthy, young adults (age: 23.9 ± 4.0 years; 6 males and 4 females) walked barefoot at 1.25 m/s on a dual-belt, force measuring treadmill. A custom orthotic positioned a 38 mm linear array transducer over the free AT of subjects' right leg, on average ~6 cm superior to the calcaneal insertion (Fig. 1). For each subject, we recorded ultrasound radiofrequency (RF) data at 155 frames/s over five strides. In synchrony, an 8-camera motion capture system (Motion Analysis, Corp., Santa Rosa, CA) recorded the 3D trajectories of retroreflective markers placed on subjects' pelvis, right and left legs, and the ultrasound orthotic. We also collected electromyographic (EMG) activities of the lateral gastrocnemius and soleus.

We manually tracked the superficial and deep edges of the AT at three locations (proximal, middle, and distal) using down-sampled (2x) B-mode images created from the RF data. We defined the AT midline as the best fit line through the average of the superficial and deep tendon edges. We defined the right ankle joint center as the midpoint of the lateral and medial malleoli markers. Finally, by transforming the ultrasound, orthotic, and motion capture kinematics into a common reference frame, we estimated the AT moment arm over the gait cycle as the perpendicular distance from AT midline to the ankle joint center (Fig. 1). A repeated measures ANOVA tested for significant ($p<0.05$) main effects of gait cycle phase (20% bins) on estimates of the AT moment arm.
Figure 1: We used ultrasound imaging and quantitative motion capture to estimate the AT moment arm during treadmill walking at 1.25 m/s.

RESULTS AND DISCUSSION

We found that the AT moment arm varied considerably during walking, increasing significantly and progressively from initial contact until after toe-off (Fig. 2B) ($p < 0.001$). The progressive increase in AT moment arm during stance corresponded with increasing plantarflexor muscle activity (Fig. 2A). In addition, the AT moment arm reached its maximum near the instant of peak plantarflexion. However, as hypothesized, and in contrast to current musculoskeletal modeling approaches, the AT moment arm during walking could not be expressed as a strict function of ankle joint angle (Fig. 2C). Our results imply that the AT moment arm varies with load during gait, presumably arising from a co-interaction between gastrocnemius and soleus forces and ankle angle.

Interestingly, we do observe some similarities between the AT moment arm measured during walking and that during isolated ankle exercises. For example, the AT moment arm immediately after initial contact, an instant of negligible muscle force [5], coincides with that previously reported at rest for the same joint angle (Fig. 2C) [1]. Additionally, the AT moment arm during late stance, when the AT is maximally loaded [5], corresponds to that reported during MVC at the same joint angle [1].

By measuring the AT moment arm *in vivo* during gait, we might better elucidate the relation between muscle-tendon architecture and performance. For example, the AT moment arm is modestly correlated with walking speed in slower old adults [6], a change that may contribute to diminished ankle power output seen in this population. This potential link between musculoskeletal geometry and performance can be directly tested using the proposed *in vivo* measurements during gait.

CONCLUSIONS

We provide evidence that the AT moment arm during walking is load dependent, likely reflecting compound changes in joint angle and muscle forces. Our results have important implications for the development of musculoskeletal models, suggesting that the AT moment arm measured during isolated ankle exercises may not accurately predict that during walking. Moreover, measuring the AT moment arm *in vivo* during walking has the potential to provide new and mechanistic insight into triceps surae muscle-tendon performance.

LUMBAR INTERVERTEBRAL DISC DEFORMATION IN VIVO DURING LIFTING MOTION

[1] Ryan Byrne, [2] William Anderst, [1,2] Xudong Zhang

[1] Department of Mechanical Engineering & Materials Science
[2] Department of Orthopaedic Surgery, University of Pittsburgh, Pittsburgh, PA, USA
email: xuz9@pitt.edu

INTRODUCTION

Low back disorders (LBD) remain one of the most prevalent, debilitating, and costly public health problems. Excessive mechanical loading on the lumbar intervertebral discs is a major risk factor for causing LBD. Assessment of the disc loading or deformation in vivo during functional activities is challenging. Most prior studies have either used models to predict the disc forces without taking into account the disc deformation [1] or have examined the force-deformation relationship in vitro by cadaveric tests and used the data to verify finite element model (FEM) predictions [2]. One study quantified the lumbar disc deformation in vivo but only for static positions [3]. We have recently succeeded in measuring 3D continuous lumbar vertebral kinematics in vivo during lifting activities, using a dynamic stereo-radiography system [4]. The purpose of the current study was to characterize the lumbar intervertebral disc deformation based on the skeletal kinematics data acquired.

METHODS

We used data of 8 asymptomatic subjects (5 male, 3 female; age: 24±2 years) who performed a straight-legged lifting motion and static standing trials while a dynamic stereo-radiography system captured their lumbar vertebral kinematics at 30 Hz. Data of two trials of lifting a 10-lbs load and one trial of static upright standing with no load were included. The recorded dynamic radiographic images were then processed using a volumetric model-based tracking procedure, resulting in 3D motion data of the vertebral bones (from L2 to S1). Details of the experimental setup, data acquisition, and data processing were described in a prior publication [4].

The intervertebral disc deformation was defined based on the relative motion between adjacent vertebral endplates, with the static position in upright standing as the reference state (Fig. 1). The disc was modeled by line segments (grey lines) perpendicular to the average (blue line) of planes fit to the adjacent endplates (red lines) in the static upright position [5]. The disc height was calculated at over 100 discrete line segments that were evenly distributed in the anterior-posterior direction throughout the mid $1/3^{rd}$ of the disc. Line segments representing the disc remained connected to the endplates as the vertebrae moved relative to each other. The deformation at each time frame was decomposed into two orthogonal components: compression and shear component; the percent change in length in the compression direction with respect to the static position was then determined (Fig. 2).
Figure 1: Definitions of the compression and shear components of disc deformation as a result of intervertebral motion. Deformation is exaggerated for visualization purpose.

Disc deformation was analyzed for three 2mm radius circular areas (most anterior, central, and most posterior) consistently defined within each disc. The line segment within each circle

experiencing the median compression-distraction at the beginning of dynamic motion was selected and tracked throughout the rest of lifting. The correlation between disc deformation and extension was determined for each motion segment for each participant.

RESULTS AND DISCUSSION

The anterior compression and posterior distraction, computed as disc height percent changes from the upright standing posture, were greatest at the beginning of a lift where the lumbar spine was most flexed (Fig. 2). The average maximum disc compression and distraction were comparable across L2-L5, but were distinctively less at L5-S1 (Table 1). The anterior compression and posterior distraction reduced, in a relatively linear fashion, with the progression of lifting (see ranges of R^2 values in Table 2).

Table 1: Maximum lumbar disc deformation.

Disc	Max Compression Mean±SD	Max Distraction Mean±SD
L2-L3	-34% (±25%)	+65% (±34%)
L3-L4	-36% (±22%)	+70% (±44%)
L4-L5	-38% (±11%)	+59% (±18%)
L5-S1	-17% (±12%)	+30% (±12%)

Table 2: Ranges of R^2 values quantifying the correlation between deformation and extension.

Disc	Anterior Compression	Posterior Distraction
L2-L3	.90 - .98	.79 - .99
L3-L4	.82 - .98	.90 - .98
L4-L5	.75 - .99	.88 - .99
L5-S1	.44 - .99	.61 - .99

Minimal deformation changes were incurred in the central areas of the discs, which on average varied from -4% to +6%, during the lifting motions.

The results that the L5-S1 disc experiences much less deformation change during a lifting motion may point to one or both of the following interpretations: (1) it is under significantly more pre-stress and deformation at the static positions, therefore reducing the appearance of compression-distraction change throughout the flexion; (2) the L5-S1 disc has distinctively different structural or material properties (e.g., is stiffer) than the other discs.

CONCLUSION

This study quantified the lumbar intervertebral disc deformation in vivo during lifting motions, showing that the discs underwent substantial deformation in the anterior and posterior regions while the L5-S1 disc exhibited unique deformation characteristics in comparison to the L2 to L5 lumbar discs.

QUANTIFYING MICROSTRUCTURAL DAMAGE ACCUMULATION IN THE ANNULUS FIBROSUS DURING INDUCED INTERVERTEBRAL DISC HERNIATION

Mamiko Noguchi*, Alexander Wong, Ibrahim Ben Daya, Troy L. Campbell, Joe Quadrilatero and Jack P. Callaghan

University of Waterloo, Waterloo, ON, Canada
*email: mnoguchi@uwaterloo.ca

INTRODUCTION

Structural damage to the annulus fibrosus is commonly observed in degenerated intervertebral discs (IVD) [1]. Approximately 40% of low back pain cases are attributed to internal disc disruption [2], which is characterized by damage to the internal structure of the IVD and is the precursor of herniation. Previous studies have proposed damage progression mechanisms by examining the magnitude of microstructural damage [3,4]. Results from these studies suggest that herniation initiates from a formation of clefts within the intralamellar matrix [3] and the most severe damage occurs in the inner annulus fibrosus [4]. However, both these studies only examined herniated discs, and only qualitatively. Therefore, it is unknown how this microstructural damage accumulates over a protocol known to induce herniation and whether the magnitude of damage can be quantified. The purpose of this study was to quantify microstructural damages to the annulus fibrosus at various time points during a herniation protocol in order to characterize accumulation of clefts (number, area, length, and major to minor axis ratio) leading up to IVD herniation.

METHODS

Ten porcine cervical functional spine units (mean age = 6 months; C3-C4 and C5-C6), each consisting of two adjacent vertebrae and the intervening IVD were used in this study. There were five loading conditions: 4000, 3000, 2000, and 1000 cycles of a herniation inducing protocol (1500 N load control; 1 Hz flexion-extension cycle), and pre-conditioning only as a control (preload at 300 N for 15 minutes followed by four cycles of passive flexion-extension test). Previous studies have shown that approximately 80% of porcine specimens partially herniate between 3000 and 7000 cycles of this protocol, suggesting that development of macrostructural damage would be captured within the design of the study [5,6].

Following the loading protocol, three tissue samples were excised from the posterior regions of the discs. These tissue samples were embedded in Optimum Cutting Temperature compound (Tissue-Tek OCT; Sakura Finetek, Torrance, CA, USA) and frozen in liquid nitrogen. Each frozen specimen was serially sectioned into 10 µm thick slices in the frontal (superficial and deep layers) and sagittal planes and stained with hematoxylin and eosin (H&E). Each section was examined using a digital camera (PixeLink, Ottawa, ON, Canada) linked to a brightfield microscope (Nikon Instruments Inc., Melville, NY, USA) and captured using Image ProPlus analysis software (Media Cybernetics, Rockville, MD, USA) (Fig.1). Three representative images were taken from each section and processed using a custom Matlab program. A Gaussian Mixture Model was used to identify the cluster for the clefts, and four cleft properties were calculated: i) number of clefts, ii) major axis length, iii) cleft area, and iv) major to minor axis ratio. The average and standard deviation of each dependent variable was calculated to demonstrate the trend across different time points during the herniation protocol.

RESULTS AND DISCUSSION

From 1000 to 3000 cycles, the number of clefts increased (over 300% increase or appearance of more than 55 clefts), while there were minimal increases in major axis length (< 9 µm) and cleft area (< 33 µm^2), suggesting that number of clefts may be an indicator of the magnitude of microstructural damage (Fig.2).

Despite the lack of any mechanical loading, the number of clefts and cleft length were higher in control (zero cycle; pre-condition only) compared to the 1000 and 2000 cycle conditions. In addition, the average cleft area was similar between control and 3000 cycles ($< 10\%$ difference). However, when comparing the total area (sum of each cleft area), it increased from control to 3000 cycles by approximately 40% in both superficial and deep

layers. By examining the images qualitatively, this trend can be explained: gaps (inherent imperfections) between collagen fibers were visible when the fibers were still crimpled in the control condition (Fig.1), whereas after 1000 and 2000 cycles, the collagen fibers stretched to the point where these gaps disappeared. By 3000 cycles, the fibers began to pull apart, forming ellipse-shaped clefts, which resulted in larger total cleft area (Fig.1).
Figure 1: Images from the superficial layers in control (left) and 3000 cycle (right) conditions, highlighting the difference between inherent and mechanical loading-induced clefts, respectively.

From 3000 to 4000 cycles, a prominent decrease in the number of clefts and increases in major axis length and cleft area were observed (Fig.2), suggesting a shift from accumulation of small clefts to formation of larger clefts by the joining of minor clefts. The number of clefts decreased to approximately half while the length and area increased by almost two- and seven-fold, respectively. The ratio between major and minor axes demonstrated less than 10% change on average, indicating that the shapes of clefts remained similar.

These results, taken together suggest that micro-structural damage progresses predominantly due to the increases in number of clefts, as opposed to major axis length or cleft area increases, similar to the mechanisms reported for bone crack initiation and propagation [7]. Overall, changes seen between the conditions were similar between superficial and deep layers; however, the damage in the superficial layers appears to be larger. A study examining the amount of radial bulge using MRI demonstrated that the superficial layers bulge out more than the deep layers by approximately 80% (0.2 mm) in flexion

[8], suggesting that the superficial layers may be more susceptible to accumulation of microstructural damages during the cyclic flexion-extension protocol as used in this study. Although some trends have emerged from this study, only a limited number of specimens have been collected. Further investigation is necessary to provide insight into why a number of degenerated discs exhibit inward collapse of the inner annulus fibrosus (inter-lamellar damage) as well as damage to the anterior annulus fibrosus.
Figure 2: The average number of clefts (top) and major axis length (bottom) across different loading cycles for the deep (blue) and superficial (red) layers.

CONCLUSION
A pathway leading up to IVD herniation may be explained by accumulation of small clefts that bridge to form major clefts - not an expansion of a single cleft.

INTRODUCTION

The medial collateral (MCL) and anterior cruciate ligaments (ACL) are primary and secondary ligamentous restraints against knee abduction during gait, respectively.[1] Knee abduction is an ACL injury risk predictor and component of valgus collapse, which is often observed during ACL rupture.[2] The MCL is a primary ligamentous restraint to knee abduction at knee flexion angles under 30°. Despite this, MCL ruptures only occur concomitantly in 20-40% of ACL injuries.[3] The purpose of this investigation was to understand how athletic tasks load the knee joint in a manner that leads to ACL failure without concomitant MCL failure. The hypothesis tested was that the ACL would provide a greater overall contribution to intact knee forces than the MCL during simulated motion tasks. A second tested hypothesis was that the ACL would demonstrate greater relative peak strain than the MCL during simulated motion tasks.

METHODS

A 6-degree-of-freedom robotic manipulator articulated 18 cadaveric knees from 11 unique donors (age = 47.6 ± 7.3 years; mass = 829 ± 199 N) through simulations of kinematics recorded from *in vivo* athletic tasks.[4] Four athletic tasks were simulated (male drop vertical jump (DVJ), female DVJ, male sidestep cutting, and female sidestep cutting) while recording forces, torques, and changes in ligament strain simultaneously. Specimens were tested in both intact-knee and isolated-ligament conditions. The isolated ligament condition was also used to identify each ligament's neutral strain position, allowing the absolute ligament strain throughout each motion to be determined. Following simulation, a uniaxial servohydraulic system tensioned each ACL and MCL to failure along their fiber orientations at a strain rate of 20% per second. Univariate ANOVA was used to evaluate statistical significance ($\alpha < 0.05$) between the ACL & MCL within each robotically simulated task.

RESULTS AND DISCUSSION

During a DVJ in the intact-knee, the ACL showed greater peak strain than the MCL (6.1% vs. 0.4%; $P < 0.01$). Greater peak ACL strains were also observed during sidestep cutting tasks (5.4% vs. 0.5%; $P = 0.02$). In all simulated tasks for the intact-knee, the ACL was continuously under greater strain than the MCL throughout the duration of landing phase (Figure 1). The isolated-ACL condition also showed greater peak anterior force (4.8% bodyweight vs. 0.3% bodyweight; $P < 0.01$), medial force (1.6% bodyweight vs. 0.4% bodyweight; $P < 0.01$), flexion torque (8.4 N*m vs. 0.4 N*m; $P < 0.01$), abduction torque (2.6 N*m vs. 0.3 N*m; $P < 0.01$), and adduction torque (0.5 N*m vs. 0.0 N*m; $P = 0.03$) than the isolated-MCL condition. During uniaxial tensioning, ACL specimens preferentially loaded in the AM-bundle exhibited plastic strain of 28.0% and failure strength of 637 N, while MCLs exhibited plastic strain of 15.0% and failure strength of 776 N.

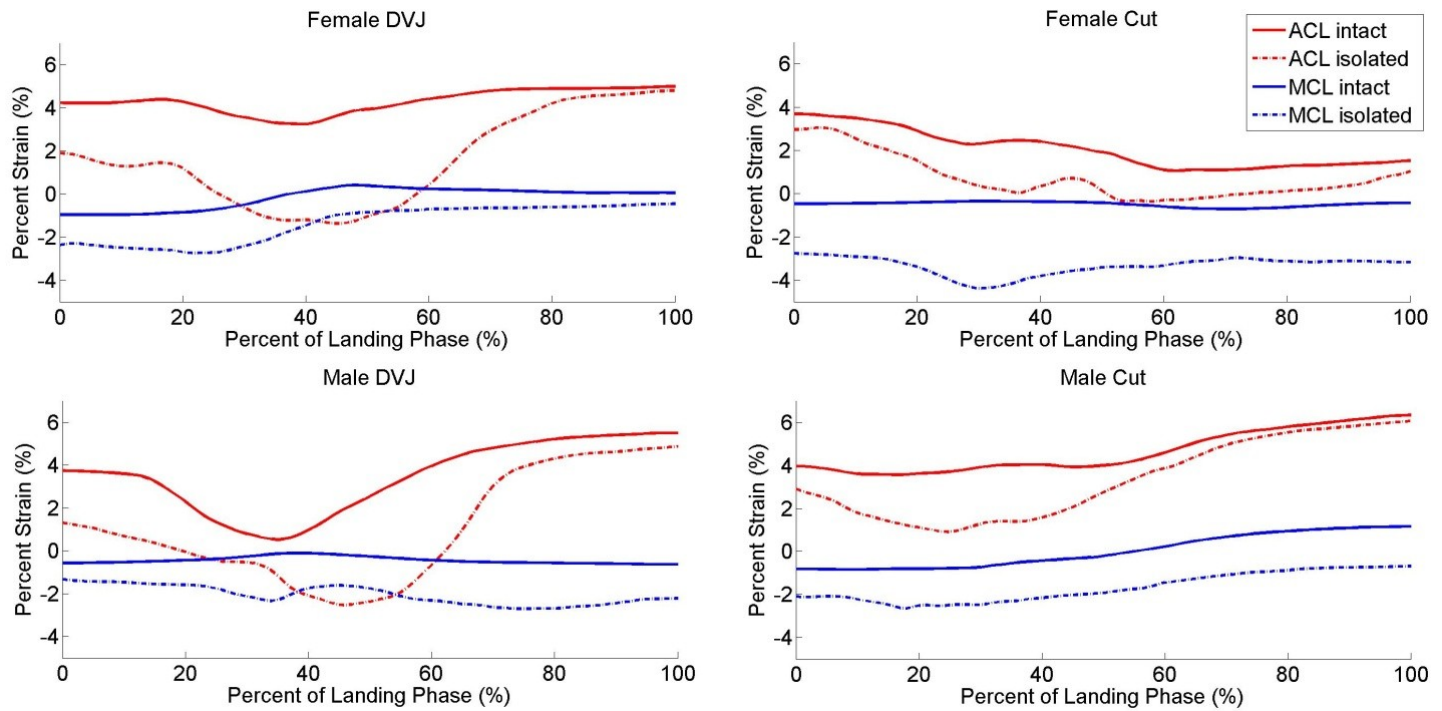
 The data confirmed the hypothesis that the ACL would make larger mechanical contributions to knee joint restraint during athletic tasks than the MCL. Irrespective of gender, DVJ and sidestep cutting tasks generated significantly greater peak loads in the ACL than in the MCL. This confirms previously reported bias in ligament loading ratios.[5]


Figure 1: Population average absolute strains for the ACL (red) and MCL (blue) in the intact-knee (solid) and isolated-ligament (dashed) condition throughout each simulated motion task. Throughout the majority of simulated tasks, the MCL was unstrained, while the ACL expressed up to 6.3% strain.

ACL:MCL loading ratios were exacerbated as the level of rigor for the simulated task increased. During the DVJ the mean ACL:MCL strain ratio was 15.3 while the sidestep cut ratio was 10.8. The increased ratios in the present study were the result of minimal strain being observed on the MCL throughout each simulation.

The ACL contributed significant torque (> 1.0 N*m) to the flexion and abduction DOFs, but not to internal torque resistance. Significant evidence, has supported valgus collapse as a primary mechanism of noncontact ACL injury.[2] In the present simulation model, the ACL made significant contributions (force > 1.0% bodyweight) to the anterior and medial forces. This corresponds with previous literature that identifies the ACL as a primary resistor to anterior tibial translation and a secondary resistor to medial tibial translation.[1]

CONCLUSIONS

Data from this investigation demonstrated the relative contributions of the ACL and MCL to knee joint restraint during simulated *in vivo* athletic tasks. In these controlled physiologic athletic tasks, where no ligament damage was inflicted on the specimen, the ACL provided greater contributions to knee restraint than the MCL, which was generally unstrained and minimally loaded. The current findings support that multi-planar loading during athletic tasks preferentially loads the ACL over the MCL, leaving it more susceptible to injury. A greater understanding of joint loading during *in vivo* tasks may provide insight that improves the efficacy of injury prevention protocols.

INTRODUCTION

The anterior cruciate ligament (ACL) serves as the primary soft tissue restraint to anterior tibial translation and as a secondary restraint to motion in additional degrees of freedom in the knee, while the medial collateral ligament (MCL) is aligned to primarily resist knee abduction.[1] Unfortunately, data extracted from various methods of mechanical knee simulations is not consistent.[2] However, novel methods of *in vitro* simulation driven by *in vivo* recorded kinematics have recently been developed to directly investigate knee mechanics during athletic tasks that may relate to ACL injury.[3] The purpose of this study was to apply robotically-controlled kinematic stimuli to joint orientations derived from *in vivo* recorded athletic activities of landing and pivoting in order to determine the effects of abduction, internal, and combined rotations on knee ligament biomechanics.

METHODS

In vivo kinematics were recorded for male and female athletic tasks using 3D motion capture. Kinematics were filtered and processed to be usable in robotic simulation.[3] 17 cadaveric lower extremities from 11 unique donors were obtained from an anatomical donations program and accepted for use in this study (age = 47.6 ± 7.3 years; mass = 829 ± 199 N). A six-degree-of-freedom robotic arm and custom mechanical fixtures were used to drive each specimen to the male- and female-specific initial contact orientations recorded for drop vertical jump (DVJ) and sidestep cutting tasks. The robotic manipulator then sequentially applied isolated ±4° rotational perturbations to the tibia in the frontal and transverse planes. Combined abduction/internal and adduction/external perturbations were also applied to each joint. Throughout each perturbation, joint forces and torques were recorded by a six-axis load cell aligned with the tibial axis and ligament strains were recorded by differential variable force transducers implanted on the ACL and MCL. A 2 x 3 ANOVA with a least significant difference post-hoc analysis evaluated significant differences ($\alpha < 0.05$) in ligament strain and joint loading between motion task and type of rotational perturbation.

RESULTS AND DISCUSSION

Perturbations ordered from greatest to least strain induced on the ACL were abduction/internal, abduction, adduction, internal, adduction/external, and external rotation (Figure 1). However, strain differences between each incremental perturbation were not statistically significant and only abduction/internal perturbation strains were significantly different than neutral alignment. Mean change induced by internal rotation was 1.01% less than abduction rotation, which was 0.26% less than combined abduction/internal rotation.

MCL strain significantly increased relative to the neutral orientation only when abduction and abduction/internal perturbations were applied. Adduction and combined adduction/external rotations completely unstrained the MCL. The MCL exhibited less change in strain than the ACL during external, internal, adduction, and adduction/internal perturbations. Similarly, the MCL exhibited smaller strain magnitudes than the ACL in all conditions apart from isolated abduction perturbation.

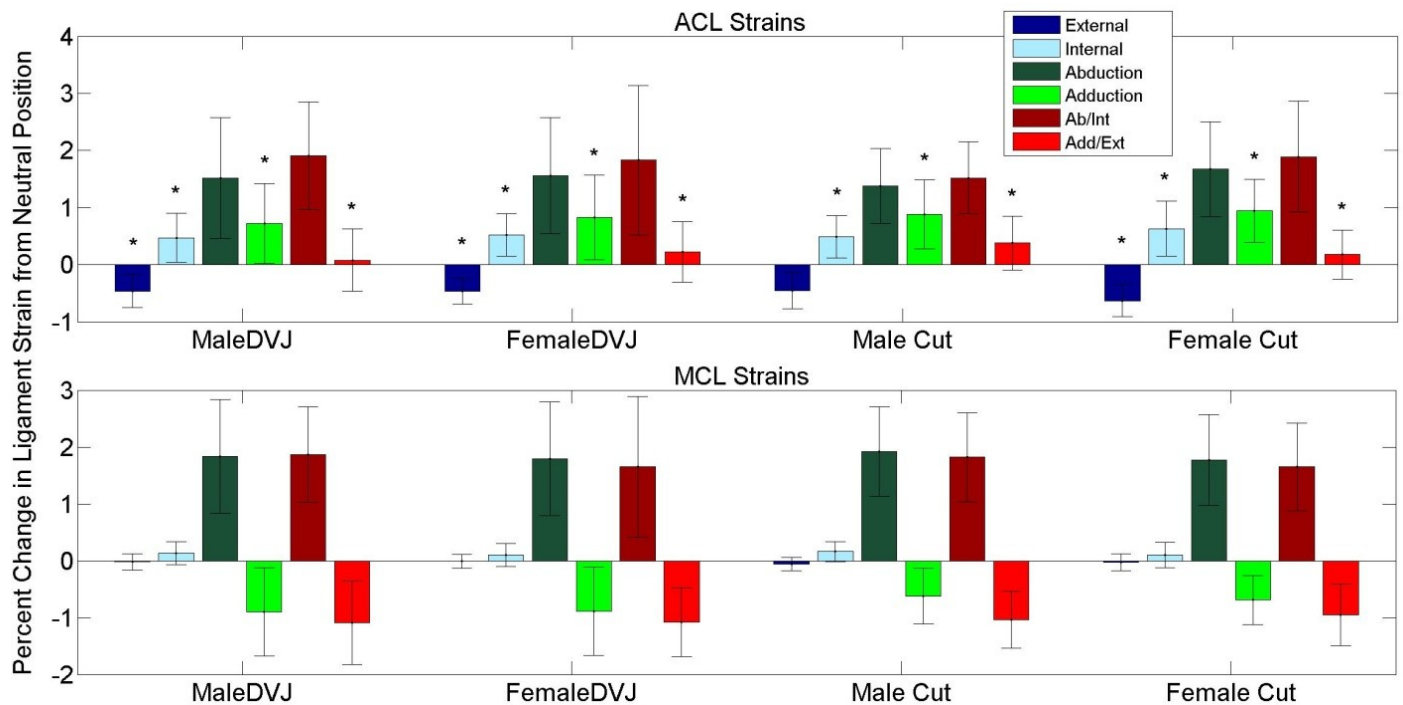
The ACL was most susceptible to combined abduction/internal perturbations as their magnitude


Figure 1: Displays the mean change (relative to the neutral position) in ACL (top) and MCL (bottom) ligament strain generated in the intact knee by each rotational stimuli. For the ACL, the mean strain changes were -0.5% external, 0.5% internal, 1.5% abduction, 0.8% adduction, 1.8% combined abduction/internal, and 0.2% combined adduction/external. For the MCL, the mean strain changes were -0.0% external, 0.1% internal, 1.8% abduction, -0.8% adduction, 1.8% combined abduction/internal, and -1.0% combined adduction/external. * indicated significant differences between ligaments.

of effected strain change was respectively 239% and 116% larger than isolated internal or abduction perturbations. This trend is supported by previous literature.[2] Transverse plane stimuli produced a linear range of strain change in the ACL, but this was not true of frontal plane rotations as both abduction and adduction perturbations increased ACL strain. Therefore, any frontal plane deviation from a neutral path throughout motion is likely to increase load on the ACL.

The present study corroborated that the MCL serves as the primary resistor to pure knee abduction rotation as this was the only perturbation that produced significant strain differences in the MCL. The generally reduced response of MCL strain to rotational stimuli may help explain why MCL failure is only observed in 20-40% of ACL failures despite a shared abduction loading mechanism.[4]

CONCLUSIONS

Combined abduction and internal rotations had the greatest influence on ACL strain. Isolated abduction

produced larger magnitudes of change than isolated internal rotation, though the differences were not statistically significant. Therefore, reduction of knee valgus through a neutral knee alignment during athletic tasks should be a focus of ACL injury prevention programs. Also, knee abduction had the greatest influence on MCL strain; however, the MCL generally expressed less absolute strain than the ACL, which may be indicative of how and why ACL failure often occurs without MCL injury.

1/f characteristics of step width during treadmill walking

INTRODUCTION

During treadmill walking, step width variability is a "robust indicator of step-to-step balance" [1]. This is underscored by the significant relationship (R^2=0.54) between step width and mediolateral kinematics of the trunk, a segment representing more than 50% of body mass [2]. Step width variability, generally calculated as a standard deviation, ignores the possibility of important information related to gait dynamics that may be imbedded in the step-to-step variations. Such variations in step time have been characterized by a shift from long-range correlations reflective of "healthy performance variability", i.e., pink noise, toward less complex, uncorrelated white noise. These shifts have been widely reported and linked to aging and fall-risk [3]. We have observed decreased fractal-like, 1/f properties of step width during treadmill walking associated with both age and with simultaneous performance of a cognitively demanding task (unpublished).

The gait of lower extremity amputees, who have a higher risk of falls than non-amputees, is generally characterized by larger step width [4,5] and larger step width variability [5] than that of non-amputees. In the present work we conducted a secondary analysis to establish if the fractal-like 1/f properties of step width during treadmill walking by transtibial amputees varies from that of non-amputee control subjects.

METHODS

Fourteen male military service members with traumatic unilateral transtibial amputations (TTA) and a control group of 12 male non-amputee military service members, walked for 10 minutes in a Computer-Assisted Rehabilitation Environment (CAREN; Motek Medical BV, Amsterdam, the Netherlands). CAREN is a fully immersive virtual environment that includes a 6 DOF motion platform and dual-belt instrumented treadmill. A visual input, synchronized to the subject's treadmill walking velocity (Froude number = 0.2) was projected onto a 180 degree visual surround (Figure 1)

Figure 1: Subject walking in the CAREN at the Naval Health Research Center in San Diego [6].

The step width time series for the 10 minute walking trial was calculated from the trajectories of and markers located on the heels collected using a 14 camera motion capture system operating at 120 Hz (Motion Analysis Corp, Santa Rosa, CA USA).

Three dependent variables were extracted from the step width time series, the average step width and its standard deviation (step width variability), and a variable, β, representative of the randomness of the time series (Fig.1). β was computed by first converting the step width time-amplitude series to a frequency-amplitude power spectrum, which was then log transformed. The resulting data were fit using linear regression. The regression coefficient

from the regression, β, was used as an index of the extent of signal randomness where as β approaches zero the signal approaches the characteristics of white noise. In contrast, as β approaches 1.0, the signal approaches the characteristics of pink noise, reflective of activity of multiple interacting control systems acting over different temporal and/or spatial scales [7].
Figure 1: (Top panel) Time series of step width (n=1124) of a non-amputee subject. (Middle panel) Power spectrum of step width time series. (Bottom panel) Log-transform of power spectrum data with the linear regression line, the slope of which, β, is interpreted to reflect the presence of randomness in the original time series.

The presence of between-group differences for the dependent variables were examined using three independent t-tests. Pearson correlation coefficients were computed to characterize the co-dependency of the dependent variables.

RESULTS AND DISCUSSION

Contrary to expectations, the step width of the TKA subjects (135±36 cm) was not significantly different than that of the control subjects (147±31 cm). However, the step width variability of the TKA subjects was significantly larger (34±7 cm) than that of the control subjects (28±7 cm).

β revealed an unexpectedly large presence of randomness for both the TKA and control group subjects, the between-group difference (TKA subjects:-0.52±0.14; control subjects: -0.51±.0.16) of which was not significant. This was not expected because, in our preliminary work, β ranged between -0.85 and 1.0 for young subjects during conditions that included normal treadmill walking, narrow base of support treadmill walking and treadmill walking while performing an attention-demanding task.

The largest contributor to this outcome may be the between-site differences in the testing environment, which includes the design and dimensions of the treadmill. The width of the CAREN treadmill is almost 2X than that of the previously used treadmill. Although the larger presence of randomness may reflect more entrainment of gait dynamics on the CAREN treadmill, it is not clear why, or even if, treadmill dimensions would modify this effect in a frontal plane gait variable.

Ultimately, the potential clinical utility of this measure will be defined by the extent to which it is affected by the variations specific to environment in which the primary data are collected as well as the relationship between β collected in these environments and that which occurs during community-based ambulation.

GAIT SPEED IS INFLUENCED BY SECONDARY TASKS IN PERSONS WITH UNILATERAL TRANSTIBIAL AMPUTATION

INTRODUCTION

Cognitive and motor functions are not independent processes. For example, the attentional demands of dual-tasking can influence the control and quality of gait [1, 2]. Among healthy individuals, common effects of dual-tasking on gait include reduced walking speed and increased gait variability; such deviations in gait with secondary tasks are often more pronounced in populations with cognitive or motor impairments [2].

Learning to walk with a prosthetic device following lower limb amputation likely imposes distinct challenges on cognitive and motor functions; however, the effects of dual-tasking on gait in this population are not well understood. Our preliminary data suggest limited biomechanical adaptations to dual-tasking in persons with amputation, though we hypothesized factors associated with forcing a consistent gait (treadmill) speed throughout the tasks confounded the results. Therefore, the objective of this study was to investigate the effects of dual-tasking on gait speed in persons with unilateral transtibial amputation (TTA) and able-bodied controls using a self-paced treadmill application. We posited that allowing participants to modulate walking speed, rather than forcing to a set pace, would better capture influences of dual-tasking during gait, and that variations in gait speed would be larger among persons with vs. without TTA across tasks.

METHODS

Five persons with traumatic, unilateral TTA, and nine able-bodied controls, completed a repeated measures design in which each participant completed three 2-minute walking trials while performing secondary tasks ("easy" and "hard") – each involving distinct attentional demands – and a no task ("baseline") trial. For the easy task, a single object was displayed on a screen within direct line-of-sight with changing shapes and participants were asked to press a button whenever a square appeared. For the hard task, two objects were displayed simultaneously, with individually changing shapes and colors, and participants were asked to press a button when both objects were either the same shape or same color. The no task condition consisted of a constant blue target, requiring no active response.

A self-paced treadmill speed algorithm was used within the Computer Assisted Rehabilitation Environment (CAREN; Motek Medical BV, Netherlands), which controls belt speed by tracking anterior-posterior pelvic position, velocity, and acceleration [e.g., 3]. Following a 4-minute acclimation period, participants walked for 2 minutes in each condition (in a random order). Treadmill belt speed was collected (300 Hz) continuously throughout each trial, and used as a proxy for gait speed [4]. Mean and standard deviation of belt speed – and their ratio (coefficient of variation; CV) – were computed in 20s windows throughout each trial, to compare among tasks and between groups. All participants provided written informed consent, and all study procedures were approved by the local IRB.

RESULTS AND DISCUSSION

Decreases in walking speed, and increases in gait variability, are common gait changes with dual-tasking [1, 2]; however, the current results did not fully support this finding. While walking speed was initially slower in the hard condition among controls (Fig. 1), they generally approached, over time, a similar speed regardless of task. In contrast, persons with TTA tended to walk faster in the easy/hard conditions relative to no task (Fig. 1), and never

approached a similar speed over time. Overall, walking speed variability, as evidenced by the CV, was also larger among persons with TTA vs. controls (Fig. 1); in both groups, these tended to decrease with time and secondary task difficulty. Faster gait speeds with secondary tasks among persons with TTA suggest these individuals may differentially prioritize cognitive and motor functions. Additionally, the attentional demands of the secondary tasks appear to influence the variability in gait speed, whereby both groups (but especially those with TTA) walked with more variability in the no vs. easy/hard tasks.

Several other factors should be considered when interpreting the results. Changes in mean gait speed and its variability, over time, may be more related to treadmill habituation than dual-tasking [5]; although participants completed a 4-min acclimation period, additional habituation time may be required. The secondary tasks used here were also visually dependent; objects were displayed on a blank screen, and did not incorporate optical flow within the virtual environment [6]. Finally, the presence of a harness (though not weight supporting) can influence gait variability and confidence in walking ability [7], perhaps "encouraging" participants to walk faster than they otherwise would unrestrained (e.g., psychologically minimizing the consequence or fear of falls). Additional biomechanical analyses are needed to better understand how these

individuals modulate walking speed while dual-tasking, as well as to determine the specific influences of these additional factors.

Lower Prosthetic Stiffness Minimizes the Metabolic Cost of Running for Individuals with Bilateral Leg Amputations

[1]Owen N. Beck, [1]Paolo Taboga, and [1,2]Alena M. Grabowski

[1]University of Colorado, Boulder, CO, USA; [2]VA Eastern Colorado Healthcare System, Denver, CO, USA
email: owen.beck@colorado.edu

INTRODUCTION

Non-amputee runners increase leg stiffness (k_{leg}) and decrease contact time (t_c) to achieve faster running speeds [1, 2]. Kram and Taylor [3] suggest that longer t_c reduces the rate of muscular force production, thereby facilitating the recruitment of slower more economical muscle fibers which decreases the energetic cost of running. Thus, it is likely that a lower k_{leg} (and longer t_c) reduces the metabolic cost of running.

While running with passive-elastic running-specific prostheses (RSPs), bilateral transtibial amputees have a lower k_{leg} with faster running speeds [2]. Due to the singular stiffness of a given RSP, it is suggested that RSPs dominate k_{leg}, thus runners with bilateral leg amputations may be able to alter their metabolic cost of running by changing the stiffness of their RSPs. We hypothesize that using RSPs with lower stiffness will reduce the metabolic cost of transport (CoT) during running in runners with bilateral leg amputations. Also, we were curious how RSP model or height affect CoT, and due to insufficient evidence, we hypothesize that neither RSP model nor RSP height will influence CoT. To test our hypotheses we measured metabolic demand, ground reaction forces (GRFs), stride kinematics, and k_{leg} from runners with bilateral leg amputations using RSPs that varied by model, stiffness category, and height.

METHODS

Three male runners with bilateral transtibial amputations participated. We obtained informed written consent, and then a certified prosthetist fit each subject with three RSP models (RSP1, RSP2, RSP3) at the recommended and ±1 stiffness categories. The height of each RSP was set to match the tallest allowed standing height as determined by the International Paralympic Committee [4] and ±2 cm. If the shortest attainable height for a RSP model was taller than recommend, the shortest height was used for that subject/model; then we altered RSP height by +2 cm, and +4 cm.

On days following the fitting session, subjects performed 5 min running trials on a force-instrumented treadmill at either 2.5 m/s (n=2) or 3.0 m/s (n=1). Each trial was completed using a different RSP model, stiffness category, and height combination. First, subjects ran using the recommended height while RSP model and/or stiffness categories were changed. Then, RSP height was altered ±2 cm (or +2 cm, +4 cm) at the optimal stiffness category; the stiffness category that elicited the lowest CoT. All trials were randomized.

We used indirect calorimetry to determine net metabolic power from the average metabolic rates during the final 2 min of each trial [5]. We converted average net metabolic power to work and divided by the product of mass and running speed, yielding CoT in J/kg/m.

We measured GRFs from 10 consecutive strides during the last 2 min of each trial. We combined the average GRFs from both legs, sampled at 1000 Hz, and processed them using a custom MATLAB script. We calculated k_{leg} according to [6]. A statistical linear mixed model was used to determine the associations of RSP model, stiffness category, and height on CoT. We also compared the effect of RSP stiffness category on peak k_{leg}, peak vertical GRF (vGRF), and peak displacement of the leg-spring (ΔL).

RESULTS AND DISCUSSION

For every one reduction in RSP stiffness category, CoT decreased by 5.1% (p<0.01) (Fig. 1).

Moreover, with our limited number of subjects (n=3), we were unable to detect significant effects from either RSP model (p=0.14) or height (p=0.59) on CoT. Based on our current sample size, our data support our hypotheses that RSP stiffness, but not model or height, influence CoT.
Figure 1. Mean (±SEM) net metabolic cost of transport (CoT) as a function of RSP stiffness category (C) for three RSP models. Dashed line is the regression line (CoT = 3.90 + 0.20 × ΔRec C).

k_{leg} increased linearly with RSP stiffness (p<0.01) (Fig. 2). Across all conditions, k_{leg} increased by 6% with a one category increase in RSP stiffness. Interestingly, peak vGRF was independent of changes in RSP stiffness category (p=0.60). Therefore, the decrease in k_{leg} was primarily due to a 7.5% increase in ΔL with each RSP stiffness category (p<0.01). Additionally, t_c increased with decreases in RSP stiffness (and k_{leg}) (p<0.01).

Therefore our data support the idea that RSP stiffness dominates k_{leg}. Because peak vGRF was invariant across RSP stiffness categories, softer RSPs (lower stiffness categories) resulted in greater leg-spring compression. The more compliant k_{leg} elicited by our subjects increased the elastic energy storage (and return) of their leg-spring.

$$EE = \frac{1}{2}k(x)^2$$

Elastic energy storage (EE) is equal to half the spring stiffness (k) multiplied by the displacement of the spring (x) squared. This increased elastic energy storage and return of the leg, coupled with

longer t_c, contribute to the decreased CoT elicited by softer RSPs.

CONCLUSIONS

Runners with bilateral transtibial amputations had lower CoT, k_{leg}, and t_c when using RSPs with lower stiffness categories. However, neither RSP model nor height significantly affected CoT.
Figure 2. Mean (±SEM) leg stiffness (k_{leg}) as a function of RSP stiffness category (C). Dashed line is the regression line (k_{leg} = 15.32 + 0.92 × ΔRec C).

INTRODUCTION

Compared to non-amputees, amputees experience increased difficulty with maneuvering tasks such as turning, which are common in daily living activities [1, 2]. While changes in sagittal-plane prosthetic foot stiffness have been shown to influence amputee walking mechanics and can be tuned to provide desired levels of body support and forward propulsion [e.g., 3], the influence of prosthetic foot stiffness on amputee turning is unknown. Turning requires the generation of appropriate mediolateral ground reaction forces (GRFs) and ankle kinematics [1, 4], which are both influenced by prosthetic foot stiffness. The purpose of this study was to assess the influence of prosthetic foot stiffness on amputee turning mechanics, which has important implications for the design and prescription of prosthetic devices.

METHODS

Three prosthetic ankles (compliant, nominal and stiff) were manufactured using an additive manufacturing process (Vanguard HiQ/HS Sinterstation, 3D Systems Corp.). The ankles were combined in series with a low-profile version of a commonly-prescribed carbon fiber prosthetic foot (Category 9, LP Vari-Flex® with EVO[TM], Össur) to create a set of ankle-foot combinations that spanned a range of stiffness values.

Unilateral transtibial amputees (n=7) free of musculoskeletal disorders and pain completed an IRB-approved protocol of turning maneuvers with each of the three ankle-foot combinations. Subjects walked overground at their self-selected speed clockwise and counterclockwise around a 1-meter radius circle with six embedded force plates (Advanced Mechanical Technology, Inc.; Kistler Instrument Corp.). Repeated trials were collected for each ankle-foot combination to obtain at least five force plate strikes per foot.

GRF and kinematic data were collected at 1200 Hz and 120 Hz, respectively, using a 12-camera motion capture system (Vicon Nexus, Vicon Motion Systems). In addition to the Plug-In Gait marker set, reflective markers were placed bilaterally on the greater trochanter and fifth metatarsal heads and four-marker clusters were placed bilaterally on the thigh and shank. Residual limb markers were placed symmetrically with intact limb markers. Hip functional joint centers were found using trials with at least five hip circumduction movements while knee functional joint axes were found using trials with at least five knee flexion-extension movements (Visual 3D, C-Motion, Inc.).

GRF and marker data were filtered using a 4th-order, low-pass Butterworth filter with cutoff frequencies of 20 and 6 Hz, respectively. Joint angles and powers were calculated using Visual 3D. Peak joint angles were averaged across trials. Positive and negative joint work were calculated as the time-integral of the positive and negative joint power, respectively, then averaged across trials. Joint work was examined in each of the six phases of the gait cycle.

RESULTS AND DISCUSSION

As in previous studies [e.g., 3], decreasing stiffness increased ankle dorsiflexion and knee flexion as well as decreased hip extension (Table 1). In addition, when the residual limb was inside the turn, prosthetic ankle energy storage and return increased with decreasing stiffness (Fig. 1). In the coronal plane, decreased ankle stiffness caused a decrease in hip adduction and, when the limb was inside the

turn, an increase in hip abduction (Table 1). Compared to the compliant and stiff combinations, the nominal ankle-foot caused greater ankle eversion when the limb was inside the turn and less ankle inversion when the limb was outside the turn (Table 1). Late stance ankle coronal-plane positive and negative work were also greater when the limb was inside the turn and lower when the limb was outside the turn for the nominal ankle-foot (Fig. 1).
Figure 1: Coronal and sagittal plane positive and negative work at the residual limb ankle and hip when the limb was inside (In) and outside (Out) of the turn with the compliant, nominal and stiff ankle-foot combinations during late stance.

Since the prosthetic foot acts like an elastic spring, deforming the ankle more in the coronal plane allowed it to store greater energy during the second

half of stance and subsequently return more coronal-plane energy at push-off (Fig. 1). A decrease in ankle stiffness caused a decrease in late-stance negative coronal-plane hip work when the limb was outside the turn and an increase in late-stance positive coronal-plane hip work when the limb was inside the turn (Fig. 1). The increased positive hip work may be a response to decreased ankle stiffness and necessary to rotate the pelvis and complete the turning task.

CONCLUSIONS

Changes in stiffness influenced sagittal-plane kinematics during turning, which were similar to those previously observed during straight-line walking [e.g., 3]. Stiffness changes also caused coronal-plane adaptations at the ankle and hip. Thus, when tuning stiffness to balance body support and forward propulsion, the effects on turning mechanics should also be considered.

WHEN SHOULD WE BIOMECHANICALLY EXAMINE A LOWER-LIMB AMPUTEE? A SYSTEMATIC REVIEW OF ACCOMMODATION TIMES

Andrea B. Wanamaker and Ajit M.W. Chaudhari

The Ohio State University, Columbus, OH, USA
email: Wanamaker.178@osu.edu

INTRODUCTION

Over two million Americans are currently living with limb loss, with 185,000 new amputations occurring annually. Of these, approximately 65% involve loss of a lower-extremity. Fifty-four percent of amputations are due to diabetic complications and 45% are due to trauma [1].

Technological advances, particularly over the past 30 years, have completely transformed the care of musculoskeletal disorders, including more advanced prosthetic devices that use a combination of sensing, actuation, and microprocessors to enhance function on even surfaces, hills and stairs, and in other high-demand applications. However, our understanding of how and when patients adapt to a new conventional or advanced prosthesis is unclear. Only one study to our knowledge specifically examined stabilization of data over time but the study was limited to one male above-knee amputee over only three weeks [2]. Other previous studies on above-knee amputees appear to have a wide range of testing timepoints, ranging from testing immediately after receiving a new prosthesis to testing after two years, making it unclear when testing should be performed to ensure accurate and relevant results.

The goal of this systematic review was to identify evidence-based consensus of when biomechanical analysis on amputees should occur after a patient receives a new prosthetic limb.

METHODS

A systematic literature search was conducted in January 2015 using PUBMED (1964-January 2015) and Scopus (1948-January 2015). The databases were searched using generic terms related to lower-limb amputation and prosthetic devices. The following lines were used: (lower limb OR lower-limb OR leg OR thigh OR shank) AND (amput* OR transtibial OR transfemoral) AND (prosth* OR (C-Leg) OR (Intelligent Prosth*) OR (BiOM)).

As the goal of this systematic review was to gather any articles related to an investigation of a prosthesis the inclusion and exclusion criteria were kept simple. The search was limited to peer-reviewed journal articles, human subjects, and the English language. Titles, abstracts, and full texts were then screened as necessary to further exclude articles: conference proceedings; theses; dissertations; reviews; case reports; studies examining bilateral amputees or subjects under the age of 18; studies examining new prosthetic components, such as prosthetic sockets and pylons, or alignment changes; and studies that did not include biomechanical analyses were all excluded from the review.

Once the search was complete, relevant data were pulled from each article. We were most interested in the amputee participant populations and if an accommodation time was given. Data extracted included sex, height, weight, age, type of amputation and cause, time since amputation, experience with a prosthetic, prosthetic device worn prior to testing, prosthetic device(s) tested, and time given to accommodate prior to testing a new prosthetic limb.

RESULTS AND DISCUSSION

A total of 7901 unique hits were found between PUBMED and Scopus. After reviewing titles and abstracts, a total of 283 articles remained. Of these, 116 matched our criteria and were included in this review. For completeness, the references of these articles were examined which resulted in an additional 28 articles for a final total of 144 articles.

A total of 2026 amputees were investigated from all 144 studies. Of these, 1113 (55%) had amputations due to trauma, 286 (14%) were due to vascular causes, 172 (8%) were due to cancer or tumor, 150 (7.4%) due to other causes, and 305 (15%) were not specified.

Of the 144 articles, there were a total of four investigations involving hip or pelvis amputation, 65 involving an above-knee amputation or knee disarticulation, and 85 involving a below-knee amputation. The median number of days given for accommodation for all investigations was 8.5 days with in interquartile range (IQR) of 30 days (Figure 1,2).
Figure 1: Number of accommodation days for the 144 investigations. Range 0-154 days.
Figure 2: For hip, above-knee, below-knee, and total population the IQR for accommodation was 57.8, 83, 21, and 30 days, respectively. Median reported in IQR range.

While many investigations clearly stated how much time was given for accommodation, many did not. A total of 53 investigations tested the day of receiving a new limb or did not specifically mention

an accommodation time (Figure 3). Phrases such as "given as long as necessary", "intensive practice phase", and "break in period" were frequently used. These investigations were placed into the not reported (NR) category and it was assumed testing was done the day of receiving a new prosthetic limb.
Figure 3: Detailed results for testing on the day of receiving a new limb. Not reported (NR).

From these results, we can see that there is no clear consensus on when a biomechanical investigation should be performed on an amputee subject. Testing time points range from within minutes or hours of receiving a new limb to 5+ months after fitting.

CONCLUSIONS

Our systematic literature search resulted in 144 unique biomechanical investigations involving the amputee population. The median number of days to accommodate to a new prosthetic limb was 8.5 days with an IQR of 30 days. Above-knee and hip amputees were given more time to accommodate than below-knee amputees.

SARCOMERE LENGTH ORGANIZATION AS A DESIGN FOR COOPERATIVE FUNCTION AMONGST ALL LUMBAR SPINE MUSCLES

Derek P. Zwambag, T. Alexander Ricketts, and Stephen H.M. Brown
Human Health and Nutritional Sciences, University of Guelph, Guelph, ON, Canada
email: shmbrown@uoguelph.ca

INTRODUCTION

The functional design of spine muscles in part dictates their role in moving, loading, and stabilizing the lumbar spine. There have been numerous studies that have examined the isolated properties of these individual muscles, and some have highlighted an interesting characteristic of the multifidus muscle; it has short sarcomeres in the neutral spine posture and reaches optimal length for force production when the spine is flexed [1]. Contrarily, longer than optimal sarcomere lengths have been measured from psoas major when the spine is in a neutral position and the hip is mildly flexed [2]. Understanding of how all the lumbar muscles interact and work together is lacking. The objective of this study was to measure sarcomere lengths of all lumbar muscles in a neutral cadaveric position and predict the operating ranges of these muscles throughout full ranges of spine movements.

METHODS

Small muscle samples (0.5 cm^2) were removed from iliocostalis, longissimus, multifidus, quadratus lumborum, intertransversarii, psoas major, and psoas minor of seven cadaveric donors embalmed in an approximate neutral spine position. Single fascicles were excised from each sample and sarcomere lengths were measured using laser diffraction. Muscle length changes through full lumbar range of motion (flexion, extension, lateral bend and axial twist) were predicted using an anatomically detailed computational model of the spine [3]. Sarcomere length operating ranges were predicted from the changes in muscle fibre length to determine force-length characteristics of each muscle in a neutral position and at end ranges of motion (Fig 1).

RESULTS AND DISCUSSION

Each of the lumbar extensors (multifidus, longissimus, and iliocostalis) was measured to have short sarcomere lengths (2.36 ± 0.05, 2.43 ± 0.05, and 2.41 ± 0.06 μm, respectively) in the neutral cadaveric spines (Fig 2A). The intermediate and anterior muscles had longer sarcomeres than the posterior extensors with quadratus lumborum close to optimal (2.66 ± 0.09 μm), intertransversarii slightly below optimal (2.53 ± 0.05 μm), and psoas major and minor longer than optimal (3.41 ± 0.07, 3.17 ± 0.12 μm, respectively).
Figure 1: Sarcomere length operating range of lumbar spine muscles. Thick lines are from a neutral posture to full flexion and thin lines are from neutral to full extension. Muscles are offset from force length curve for clarity.
Figure 2: (A) Sarcomere lengths (µm) measured from lumbar spine muscles in a neutral cadaveric position and (B) modelled sarcomere lengths at full spine flexion. Blue, white, and red corresponds to sarcomeres on the ascending limb, plateau, and descending limb of the sarcomere force length curve, respectively. M, multifidus; L, longissimus; I, iliocostalis; QL, quadratus lumborum; IT, intertransversarii; and P, psoas major.

During modelled flexion the extensor and intermediate muscles lengthened so that all muscles operated in the approximate same location on the descending limb (range 3.11-3.48 µm; Table 1) of the force-length relationship (Fig 2B). Flexion caused multifidus fibres to lengthen by 50.0%, while iliocostalis and longissimus fibres

lengthened by 38.1%. Quadratus lumborum and intertransversarii were less affected by spine flexion lengthening 29.2% and 23.3%, respectively. The anterior muscles were largely unaffected by spine flexion.

During lateral bend, quadratus lumborum had the largest operating range due its location furthest from the axis of rotation. Axial twist had minimal effect on sarcomere lengths of all lumbar muscles.

CONCLUSIONS

The sarcomere lengths of multifidus and psoas major in a neutral spine posture were consistent with those in the literature [1,2]. However, multifidus is not unique in comparison to sarcomere lengths of the other low back muscles. In a neutral position, there appears to be a pattern for muscles anterior to the spine to have long sarcomere lengths and those posterior to have short sarcomeres. Spine posture significantly altered the maximum isometric active force generating capability of lumbar muscles. The extensor muscles are all designed to produce maximum force in a mid-flexed posture, and all lumbar muscles operate at similar locations of the force-length relationship at full spine flexion. The intrinsic design of sarcomere organization appears to provide an inherent mechanism for balancing force production throughout spine motion.

FUNCTIONAL IMPORTANCE OF FASCIA IN THE PRESERVATION OF MUSCLE TENSION

Roy J. Ruttiman, David Sleboda, Thomas J. Roberts

Brown University, Providence, RI, USA
roy_ruttiman@brown.edu, http://brown.edu/research/labs/robertslab/

INTRODUCTION

Fibrous extra-muscular connective tissue, also known as fascia, delineates and encloses functional muscle groups, thus forming discrete fascial compartments. These fascial compartments have clinical significance, as increased pressure within a compartment can compromise the blood supply and function of the tissues enclosed. However, it is unclear how fascial compartments influence normal muscle performance. We explored the relationship between fascial compartments and muscle tension in the ventral interosseous of the wild turkey (*Meleagris gallopavo*), a bipennate distal wing muscle bordered by bone and enclosed within a fascial compartment.

METHODS

Birds were anesthetized with inhaled isoflurane. The *Ramus superficialis*, a distal branch of the ulnar nerve, was isolated immediately distal to the carpometacarpal junction and connected to a bipolar stimulating electrode. The wing was fixed to a rigid custom-made aluminum frame, and the distal tendon of the muscle was isolated and attached to the lever of a servomotor via Kevlar thread (Figure 1).

Muscles were stimulated supramaximally under isometric conditions. Each muscle was subjected to approximately 5-7 contractions at different muscle lengths. The muscle was allowed a minimum of 5 minutes between contractions to prevent fatigue. After length-tension (LT) relationship of the muscle was established, a repeat isometric contraction was performed at optimum length (L_o) to assess muscle fatigue.

Fascial release treatment was achieved via skin incision on the ventrum of the distal wing; followed by careful surgical removal of the ventral fascia overlaying the ventral interosseous. The muscle was once again subjected to approximately 5-7 contractions at different muscle lengths, constructing a post-fascial release LT relationship. Repeat isometric contraction assessed muscle fatigue.
Figure 1: *In situ* preparation. Distal tendon of ventral interosseous attached to the servomotor lever via Kevlar thread. The distal tendon was maneuvered until a direct line of pull between the muscle and the servomotor was established.

RESULTS AND DISCUSSION

In trials performed on the plateau region of the LT curve, peak isometric force decreased by 22.3% following fascial release (Figure 2). Aside from peak magnitude, there was no noticeable difference in the contraction waveform between the intact compartment condition and the post-fascial release condition. Within each segment of the ventral interosseous's length tension curve, fascial release was associated with a reduction in isometric force production.
Figure 2: Pre and post-fascial release contraction patterns from the plateau region of the muscle in the same individual. Muscle was stimulated for a 400ms train duration.

In five individuals, fascial release resulted in an average decrease in muscle force output of approximately 19% along the ascending, plateau and descending regions of the length-tension curve. The force deficit associated with fascial release increased as muscle length increased, ranging from 13% along the ascending limb to 24% on the descending limb.
Figure 3: The effect of fascial release on maximal force generation along the length-tension curve of ventral interosseous muscle. Normalized isometric contractions from five experiments demonstrate

ventral interosseous muscle force generating capacity within an intact fascial compartment (red) and after fascial release (blue). Each marker represents an individual experiment.

CONCLUSIONS

Gross partitioning of synergistic muscles into fascial compartments is a widespread feature of mammalian limb anatomy. Yet few studies have explored the functional importance of having such a muscle and connective tissue arrangement. In this study, we accounted for muscle length and supramaximally simulated the ventral interosseous to achieve maximal force production along different muscle lengths both before and after fascial release treatment. Fascial release repeatedly and reliably reduced peak force production in the ventral interosseous muscle. These results, along with previous work on dog hindlimb muscles [1], suggest that releasing fascial constraints reduces muscle force output; and by extension suggests that fascia may play a critical role in preservation of muscle tension.

A mechanistic explanation for the observed reduction in muscle tension after fascial release remains elusive. Our findings question whether fascial release treatment is an entirely benign procedure, particularly in cases of chronic exertional compartment syndrome [2].

MULTISCALE MUSCLE MODELS PREDICT
HOW ACCUMULATED MICROTEARS LEAD TO ACUTE MUSCLE INJURY

[1] Kelley M. Virgilio, [1]Kyle M. Martin, [1]Shayn M. Peirce, and [1] Silvia S. Blemker

[1] The University of Virginia, Charlottesville, VA, USA
Email: kam8kc@virginia.edu

INTRODUCTION

Eccentric contractions have been linked to muscle injuries [1]; however, the mechanisms leading to acute strain injury are poorly understood. At the macro-level, a gait analysis study which captured an acute sprinting-related muscle strain injury indicated that the injury was not caused by a dramatic change in gait or misstep, suggesting that accumulated damage (microtears) may escalate to a major injury [1]. At the tissue level, previous work has demonstrated that the inherent architecture of the muscle influences its injury susceptibility by generating regions of high-localized strains [2]. At the fiber level, studies have shown a loss of force-transmitting proteins (dystrophin) immediately after eccentric contractions [3], which would compromise the mechanical integrity of the fibers since dystrophin is known to protect the muscle membrane from damage [4]. Together, these important factors all influence the resulting extent of muscle injury; however, since they cross multiple scale lengths, it is challenging to integrate them into one holistic understanding. The goal of this study was to address this critical gap in the field by creating multiscale models of skeletal muscle that represent the macro-scale loading, the tissue-level strains, and the micro-level damage during sprinting. Once developed, we used the models to explore the mechanisms underlying accumulated muscle damage and resulting injury.

METHODS

The modeling framework included seven key steps. Step 1 was to use a finite element (FE) model of the biceps femoris long head (BFLH) to determine the along fiber shear strain distribution throughout the muscle [2]. Step 2 was to utilize an agent-based model (ABM) to create a cross-section of a muscle fascicle for the micromechanical FE model, with fibers, ECM, and nonlinear elastic springs to represent dystrophin. The ABM allowed for the rapid generation of muscle cross-sections that account for physiological variability [5]. Step 3 was to apply boundary conditions based on the shear strains in two regions (high and low strain) of the macroscale BFLH model (Fig 1). Step 4 was to simulate contraction by applying the representative shear displacements to the micromechanical model. Step 5 was to calculate the strain between the muscle fiber and the ECM (membrane strain). Step 6 was to update the model so that proteins with a membrane strain greater than the prescribed threshold, based on the estimated extensibility of dystrophin [6], were deleted. Step 7 was to create a new "damaged" micromechanical model with the remaining proteins. Step 4-7 were repeated until no additional damage was generated in the membrane.
Figure 1: A BFLH model indicates non-uniform along fiber shear strain during sprinting. Two micromechanical models of muscle fascicles were developed with boundary conditions to simulate the local mechanics at high and low strain regions

RESULTS AND DISCUSSION

The whole-muscle model of the BFLH illustrated how local peak strains during eccentric contractions could lead to damage in specific regions of the muscle (Fig 1). At a smaller scale, the micromechanical model demonstrated this same phenomenon of non-uniform shear strain profiles within the fibers, based on the geometry and material properties of the ECM and the fiber. We found that micro-damage at the force-transmitting proteins (dystrophin) escalated from a single small tear (after a single eccentric contraction), into a substantial tear in the muscle membrane (after multiple contractions), which could ultimately result in an acute injury (Fig 2). In comparison, the region of the muscle with low local strains did not exhibit this same behavior and did not lead to acute muscle injury, consistent with the observation that injuries only occur in certain regions of a muscle.

This modeling framework illustrated a potential mechanism for the initial mechanical injury that could lead to an acute muscle injury, and suggested a number of important avenues for future exploration. First, we found that the prescribed thresholds for the damage to the dystrophin proteins and the onset of an acute muscle injury are important determinants of the outcome, and thus need to be better characterized from experimental studies of membrane damage and dystrophin structure. Additionally, although the micro-scale model was informed by deformation patterns from the whole muscle, our future work aims to expand the simulations to include multiple deformation patterns, and verification with animal models of eccentric contraction injury.

CONCLUSIONS

This study proposed a novel multi-scale modeling framework to describe how high localized strains in the muscle during eccentric contraction could introduce small microtears that rapidly develop into an acute muscle injury.

EFFECTS OF STRENGTH TRAINING ON MUSCLE FORCE PRODUCTION AND MUSCLE FUNCTION IN CHILDREN WITH CEREBRAL PALSY

Amy K. Hegarty[1], Max J. Kurz[2], Wayne Stuberg[2] and Anne K. Silverman[1]

[1]Department of Mechanical Engineering, Colorado School of Mines, Golden, CO, USA
[2]Physical Therapy Dept., Munroe-Meyer Institute, University of Nebraska Medical Center, Omaha, NE, USA
email: ahegarty@mymail.mines.edu, web: http://fbl.mines.edu

INTRODUCTION

Cerebral palsy (CP) is a neurological disorder caused by an insult to the brain, which often leads to neuromuscular impairments. Strength training for children with CP increases isometric muscle strength and walking speed [1, 2], as well as affects muscle force and lower limb extension capacity during walking [3]; however, changes in muscle contributions to body center of mass (COM) accelerations after training have not been evaluated. The purpose of this study was to expand on previous work by evaluating changes in dynamic muscle force production and function in a group of children who participated in strength training.

METHODS

Four children with spastic CP participated in a six-week strength training protocol. Lower body kinematics and ground reaction forces were collected at 120 Hz during overground walking. Isometric muscle strength was measured with a handheld dynamometer for lower-limb joints before and after training. A generic musculoskeletal model with 14 segments, 21 degrees of freedom, and 92 Hill-type musculotendon actuators was scaled for each child. Three walking trials for each child before and after strength training were simulated in OpenSim 3.2 (www.simtk.org). A computed muscle control algorithm was used to estimate muscle excitations required to reproduce the experimentally measured kinematics. The contributions to body COM acceleration were analyzed using an induced acceleration analysis. Changes in mean dynamic muscle force production and contributions to COM acceleration before and after strength training were quantified over three stance phases of the gait cycle (GC) including: Double Support 1 (DS1, ~0-10% GC), Single Limb Stance (SS, ~10-50% GC), and Double Support 2 (DS2, ~50-60% GC). A two-way repeated-measures ANOVA was used to assess differences (α=0.05) in muscle forces, joint isometric strength, and muscle contributions to COM acceleration between legs, and as a result of training.

RESULTS and DISCUSSION

Few significant training main effects were found (Fig. 1). Several significant leg main effects indicated bilateral asymmetry not affected by training. Significant leg × training effects indicated different left and right leg muscle responses to training. Soleus (SOL) contributions to the body COM vertical acceleration (support) were significantly increased after training in DS2. Also in DS2, significantly increased unilateral dynamic force in the gastrocnemius (GAS) was found.
Figure 1: Mean dynamic muscle forces during DS2 (top) and average isometric joint strength (bottom). Left leg (light gray) and right leg (dark gray) were compared before (left bar) and after (right bar) training. Significant ANOVA leg ([a]), training (°), and leg × training interaction (*) effects are shown.

However, muscles that had significant increases in dynamic force production after training did not correspond with muscle groups that had significantly greater isometric strength. Isometric strength of the hip extensors and hip flexors significantly increased after training (Fig. 1), but this was not found in the walking simulation results. Bilateral asymmetry in isometric knee extensor strength, not affected by training, was not found in the dynamic knee extensor muscle force estimates during walking.

Increased dynamic force production in the GAS and increased SOL contributions to body support in DS2 suggest a shift toward able-bodied mechanics after training [4-6]. However, high variability was found across children in muscle contributions to the COM acceleration. Thus, evaluating muscle results on an individual child basis may be a better approach for evaluating the effects of strength training on muscle function. For example, one child in the study had substantial changes in muscle contributions to support in the gluteus medius, vasti and soleus, all shifting towards able-bodied muscle function (Fig. 2) [6,7]. However, these results were not consistent for all children, and were not apparent in the group average results.

Increases in isometric strength measurements did not correspond to increases in dynamic muscle force production during walking. These results suggest that increases in static strength do not always translate to how a muscle is used dynamically during a movement. Similar changes in dynamic and static joint ranges of motion were found after strength training [8]. This may help explain why highly variable mobility improvements are associated with strength training [2]. In addition, these results

highlight how modeling and simulation analyses can assess dynamic muscle behavior during movement tasks that are not reflected in joint-level static testing.

CONCLUSIONS

These results suggest that strength training results in increased dynamic force and improved function in the ankle plantarflexors during gait. Strength training may also improve muscle function to provide body support and propulsion in other muscles groups, as in Child 1 (Fig. 2), although the responses of individual children are highly variable. Modeling and simulation analyses have the potential to guide therapy protocols that address muscle functional deficits on an individual child basis, and provide additional information regarding muscle mechanics not revealed by isometric strength testing.

EXTENSOR MUSCLE SEQUENCING DURING RETURN TO STAND IN A SUBGROUP OF INDIVIDUALS WITH LOW BACK PAIN: RESPONSE TO EXERCISE

Erika Nelson-Wong

Regis University School of Physical Therapy, Denver, CO, USA
email: enelsonw@regis.edu

INTRODUCTION

It has been recognized that LBP cannot be treated as a singular disorder and outcomes improve when individuals are subgrouped according to etiology and clinical presentation. Several sub-classification paradigms are used clinically, with Treatment Based Classification (TBC) being one of the more common approaches used by physical therapists. This approach categorizes individuals with LBP into 1 of 4 subgroups, Manipulation, Direction Specific Exercise, Traction, and Motor Control/Stabilization according to their clinical presentation [1], and is meant to direct appropriately matched interventions. Observation of aberrant motions during forward flexion in standing (FS) is one of the criteria for classification into the Motor Control/Stabilization (Stab) subgroup, with reversal of lumbopelvic rhythm being one of the aberrant motions described. Observation of lumbopelvic reversal during FS has poor inter- and intra-rater reliability [2], which makes its inclusion in the sub-classification algorithm questionable. However, there is evidence that sequencing of extensor muscle activity during FS differs between individuals with and without LBP. A 'bottom up' (gluteus maximus followed by erector spinae) muscle activation sequence is considered to be typical in healthy individuals during the return to stand (RTS) phase of FS. A reversal of this pattern during RTS has been observed in individuals predisposed to LBP during a prolonged standing protocol [3]. Extensor muscle activation sequencing during FS, and response to appropriately matched intervention, has not been investigated in individuals meeting TBC criteria for Stab. Therefore the purpose of this study was to investigate differences in extensor muscle sequencing during the RTS phase of FS between healthy controls and individuals with LBP classified into the Stab subgroup, and to determine response to a stabilization-based exercise intervention.

METHODS

Fourteen individuals with LBP (36% male, age 36.9 ± 13.8 years) meeting TBC criteria for Stab and 13 healthy control participants (36% male, age 30.6 ± 9.5 years) enrolled in this study. Following baseline data collection, participants completed a standard stabilization-based, progressive exercise program for 6 weeks, then returned for a post-intervention assessment. The protocol for baseline and post-intervention data collections was identical. Surface electromyography (EMG) data were collected from left lumbar erector spinae (ES) and gluteus maximus (GMx) muscles. Kinematic data were collected to construct a 4-segment (trunk, pelvis, bilateral thighs) model. Participants performed a single trial of self-paced FS. EMG data were filtered for noise removal, linear enveloped and normalized to reference contractions. Kinematic data were used to extract windows isolating the RTS phase of motion. Cross correlation analyses were used to quantify relative timing between the ES and GMx muscles, with phase lag at maximal spatial correlation extracted from a physiological window of +/- 250 msec [3]. Phase lags were dichotomized as Bottom Up (BU) where GMx activated first, or Top Down (TD) where ES activated first, strategies. Chi-square analyses were used to determine associations between LBP status and baseline strategy and changes in strategy following intervention for the LBP group with $\alpha = .05$.

RESULTS AND DISCUSSION

The individuals with LBP in this study reported relatively low disability with mean baseline pain (100 mm visual analog scale, VAS) of 12.1 mm (range: 0 - 52 mm) and Oswestry Disability Questionnaire (ODQ) scores of 15.1% (range: 2 - 42 %). Reversal of lumbopelvic rhythm (visual observation) was noted in 57% of the LBP sample

at baseline. There was a significant association between LBP status and extensor muscle sequencing strategy at baseline (χ^2=6.0, $p<.05$) with most control participants utilizing a typical BU strategy (76.9%) and most LBP cases demonstrating a TD strategy (71.4%) (Figure 1).
Figure 1: Individuals with LBP primarily used a top down strategy while healthy controls used a bottom up strategy.
Figure 2: There was a favorable change in muscle activation strategy for individuals with LBP following exercise intervention.

Of the 14 individuals with LBP, 10 completed the exercise intervention and post-intervention assessment (2 withdrew for medical reasons, 2 were completing the intervention at time of abstract submission). EMG data were not available for 1 participant due to technical issues. Therefore, pre-post intervention analysis includes data from 9 participants with LBP. Following exercise intervention there was a decrease in average pain on

VAS (4.9 mm, range: 0 – 15 mm) and disability on ODQ (9.9%, range: 2 – 24%). Observed reversal of lumbopelvic rhythm was noted in 11% of the sample. There was a significant change in extensor muscle sequencing strategy following exercise intervention (χ^2=5.6, $p<.05$) with 77.8% of LBP cases demonstrating a BU strategy (compared with 22.2% baseline) and 22.2% using TD strategy (versus 77.8% at baseline) (Figure 2). Of the LBP cases using TD strategy at baseline, 71.4% converted to a BU strategy following exercise intervention.

CONCLUSIONS

These findings showed clear differences in extensor muscle strategy during RTS phase of FS between healthy controls and individuals with LBP meeting the TBC criteria for Stab. Although reliability of observed lumbopelvic rhythm reversal has been questioned, individuals in the TBC Stab subgroup demonstrated altered movement strategies in FS. It is encouraging that these atypical strategies appear to be modifiable through a standard exercise program targeted towards the Stab subgroup. It should be noted that the intervention did not include any exercises involving standing flexion. It may be that improvements in trunk and hip strength and control gained through the intervention allowed participants to use a more typical BU strategy during the RTS phase of FS. These findings provide further support for stabilization based exercise intervention in patients with LBP meeting the TBC criteria for Motor Control/Stabilization sub-classification.

INTRODUCTION

Biomechanics provides an engaging vehicle for exploring fundamental questions at the interface of engineering, physiology, and health. Through guided-experiential learning, students can gain exposure, experience, and expertise as they begin to embed the use of fundamental principles in their self-discovery[1] of mechanisms governing movement. Since 1988, members of the USC Biomechanics Research Lab have been actively involved in a wide range of Science, Technology Engineering, Art, and Mathematics (STEAM) outreach activities. The focus of this paper is to share what we have found to be "Best Practices" for engaging young audiences and embedding the use of scientific processes and engineering design in the study of human biomechanics.

METHODS

Two outreach initiatives will be discussed: Body Engineering-Los Angeles (BELA) and Get SSET Academy (Sport Science, Engineering and Technology). BELA is a year-long program that partners doctoral students in engineering with teachers in urban middle schools. STEM standards are met by investigating the human body as a machine. Lessons are generated and led by both the teacher and doctoral student on a weekly basis throughout the year. This project has been funded in part by National Science Foundation Grant DGE 1045595) and the USC Viterbi School of Engineering.

The *Get SSET* (Sport Science, Engineering, and Technology) Academy is an informal educational experience aimed at first-generation college-bound 9-10 grade female students interested in sports and science. Our aim in this 3.5 day residency program is to provide students with an experience of college life and exposure to engineering, prior to making decisions regarding high school coursework.

Participants are recommended by both their science or mathematics teacher and their coach to confirm that the student-athlete has the desire to improve. Advancement in sport often involves hours of practice, failures, observation of performance related issues, and resolution of these issues through creative solutions and persistence. These same processes are key in becoming an effective engineer or scientist. While academy activities have varied, all have included a sport aerodynamics activity, a design methodology activity, a biomechanics motion capture and analysis activity, a visit to a local sport, science or other engineering facility, and final presentations from the students to the sponsors, faculty, staff and their families.

RESULTS AND DISCUSSION

"Best Practices" in both of these initiatives has involved an intriguing hook that engages and is relevant to the participants. This hook must be supported with fundamental science and engineering principles through interactive discussion and exploration of concepts. By balancing lecture (<7 minutes) with video and structured participation, students develop active interest. This allows the educators to transition into inquiry-based experiments or engineering design challenges. To facilitate implementation, low-cost readily available materials are typically used with open-source software. To measure learning outcomes, student presentations, electronic journals, and peer review sessions can be used.

INTRODUCTION

Interactive, immersive, and engaging science lessons can have lasting effects in students. For diverse student populations, optimal learning occurs via different modes (experiential, tactile, auditory, visual). Our lab conducts human neuromuscular EMG studies with expensive lab-based equipment not suitable for use in the outreach setting. We have leveraged our scientific expertise to create novel, effective community-based neuroscience outreach.

METHODS

In 2012, our CSU group helped Backyard Brains, Inc. produce the new EMG Spikerbox, a small, inexpensive bioamplifier that for the first time allowed students to experience, hear, see, and record their own muscle electrical activity outside of the research lab. The EMG signal is detected with 10-cent disposable electrodes made from popsicle sticks and brass brads, displayed visually in real time on iPods with the Spike Recorder App, and the audio is played through hobby speakers.

We also use commonly available vibrating massagers to elicit the tonic vibration reflex and attention-getting, fun, experiential proprioceptive illusions.

The novel EMG kits and proprioception demos are the centerpiece of our 2.5 yr-old program *Muscles Alive!*, named as an homage to the classic EMG text. Offering vivid visual and audio feedback, our participatory demonstrations usually involve small groups of students and include:

1) Live visual/auditory display of raw EMG signals from muscles of the hand, arm, leg, and face during different tasks.
2) Jaw muscle activity - chewing experiments with foods of different consistencies.
3) Weight lifting and arm wrestling.
4) Motor Unit Hunt – perhaps surprisingly, we can commonly record single motor unit discharge with these 10-cent electrodes, allowing direct observation of motor neuron discharge behavior.
5) Tendon vibration demos with 60Hz massagers that target afferent muscle sensors: *The Phantom Limb* (biceps brachii tonic vibration reflex) and *The Neurophysiology Trust Fall* (a robust proprioceptive illusion).
6) Live recording of the EMG of the patellar tendon tap reflex (stretch reflex).
7) Stretch reflex circuit timing (25-40ms) with a $15 instrumented reflex hammer.
8) Human-to-Human interface: control your friend's arm with your own EMG.

RESULTS AND DISCUSSION

Our demonstrations are accompanied by age-appropriate displays designed to teach students about 1) biological electricity and excitable cells, 2) the relation between brain command and muscle activation, 3) how action potentials are transmitted efferently to muscle and converted to force, 4) the role and extreme sensitivity of muscle sensors (spindles) in reflexes and proprioception, 5) the speed and necessity of reflexes, 6) neuromuscular anatomy, and 7) the critical role of voluntary muscle control in making us human.

We maintain an undergrad/grad team who lead the demonstrations and benefit from the teaching and community involvement. They must use their classroom knowledge in an applied context.

Impact - We have interacted with ~3,200 9-18 year-olds during > 45 events in public schools, science fairs, expos, science museums, community events, university events, and after school programs. The same equipment and concepts have been used successfully in public science settings with adults. Recently we have used these kits and techniques in university courses in neuromuscular physiology and anatomical kinesiology.

THE REBEL "STEM" ACADEMY: BRINGING STUDENTS TO THE SCIENCE

[1] Janet S. Dufek and [2]Christopher L. Heavey

[1] Department of Kinesiology and Nutrition Sciences
[2]Assistant Vice Provost for Undergraduate Education
University of Nevada, Las Vegas, Las Vegas, NV, USA
email: janet.dufek@unlv.edu; website: http://www.unlv.edu/kns/kinesiology

INTRODUCTION

The Rebel Science, Technology, Engineering, and Mathematics (STEM) Academy, developed jointly by the Office of the Provost and the Office of Admissions, brings high-achieving local high school students and their teachers to the University of Nevada, Las Vegas (UNLV) campus to spend a Saturday participating in hands-on experiences in STEM laboratories. The REBEL (Rehabilitation, Engineering, Biomechanics, Exercise Science, Life Sciences) Human Performance Group, formerly, the "Biomechanics Laboratory" is a participant in this event.

METHODS

Invitations are sent out the local school district's STEM teachers to gather students and participate in the event. Note that the "local" school district (Clark County School District) is the fifth largest in the country, thus a wide net is cast. Participating teachers and their students visit the UNLV campus on what is affectionately referred to as "STEM Saturday". Up to 10 high-profile laboratories on the UNLV campus participate in the event. The students visit laboratories that are conducting research in solar energy, water quality, renewable energy research, genomics, and *biomechanics*.

RESULTS AND DISCUSSION

The inaugural REBEL STEM Academy was held during the spring of 2013. It was attended by five teachers and 23 of their students. Each student participated in two different laboratory experiences spread across five different laboratories offered by faculty and graduate students from the College of Engineering, Sciences, School of Allied Health Sciences, and School of Community Health Sciences. Subsequent STEM Academies have averaged 10 teachers and 42 students. Our next Rebel STEM Academy is scheduled for April 2015. We already have 10 teachers and over 100 students signed up to participate. In addition to participating in the hands-on laboratory experiences, students and teachers join us for lunch, receive some UNLV swag, and learn about degrees and opportunities available at UNLV. Those who have attended have described it as a wonderful and eye-opening day.

When the students arrive at the site of the REBEL Human Performance Group, they are introduced to a variety of biomechanics tools. We demonstrate motion capture techniques by instrumenting one of the students and capturing locomotion data. Three-dimensional images are reconstructed and discussed. Other student participants will run or jump on the force platforms. Not only do students see force-time curves illustrated, but we explain salient characteristics, which typically leads to eagerness to repeat the experiment by running faster or jumping higher (adding a second "experimental condition"). One of the annual highlights is placing someone in our positive pressure treadmill and allowing them to run at reduced body weight. Here, we demonstrate that biomechanics can lead to a sense of weightlessness!

CONCLUSION

The Rebel STEM Academy is a fun day and a great way to showcase the impressive scientific research being done on our campus, including the lesser known science of biomechanics. We expect this event to continue to grow in the future as more teachers and students learn about it and as we continue to increase the number of participating STEM laboratories. We encourage others adopt this model to encourage biomechanics to "get younger".

BRIDGING ENGINEERING, SCIENCE AND TECHNOLOGY IN MEDICINE (BEST MEDICINE)

[1] Brian L. Davis, and [1]Carin A. Helfer

[1] Department of Biomedical Engineering
The University of Akron, Akron, OH, USA
email: bdavis3@uakron.edu; website: http://www.uakron.edu/bestmedicine

INTRODUCTION

"Bridging Engineering, Science and Technology in Medicine," (aka BEST Medicine) is an engineering fair in which 6th-12th graders create solutions to medical problems. BEST Medicine inspires students to seek solutions to health issues (often musculoskeletal) that they encounter in their home or social environment − while reinforcing math and science concepts they learn at school (Table 1).

Table 1. Goals and relationships to standards.

Goal	Relevant Standards
Grow vocabularies in science, engineering, and medicine	Common Core State Standards Connections (CCSSC) ELA/Literacy RST.6-8.8
Become proficient at testing a concept and improving ideas	Next Generation Science Standard (NGSS) MS-ETS1-4
Present logical arguments based on substantive claims, sound reasoning, and evidence	CCSSC ELA/Literacy SL8.5
Develop familiarity with 21st century media and technology	CCSSC ELA/Literacy SL8.5
Apply mathematical thinking to real world challenges	CCSSC Mathematics 7.EE.3
Become familiar with the engineering design process	NGSS MS-ETS1

Incorporating the engineering design process into the curriculum at the middle school level may seem a challenge at first glance. However, including engineering is a necessity since the Next Generation Science Standards (NGSS Lead States 2013) include engineering design process at the middle school level. At this grade level, the students are to "learn to sharpen the focus of problems by precisely specifying criteria and constraints of successful solutions" (NGSS Lead States 2013). Also, students should understand that engineering is critical to addressing future challenges in society (NRC 2012). Within the broad field of engineering, our experience shows that biomechanics is particularly suited to this endeavor. Each year, students showcase novel ideas for prosthetic and other rehabilitation devices, footwear, robotic approaches in medicine and human movement projects.

METHODS

BEST Medicine has been hosted for the past 5 years at the National Inventors Hall of Fame Middle School in Akron, Ohio. Typically 120 students (who have been preselected through other school or regional science fairs) participate. Holding a fair that highlights biomechanics is an excellent approach for teaching students about interdisciplinary science and/or the engineering design process. Local medical professionals (biomechanics faculty, physical therapists, clinicians etc.) attend the fair and this allows students to explore potential career opportunities. Concurrent teacher workshops are offered while the student projects are being judged.

RESULTS AND DISCUSSION

Each year approximately 30 to 40% of all projects submitted to BEST Medicine are related to biomechanics. Examples include (i) reducing the risk of concussion in sports, (ii) developing improved prosthetic sockets, (iii) decreasing the risk of bathroom falls, (iv) predicting knee stress through a computer model and (v) an ergonomic power-assisted wheelchair transfer system.

CONCLUSION

By middle school, students are aware of many medical problems, often through personal experiences of friends and family members. Therefore, projects that involve engineering solutions to biomechanical issues allow students to solve real human problems for which they have a personal interest.

SUBCHONDRAL STRAINS AND INITIATION OF OSTEOARTHRITIS IN THE RADIOCARPAL JOINT

[1] Joshua E. Johnson and [1] Karen L. Troy
[1] Worcester Polytechnic Institute, Worcester, MA, USA
email: jejohnson@wpi.edu

INTRODUCTION

Prevalence of radiographic osteoarthritis (OA) is highest in the hand, and secondary OA due to injury is a significant problem. Peak contact pressure (CP) on the radius articular surface is an important mechanical factor in OA initiation, and is affected by joint injury and subsequent abnormal load transfer [1]. However, distal radius strains due to abnormal joint loads may also influence the degenerative response from the subchondral level. The goal of this study was to investigate whether changes in distal radius subchondral strains are related to changes in peak CP, to better understand the mechanism of OA initiation. Our hypothesis was that increases in peak CP would result in a similar (or greater) increase in peak strains.

METHODS

Radiocarpal joint finite element (FE) models were created using computed tomography (CT) data acquired from two female subjects (mean age 27.5 years), after IRB approval. Proximal wrist and forearm images were acquired at 234×234×625 µm voxel size (Fig. 1A).
Figure 1: (A) CT data used to construct FE models of the radiocarpal joint (B).

The methods used have been previously validated for evaluation of distal radius mechanics [2]. The radius and carpal bones (lunate, scaphoid) were segmented from the images in Mimics (Materialise, Leuven, Belgium). Cartilage was created by expanding the distal radius surface to achieve an average thickness of 1.4 mm, similar to values reported in literature. Bone and cartilage geometries were converted to quadratic tetrahedral meshes (Fig. 1B). Cartilage was assigned a Neo-Hookean hyperelastic material property. Based on an established density-elasticity relationship, the radius was assigned a linear elastic, inhomogeneous property. Normal behavior between the contacting surfaces was modeled using a finite sliding formulation, while a penalty method was used to model tangential behavior. To simulate physiologic loading (leaning onto the palm), proximal radius nodes were fixed, while an axial force was applied through the scaphoid and lunate centroids based on percentage of load transfer through the joint.

Loads were applied ranging from 50-500 N (50 N increments) to represent abnormal changes due to joint injury, resulting in 10 simulations per subject. All simulations were performed in Abaqus (Simulia, Providence, RI). Energy equivalent strain $\bar{\varepsilon}$ ($\sqrt{(2 \times U/E)}$, U=strain energy density; E=modulus) was chosen as the strain outcome because of its association with bone adaptation. For both the radioscaphoid (RS) and radiolunate (RL) articulations, percent changes versus baseline (50 N) in peak CP were compared to percent changes in peak $\bar{\varepsilon}$, determined from subchondral radius elements (3 mm average length) in regions underlying contact pressure distribution.

RESULTS AND DISCUSSION

Average results of the two subjects were analyzed. With increasing load, percent changes in peak $\bar{\varepsilon}$ versus baseline for the RS articulation trended higher than peak CP (Fig. 2). On the other hand, changes in peak $\bar{\varepsilon}$ trended lower than peak CP for

the RL articulation (Fig. 3). Figure 4 shows example CP distributions (top row) from 100 N and 300 N joint load simulations for the RS and RL articulations, and corresponding $\bar{\varepsilon}$ distributions on the distal radius surface (bottom row).
Figure 2: Percent changes in RS peak CP and $\bar{\varepsilon}$.
Figure 3: Percent changes in RL peak CP and $\bar{\varepsilon}$.

The mechanism leading to the onset of post-traumatic OA is not well understood. Only a portion of the radius cartilage is loaded during normal functional wrist motion (average 21%) [3]. It is possible that the tissue preconditions to physiologic loading over time, and may be sensitive to changes in magnitude or location of peak contact pressure. Also, $\bar{\varepsilon}$ values above a threshold are associated with bone apposition and vice versa. Higher changes in peak $\bar{\varepsilon}$ were observed only on the scaphoid side. These higher strains could result in local bone formation and consequently local increases in stiffness. This could lead to local stress concentrations at the cartilage-bone interface, resulting in a degenerative response also at the subchondral level. Also, the increased stiffness of the subchondral bed would lead to subsequent increases in peak contact pressure - essentially a

positive feedback loop. This combination of peak contact pressure and $\bar{\varepsilon}$ could predispose the scaphoid fossa to higher OA risk, which interestingly, is clinically observed to initiate on the scaphoid side [4]. Further, shift in location of peak contact pressure due to injury may result in even higher increases in peak strain. Due to its shape, the lunate articulation may be protected from increases in subchondral strains as a result of even load distribution. However, the progression of joint instability and degeneration eventually result in the lunate fossa also succumbing to OA (scapholunate advance collapse pattern of wrist OA).
Figure 4: CP (top; MPa) and $\bar{\varepsilon}$ (bot) distributions.

One limitation of the study was using a "projected" cartilage surface, which is less accurate to estimate contact pressure than actual cartilage surface. However, using the radius surface instead of an idealized surface, improved the geometric accuracy of the scaphoid and lunate articular fossae.

CONCLUSIONS

We observed higher changes in peak $\bar{\varepsilon}$ in relation to peak CP, which suggests a mechanism of OA initiation also at the subchondral level.

INTRODUCTION

A healthy wrist is essential for hand function. Yet, the complexity of these two, highly integrated, multi-body, multi-joint systems often necessitates studying their biomechanical features in isolation. Experimental studies, for example, have separately studied the kinematics of carpal, metacarpal, and phalangeal joints [1-3]. Even simulation studies rarely integrate the wrist and hand, due to the computational challenges associated with building robust musculoskeletal models of these intricate, low mass, low inertia systems. For example, the wrist has previously been excluded from models implemented to analyze force production by the thumb, index finger, and in multi-finger grip [4-6].

This study leverages the available experimental data and the computational advances of previous models to develop simulations of lateral pinch force that integrate the wrist and thumb. We specifically study scaphoid-excision four-corner fusion (SE4CF) and proximal row carpectomy (PRC), common surgeries to treat wrist osteoarthritis. These procedures provide an ideal context to examine biomechanical coordination between the wrist and thumb. Notably, even though SE4CF and PRC surgically alter only the wrist, they are known to result in decreased lateral pinch strength [7]. Also, these surgeries dramatically, but distinctly, alter the wrist's bone geometry (Fig. 1A) and kinematic function.

METHODS

To examine how surgically altering the wrist affects lateral pinch force production, biomechanical models of the nonimpaired wrist [8] and thumb [5] were adapted to develop dynamic simulations for three wrist conditions (nonimpaired, SE4CF, and PRC; Fig. 1). The three models included fourteen muscles (5 primary wrist, 4 extrinsic thumb, and 5 intrinsic thumb muscles). Condition-specific joint kinematics and moment arms for each model were based on experimental data [8, 9, 10].
Fig. 1. (A) Wrist bone geometry. (B) Pinch posture.

Seven lateral pinch tasks (magnitude 0-60 N in 10 N increments; direction pure palmar) were simulated with each of the three biomechanical models using two simulation approaches (Fig. 2). All simulations were performed in OpenSim v. 3.1 [11].

To compare the joint torques necessary to produce a given level of lateral pinch force across wrist conditions, we implemented a computed torque control algorithm (Fig. 2A). Each simulation involved maintaining a static wrist posture while producing the target endpoint force. These simulations did not include muscle-tendon units. Differences in the resulting torques isolate the effects of wrist kinematics on the transformation from joint torques to thumb-tip endpoint force.
Fig. 2. Summary of the simulation approaches.

To compare how effectively muscles produce lateral pinch force across wrist conditions, forward dynamic simulations were performed (Fig. 2B). In each forward simulation, the inputs were the muscle activations required to reproduce the lateral pinch tasks in the nonimpaired model, calculated using computed muscle control. Because muscle activations were held constant across wrist models, any differences in the simulated pinch force vectors arise from the changes to wrist joint kinematics and musculoskeletal geometry imposed by the surgeries. Results of the forward simulations were compared when the simulations reached equilibrium.

RESULTS AND DISCUSSION

Regardless of the magnitude of endpoint force simulated, the SE4CF and PRC models required wrist torques larger than those required by the nonimpaired model (Fig. 3). The PRC model consistently required the largest wrist torques (more than 3.5 times larger than the nonimpaired model). Torques across the three thumb joints were similar across all models (results not shown).
Fig. 3 Magnitudes of wrist joint torque versus thumb-tip endpoint force for the nonimpaired (gray), SE4CF (blue), and PRC (red) models. Torques were decomposed into a common anatomical frame for direct comparison.

Given the same muscle activations, the SE4CF and PRC models produced thumb-tip endpoint forces that were smaller in magnitude and misdirected compared to the nonimpaired model (Fig. 4). The misdirection of the force depended on the surgery; SE4CF produced force in palmar and medial directions, PRC produced force in palmar and proximal directions (Fig. 4). The posture at equilibrium was also different across the three models. In addition to changes in thumb joint posture (Fig. 4), the wrist moved by nearly 10° in both surgical models. The equilibrium wrist posture was neutral for the nonimpaired model, combined radial-extension for SE4CF, and ulnar deviation for

PRC. These postures reflect post-operative changes in muscle moment arms [10].
Fig. 4 Representative endpoint forces from forward simulations to produce 40 N target endpoint force. The SE4CF (blue) and PRC (red) results are superimposed on the nonimpaired (gray) results. Arrows represents force (magnitude and direction); thumb illustrates the final, equilibrium posture.

CONCLUSIONS

Changes in joint kinematics and musculoskeletal geometry following wrist surgery likely contribute to impairments in lateral pinch strength. Our simulations indicate that muscles must generate larger torques about the wrist following surgery to produce a given magnitude of lateral pinch force (Fig. 3). Many muscles actuating the wrist also actuate the hand. Thus, impairments in lateral pinch may reflect an inability to effectively coordinate muscle activation patterns across the wrist and hand to meet this additional task requirement. In addition, we demonstrate that altered wrist musculoskeletal geometry changes the transformation between muscle activations and lateral pinch force (Fig. 4). Both simulation studies suggest new muscle control strategies must be learned following surgery. As a whole, our work highlights the complex, integrated biomechanics of the wrist and thumb.

INTRODUCTION

Carpal tunnel syndrome (CTS) is a common compression neuropathy of the upper extremity, caused by entrapment of the median nerve in the carpal tunnel. Deficient sensorimotor function associated with CTS may cause dyscoordination of digit forces and muscle activities in dexterous tasks. There has been report about unstable pinch forces in CTS patients [1], however, there is limited understanding of CTS effects on muscle activities during precision pinch. Coherence between two electromyography (EMG) signals can be used to quantify the coordination of muscle pairs. Specifically, muscle coherence in the 15-30 Hz range (β-band) has been shown to be associated with maintaining steady force output [2]. The purpose of this study was to investigate the effects of CTS on force coordination between digits and β-band coherence between intrinsic muscles during sustained precision pinch. In addition, wrist flexion (i.e. Phalen's maneuver) is commonly used to provoke CTS symptoms for diagnosis purpose. Therefore, a precision pinch task with varied wrist postures was implemented for investigation of force and muscle dyscoordination.

METHODS

Eight CTS patients (50.9 ± 10.8 years old) and eight asymptomatic controls (47.6 ± 14.9 years old) participated in this study. An apparatus consisting of two six-component force/torque transducers was developed to measure the digit forces. A surface EMG system was used to monitor the activities of the abductor pollicis brevis (APB) and first dorsal interosseous (FDI) muscles. Customized splints were used to stabilize the wrist in 30° extension, anatomical neutral, and 30° flexion (Fig. 1). First, participants were instructed to maximally pinch the apparatus with the thumb and index finger, reaching their maximum force within 5 sec. Three maximum pinch trials were performed for each wrist posture. Then, the maximal pinch forces at each posture were averaged and 10% of the averaged maximal force was set as the target for the subsequent submaximal task. For the submaximal task, participants were asked to pinch the apparatus and match the target force for 15 sec according to graphical feedback. Ten submaximal trials were performed for each wrist posture. The three wrist postures were randomized and a 1-minute rest was given between trials. Force and EMG data were collected at a sampling rate of 1000 Hz. To avoid the non-stationary effects at the beginning of each submaximal trial, the data in the first 5-sec were excluded from analyses. A force difference index was determined as the magnitude difference between the resultant forces of the index finger and thumb normalized by target force. In addition, a force angle was calculated between the 3D force vectors of the two digits to quantify the directional opposition. Muscle coherence was computed as the cross-spectrum normalized with respect to the square root of the auto-spectra of the associated EMG signals, followed by a Fisher's Z-transformation. The average coherence in the β-band between the APB and FDI muscles was calculated.
Figure 1: Experimental setup with the wrist in 30° extension (A), anatomical neutral (B), and 30° flexion (C).

Two-way repeated measures ANOVAs (one factor repeated) were performed to test the effects of group (CTS and control) and wrist posture (extension, neutral, and flexion) on force difference index, force angle, and muscle coherence. Post hoc Tukey's tests were performed for pairwise comparisons. The α level was set at 0.05.

RESULTS AND DISCUSSION

An interaction effect of group and posture was found on the force difference index ($p = 0.01$), although the main effect of group or posture was insignificant. Within the control group, there was a significantly higher value of force difference index in flexion than in extension (Fig. 2A). On average, the greatest group difference in the force difference index was found in wrist flexion (0.34 ± 0.23 for controls and 0.17 ± 0.29 for CTS patients). For the force angle, the difference between groups was on average greatest in wrist flexion (Fig. 2B), although the difference was not significant. In wrist flexion the control group had a force angle of $158.3 \pm 4.5°$, whereas the CTS group had an angle of $164.8 \pm 6.2°$. For the β-band coherence, the largest difference between groups was also found in wrist flexion (Fig. 2C). The control group had a coherence value of 0.14 ± 0.03 in wrist flexion while the CTS group had a value of 0.16 ± 0.03; however, the difference was not statistically different.

The wrist flexion posture at 30° employed in this study was relatively moderate in comparison to the clinically used wrist flexion for Phalen's test. We expect that a more flexed wrist flexion would allow us to observe a greater difference between groups. Furthermore, this preliminary study has a small sample size. Statistical power is expected to increase when more subject data are collected. Consistent with previous findings [1], the index finger generated more force than the thumb during submaximal pinch. In the control group, the force contribution of the index finger significantly increased in wrist flexion relative to extension, which may be due to more diminished thumb flexor function with flexed wrist [3]; however, the trend was not observed in the CTS group. Additionally, on average, the CTS group had a greater force angle (i.e. better opposition) than the control group. This

counterintuitive result may be attributable to thenar muscle weakness in CTS patients [4]. Weak thenar muscles decrease thumb abduction, making the thumb force vector orient more towards opposition. Furthermore, better opposition of the thumb and index finger may lead to less force difference between digits for the torque balance. Although thenar muscle weakness may result in greater digit force opposition during pinching on a stabilized object, this mechanism may not be practical for daily activities requiring high-level sensorimotor control. In the results of muscle coherence, on average, a higher value of β-band coherence was observed in CTS patients with their wrists in flexion. The modulation of muscle coherence has been associated with sensorimotor processing, which could be sensitive to changes in peripheral inputs [2]. It could be postulated that the increase in β-band coherence in CTS patients is a compensatory mechanism for flexion-induced exacerbation of symptoms.

INTRODUCTION

The goal of this study was to develop and validate a new clinically applicable approach to measuring scapulothoracic (ST) kinematics among typically developed individuals. Accurate assessment of ST kinematics is important for understanding functional limitations of the shoulder and upper extremity [1]. Current efforts to measure shoulder function often provide no differentiation between scapulothoracic and glenohumeral joint contributions to shoulder motion [2]. Techniques that attempt to quantify these measures are often inaccurate, invasive, time consuming, induce large amounts of radiation exposure, and/or require the subject to lie horizontally in an enclosed space. Traditional 3D motion capture has been used effectively to measure kinematics of bones that move with the skin, such as the humerus, but has failed to provide accurate estimates of scapular kinematics. We believe, however, that 3D motion capture data can be used in an innovative way to estimate scapular kinematics. Individualized mathematical algorithms that estimate dynamic scapular orientation based on measured humeral orientations and/or acromion process (AP) displacements were developed using motion capture data collected in multiple static poses. The mathematical algorithms were validated using a technique recently established by our lab that utilizes bone models and biplane fluoroscopy to perform a 2D to 3D matching process [3]. The algorithms provide a clinically useful tool for measuring ST kinematics that can be extended to patient populations.

METHODS

Individualized mathematical algorithms were developed for two subjects. Algorithm development is based on the principle that scapular orientation is a function of humeral orientation and AP displacement. For any given humeral orientation and AP displacement, the scapular orientation is expected to be consistent, regardless of the path of motion used to reach that position. This approach also assumes that the scapula moves in a consistent manner throughout an individual's entire range of motion. Mathematical algorithms were created for each subject using motion capture data (Motion Analysis Corp, Santa Rosa, CA) from eleven static positions: neutral, abduction, hand to mouth, hand to neck, elevation, forward reach, extension, hand to spine, external rotation, internal rotation, and flexion. Equations to estimate scapular orientation from AP displacement data and humeral orientation were developed using two different approaches: multiple linear regression (LR) and artificial neural networks (NN). Humeral orientation was calculated as humerothoracic (HT) helical angles, i.e. the helical angle between the trunk and the humerus, and AP displacement was calculated as the displacement of the AP marker along the Y axis (inferior/superior) and the X axis (anterior/posterior) of the trunk. The predicted values were scapula orientation, calculated as ST helical angles, i.e. the helical angle between the trunk and the scapula. Helical angles are calculated as a theta angle and an XYZ vector. The theta and vector are then resolved into the X, Y, and Z components. Each individual has an equation to estimate the ST X component, an equation to estimate the ST Y component, and an equation to estimate the ST Z component. The LR algorithms and the NNs were applied to dynamic trials in which the individual moved continuously through the eleven positions listed above. The accuracy of the algorithms was determined by the correlations and average differences between the algorithms predicated ST angles and the validation ST angles.

RESULTS AND DISCUSSION

The ST X and ST Z angles estimated from the linear regression algorithms for subject 1 were highly correlated with the validation ST X and ST Z angles, while the ST Y angles were mildly correlated (Table 1). All three ST angles estimated from the linear regression algorithms for subject 2 were highly correlated with the validation ST angles. Subject 2's neural network estimated ST angles were all highly or mildly correlated with the validation ST angles (Table 1). Subject 1's ST Y neural network angles were poorly correlated with the validation angles, but the ST X and ST Z neural network angles were very highly correlated with the validation ST angles.

Table 1: Correlations

	LR X	LR Y	LR Z	NN X	NN Y	NN Z
Subj 1	0.93	0.54	0.90	0.90	*0.43	0.91
Subj 2	0.90	0.75	0.96	0.89	0.51	0.67

* r < 0.5 signifies a poor correlation

Clinical accuracy was determined with average differences presented in Table 2. All average differences were less than 10° for both subjects and both mathematical approaches. Figure 1 shows the actual ST motion about all three axes as compared to the ST motion estimated with LR and NN during the dynamic trials.

Although both mathematical approaches were able estimate ST angles throughout the entire motion, the LR technique estimated ST angles that resulted in higher correlations and smaller average differences when compared to the validation angles. The LR technique is also easier to implement, making this method extremely clinically applicable.

Regional clinicians have expressed that errors less than 10° provide the accuracy needed to aid in reconstructive surgery decisions, outcome

assessments, and rehabilitation strategies. While the LR equations were not as highly correlated for the ST Y angles, the average differences for all axes were well below 10°. It takes less than thirty seconds of computing time to generate the three LR equations for one subject, and less than thirty minutes to collocate the necessary motion capture data, making the algorithm development a fast, non-invasive, and clinically accurate tool for determining dynamic scapular orientation. This new technique is expected to drive future work in musculoskeletal modeling, clinical trials, and basic research that will add further insight into impaired shoulder function.

QUANTIFYING KINEMATIC AND MUSCULAR ADAPTATIONS TO ROTATOR CUFF FATIGUE

Department of Kinesiology, McMaster University, Hamilton, ON, Canada, L8S 4K1
email: pjkeir@mcmaster.ca

INTRODUCTION

Work-related musculoskeletal disorders (MSDs) of the upper extremity are one of the most frequently reported workplace injuries in Ontario Canada [1]. The rotator cuff muscles of the shoulder are frequently injured in the workplace. These muscles are important in maintaining glenohumeral stability and function.   These roles make it valuable to understand the implications of fatigue in this muscle group. Muscle fatigue during repetitive work can cause people to adopt kinematic and muscular strategies to continue working and maintain task performance [2].   These compensations can be adaptive to maintain task performance or maladaptive and increasing risk of injury.   To understand these complex compensations during work tasks we must first understand how simple movements are impacted by muscle fatigue.   The purpose of this study was to quantify kinematic and muscular compensations to rotator cuff muscle fatigue during simple glenohumeral motions.

METHODS

Male participants (n=10) completed 5 glenohumeral motions before (pre-fatigue) and after (post-fatigue) a fatigue protocol designed to target the internal and external rotators of the shoulder complex. The 5 glenohumeral motions were: (i) 120° sagittal plane elevation, (ii) 120° scapular plane elevation, (iii) 120° frontal plane elevation, (iv) cross-flexion/extension, (v) internal/external rotation. All exertions were performed while holding a 2 kg weight. Participants were given 10 seconds to complete each exertion and instructed to move at their own pace.   The fatigue protocol consisted of a series of dynamic and isometric efforts completed in a cyclic manner using a dynamometer (Biodex System 4, Biodex Medical Systems, NY, USA). The dynamic efforts consisted of 10 concentric-concentric isokinetic exertions (60°/s, 15% MVC)

and the static efforts were 30 seconds of external rotation followed by 30 seconds of internal rotation (both at 45° external rotation, 25% MVC). The dynamometer constrained movement speed and torque level was maintained using visual feedback (Labview 8.2, National Instruments, Texas, USA). This cycle was continued until participants were unable to maintain the required 25% force output for 2 consecutive cycles or voluntarily ended the protocol. The 5 glenohumeral motions were repeated immediately following the fatigue protocol. To minimize order effects, the pre- and post-fatigue exertion orders were randomized.

Kinematic data were collected using an electromagnetic tracking system (Polhemus 3Space, Fastrak, Colchester, VT, USA). Scapular kinematics were measured using an electromagnetic sensor placed on the base of a custom scapular tracker [3]. A digitizing stylus was used to digitize bony landmarks.   Muscle activity from 14 upper extremity, back and chest muscles were recorded using surface electromyography (TrignoTM, Delsys, MA, USA).   To quantify fatigue, submaximal static reference efforts and maximal internal-external rotation efforts (Series 5 Mark-10 force gauge) were performed before and immediately after the fatigue protocol.
Figure 1. **(A)** Internal/external rotation fatigue protocol in Biodex dynamometer **(B)** Participant performing 120° of elevation in the frontal plane.

Joint angles for the humerus, thorax and scapula were calculated in accordance with ISB standards. EMG data were linear enveloped (F_c=3 Hz) and normalized to each muscle's maximum activation. Using the resultant humeral angular displacement, the EMG and kinematic data were cut to include the motion portion of each trial. Summary variables (mean, peak) were calculated for 3D joint angles and muscle activity. Time to peak angular displacement, velocity and acceleration were also included in the analysis. Multiple repeated measures ANOVA were used for the statistical analyses (SPSS 20.0, SPSS Inc., Chicago, IL, USA).

RESULTS AND DISCUSSION

Following the fatigue protocol, participants displayed signs of muscle fatigue (>8% decline in median power frequency between pre and post fatigue submaximal reference exertions) in 5/14 of the monitored muscles: infraspinatus, clavicular head of pectoralis major, triceps brachii, latissimus dorsi, and serratus anterior.

Specific muscle activity compensations following fatigue were dependent on the glenohumeral motion examined. After the fatigue protocol, participants used a combination of increased mean deltoid (anterior, middle and posterior), trapezius (middle, upper) and latissimus dorsi activity (all $p < 0.05$) to elevate the arm in the scapular plane.

Most participants displayed noticeable kinematic differences during the post-fatigue movements. Variability in the response between participants (Figure 2), make it challenging to fully capture these compensations using descriptive statistics. No significant kinematic changes were seen during elevation in the scapular plane. However, there was a slight reduction in trunk flexion in the frontal plane. During cross flexion, humeral, scapular and trunk joint angles were all affected by rotator cuff muscle fatigue ($p < 0.05$). Preliminary analyses suggest scapular adaptations may serve to increase the width of the subacromial space. These impingement sparing adaptations have also been observed during more complex work tasks [2].

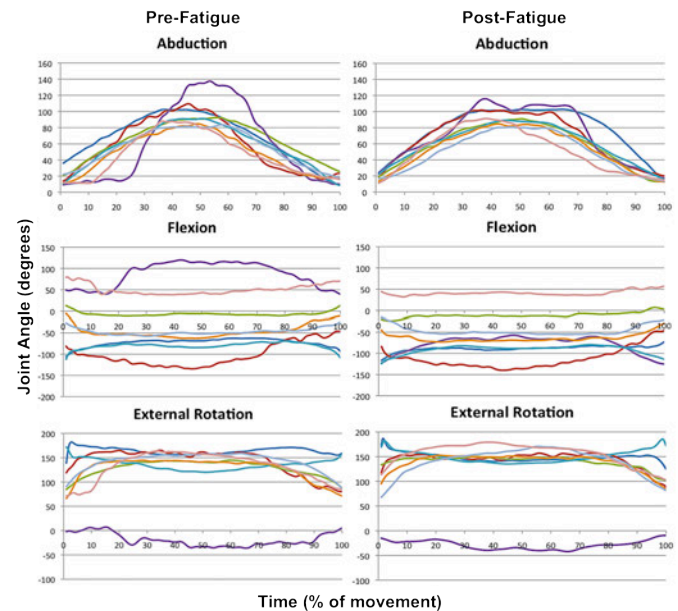
Participants were able to utilize the kinematic and muscular flexibility afforded by the shoulder to perform glenohumeral motions following rotator cuff fatigue. Applying these compensations to more complex workplace tasks will give insight into expected strategies to repetitively perform these tasks.


Figure 2: Humeral angles with respect to the thorax during a glenohumeral abduction-adduction movement (frontal plane) pre- and post-fatigue. Each line colour represents a different participant (n=8). The length of each trial is normalized to 100% of the motion.

INTRODUCTION

The shoulder is stabilized by passive structures and active muscle forces. The interaction between these factors is critical for normal joint function and the evaluation of shoulder pathologies. The objective of this study was to investigate how passive structures and actives muscle forces regulate three-dimensional (3D) joint mechanics during volitional contractions. We quantified impedance of the shoulder in three clinically relevant planes of motion to reliably assess multidimensional joint function. We hypothesized that the coupling of joint impedance between different planes of motion of the shoulder would be significant and enhanced with muscle activation. This work may provide a novel approach for quantifying the 3D mechanics of the human shoulder, and ultimately for tracking altered mechanics following injury or rehabilitation.

METHODS

The right shoulder of four male subjects (mean age: 35 yrs, weight: 71 kg, height: 176 cm) with no history of shoulder injury was placed in a removable cast and attached to a high-precision rotary motor with an encoder and six-degree of freedom load cell. Subjects were perturbed in one of three planes of motion in a random order, while the resultant torques were measured in all three degrees of freedom (Fig. 1). Our measurement coordinate system was aligned with established biomechanical guidelines [1]. Subjects were asked to maintain a constant shoulder torque during 60-second experimental trials. In each perturbation direction, measurements were acquired as subjects maintained a net torque level scaled to ±10% of their maximum voluntary contraction (MVC) in each of the three torque directions. Measurements were also made in the passive condition. Two trials were performed in each of the seven testing conditions and three perturbation directions, yielding 42 trials.

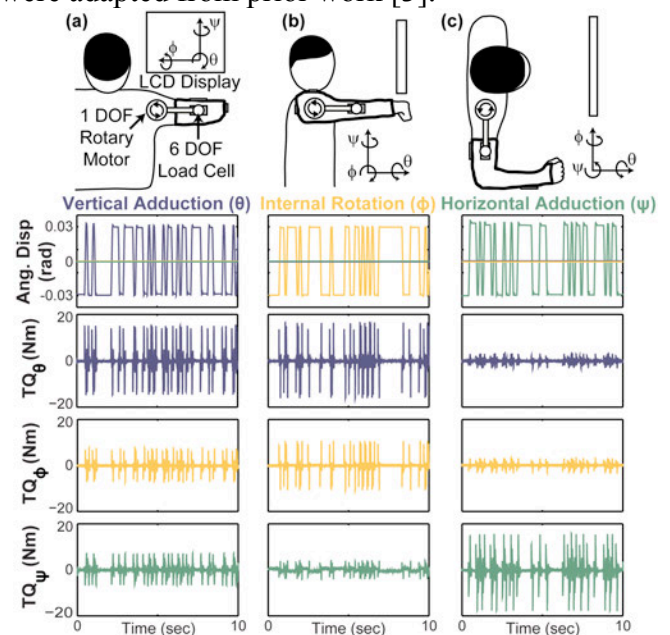
Joint impedance, the dynamic relationship describing the torque response to an imposed change in joint angle, was estimated using small, stochastic perturbations. Model structure was determined with nonparametric identification; these estimates were then approximated by a 2nd order linear system with inertial, viscous and elastic parameters [2]. The current study focused on the elastic parameter, otherwise known as stiffness. For each perturbation and torque direction, stiffness was represented as 3 x 3 matrix, where the diagonal terms are the direct response and the off-diagonal terms are the coupled response to a perturbation of posture. A bootstrapping procedure was used to estimate the mean and confidence intervals for the stiffness matrices for the different experimental conditions for each subject. These matrices were represented as 3D stiffness ellipsoids. Descriptions of these ellipsoids (size, shape, and orientation) were adapted from prior work [3].


Figure 1. A single-axis rotary motor perturbed the shoulder in one of three orthogonal directions (a)–(c). Visual feedback assisted subjects in matching the desired target. The coordinate system is also shown. Exemplar passive trials show the resultant 3D torque response to the imposed perturbation is shown below each illustration.

RESULTS AND DISCUSSION

Stiffness ellipsoids for a typical subject are shown in Figure 2, which graphically depict the directions where the shoulder is most resistant to external perturbations of posture. Muscle activation increased stiffness, as demonstrated by the larger size of the active ellipsoids when compared to the passive ellipsoid. The norm of the stiffness matrix eigenvalues is indicative of the greater shoulder stiffness across subjects with volitional activation (Table 1). Shoulder stiffness was highly anisotropic, or stiffer in certain direction that others. Shape, or the ratio of the matrix eigenvalues, is indicative of this anisotropy. Ratios equal to one are indicative of isotropic stiffness, but these ratios were less than one across subjects (Table 1).

The stiffness ellipsoids provide insights into the coupling between different degrees of freedom of the shoulder. The production of a net torque in a given direction should orient the stiffness ellipsoid along the orthogonal axis of torque generation if no stiffness coupling was present. The ellipsoids in Figure 2 indicate stiffness coupling is present. Passive shoulder stiffness was orientated away from the orthogonal shoulder axes, as the relative angle

between the principal axis of the passive stiffness ellipsoid and the closest orthogonal shoulder axis was $30.5 \pm 8.1°$. The direction of torque production altered the degree of coupling as well, as the stiffness ellipsoids were aligned closest to the axis of torque generation (Table 1).

There is a pertinent clinical need to better prevent, diagnose and treat shoulder injuries. The current study shows the utility of quantitative impedance methods in estimating the 3D mechanics of the healthy shoulder. The anisotropy of shoulder stiffness indicates certain directions are less resistant to external perturbations, and therefore may be more prone to injury. The observed stiffness coupling within the shoulder is indicative of underlying neuromuscular mechanisms. These methods will enable future work to compare how coupling differs for different shoulder pathologies.

CONCLUSIONS

The shoulder muscles provide significant mechanical coupling between different degrees of freedom, and may offer a more complete description of healthy joint mechanics.

LOADING PATTERNS VARY BY DIRECTION, FOOTWEAR, AND FOOT-STRIKE IN RUNNING

Andrew D. Nordin and Janet S. Dufek

University of Nevada, Las Vegas, Las Vegas, NV, USA
email: nordina@unlv.nevada.edu

INTRODUCTION

Foot-strike pattern manipulations in running have previously identified alterations in three-dimensional (3D) loading rates, with potential implications for understanding injury mechanisms [1,2]. The use of minimalist footwear has also been promoted as a means of reducing running injuries, ostensibly mimicking barefoot running and facilitating foot-strike changes [3]. Comprehensive analysis of 3D loading patterns across footwear and foot-strike manipulations may therefore provide insight into interactions among these factors.

The purpose of this investigation was to examine 3D loading patterns following footwear and foot-strike manipulations in over-ground running. Inter-axis loading pattern changes were hypothesized in contrasting footwear and foot-strike conditions.

METHODS

Twenty volunteers free of lower extremity injuries (9M, 11F, age: 25.3 ± 3.6 y, mass: 73.2 ± 13.7 kg, height: 1.68 ± 0.09 m) provided institutionally approved informed consent prior to participation. Subjects completed 15 over-ground running trials (14 analyzed) in each of 6 experimental conditions, including 3 foot-strike (forefoot, mid-foot, rear-foot strike; FFS, MFS, RFS, respectively) and 2 footwear conditions (neutral cushioned [New Balance ® 680V2] & minimalist [New Balance ® Minimus Hi-Rez]).

Prior to over-ground running trials, a treadmill warm-up was completed using each subject's natural foot-strike pattern (self reported and visually identified: 50% RFS & 50% MFS/FFS among subjects). Approximately 5-minute accommodation periods were provided in each footwear type, simultaneously obtaining preferred running speed.

Over-ground running trials were carried out on a 20m runway, controlling running speed via timing gaits (±5% preferred speed; Lafayette Model 63501IR). Instructional videos and practice trials were provided before blocked foot-strike and footwear conditions. Condition order was counterbalanced.

Kinetic data were collected during the stance phase of the right limb using a force platform (Kister Type 9281CA; 2000Hz; GRFz > 20N), with synchronized kinematic data collected via 10-camera motion capture system (Vicon Plugin-Gait; MX-T40S; 200Hz) and sagittal reference video of the foot at ground contact (Basler piA640-210gc; 50Hz). Kinematic analyses were limited to foot segment angle at ground contact and point of foot contact from sagittal video as means of corroborating foot-strike patterns. Kinematic and kinetic data were low-pass filtered (15 & 50Hz cutoffs, respectively). GRFz data were normalized to bodyweight (BW), with loading rate-time profiles computed independently for X, Y, & Z axes using first central difference differentiation (BW/s).

Loading patterns were assessed using principal component analysis (PCA) on the 3D loading rate-time series in each axis, footwear and foot-strike condition. Prior to performing PCA, each time series was temporally normalized to 101 data points using cubic spline interpolation. Loading rate time series variables were converted to z-scores in each axis (X, Y, Z), subtracting the mean and normalizing to the standard deviation of each subject's condition. PCA was then performed on a 5040x101 dimension matrix (20 subjects x 14 trials x 3 axes x 3 foot-strike x 2 footwear). PCs exceeding 10% explained variance were interpreted. Inferential testing was carried out on PC scores after computing the mean from each participant.

Separate 3-way repeated measures factorial ANOVAs (3x3x2; axis x foot-strike x footwear) were conducted for each PC, testing differences among loading patterns observed in each axis, foot-strike, and footwear condition. Follow-up factorial and one-way repeated measures ANOVAs, along with pairwise comparisons, were carried out as necessary. Degrees of freedom were adjusted with Huynh-Feldt corrections, with Bonferroni adjusted pairwise comparisons (α=0.05). Differences among foot segment angle at ground contact in each desired foot-strike pattern were tested via one-way repeated measures ANOVA.

RESULTS AND DISCUSSION

Foot segment angle at contact differed among desired foot-strike patterns (FFS: -12.0±7.1°, MFS: 2.5±10.8°, RFS: 20.3±5.3°; $F[2,38]$=122.0, $p<.001$, η^2=.87; pairwise comparisons: $p<.001$), verifying the distinction among foot-strike conditions.

Two PCs were extracted (PC1: 42.5% & PC2: 22.8% explained variance). From visual inspection, PC1 captured a source of variation characteristic of loading rate-time curves lacking an observable GRF impact peak during braking [1,2]. In contrast, PC2 captured a source of variation characteristic of loading rate-time curves demonstrating a GRF impact peak during braking [1,2]. The interaction among axis, footwear and foot-strike was significant in each PC (PC1: $F[2.1,40.1]$=5.6, p=.007, η^2=.23; PC2: $F[2.0,38.4]$=62.3, $p<.001$, η^2=.77).

PC1 scores were interpreted in the context of impact attenuation, differing by axis, footwear, and foot-strike pattern. In each footwear condition, vertical PC1 scores during FFS exceeded MFS and RFS ($p\leq.016$), indicating FFS impact attenuation. Vertical impact attenuation in cushioned RFS exceeded minimalist RFS ($p<.001$). In each footwear condition, anterior-posterior PC1 scores differed by foot-strike (RFS>MFS>FFS, $p<.001$), highlighting anterior-posterior impact attenuation in RFS. Anterior-posterior impact attenuation in minimalist FFS exceeded cushioned FFS ($p<.001$), while cushioned RFS impact attenuation exceeded minimalist RFS (p=.013). In each case, vertical PC1 scores exceeded anterior-posterior and medial-lateral ($p<.001$), demonstrating lesser sensitivity to vertical impact features [2].

PC2 scores were interpreted relative to impact characteristics typically observed during braking in 3D loading rate-time series [1,2]. Greater vertical PC2 scores were observed in minimalist RFS, relative to minimalist FFS and MFS ($p<.001$), indicating greater impact characteristics in minimalist RFS. Cushioned FFS demonstrated greater impact characteristics relative to minimalist FFS ($p<.001$). In each footwear condition, anterior-posterior PC2 scores differed by foot-strike (FFS>MFS>RFS, $p\leq.003$), indicating greater anterior-posterior impact characteristics in FFS and MFS. Anterior-posterior impact characteristics in cushioned FFS exceeded minimalist FFS ($p<.001$). Medial-lateral impact characteristics were lesser in RFS, relative to FFS and MFS in both cushioned and minimalist shoes ($p<.001$). Medial-lateral impact characteristics for cushioned shoes exceeded minimalist for both FFS and RFS ($p\leq.002$).

CONCLUSIONS

Assessment of the loading rate-time series via PCA allowed distinct impact features to be identified, highlighting inter-axis changes among footwear and foot-strike conditions. Cushioned footwear provided vertical impact attenuation in RFS running, though minimalist footwear demonstrated anterior-posterior and medial-lateral impact attenuation relative to cushioned FFS running. The selection of appropriate footwear is therefore likely dependent on foot-strike pattern. Changes in foot-strike, however, alter impact-loading direction, which likely requires time for adaptation following interactive footwear and foot-strike adjustments.

THE IMMEDIATE EFFECTS OF FOOTSTRIKE LOUDNESS FEEDBACK IN REDUCING IMPACT LOADING IN RUNNERS

INTRODUCTION

Past studies have investigated the use of gait retraining programs aimed at reducing impact loading in runner at risk of tibial stress fractures. In one study, Crowell and Davis [1] attached a hardwired accelerometer to runner's legs to provide them with visual feedback of the tibia shock associated with impact. Runners were also instructed to "run softer" and "make their footfalls quieter". Runners successfully demonstrated a significant reduction in impact forces and tibial shock after 2 weeks of training and 1 month later. One limitation to this method of gait retraining is the cost of the equipment and technical training required to provide the accelerometer feedback.

Verbal instructions related to the sound of impact have been implemented successfully in the retraining of other motor activities, such as jump landings [2]. Recent advances in technology have provided researchers with mobile devices (eg, smart phones and tablets) that are capable of providing objective feedback (eg, decibel levels) via built in microphones. It remains unknown if a simple verbal instruction and external feedback of the loudness of a runner's impact could result in meaningful reductions in impact forces during running. Therefore, the aim of this study was to assess the immediate effects of verbal instructions with and without decibel meter feedback during running on key variables associated with tibial stress fractures [3].

METHODS

A total of 19 recreational runners participated in this study. Participants either received verbal instructions only (VO) or verbal instruction plus decibel meter feedback (V+DM) (Table 1). Each participant met the following criteria: 1) currently running at least 6 miles/week; 2) rearfoot striker; 3) familiar with treadmill running; 4) no known hearing problems; and 5) free of any current lower extremity injuries. The study was approved by the university's IRB and informed consent was obtained from each participant.

Table 1: Mean (SD) for group demographics.

	VO group n=8; 2F/6M	V+DM group n=11; 9F/2M
Age, yr	20.4 (2.1)	24.0 (2.0)
Height, m	1.67 (0.8)	1.74 (0.07)
Weight, kg	59.2 (7.5)	66.9 (9.6)
Running speed, $m*s^{-1}$	2.98 (0.32)	2.93 (0.25)

Participants first performed a 5-minute run on a treadmill to serve as a warm-up and establish their self-selected running speed. Baseline data collection was then performed for over-ground running. Participants ran along a 10m runway landing with the right foot on a 40 X 60cm force plate (sampled at 1200Hz) centered along the runway. Each participant performed 5 good trials at their self-selected running speed. After baseline data collection, participants underwent gait retraining on the treadmill. Participants in the VO group were instructed to "run as quietly as possible". Participants in the V+DM group received continuous decibel meter feedback provided visually via an IPad application (SPLnFFT Sound Meter, version 5.2) and were instructed "to decrease the decibel level as much as possible while trying to run as quietly as possible". Each participant performed the gait retraining for 15 minutes at his or her self-selected speed. After gait retraining, participants performed 5 more acceptable trials of over-ground running at their previously determined speed. Participants were reminded to use the same

running strategy he or she used during gait retraining.

Kinetic variables of interest were identified using a custom LabVIEW program. An independent t-test determined whether there were group differences in running speed. Mixed-model ANOVAs were used to analyze differences in the following variables at baseline and after gait retraining: vertical impact peak (VIP), vertical instantaneous loading rate (VILR), vertical average loading rate (VALR), and vertical propulsion peak (VPP).

RESULTS AND DISCUSSION

No group difference was demonstrated in self-selected running speed. Each mixed-model ANOVA revealed a significant main effect for time for VIP, VILR, and VALR indicating a decrease in magnitude as a result of gait retraining (Table 2). The main effect for group was not statistically significant for VIP, VILR, or VALR. A trend (P=0.07) for VIP interaction effect indicated a greater decrease in the V+DM group compared to the VO group. Percent changes in VIP, VILR, and VALR for the VO group ranged from 10-22%, while percent changes in the same variables for the V+DM ranged from 30-38%. There were no significant main effects or interactions for VPP.

Gait retraining consisting of verbal instructions with and without decibel meter feedback resulted in clinically meaningful changes in variables associated with tibia stress fractures. Based on the percent changes, it appears that the addition of the decibel meter feedback resulted in a greater reduction in vertical impact peaks and vertical loading rates.

Verbal instructions with decibel meter feedback provided via portable devices that many people own may provide clinicians with a simple way to provide gait retraining to runners at risk of tibial stress fracture. It remains unknown if the immediate reductions demonstrated in this study would become permanent. Further research is needed to demonstrate if permanent change (ie, motor learning) would occur with additional training. Further research is also warranted to compare the magnitude of reductions in loading achieved with this method of gait retraining to comparable methods (eg, cadence modification).

THE EFFECT OF HIGHLY CUSHIONED SHOES ON TIBIAL ACCELERATION IN RUNNERS

[1] Matthew C Ruder, [1] Phattarapon Atimetin, [1-2] Steve T Jamison, and [1] Irene Davis

[1] Spaulding National Running Center, PM & R, Harvard Medical School, Cambridge, MA, USA.
[2] University of Delaware, Newark, DE, USA

INTRODUCTION

In stark contrast to the recent trend of minimalist running shoes, highly cushioned shoes have begun to emerge on the running shoe market. These types of shoes have noticeably thicker midsoles, with up to 2.5 times more cushioning than standard running shoes. Manufacturers claim their designs offer more shock attenuation upon impact, thereby reducing injury risk as (Fig. 1a). [1] It has been documented that vertical impact loading and loading rates have been linked to injuries in runners. [2,3] We have previously reported higher vertical ground reaction force loading rates in runners while wearing highly cushioned shoes compared to standard neutral shoes. [4] Ground reaction forces are measured at the shoe-ground interface and may not directly reflect what the leg is experiencing. Therefore, we sought to examine the effect of the additional cushioning on distal tibial accelerations. Based on our previous findings [4], we expected that tibial accelerations would be higher when running in the highly cushioned shoes.

Figure 1: Medial right foot in A) high-cushioned and B) standard shoes. C) Accelerometer coordinate system.

METHODS

7 healthy male runners (age = 32.9±12.3 years, height=1.767±0.040 m, weight=72.58± 12.75 kg) have been recruited, to date, in this ongoing study. All participants had to run at least 10 miles per week in standard running shoes. Prior to data collection, tri-axial accelerometers (IMeasureU, Auckland, NZ) were strapped around the ankles bilaterally. The accelerometer was affixed tightly to the distal medial tibia such that the vertical axis was aligned with the long axis of the tibia (Fig. 1c). A single marker was placed on the lateral aspect of the right foot in order to match the foot to the correct ground reaction force data. Following a 3-minute warm-up period, subjects ran on an instrumented treadmill (AMTI, Watertown, MA) in a standard neutral shoe (SNS; Nike Air Pegasus) at a self-selected speed (mean: 2.61 m/s) and 20 consecutive footstrikes were collected. The process was then repeated in the highly cushioned shoes. (HCS; Hoka One One, Stinson). An 8-camera motion capture system (Vicon, Oxford, UK) recorded both the force (1500 Hz) and marker (250 Hz) data. Acceleration data was collected at 1000 Hz using a trigger from Vicon to start and stop collection.

To ensure accelerometers were on the tibia, they were placed slightly anterior (Fig 1c). This results in the accelerometer's AP and ML axes only being in the vicinity of tibial anatomical AP and ML axes, respectively. Because the accelerometer and anatomical axes are not aligned, results will be reported in the coordinate system of the accelerometer (Acc). The longitudinal axis of the tibia and the vertical axis of the accelerometer (VAcc) were better aligned.

Variables of interest were the peak tibial accelerations in the vertical (VAcc), medial (MAcc), lateral (LAcc) and posterior (PAcc) directions, as well as the resultant acceleration (RAcc). The vertical average loading rates (VALR) was also assessed.

Due to the preliminary nature of these data, only descriptive statistics are being presented. This includes the comparison of means (sd) and percent differences across groups as well as a scatterplot relating VAcc with VALR. A more robust analysis will be performed once the study is complete.

RESULTS AND DISCUSSION

The acceleration data for two of the subjects exceeded the maximum range of the accelerometer (16G) thereby clipping the signal. One subject exceeded this in both their neutral and highly

cushioned shoe conditions, the other in just their highly cushioned shoe condition. Therefore, these two subjects were excluded, leaving 5 subjects for analysis. The three components of the tibial acceleration from a representative participant are seen in Figure 2. The vertical component is the largest, followed by the anterior, then medial.
Figure 2: Representative acceleration signals in the vertical, mediolateral and anteroposterior directions.

All acceleration variables were greater in the HCS on average (Fig. 3). Variables ranged between 8.1 and 24.3% higher in the HCS.
Figure 3: Comparison of peak tibial accelerations in the SNS and HCS.

It might be argued that the additional cushioning in the highly cushioned shoes should reduce the shock experienced by the lower extremity. However, it has been shown that individuals tend to stiffen their leg when landing on soft surfaces [5]. A stiffer leg during landing is not likely to attenuate shock as well as a compliant one. This will result in greater shock experienced by the leg.

The association between the VAcc and the VALR can be seen in Figure 4. While these data are preliminary, this plot suggests there may be a moderate relationship between these variables. If this is confirmed with additional data, measurement

of VAcc may be a good surrogate for VALR. This can be extremely useful in the clinic when a force plate is not available or when monitoring of vertical loading during running in the community is desired.
Figure 4: Correlation between peak VAcc and Vertical Average Loading rate with confidence intervals.

Because kinematics were not yet available for this investigation, it is not known how gait patterns differ between the two conditions. It is also important to note that the subjects in this study were not habituated to running in highly cushioned shoes. Therefore, these results may not represent those of runners who are habituated to this footwear. We are currently collecting data on these runners as well.

CONCLUSIONS

These preliminary results suggest that running in highly cushioned running shoes results in increased tibial shock compared with a standard neutral shoe.

SUBJECT-SPECIFIC TIBIAL STRESSES DURING SHOD AND BAREFOOT RUNNING

[1] Elizabeth R. Boyer and [1] Tim R. Derrick

[1] Iowa State University, Ames, IA, USA

email: ehageman@iastate.edu, web: http:// http://www.kin.hs.iastate.edu/

INTRODUCTION

Our purpose was to compare distal tibia bone stresses in habitual rearfoot strikers (hRF) and habitual mid/forefoot strikers (hFF) during 1) shod rearfoot striking (RF), 2) shod mid/forefoot striking (M/FF), and 3) barefoot M/FF (BF). The secondary purpose was to see if these stresses decrease with an 8% shorter stride length.

METHODS

Recreational/competitive runners age 18-35 were recruited (Table 1). Participants ran overground at 3.5 m/s (±3%). Preferred stride length (PSL) was determined while participants ran on the treadmill at 3.5 m/s. They then performed 6 overground conditions: 1) shod RF at PSL, 2) shod M/FF at PSL, 3) BF at PSL, 4) shod RF at -8%PSL, 5) shod M/FF at -8%PSL, 6) BF at -8%PSL. Force platform data were collected at 1000 Hz and marker positions at 200 Hz.

A 2-mm thickness CT scan was obtained for each participant's right leg 1/3 of the way from the ankle to the knee. This location was chosen because it is a common site for stress fractures [1]. Based on the relationship between the Hounsfield scale and apparent bone density, the elastic modulus of all elements was determined from the CT image. Joint reaction forces and moments were combined with muscle forces (estimated using static optimization) to calculate joint contact forces. Forces and moments acting at the level of the CT scan were estimated and used as inputs to a finite element mesh to estimate bone stresses [2]. Peak compressive (C), tensile (T), and shear (S) stresses during stance phase were the dependent variables.

Data were analyzed with a repeated measures MANOVA ($2 \times 3 \times 2$) (group $\times$ run style $\times$ SL). Significance was assessed at $\alpha < 0.05$.

RESULTS AND DISCUSSION

Five hRF and 6 hFF have completed the study. Groups did not significantly differ based on age, height, mass, BMI, or weekly mileage (all p>0.37).

The three-way interaction was not significant (p=0.252), nor was group $\times$ SL (p=0.225), SL $\times$ run style (0.419), or group $\times$ run style (p=0.389). There was not a main effect for group (p=0.295), and SL bordered on significance (p=0.089). Run style was significant (p=0.002). Data are shown in Figure 1 and Table 2.
Figure 1. Peak stresses for the PSL condition Significant differences are indicated by the *.

Both peak C and T stresses were larger for the shod M/FF condition relative to RF, but not different for the other pairwise comparisons. Our data agree with the trends previously observed [3].

The highest C stress consistently occurred in the posteromedial quadrant, which agrees with the location stress fractures most commonly occur in

runners [1]. Tensile stresses were highest in the anterolateral quadrant.

The greater work performed by the plantarflexors during M/FF and BF likely resulted in the greater tibial stresses at the cross-section of interest. Like Altman and Davis [3] hypothesized, perhaps shod M/FF compressive stress was larger than BF because a larger plantarflexion angle is needed to accommodate the shoe midsole. Interestingly, peak plantarflexion moment was greatest for BF (RF: -0.271±0.25, M/FF: -0.322±0.28, BF: -0.333±0.32 BW*m), but that did not equate to the largest stresses. Perhaps the larger vertical knee reaction forces for M/FF v. BF (2.09±0.17 v. 2.04±0.14 BW, p=0.034) partially explains the differences.

It has been suggested that decreased loads during BF running are primarily due to a shorter SL [4]. Since we controlled for SL, the differences observed in tibial stresses seem to be due to foot strike/footwear. An 8% shorter SL did not significantly decrease peak compressive stress (1.4%, p=0.305) but decreased peak tensile stress ~2.1% (p=0.062) and peak shear stress ~7.0% (p=0.015) across the 3 running styles. While these decreases seem small, because of the exponential association between stress magnitude and cycles to failure in bone [5], use of a shorter SL may significantly decrease bony injury risk.

Our peak tibial stresses are relatively high compared to the literature. As such, the relative differences are more important than the absolute stress values.

CONCLUSIONS

Peak T and C tibial stresses are greatest during shod M/FF. Runners choosing to switch to this M/FF running should do so gradually to allow adequate time for bones to adapt to the higher stresses to help avoid injury. An 8% shorter stride length only minimally decreases peak stresses.

FREQUENCY CONTENT OF THE VERTICAL IMPACT PEAK DURING REARFOOT AND FOREFOOT RUNNING

[1]Allison H. Gruber, [2]W. Brent Edwards, [3]Joseph Hamill

[1]Biomechanics Laboratory, Indiana University Bloomington, Bloomington, IN, USA
[2]Human Performance Laboratory, University of Calgary, Calgary, AB, CAN
[3]Biomechanics Laboratory, University of Massachusetts Amherst, Amherst, MA, USA
email: ahgruber@indiana.edu

INTRODUCTION

The wavelet transform has been used to evaluate the frequency content of various biological signals such as heart rate [e.g. 1] and vertical ground reaction forces [e.g. 2]. One benefit of the wavelet transform over other frequency analyses is that both time- and frequency-domain information of the signal is maintained. Therefore, wavelet transforms permit examination of specific events within a time series that may lead to improved understanding of the biological significance of such events.

The impact peak within the vertical component of the ground reaction force (GRF) has been suggested to be a major factor in the development of running related overuse injuries. This impact peak is observed in the time-domain during running with the rearfoot (RF) pattern but is blunted or absent when running with a forefoot (FF) pattern. However, a previous study using the continuous wavelet transform identified that the vertical impact peak was present in FF running but was visually obscured in the time-domain by the active peak [3]. Although there are many benefits of the continuous wavelet transform, the frequency component of a time-series event cannot be assigned exactly from the scaling parameter and decisions as to what frequency ranges to examine must me made *a priori*. The discrete wavelet transform, however, does not require *a priori* decisions of the frequency ranges to analyze and may be more accurate at reconstructing finite, non-periodic, and non-stationary signals compared with the Fourier and continuous wavelet transforms. The purpose of the present study was to compare the frequency components within the vertical GRF impact peak between RF and FF running using the discrete wavelet transform. This analysis may provide greater insight to the potential biological significance of this event between footfall patterns.

METHODS

Twenty habitual RF runners (males/females 13/7; age 26±6 yrs; height 1.8±0.1 m; mass 69.9±9.8 kg) and twenty habitual FF runners (males/females 15/5; age 25±6 yrs; height 1.8±0.1 m; mass 70.3±10.6 kg) participated after given written informed consent. Participants ran over a force platform (1200 Hz) that was located in the center of a 20 m runway. Participants ran with their habitual footfall pattern at a standardized speed ($3.5 m \cdot s^{-1} \pm 5\%$). Raw vertical GRFs during the stance phase were processed with the discrete wavelet transform (DWT) for levels 1–6 using the discrete Meyer mother wavelet. Each level acted similarly to a band-pass filter with different cut-off frequencies. The 'approximates' comprised the filtered reconstruction of the original signal in the time-domain. The 'details' comprised the frequency components of the original signal that were filtered out then reconstructed in the time-domain. The Hilbert transform was performed on the details to determine signal amplitude [1]. The impulse of the signal amplitude of the details (ImpA) was calculated by numeric integration with respect to time. Differences in signal impulse at each level between groups was assessed with a student's t-test ($\alpha=0.01$).

The range of frequencies contained within the details of each level were determined by performing the DWT analysis on a chirp function which linearly increased in frequency from 0–80 Hz in 0.23 s. This frequency range and time equated to the range of frequencies that contain 98% of the power in the vertical GRF and the average stance time of all trials performed by the participants (0.23±0.02 s).

RESULTS AND DISCUSSION

Levels 4–6 caused some attenuation of the impact peak compared with the original signal (Fig. 1, column 1). The signal details of these levels show a prominent impact peak in both footfall patterns (Fig. 1, column 2). Compared with the other levels, RF running resulted in a greater impact peak magnitude at level 5 (Fig. 1, column 2) but greater ImpA at level 6 (Table 1). FF running resulted in a greater impact peak and ImpA at level 6 compared with the other levels (Fig. 1, Table 1).

ImpA was not different between RF and FF running at levels 1–2 (Table 1). RF running resulted in significantly greater ImpA than FF running for levels 4 and 5, indicating greater vertical GRF signal power of frequencies between 20–80 Hz ($P>0.000$). FF running resulted in greater ImpA than RF running for levels 3 and 6 ($P>0.000$). ImpA at level 3 was less than 1 Ns for both footfall patterns and thus the statistical difference at this level may not be biologically meaningful. The largest difference in ImpA between patterns was observed at level 5 representing frequencies 20–37 Hz.

CONCLUSIONS

The DWT identified that the RF and FF patterns contain a vertical impact peak that may have a primary frequency content of 9–20 Hz for both patterns. Due to the limitations of the DWT, some of the power in this frequency band may be attributed to the active peak. Future studies should separate the impact peak from the active peak before calculating time domain variables such as vertical loading rate.

EFFORT-O-METER: THE RELATIONSHIP BETWEEN EFFORT OF WALKING AND AMOUNT OF WALKING PERFORMED

[1] Mailing Wu, [2] Peter Adamczyk, and [1] Steve Collins

[1] Carnegie Mellon University, Pittsburgh, PA, USA
[2] Intelligent Prosthesis Systems, LLC, Ann Arbor, MI, USA
email: mailingwu@cmu.edu

INTRODUCTION

Walking is an effective method for promoting activity among sedentary groups, and people adhere to walking routines more than other, more vigorous exercise regimens [1, 2]. Slightly increasing the metabolic cost of walking could be a simple method of increasing overall physical activity in the overweight or obese. However, while increasing the energy cost per step would increase net metabolic cost if all conditions (distances, velocities, etc.) were kept constant, this benefit could be reduced or eliminated if the subject reduces overall activity due to the higher cost.

We explored whether a modest increase in energy cost per step affected overall energy consumption from walking over a one week period compared to normal walking energy expenditure. We hypothesized that even a small increase in energy cost per step would cause the amount of walking performed to be reduced so dramatically that the overall energy cost would be decreased. The results of this study not only have implications for prescribing exercise regimens to improve public health and promote weight loss, but also help understand the expected impact of energy-saving prostheses and orthoses on exercise obtained during walking.

METHODS

Two pairs of sneakers were constructed: one pair weighted and one pair unweighted. A platform was attached to the sole to house an inertial monitoring unit (Sapphire Inertial Monitor, APDM, Inc.) and weight, if applicable. A steel bar was used to generate the appropriate mass, which was calibrated to equal approximately 2.5% of the user's body weight. The total load was expected to correspond to roughly a 25% energy increase per step in the user [3].

24 able-bodied participants with no major health concerns were recruited at Carnegie Mellon University. Five voluntarily withdrew before completion of the protocol due to discomfort while wearing the shoes, especially the weighted shoes. An additional nine had unusable data for a variety of reasons, including not wearing the shoes for more than 12 hours per day, large periods of unexplained time (> 4 hours) spent with the shoes off, and changing environmental conditions between the two weeks.

The remaining subjects (n=10, 7 male, 3 female, 23.60 ± 2.88 years, 22.86 ± 2.52 kg/m^2 body mass index) were asked to wear both shoes all day except when sleeping or bathing for one week each. Additional activities that required the use of other shoes or no shoes (running, swimming, etc.) were logged and kept consistent between the two weeks to minimize misrepresentations in total energy costs. Subjects were not informed of the exact nature of the data being collected and motivation behind the study to minimize data biases due to conscious decisions to alter walking behavior. Study protocol was approved by the Carnegie Mellon University Institutional Review Board, and written informed consent was obtained from all subjects after the nature and possible consequences of the study were explained.

At the completion of the community-based collection, the participant answered a survey regarding the shoes (Fig. 1). Subjects then walked on a treadmill wearing each pair of shoes at various speeds and grades while oxygen consumption was measured using an indirect respirometry system (Jaeger Oxycon Mobile).
Figure 1: Survey results from all participants showing strong dislike of the heavy shoes. Asterisks denote a significant difference.

Data from the inertial monitor was numerically integrated [4] using IMUWalk software (Intelligent Prosthetic Systems, LLC) to estimate foot placement and timestamps for each step. Subjects' metabolic power data was used in conjunction with the processed monitor data to determine total metabolic cost while wearing the shoes. A paired t-test was used to determine statistical significance at 95% CI.

RESULTS AND DISCUSSION
The shoes were worn for at least 12 hours per day (14.25 ± 1.32 hours unweighted, 13.95 ± 0.97 hours weighted) and no significant difference in times ($p = 0.22$). The weighted shoes created a $27.1\pm16.4\%$ increase in metabolic rate while walking at 1.25 m/s on level ground.

Increasing metabolic cost of walking caused acute discomfort in users. Survey results (Fig. 1) revealed participants strongly disliked wearing the weighted shoes ($p < 0.001$), and found them much more tiring ($p < 0.01$).

Despite their dislike of the shoes, participants maintained the same distance walked per day ($p = 0.91$) and number of strides per day ($p = 0.87$), with no change in average velocity ($p = 0.98$), resulting in a significant increase in total energy cost when wearing the weighted shoes compared to the unweighted shoes ($6,739\pm5,576$ J/kg/day in unweighted, $8,058\pm6,152$ J/kg/day in weighted, $p = 0.002$) (Fig. 2). Indeed, all but one subject had increased energy expenditure in the weighted shoes despite large differences in baseline energy use.
Figure 2: Average values for energy cost, distance traveled, and strides/day. Asterisks denote a significant difference.

Ultimately, our hypothesis was incorrect; subjects did not significantly change their behavior when presented with high-effort shoes. However, more extreme behavioral changes may appear over longer periods of time. Poor protocol adherence was major problem among our subjects, largely due to the discomfort of the weighted shoes, an effect which may be compounded in the long term. More study is needed among clinically overweight and obese individuals who lead sedentary lifestyles.

BIOMECHANICAL DETERMINANTS OF MUSCLE METABOLIC ENERGY CONSUMPTION IN LOCOMOTION

Russell T. Johnson and Brian R. Umberger

University of Massachusetts Amherst, Amherst, MA, USA
email: russellj@kin.umass.edu, web: http://www.umass.edu/locomotion

INTRODUCTION

Individuals tend to walk at a speed that minimizes the metabolic energy consumption per unit distance. Within a speed, individuals self-select a stride frequency (SF) that minimizes the energy cost for that particular speed [1]. It remains unclear exactly why metabolic energy is minimized at the preferred SF. A better understanding of the factors that determine the cost of locomotion would shed light on this issue. Two different hypotheses have been proposed regarding the biomechanical determinants of the metabolic cost of locomotion. One hypothesis states that the mechanical work done by the muscles is the primary determinant of the metabolic cost [1]. The other hypothesis states that the metabolic cost of locomotion is determined by the magnitude and rate of muscle force generation [2]. Since force and work are not completely independent, another possibility is that both are important determinants of locomotor costs.

A U-shaped relationship between metabolic energy and SF has been well established in whole body studies [1]. However, the nature of the relationships for individual muscle groups is unknown. Energy consumption cannot easily be measured in individual muscles while human subjects are walking. However, using a computer modeling approach [3] it is possible to estimate the metabolic energy consumed by individual muscles during walking. We focused on the triceps surae muscles for this study due to the relative simplicity of the ankle plantar flexors and the important role they play in locomotion. The specific purpose of this study was to examine the relationships among metabolic energy consumption, mechanical work and rate of force generation during walking in the triceps surae muscle group.

METHODS

Data were collected for five able-bodied male (n=3) and female subjects [age = 25±1.8 years, height = 1.74±.08 m, mass = 77.1±12.7 kg]. The subjects provided written informed consent before participating in the study. Three dimensional kinematic and kinetic data were collected using a motion capture system as subjects walked overground at their preferred SF (PSF), and at frequencies 20% greater (+20% SF) and 20% less (-20% SF) than preferred. Subjects matched their SF to the beat of a metronome. Five trials were collected for each subject at each SF.

Lower limb joint angles and joint moments were calculated in OpenSim [4]. Static optimization was performed for each trial using a musculoskeletal model with 23 degrees of freedom and 92 muscle actuators to obtain estimates of the individual muscle forces. OpenSim was also used to obtain estimates of the instantaneous muscle-tendon lengths over the stride. The muscle-tendon length and muscle force data were averaged across trials and subjects for each SF, and then analyzed using a custom MATLAB program to calculate muscle mechanic and metabolic variables [3].

Muscle metabolic power was plotted versus average positive mechanical power and versus the rate of force generation for the triceps surae muscles. We predicted that if either mechanical power or rate of force generation was a strong determinant of the cost, then there would be a linear trend with metabolic cost. However, given the nature of the data, correlation coefficients were not calculated.

RESULTS AND DISCUSSION

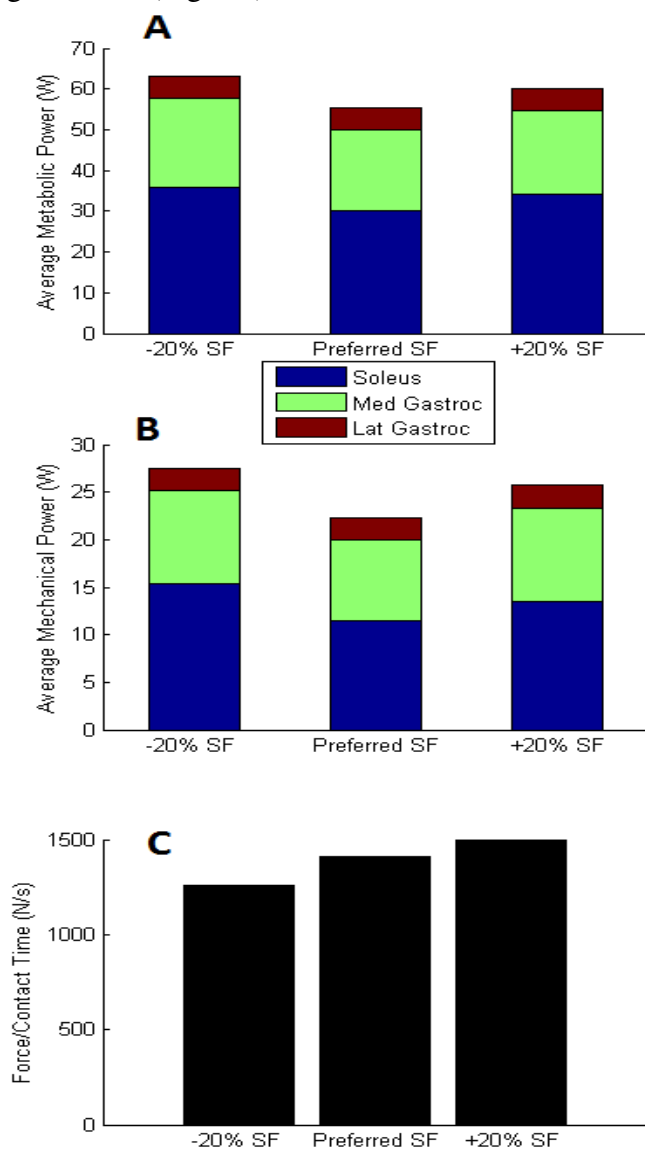
The triceps surae metabolic power was lowest at the PSF and highest at the -20% SF (Fig. 1A), consistent with whole-body results [1]. Mechanical power followed a similar trend (Fig. 1B), resulting in a linear dependence of metabolic power on mechanical power (Fig. 2A). The rate of force generation was greater at higher SFs (Fig. 1C). The average triceps surae force was similar across SFs, so the trend was due almost entirely to the smaller ground contact times at higher SFs. There was no clear relationship between muscle metabolic power and rate of force generation (Fig. 2B).


Figure 1: A: metabolic power vs. stride frequency, B: positive mechanical power vs. stride frequency, C: rate of force vs. stride frequency.
Figure 2: A: metabolic power vs. mechanical power. B: metabolic power vs. rate of force generation.

CONCLUSIONS

The demand to generate mechanical power appears to be the primary biomechanical determinant of the metabolic cost incurred by the triceps surae in human walking. In future research, we will extend the present analyses to include other major muscle groups of the lower limb.

IS THE FOOT WORKING WITH OR AGAINST THE ANKLE DURING HUMAN WALKING?

[1] Karl E. Zelik

[1] Vanderbilt University, Nashville, TN, USA
email: karl.zelik@vanderbilt.edu, web: my.vanderbilt.edu/batlab/

INTRODUCTION

The muscles and tendons acting about the ankle joint perform a critical Push-off function that facilitates economical human gait. This ankle Push-off, due in part to elastic recoil of the Achilles tendon, is primarily transmitted upward along the leg to the rest of the body, and helps to redirect the body's center-of-mass during step-to-step transitions in walking. However, biomechanical estimates indicate that the foot dissipates substantial energy during this Push-off phase of gait. This foot energy absorption detracts from the positive ankle Push-off work, and may therefore undermine the power transferred to the rest of the body and the energetic benefits of the Achilles tendon, potentially degrading gait economy. From a basic science perspective the foot's behavior is perplexing. From a translational science perspective, it is unclear if prosthetic feet should be designed to mimic this dissipative foot behavior, or if non-biomimetic prostheses might instead improve gait beyond natural capabilities. These unresolved questions motivated our recent studies of foot function. The purpose of this research abstract is threefold:
1. To summarize our recent work on the coordination of foot muscles during gait
2. To review our recent findings on foot kinetics within the context of prior experimental and theoretical research
3. To discuss various plausible explanations for the seemingly wasteful foot behavior, and its interplay with the ankle during walking

METHODS

We performed two studies of healthy human walking. The first investigated the coordination of intrinsic and extrinsic foot muscles [1], and the second quantified foot and lower-limb joint kinetics during gait [2]. Experiment 1: We analyzed surface electromyographic (EMG) recordings of 11 foot muscles in healthy individuals during level treadmill walking at 1.1 m/s (3 males, 4 females, 25.9 ± 2.7, years old, 1.76 ± 0.11 m, 74 ± 16 kg). Experiment 2: We analyzed 6 degree-of-freedom (6DOF) foot kinetics, in conjunction with 6DOF ankle, knee and hip kinetics during human gait (7 males, 3 females, 24 ± 2.5 years old, 1.76 ± 0.11 m, 73.5 ± 15 kg). We computed power due to compression and rotation of the foot (and shoe), using a deformable body model [3] to account for the foot's many internal degrees of freedom (e.g., metatarsophalangeal (MTP) joints, heel pad, arch).

RESULTS AND DISCUSSION

We found that groups of intrinsic and extrinsic foot muscles exhibited peak activations in a consistent progression during forward walking. The period around Push-off could be roughly characterized by sequential peak muscle activity from the ankle plantarflexors, MTP flexors, then MTP extensors and finally ankle dorsiflexors (Fig. 1). Functionally, this muscle activation sequence represents torque contributions to ankle plantarflexion Push-off, followed by an MTP flexion moment near terminal stance phase. MTP flexor activity has been suggested to support/stabilize the foot arch, but these muscle-tendon units may also perform negative work against the extending toe joint, contributing to energy absorption in the foot.

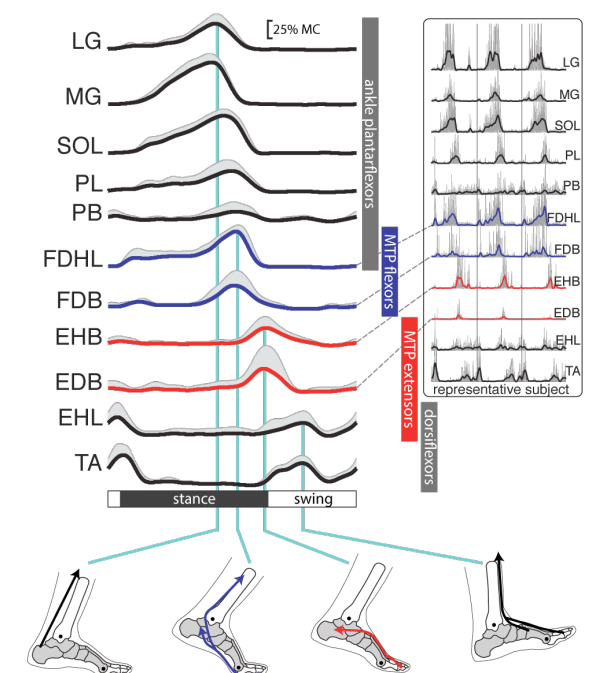
We estimated ankle Push-off work to be approximately 23 J at 1.4 m/s (Fig. 2). However, we also found about -6 J of simultaneous work done by the foot, similar to previous studies (e.g., [4]). The magnitude of foot work during Push-off was comparable to the simultaneous work performed about the knee joint, indicating that foot contributions should not be neglected in understanding whole-body gait dynamics.


Figure 1: Foot muscle EMGs during walking [1]. Lateral (LG) & medial (MG) gastroc., soleus (SOL), peroneus longus (PL) & brevis (PB), flexor dig./hal. longus (FDHL), flexor dig. brevis (FDB), extensor hal. (EHB) & dig. brevis (EDB), extensor hal. longus (EHL), tibialis anterior (TA). EMG is depicted as percent of maximum contraction (MC).

We observed evidence that substantial energy is absorbed during the Push-off phase of walking, which may be due in part to negative muscle-tendon work as the toes extend in late stance. This foot behavior may subvert the energy-saving benefits of Achilles tendon recoil and ankle Push-off during walking. Several plausible explanations exist for this observed phenomenon:

I. The foot is working *against* the ankle… One possibility is that the foot absorbs substantial energy through deformation and rotation of structures within the foot/shoe, and that this dissipation is indeed detrimental to level-ground walking economy [5]. However, perhaps this foot behavior is useful for other reasons (e.g., balance, adaptability, non-level terrains), and it would be valuable to further explore functional trade-offs.

II. The foot is working *with* the ankle, indirectly… Another possibility is that the foot absorption is beneficial to gait economy, albeit indirectly; for example, by facilitating economical

force production of the calf muscles [6], or contributing to arch support during gait.

III. The foot is working *with* the ankle, but our conventional biomechanical estimates fail to capture it… Yet another possibility, and one that has received little attention, is that the foot may not absorb as much energy as it presently appears. Methodological limitations might result in over-estimating the magnitude of negative foot work, and failing to capture positive work performed by structures within the foot and shoe. For instance, apparent foot dissipation may be due to limitations in conventional biomechanical estimates, which fail to account for multiarticular muscle contributions.
Figure 2: Ankle Push-off may be undermined by energy dissipation in the foot during walking [2].

In summary, we present recent findings on foot muscle coordination and kinetics, and propose several potential explanations for the peculiar foot behavior observed during the Push-off phase of walking. Additional studies are needed to discern these various explanations of foot function during gait, which have implications for prosthetic foot design, walking simulations and our fundamental understanding of bipedal locomotion.

A KINEMATIC AND ENERGETICS MODEL OF SHANK PROGRESSION DURING STANCE

Travis R. Pollen, Elisa S. Arch, Steven J. Stanhope

University of Delaware, Newark, DE, USA
email: trpollen@udel.edu, web: http://www.udel.edu/bioms

INTRODUCTION

Individuals with transtibial amputations depend on prosthetic ankle-feet to ambulate. However, due to the design of modern devices, analyzing prosthetic systems using traditional methods like inverse dynamics proves challenging [1]. As a result, appropriate characterization of prosthetic ankle-foot function and, subsequently, objective guidelines for the prescription and customization of these systems are lacking. Component selection depends on the prosthetist's training and intuition. Roll-over shape, the geometry the ankle-foot conforms to during the stance phase of gait, has been proposed as an improved characterization method [2]. While useful, roll-over shape fails to account for the period of late stance during which propulsion occurs.

The kinematics (rotation and translation) and energetics (flow of segmental power) of shank progression may provide a more complete description of ankle-foot function. The purpose of this study was to quantify and model the kinematics and energetics of shank progression over the stance phase of typical gait.

METHODS

Analyses were performed on ten typical adult participants (age 20-29, height 1.63-1.84 m, body mass 59.5-86.5 kg) who completed barefoot overground instrumented gait analysis at a scaled normal walking velocity (0.8 statures/second). Kinematic data were tracked using a 6 degrees-of-freedom marker set and sampled at 240 Hz using a six-camera motion capture system (Motion Analysis Corp. Santa Rosa, CA). Kinetic data were sampled at 1200 Hz using a strain gauge force platform (AMTI, Watertown, MA). Kinematic and kinetic data were filtered at 6 Hz and 25 Hz, respectively, using Visual3D software (C-Motion, Inc.,

Germantown, MD). From these data, kinematic and energetics models of shank progression were developed. The models were evaluated by comparing model predictions to shank progression quantified from the ten participants.

RESULTS AND DISCUSSION

A kinematic model (Fig. 1) was developed to predict stance phase ankle and knee joint center anterior-posterior (y) and superior-inferior (z) positions in the laboratory coordinate system:

$$y_{ankle} = y_{MH2} - sin(\theta)*L_{foot} \qquad (1)$$
$$z_{ankle} = z_{MH2} + cos(\theta)*L_{foot} \qquad (2)$$
$$y_{knee} = y_{ankle} - sin(\theta_0 - \varphi)*L_{shank} \qquad (3)$$
$$z_{knee} = z_{ankle} + cos(\theta_0 - \varphi)*L_{shank} \qquad (4)$$

where L_{foot} and L_{shank} are the lengths of the foot and shank; $MH2$ is the position of the second metatarsal head; θ is the foot-to-floor angle; θ_0 is the foot-to-floor angle normalized to $0°$ in the static pose; φ is the ankle (shank-to-foot) angle; and $\theta_0 - \varphi$ is the shank angle relative to the z-axis of the lab. Model-based and motion-capture derived positions were all strongly correlated ($R^2 > .98$).
Figure 1: Kinematic model of shank progression in the laboratory sagittal plane.

Model-based and motion capture derived shank angles were also strongly correlated ($R^2 = 0.999$), and the contributions of the ankle and foot-to-floor angles to shank angle were determined (Table 1). Using the model, it was determined that foot-to-floor motion produces the forward rotation of the shank during late stance, while ankle plantar flexion produces the trajectory of the knee joint center necessary for forward propulsion.

A sagittal plane energetics model of shank progression during stance was also developed as per Robertson & Winter [3]. Net segmental power of the shank (P_{shank}) was calculated as the sum of the proximal muscle power (P_{pm}), proximal joint force power (P_{pj}), distal muscle power (P_{dm}), and distal joint force power (P_{dj}) of the shank:

$$P_{shank} = P_{pm} + P_{pj} + P_{dm} + P_{dj} \quad (5)$$
$$= M_{proximal} \bullet \omega_{shank} + F_{proximal} \bullet v_{proximal}$$
$$+ M_{distal} \bullet \omega_{shank} + F_{distal} \bullet v_{distal}$$

$M_{proximal}$ and M_{distal} correspond to the moments applied to the shank about the medio-lateral x-axis at the proximal and distance ends; $F_{proximal}$ and F_{distal} to the joint reaction forces applied to the proximal and distal ends of the shank; $v_{proximal}$ and v_{distal} to the translational velocities of the proximal and distal ends of the shank; and ω_{shank} to the angular velocity of the shank about the x-axis. Analogous calculations were made for the foot.

Mean scaled peak ankle power for the 10 participants occurred at 89% of stance. At this point in stance, the ankle plantar flexors were generating power through the active muscle terms, and the shank received 6.12 W/kg of power via the distal joint force segmental power term (Fig. 2). A small amount of energy (1.62 W/kg) left the foot distally via the joint force power term.
Figure 2: Dynamics of energy flow at peak ankle power (89% of stance). The shank received 6.12 W/kg of power via joint force power.

CONCLUSIONS

The kinematic and energetics shank progression models capture ankle-foot function during the entire stance phase of gait more completely than other methods, like roll-over shape. This study reveals the interrelationships between the ankle, foot-to-floor, and shank angles, as well as the dynamics of energy flow into the shank via the distal joint force segmental power term. These results can be used in the future to design novel prosthetic ankle-foot systems that better mimic natural shank progression, which may lead to improved functional outcomes for individuals with transtibial amputation.

Asymmetric Forces Increase the Metabolic Cost of Running for Individuals with a Unilateral Leg Amputation

[1]Owen N. Beck, [1]Paolo Taboga, and [1,2]Alena M. Grabowski

[1]University of Colorado, Boulder, CO, USA; [2]VA Eastern Colorado Healthcare System, Denver, CO, USA
email: owen.beck@colorado.edu

INTRODUCTION

Asymmetrical step lengths and step frequencies are associated with an elevated metabolic cost of locomotion [1]. Runners with a unilateral transtibial amputation using running-specific prostheses (RSPs) exhibit asymmetric ground reaction forces (GRFs), contact times (t_c), step lengths, step frequencies, and leg stiffness (k_{leg}) over a range of running speeds [2, 3]. Furthermore, a study of two runners with unilateral transtibial amputations using RSPs showed that changes in RSP stiffness (±0.5 category) and height (±1.27 cm) resulted in altered GRF and kinematic asymmetry between the affected leg (AL) and unaffected leg (UL) [4]. However, it is uncertain how asymmetric GRFs and stride kinematics affect the metabolic cost of runners with leg amputations. Therefore, we compared amputee runners using RSPs that varied by model, stiffness category, and height while measuring metabolic cost, GRFs, stride kinematics, and k_{leg}. We hypothesized that more symmetric vertical GRFs and stride kinematics would lower the metabolic cost of running for individuals with a unilateral leg amputation.

METHODS

Nine runners with unilateral transtibial amputations (7 M; 2 F) gave written informed consent to participate. Subjects were fit with three different RSP models (RSP1, RSP2, and RSP3) at the manufacturer recommended and ±1 stiffness categories by a certified prosthetist. Next, the prosthetist aligned each RSP at the manufacturer recommended height and ±2 cm.

On subsequent days, subjects performed 5 min running trials on a force-instrumented treadmill. Subjects ran 3 m·s⁻¹ unless they were unable to maintain primarily oxidative metabolism, denoted by a RER ≥1.0, in which case they ran 2.5 m·s⁻¹. Each subject ran using 15 different combinations of RSP model, stiffness category, and height. Initially, subjects ran using each RSP model at the 3 different stiffness categories with the recommended height. The stiffness category for each RSP model that required the lowest metabolic cost of transport (CoT) was deemed optimal. Subsequently, subjects ran with the optimal stiffness category of each model at heights of ±2 cm. All trials were randomized.

We measured metabolic energy expenditure using indirect calorimetry to calculate the average net metabolic power during the last 2 min of each trial using a standard equation [4]. Then, we converted average net metabolic power to work and divided by the product of mass and running speed to yield CoT in J/kg/m.

We measured GRFs from 10 consecutive strides during each trial (1000 Hz) and processed the data using a custom MATLAB script. We defined asymmetry as:

$$\frac{UL - AL}{0.5(UL + AL)}$$

and reported it as a percentage [5]. We used a statistical linear mixed model to test the associations between RSP model, stiffness category, and height on CoT. Next, we determined the associations between peak vertical GRF, step length, step frequency, t_c, and k_{leg} asymmetries on the CoT using the same statistical method.

RESULTS AND DISCUSSION

While controlling for other variables, across all conditions, RSP3 elicited a 5.2 and 4.2% lower CoT than RSP1 and RSP2, respectively (p<0.01) (Fig. 1). The CoT elicited from using RSP1 and RSP2 were similar (p=0.27). Across RSP models, stiffness category had no effect on CoT (p=0.54) (Fig. 1), whereas decreased RSP height was associated with a lower CoT (p=0.02). For every 2 cm reduction in RSP height, CoT decreased by 1.3% (Fig. 2).
Figure 1. Average (±SEM) net metabolic cost of transport (CoT) while using three RSP models with the recommended stiffness category (Rec C) and ±1C at the recommended height.

Consistent with previous research, subjects exhibited lower peak vertical GRFs, longer t_c, and lower k_{leg} with their AL compared to their UL ($p<0.01$) (Table 1). Yet, CoT was independent of step length, step frequency, t_c, and k_{leg} asymmetries ($p \geq 0.30$). Peak vertical GRF asymmetries were associated with higher (worse) CoT ($p<0.01$). For example, across all conditions our subjects generated 14% lower peak vertical GRFs with their AL compared to their UL ($p<0.01$). If their legs had produced symmetric peak vertical GRFs, CoT would have decreased by 2.7%. Interestingly, when legs were compared separately, CoT was independent of the AL peak vertical GRF ($p=0.18$), yet was higher with increases in UL peak vertical GRF ($p<0.01$).

Practical implications from our study are that shortening RSP height and reducing peak vertical GRF asymmetries by lowering UL peak GRFs may reduce the metabolic cost of running for individuals with a unilateral transtibial amputation.
Figure 2. Average (±SEM) net metabolic cost of transport (CoT) using three RSP models with the optimal stiffness categories at the recommended height (Rec Ht) and ±2 cm. The dashed line is the regression line (CoT = 4.00 + 0.03 × ΔRSP Ht).

INTRODUCTION

Strength and performance symmetry are common benchmarks for rehabilitation and readiness for return to sport after anterior cruciate ligament (ACL) reconstruction. However, movement symmetry is less frequently used in clinical decision-making. Asymmetries in movement patterns and decreases in external moments on the involved limb are frequently reported in ACL-reconstructed subjects. [1] Identification of such asymmetries usually requires complex, costly motion analysis equipment that may not be available clinically. Avoidance strategies should be mitigated to reduce the likelihood of developing strong limb preferences, and to create the optimal scenario for safe return to sport after ACL reconstruction. [2] The goals of this study were to: 1) Identify ACL-reconstructed patients who exhibit under-loading [lower peak vertical ground reaction force (vGRF)] of the injured limb during the drop vertical jump (DVJ) test, and 2) identify the kinematic strategies that characterize under-loading to guide clinical evaluations of biomechanical symmetry. The hypothesis tested was that patients who demonstrated decreased peak vGRF on the involved limb would also demonstrate significant kinematic asymmetries.

METHODS

Twenty-five ACL-reconstructed patients (12 males and 13 females, 19.6±7.2 years old) were evaluated upon discharge from supervised rehabilitation. Patients performed three successful trials of a drop vertical jump (DVJ) in the capture volume following several practice repetitions to ensure consistency in performance. The DVJ task involves a bilateral drop from a 31 cm high box, followed directly by a maximum effort vertical jump. Patients were specifically instructed to leave the box with both feet simultaneously, to avoid any asymmetry in landing due to stepping off with one leg first. The contact phase of the DVJ task was normalized so that initial contact occurred at 0% of the contact phase, and takeoff occurred at 100%. Hip, ankle, and knee joint angles in all three anatomical planes were calculated in Visual3D. Discrete variables for statistical analysis included joint angles at initial contact, maximum and minimum joint angles, and joint excursions during the landing. Two-by-two (group-by-limb) analysis of variance (ANOVA) models were used for statistical comparisons. *Post-hoc*, two-tailed t-tests were used to compare values between the involved and uninvolved limbs (paired tests) or between groups (unpaired tests).

RESULTS AND DISCUSSION

Eighteen (18/25, 72%) patients were classified as under-loaders (UL), and demonstrated 25±14% lower peak vGRF on the involved limb compared to the uninvolved limb. Under-loaders demonstrated significantly increased hip flexion (UL_Involved: 34.2±7.7 degrees, UL_Uninvolved: 29.8±7.7 degrees; p=0.0001) and knee flexion (UL_Involved: -21.6±8.5 degrees, UL_Uninvolved: -16.2±5.5 degrees; p=0.002) on the involved limb, and a trend toward greater ankle plantar flexion at initial contact compared to subjects who did not under-load (Others, 7/25, 38%) (UL: -46.3±7.0 degrees, Others: -40.7±8.5 degrees; p=0.07). Conversely, in patients who did not under-load the involved extremity, hip and knee flexion at initial contact were greater on the uninvolved limb.

The purpose of this investigation was to assess hip, knee, and ankle kinematic asymmetries during a drop vertical jump task in individuals
Figure 1: Representative sagittal view of a subject at initial contact that exhibited under-loading strategies on the involved limb. Joint flexion values indicated in the figure are actual values from this frame.

following ACL reconstruction and supervised physical therapy. Nearly three quarters (18/25) of our patients demonstrated a lower peak vGRF on the involved limb, with an average 25% reduction in this subgroup of "under-loaders". The primary findings of this study are that under-loaders appear to land with greater ankle plantar flexion compared to patients who do not under-load, and demonstrate significantly asymmetries in hip and knee flexion at initial contact. Specifically, at initial contact patients classified as under-loaders demonstrate greater hip and knee flexion at initial contact on the involved limb (**Figure 1**). The magnitude of asymmetries in sagittal plane knee kinematics in subjects that did not under-load was comparable to the asymmetries observed in under-loaders; however, the off-loading tendencies were observed in the uninvolved limb. While neither of these asymmetries was observed in the "other" (non-

under-loader) group, this may be attributable to the relatively small group sample size.

CONCLUSIONS

We focused on the identification of kinematic strategies that could potentially be observed in a clinical setting, without complex biomechanical analyses. This paper demonstrates residual avoidance patterns in a vast majority of ACL-reconstructed subjects during a common screening task, and identifies movement patterns associated with under-loading the involved limb. Future studies may benefit from identifying patients as 'under-loaders' or 'over-loaders' to identify limbs at increased risk for second injury, or quantify existing deficiencies in movement patterns. Despite discharge from physical therapy, the majority of ACL-reconstructed patients demonstrated under-loading of the surgical limb. Kinematic strategies consistent with under-loading may be identifiable through techniques such as sagittal plane video analysis, particularly during bilateral tasks where the patient may rely on the uninvolved limb.

SAGITTAL PLANE KNEE EXCURSION IS KEY PREDICTOR OF LOWER EXREMITY PERFORMANCE DURING SINGLE LEG HOP

INTRODUCTION

Each year, approximately 125,000 people in the United States require surgical reconstruction of the anterior cruciate ligament (ACL) [1]. Following surgery, most athletes exhibit significant biomechanical and performance-based asymmetries between the injured and uninjured limbs [2]. Clinicians frequently utilize the single leg hop (SLH) for distance and isokinetic quadriceps strength tests to identify residual functional deficits in the ACL-injured population. While biomechanical imbalances are observed between involved and uninvolved limbs during both tasks, the relationship(s) of these deficits to power generation and joint work are unclear [2]. The purpose of this study was to analyze power generation and total joint work in the lower extremities of ACL-reconstructed subjects. We aimed to establish key biomechanical asymmetries during the propulsion phase of a SLH task. In addition, we used clinically-based measures to develop predictive models for total power and work output at the joints.

METHODS

Nineteen (n=19, males n=5, females n=14) ACL-injured subjects cleared for discharge from supervised rehabilitation were included in this study. Peak isokinetic quadriceps strength normalized by body mass was recorded at 60°/s. Three-dimensional (3-D) motion capture data from the propulsion phases of two bilateral SLH trials, and the total distance hopped were analyzed for each subject. The distance hopped was averaged for each limb over the two trials. Kinematics and kinetics at the hip, knee, and ankle were averaged for each limb over the propulsion phase of the two trials. The propulsion phase was operationally defined as the period between peak knee flexion and toe off. The sum of peak sagittal plane hip, knee, and ankle power and peak sagittal plane total joint power were examined. In addition, joint work was determined by Trapezoidal Riemann Summation of hip, knee, and ankle power time series curves. Individual joint work curves were summed to calculate total joint work. Paired t-tests were used to determine limb asymmetries. In addition, multivariate linear regression models were developed to predict power and work output.

RESULTS AND DISCUSSION

Normalized peak isokinetic strength (p-value, uninvolved limb mean ± standard deviation, involved limb mean ± standard deviation; p<0.001, 2.46±0.47 Nm/kg, 2.14±0.51 Nm/kg) and SLH distance (p=0.019, 127.0±28.4 cm, 119.0±32.0 cm) were significantly greater for the uninvolved limb compared to the involved limb. In addition, the uninvolved limb generated statistically greater sum of peak hip, knee, and ankle joint powers (p=0.007, 23.7±6.1 Watt/kg, 21.5±6.8 Watt/kg) and peak total joint power (p=0.012, 17.6±4.1 Watt/kg, 15.7±5.2 Watt/kg). Finally, more total joint work was produced by the uninvolved limb (p=0.008, 1106.1±312.3 J/kg, 985.9±332.3 J/kg).

Sagittal plane knee excursion (KE_{SAG}), defined as the range between peak knee flexion and peak knee extension during SLH propulsion, was significantly greater (p<0.001, 37.8±8.8°, 30.6±9.9°) for the uninvolved limb. KE_{SAG} symmetry ratio (involved/uninvolved) was 0.81±0.14, and 18 of the 19 subjects displayed less knee excursion in the sagittal plane on the involved limb.

Three multivariate linear regression models were constructed with summed peak joint power, peak total joint power, and total joint work as dependent outcome variables. For each model, KE_{SAG} and SLH distance hopped were the independent predictor variables. The adjusted R^2 value for the summed peak joint powers regression model was 0.757 (Figure 1a), and the p-values for KE_{SAG} and SLH distance were <0.001 and 0.002, respectively (Table 1). The model for TJP demonstrated an adjusted R^2 of 0.695 (Figure 1b). The p-values for this model were <0.001 for KE_{SUM}

and 0.042 for SLH distance hopped (Table 1). Finally, the adjusted R^2 value for the total joint work regression model was 0.621, and the p-values for KE_{SAG} and SLH distance were <0.001 and 0.032, respectively (Table 1). Separate models that included peak isokinetic quadriceps strength were performed, but this measure was not statistically significant.
Figure 1. Fit of Power Generation Regression Models: This figure illustrates the fit for the summed peak joints powers [top (a)] and the peak total joint power [bottom (b)] regression models.

This study demonstrates significant performance imbalances between the involved and uninvolved limb. Furthermore, the regression models exhibit good-to-excellent correlation with actual total power and work produced at the joints. Although the kinematic and kinetic imbalances are consistent with outcomes previously reported by Orishimo et al, our models must be validated in an independent data set prior to clinical implementation [2].

While this study shows significant differences between limbs in an injured population, comparison of performance and biomechanical measures to a healthy population has not been performed. In addition, the small sample size and predominantly female cohort may limit the impact of these findings. Therefore, future research should compare power generation and work done between injured and healthy populations. Furthermore, the injured population should be expanded to include more male subjects.

CONCLUSION

The multivariate linear regression models developed for summed peak joint power, peak total joint power, and total joint work indicate that both KE_{SAG} and SLH distance are significant predictors of total power and work output at the joints. Currently, clinicians utilize SLH distance and peak isokinetic quadriceps strength to assess power generation imbalances. However, these models illustrate that differences in KE_{SAG} between limbs during the SLH task should be considered. KE_{SAG} can be measured by sagittal plane reference video recording of SLH tasks. Most clinics are equipped with the hardware and software to calculate KE_{SAG}, so application of this model in a clinical setting is feasible. Therefore, measurement of these predictors for total power and work outputs at the joint following ACL reconstruction may provide clinicians an improved understanding of performance during rehabilitation.

INTRODUCTION

In subjects with unilateral anterior cruciate ligament reconstruction (ACLR), changes in knee joint mechanics post-surgery are thought to contribute to altered cartilage stresses, which in turn is believed to cause premature knee osteoarthritis (OA) [1]. We have reported that unilateral ACLR subjects who get medial compartment OA in the involved knee demonstrate lower joint forces compared to non-OA subjects, as early as six months post-surgery [2]. In subjects that get OA five years after unilateral ACLR, we have observed that radiographic osteophytes are most commonly seen near the medial margin of the medial knee compartment, i.e. the joint region closer to the midline of the body. While it has been shown that the knee cartilage is thinner in that region (compared to the central region of the joint) [3], the spatial variation that occurs in knee cartilage stress distribution after ACLR is not clearly understood [4]. Specifically, it is not clear whether cartilage stresses near the medial margin of the medial knee compartment can be higher (and hence detrimental) even though the joint force is lower, in OA vs. non-OA subjects.

With that background, the purpose of this study is to evaluate kinematic/kinetic differences in the involved knee between subjects with/without knee OA five years after unilateral ACLR. The comparisons are made at the first peak of vertical ground reaction force (vGRF) during gait. We further evaluate the effect of typical kinematics/kinetics on medial tibial cartilage stress distribution, for a non-OA vs. OA subject.

METHODS

The subject population includes 37 unilateral ACLR subjects (14 females, 23 males, Age Range: 14 to 46 years) at the five year post-surgery time point. Weight-bearing anterior-posterior radiographs were graded using the Kellgren-Lawrence (K-L) scale. A K-L grade ≥ 2 was defined to be indicative of OA. 8 out of 37 subjects showed signs of OA in the medial compartment. The testing protocol included gait analysis using an 8-camera video system (Vicon, Oxford Metrics Limited, London, UK) and a force platform (Bertec Corporation, Worthington, OH). Electromyography (EMG) analysis was conducted using surface-EMG recordings (Motion Lab Systems, Baton Rouge, LA) collected from seven muscles crossing the knee joint. A validated Hill-type EMG-informed musculoskeletal model [5] was used to estimate joint force. Student's t-test ($\alpha = 0.05$) was used to evaluate differences in kinematics/kinetics between the non-OA vs. OA group, at the first peak of vGRF.

Quasi-static finite element analysis at the first peak of vGRF was conducted using Open Knee [6] in FEBio (Musculoskeletal Research Laboratories, Salt Lake City, UT), with material properties derived from literature [6-9]. The Open Knee model (Figure 1) was scaled based on subject-specific knee epicondylar width measurements of one non-OA and one OA subject, each of whom demonstrated kinematics/kinetics similar to mean values demonstrated by their respective groups. The tibia was held fixed while the knee flexion angle was prescribed to the femur. Subject-specific joint force, frontal plane moment and transverse plane moment were applied to the femur. The resultant medial tibial cartilage stress distributions for the non-OA vs. OA subject were compared.

RESULTS AND DISCUSSION

The OA group demonstrated significantly lower flexion angle, sagittal plane moment and transverse

plane moment, compared to the non-OA group (Table 1. Mean ± 1 standard deviation). The OA group also demonstrated a lower joint force and a higher frontal plane moment, but these differences were not significant.

Differences in medial tibial cartilage stress distribution were observed for typical kinematics/kinetics representing the non-OA vs. OA subject (Figure 1). While the maximum medial tibial cartilage stress for the OA subject was lower (non-OA: 6.2 MPa, OA: 4.9 MPa), the maximum stress near the medial margin of the medial tibial cartilage (region circled in red in Figure 1) was higher for the OA subject (non-OA: 3.3 MPa, OA: 4.9 MPa). This is the region where cartilage tends to be thinner (compared to the central region of the joint) and also the region where we have observed radiographic osteophytes in unilateral ACLR subjects.

In summary, these results provide insight pertaining to altered cartilage stress distribution as a result of altered joint mechanics, and can help solidify the link between altered joint mechanics and premature knee OA in unilateral ACLR subjects.

INTRODUCTION

Biomechanical maladaptations during double-limb drop vertical jumping increase the risk for primary anterior cruciate ligament (ACL) injury.[1] Following ACL surgery, the contralateral limb may be used to compensate for unilateral deficits.[2] As such, unilateral landing tasks may be better able to elicit and identify deficits in individuals at risk for ACL injury or following surgery.[3] Therefore, the purpose of this case-control study was to evaluate single-limb drop landing biomechanics in individuals after successful ACL surgery and rehabilitation.

METHODS

Twenty patients at least one year following ACL surgery and 20 healthy individuals matched by gender, age, body mass index, limb dominance and activity level, participated in this study (Table 1).

Table 1. Demographic characteristics of the participants.

	ACL (n=20)	Control (n=20)
Gender	17 F, 3 M	17 F, 3 M
Age (yr)	22 ± 2.5	21 ± 3.2
Height (m)	1.7 ± .07	1.7 ± .09
Weight (kg)	65 ± 10.7	62 ± 10.4
BMI, (kg/m^2)	22.8 ± 2.2	22.2 ± 1.8
Tegner Activity Level	6.8 ± .89	6.9 ± .93
Time since surgery (mo)	58.4 ± 33.2	

Retro-reflective markers were placed on the trunk, pelvis, thigh, shank, and foot of either the involved leg of the ACL patients or the dominance-matched leg of the control group. After the calibration trials, subjects stood on a 30cm tall box with all their body weight on the test leg. They were told to drop down onto the force plate in front of them, to land on the test leg only, and to briefly hold the landing position. Landings that involved any temporary loss of balance or involved double-striking were excluded. Subjects were allowed to practice the drop landing task as needed. Five landing trials were captured.

Marker trajectories and kinetic data were acquired at 150Hz and 1500Hz, respectively, and smoothed using low-pass filtering (8Hz and 50Hz). Data were analyzed during the interval between initial contact (IC) and lowest vertical position of the L5S1 marker (LOW). IC was determined when the ground reaction force exceeded a 25N threshold. Data were then time normalized according to the interval between IC and LOW. Five trials were collected and averaged for the analysis. Time series curves were visually inspected for quality control considerations. Discrete variables were calculated at 25, 50, 75, and 100% of the landing time-series interval (IC – LOW).

The vertical displacement of the L5S1 marker between IC and LOW was calculated and reported as percentage of the subject's height. Kinematic and kinetic variables at the ankle, knee and hip joint were calculated in the sagittal plane. Kinematic variables included joint angles and angular velocities. Kinetic variables included normalized (body mass, kg) vertical ground reaction force (vGRF), external joint moment, and joint power; these were calculated using an inverse dynamic approach and normalized to body mass*height (kg*m). Total support moment (TSM) represents the magnitude of the lower limb extensor synergy, and was calculated by summing the internal extensor moments at the ankle, knee, and hip joints. Percentage contributions of each joint to the TSM were calculated by separately dividing the internal moment of the ankle, knee and hip by the TSM at the 25, 50, 75, and 100% indexed timepoints. Data were compared between groups using independent samples t-tests.

RESULTS AND DISCUSSION

There were no group differences at any indexed interval for L5S1 marker displacement, vGRF, or TSM, suggesting that overall whole-body COM descent and external demands of the drop landing were similar between groups (Figure 1A and 1D).

At 25% of the landing, no group differences were observed. Visual analysis of the time-series curves revealed that vGRF and TSM were increasing throughout the 0-25% time interval and this pattern was consistent between groups.

At 50% of the landing, the joint power data showed that greater energy was absorbed by the control group at the knee (+40%, p = 0.02), but no other differences were seen. By 50% of the interval, the vGRF and TSM curves had already peaked (Figures 1A and 1D).

At 75% of landing, a number of group differences emerged. The ACL group had a larger moment at the hip (+86%, p = 0.02) and a smaller moment at the knee (-23%, p < 0.01, Figure 1E). Also, the relative contributions of the hip and knee joints to the TSM were 13% greater (p < 0.01) at the hip and 10% lower (p < 0.01) at the knee in the ACL group. The ACL group also had less angular velocity (-25 and -33°/sec, Figure 1F) and less power absorption (-40 and -43%, Figure 1C) at the ankle and knee joints, respectively (all p < 0.05), suggesting a stiffer landing strategy.

The differences in the joint moments and the percent TSM contributions were still present at the end of landing (100%). The knee joint moment was 21% smaller (p < 0.01, Figure 1E), and the contribution of the hip and knee joints to the TSM were 7% greater at the hip (p = 0.02) and 6% lower at the knee (p < 0.01) in the ACL group compared to the control group.

CONCLUSIONS

The demands of the external loads during the earlier phases of landing did not elicit altered joint mechanics. Further exploration of this kinematic-kinetic relationship during early loading is warranted. Conversely, later in the task, the ACL group did demonstrate an altered neuromuscular strategy that largely affected the proximal joints. Greater reliance on the hip joint and decreased reliance on the knee to meet the extensor demands of the task were observed. Overall, these data suggest that movement abnormalities persist years after successful ACL reconstruction and conventional rehabilitation. Understanding both the inability to compensate during the initial portions of the task and the different adaptations during the latter portion of the task will inform evidence-based care of these individuals.

THE IMPACT OF VARIOUS MEASURES OF QUADRICEPS STRENGTH ON LANDING MECHANICS IN YOUNG ATHLETES AFTER ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION: IMPLICATIONS FOR SECOND ACL INJURY RISK

Matthew P. Ithurburn[1], Mark V. Paterno[2], Kevin R. Ford[3], Timothy E. Hewett[1,2], Laura C. Schmitt[1,2]

INTRODUCTION

Alterations in landing mechanics are common after anterior cruciate ligament (ACL) reconstruction (ACLR) and contribute to second ACL injury risk in young, active individuals. Specifically, frontal plane knee motion, transverse plane hip kinetics, and side-to-side asymmetries in sagittal plane knee moment were risk factors for a second ACL injury after ACLR and return-to-sport [1]. While decreased quadriceps strength, a persistent impairment after ACLR, contributes to altered mechanics [2, 3], it remains unknown which measures of quadriceps strength impact landing mechanics that contribute to second ACL injury risk after ACLR. The hypothesis tested was that in young athletes after ACLR, kinematic and kinetic variables of interest during a double-leg landing task would be predicted by isometric and isokinetic quadriceps strength at 180°/s, but not by isokinetic quadriceps strength at 300°/s.

METHODS

Participants included 84 young athletes (age=17.4 yrs; 59 females, 25 males) after primary, unilateral ACLR cleared and planning to return to cutting/pivoting sports. All participants and/or parents provided written informed consent prior to participation. An isokinetic dynamometer (Biodex) was used to quantify peak isometric quadriceps torque (Nm) and peak isokinetic quadriceps torque at 180°/s and 300°/s (Nm). Kinematic and kinetic data were collected by tracking 37 retroreflective markers with a 10-camera motion analysis system (Motion Analysis Corp.; 240 Hz) during the initial landing phase of a drop vertical jump task (Figure 1). Participants landed with each foot onto a separate force plate (AMTI; 1200 Hz). Kinematic and kinetic variables of interest were calculated with Visual3D and MATLAB. Variables of interest

were based upon biomechanical risk factors for second ACL injury and common asymmetries in landing after ACLR. These included involved and uninvolved knee flexion motion (initial contact through peak flexion); involved and uninvolved frontal plane knee motion (initial contact through peak valgus); involved, uninvolved, and side-to-side differences in peak internal knee extension moment; involved, uninvolved, and side-to-side differences in peak vertical ground reaction force (VGRF); and involved and uninvolved transverse plane hip kinetics. Low-pass Butterworth filters were used to filter trajectories and force plate data used in calculating joint moments (12 Hz) and to filter force plate data (100 Hz). Joint moments were not normalized. Linear regressions were used to identify the impact of each quadriceps strength measure on variables of interest, after controlling for weight and height (α<.05).

Figure 1. Example of the drop vertical jump task (From Paterno 2010 [1], with permission).

RESULTS AND DISCUSSION

Isometric and isokinetic quadriceps strength at 180°/s and 300°/s predicted involved peak internal knee extension moment (Table 1). Both isometric and isokinetic quadriceps strength at 180°/s predicted side-to-side differences in peak internal knee extension moment, uninvolved peak VGRF,

side-to-side differences in peak VGRF, and involved hip rotation moment impulse (all p<.05) (Table 1). Quadriceps strength measures were not predictive of involved or uninvolved knee flexion motion or frontal plane knee motion, uninvolved peak internal knee extension moment, involved peak VGRF, or uninvolved hip rotation moment impulse (all p>.05).

The cohort in this study consisted of young, active individuals that at the time of return-to-sport were planning on returning to cutting and pivoting sports. Previous work has demonstrated second ACL injury rates as high as 29.5% within 2 years of ACLR and return-to-sport in this population [4]. Thus, given that quadriceps strength deficits are nearly ubiquitous after ACLR, understanding the impact of common measures of quadriceps strength testing on known contributors to the risk of second injury is critical. All measures of quadriceps strength in this study predicted side-to-side differences in knee extension moment, which has been linked with second ACL injury risk during a drop vertical jump [1]. Across all variables of interest for which isometric and isokinetic quadriceps strength at 180°/s were significant predictors, isometric quadriceps strength predicted more of the variance in each variable, excluding involved peak internal knee extension moment (Table 1). While previous work has shown that individuals with decreased isometric quadriceps strength symmetry

demonstrate altered landing mechanics during a drop vertical jump task after ACLR [3], this appears to be the first study to identify the impact of several commonly used measures of quadriceps strength on altered landing mechanics that contribute to increased second ACL injury risk. Interestingly, in addition to not contributing to most kinetic variables of interest in this study, isokinetic quadriceps strength testing at 300°/s has also previously not been correlated with functional performance tests after ACLR [5].

CONCLUSIONS
Both isometric and isokinetic quadriceps strength at 180°/s predict important biomechanical variables during landing that are known contributors to second ACL injury risk after ACLR and return-to-sport. Measuring isokinetic quadriceps strength at 300°/s may not be important in predicting double-leg landing mechanics after ACLR.

Table 1. Regression Models for Quadriceps Strength Measures on Kinematic and Kinetic Variables of Interest

	Model 1: Including Height/Weight (R^2 adj.)	QF-Iso (R^2 change from Model 1, P-value)	QF-180 (R^2 change from Model 1, P-value)	QF-300 (R^2 change from Model 1, P-value)
Involved Peak IKEM	21.4%	4.5%, .028	14.3%, <.001	5.4%, .016
Side-to-Side Differences in Peak IKEM	7.4%	18.1%, <.001	13.5%, <.001	2.8%, .111
Uninvolved Peak VGRF	47.6%	11.7%, <.001	6.7%, .001	1.9%, .083
Side-to-Side Differences in Peak VGRF	2.1%	16.4%, <.001	14.8%, <.001	3.0%, .108
Involved Hip Rotation Moment Impulse	2.1%	19.1%, <.001	4.8%, .048	3.1%, .110

Each model with strength measure (columns 3-5) demonstrates R^2 change after accounting for height and weight; QF-Iso = peak isometric quadriceps torque; QF-180 = peak isokinetic quadriceps torque at 180°/s; QF-300 = peak isokinetic quadriceps torque at 300°/s; IKEM = internal knee extension moment; VGRF = vertical ground reaction force; Hip rotation moment impulse over first 10% of landing

SINGLE-LEG HOP DISTANCE AS A FUNCTIONAL SURROGATE FOR LOWER EXTREMITY JOINT POWER IN HEALTHY ADULTS

INTRODUCTION

Joint power is a good indicator of muscle function in many populations. However, joint power cannot be easily measured in a clinical setting without access to biomechanical tools such as 3D motion capture and force plates. For this reason, it is important to find a comparable measurement for function that can be easily implemented and used in a clinical or athletic performance setting. A forward single-leg hop for distance is a common test for overall function in physically active populations. However, function is usually determined by limb symmetry rather than hop distance [1].

Therefore, the purpose of this study was to determine the relationship between lower extremity joint power and function (single-leg hop distance). The hypothesis tested was that there would be a positive relationship between total lower extremity joint power and hop distance.

METHODS

Sixteen healthy adults volunteered to participate in this study and gave written informed consent (n = 8 females; n = 8 males). To measure whole body kinematics, each subject was fitted with 55 retro-reflective markers to define joints and segments. Markers were tracked in 3-dimensional space using 12 Motion Analysis cameras. To measure kinetics, ground reaction forces were measured using 4 imbedded Bertec force plates. Data were analyzed using Motion Analysis Cortex, Visual3D, and MatLab.

All measurements were taken for the dominant limb. Limb dominance was determined by asking the subject which leg he or she would choose to kick as soccer ball. To measure the take-off phase of a single-leg hop for distance, subjects began the movement on the force plate with their foot lined up with the edge of a standard measuring tape. Subjects were instructed to hop as far as they could forward on one leg and maintain balance on or 'stick' the landing. The distance of the hop was measured at the location of the heel in the nearest centimeter. Subjects were allowed to practice the hop twice and then performed two successful trials. A trial was considered successful if the subject only used one leg to push off and land.

Total peak lower extremity power was determined from the sum of the peak hip, peak knee, and peak ankle powers for each subject. Pearson's product-moment correlation was used to determine the relationship between total lower extremity joint power and hop distance.

RESULTS

A strong positive correlation was observed between single-leg hop distance and peak total lower extremity joint power (Figure 1). In addition, hip range of motion accounted for ~56% of the variance in hop distance, knee range of motion for ~32%, and ankle range of motion accounted for ~4% of the variance in hop distance (Table 1). Peak hip power accounted for ~60% of the variance in hop distance, peak knee power for ~13%, and peak ankle power accounted for ~11% of the variance in single-leg hop distance (Table 1).

DISCUSSION

The results from this study confirm the postulate of a strong positive relationship between total lower extremity joint power and single-leg hop distance. Furthermore, these results offer promising evidence for the use of a single-leg hop test as a measure of function. Previous research has demonstrated very good reliability of functional tests such as the

single-leg hop [1] and their usefulness at discriminating between injury recovery status [2]. Therefore, clinicians should consider the use of hop distance as a measure of function as well as distance asymmetry between limbs due to the strong positive correlation between hop distance and total lower extremity joint power.

Moreover, the strong positive relationships between lower extremity joint ranges of motion and lower extremity joint power offer another simple and straightforward measure of function. Two-dimensional video analysis is a cheap and readily available too for clinical use and can quickly assess joint ranges of motion during functional tasks such as the single-leg hop.

CONCLUSIONS

Utilization of a combination of outcome measures such as total hop distance, distance symmetry between limbs, and lower extremity joint ranges of motion, clinicians and athletic performance specialists can quickly and effectively screen patients for muscle function as it relates to risk of injury and recovery of injury. Further research will investigate the role of limb dominance on functional test performance.

INTRODUCTION

Many of the clinical tests to assess skill in using an upper limb prosthesis measure speed of performance of a pre-defined set of tasks [1]. However, speed of task completion is only one of several factors which characterize skilled prosthetic use [2]. Recently, Major et al. [3] showed that joint angle variability is higher in amputees than controls, and in amputees it is correlated with years of experience of prosthetic use. In common with almost all studies of upper limb functional task performance, in [3] joint angle trajectories were first linearly normalized with respect to time. However, the relative duration of different phases of the task can vary from trial to trial, linear time normalization of the entire task cannot take this into account [4]. In this paper we report on the characterization of functional task performance using an upper limb myoelectric prosthesis using a time warping method which allows for differentiation between temporal and trajectory variability. In Study 1 we validated the approach with a comparison of amputees and anatomically intact (AI) controls. In Study 2 we report on the changes in temporal and trajectory variability with practice using a myoelectric prosthesis simulator in AI subjects.

METHODS

Study 1 (carried out at Northwestern University, USA): Full details of the protocol are provided in [3]. Following ethical approval, six AI individuals (3 male, 35±11 years of age) and seven myoelectric transradial prosthesis users (5 male, 49±18 years of age, 20±18 years of prosthesis experience) were recruited to the study. Subjects visited the lab on one occasion to perform five trials of three seated tasks (selected from the Southampton Hand Assessment Procedure (SHAP) [1]): 1) lifting a carton and emptying liquid contents into a jar using their non-dominant or prosthetic limb, 2) lifting and transferring a weighted container across a low-level barrier using their non-dominant or prosthetic limb, and 3) lifting and transferring a tray across a low-level barrier using both hands. Subjects also completed the entire SHAP protocol. During each task, marker position approximating location of the radial and ulnar styloid processes were collected and used to track the virtual wrist joint center. Estimation of wrist joint three-axis accelerations were used to calculate inter-trial temporal (warp cost) and trajectory (RMS error) variability [4,5].

Study 2 (carried out at University of Salford, UK): Full details of the protocol are provided in [6]. Following ethical approval, seven AI individuals (4 male, 6 right handed, 36±10 years of age) were recruited to the study. Subjects visited the lab on four occasions, spaced over approximately 2 weeks. On visit one, subjects were asked to perform a seated task which involved reaching with their anatomic hand for a juice carton, picking it up and pouring the liquid into a cup, before returning it to its original location, then moving their hand back to the original resting point. The location of the carton, cup and starting point for the hand were fixed for each subject across all trials. Subjects repeated the task 12 times on each visit. For visits 2-4 subjects performed the task with a custom-made myoelectric prosthesis simulator [6]. In between visits subjects carried out the SHAP with the prosthesis simulator on four occasions between visits 2 and 4 for practice. During task performance, position data of a cluster of 4 reflective markers located on the forearm were collected. These data were then used

to calculate the simulated output of a three-axis accelerometer [5]. Subsequently, temporal and trajectory variability within session were calculated.

RESULTS AND DISCUSSION

Table 1 displays results of Study 1 comparing AI control and prosthesis user task performance. Tables 2 and 3 display results of Study 2 observing changes in variability due to practice.

Study 1 found differences in temporal inter-trial variability between amputees and controls, but less clear differences in trajectory variability. The finding demonstrates for the first time the nature of differences in trial-to-trial variability between experienced users of myoelectric prostheses and controls. These results reflect those previously observed in [3] regarding greater joint-level kinematic variability and reduced SHAP scores of prosthesis users compared to controls, thereby validating this method and demonstrating the contribution of temporal variability to prostheses user movement quality during task execution.

In Study 2 we demonstrated that trial-to-trial temporal variability in a carton pouring task increases dramatically on first use of a prosthesis simulator, then declines with practice. Consistent with the findings in Study 1 trajectory variability showed less clear changes both on first introduction of the prosthesis simulator and with practice.

The reasons for these findings requires further work, but it is possible to speculate that in this case when using a prosthesis the limb trajectory variability is relatively constrained by the limited degrees of freedom and fixed task characteristics. However, all of the tasks studied involved acquiring and releasing objects using the prosthetic hand; if opening the hand to acquire the object, or release the object was difficult, then this may be one of the sources of higher timing variability seen in prosthesis results. The study reported here used camera based techniques to derive overall task completion time and simulated accelerometer trajectories. However, both of these parameters could be derived from a real accelerometer located on the wrist and hence the approach offers the potential for clinicians to characterise both overall task completion time and trial-trial temporal and trajectory variability using low cost instrumentation.

JOINT POWER ADAPTATIONS TO RUNNING SPEED IN INDIVIDUALS WITH AMPUTATION USING RUNNING-SPECIFIC PROSTHESES

INTRODUCTION

Running after lower limb amputation leads to altered joint powers. The ankle joint is the primary power generator during able-bodied running [1, 2], and prostheses may not effectively replace this joint's function. Existing literature is conflicting with limited sample sizes reporting joint powers. Two athletes with unilateral transtibial amputations generated lower peak ankle power with their running-specific prostheses (RSPs) than their intact ankle joint while sprinting [3]; however, a sprinter with bilateral transtibial amputations has exhibited greater peak ankle powers than a control group [4]. To account for altered ankle powers, knee powers may be reduced [3, 4] or increased [3] relative to control limbs, while longer positive hip power periods have been observed in prosthetic limbs [3].

Further study of joint powers in running after amputation will provide insights into muscular adaptations, which can lead to advances in training and rehabilitation. Joint powers when using RSPs at submaximal speeds and across a range of speeds are poorly understood since prior literature focuses on sprinting. Hence, the purpose of this study was to investigate lower limb joint powers when running with RSPs at different speeds. We hypothesized that (1) the prosthetic limb would exhibit lower peak joint powers than the intact and control limbs at each speed, and (2) increased speed would result in increased peak joint powers in the limbs.

METHODS

8 males with unilateral transtibial amputation wearing RSPs and 8 male controls ran overground at three speeds (2.5, 3.0, and 3.5 m/s). 10 motion capture cameras captured kinematic data (200 Hz) while 10 force platforms collected ground reaction forces (1000 Hz). Tracking markers were placed bilaterally on the lower extremities and on the prostheses. The prosthetic limb "ankle" joint was defined as the RSP's most acute point of curvature. Ankle, knee, and hip joint powers were calculated via inverse dynamics using Visual3D (C-Motion). A 3-way (Group x Leg x Speed) ANOVA was used to test for peak joint power differences with α=0.05.

RESULTS

Table 1 presents the peak power data. Peak ankle powers showed significant speed effects (p< 0.001) where generation and absorption increased with speed. Significant leg effects (p=0.018) and leg x group interactions (p=0.009) existed where the prosthetic limb generated less power than the intact limb. The prosthetic limb generated lower ankle power than the control limbs at 3.5 m/s (p=0.036).

Stance phase knee power absorption and generation exhibited significant speed effects (p<0.001) where peak magnitudes increased with speed. These variables had significant leg x group interactions (p<0.007) where the prosthetic limb knee absorbed and generated less power than the intact and control limb knees. Knee swing power absorption showed significant speed (p<0.001), leg (p=0.014), leg x group interaction (p=0.005), speed x leg interaction (p=0.001), and speed x leg x group interaction (p=0.005). All limbs increased peak knee absorption with speed during swing phase, and the prosthetic limb knee absorbed less power than the intact and control limbs. During swing phase, the intact and control limbs both increased peak power absorption with speed at a greater rate than the prosthetic limb.

Peak hip powers had significant speed effects (p≤0.004) where power absorption and generation increased with speed during both stance and swing phases. The prosthetic limb generated greater peak power during stance than the control group (p=0.035). Significant leg x group interactions for peak hip stance absorption (p=0.029) and swing generation (p=0.034) indicated that the amputation group limbs had greater differences than the control group limbs. The prosthetic limb hip absorbed and generated less power than the intact limb hip.

DISCUSSION AND CONCLUSIONS

Our first hypothesis that ILEA would exhibit lower peak joint powers in the prosthetic limb than the intact and control limbs at each speed was supported for most parameters, but notably not for hip power generation. The prosthetic ankle had lower power absorption and generation than the intact limb, supporting the idea that running prostheses are much more limited in their ability to contribute to energy used during running [3]. However, since prosthetic ankle power was only lower than controls at 3.5 m/s, this limitation may only be exacerbated at faster running speeds. Lower prosthetic limb knee powers suggest either greater muscular co-contractions that reduce the net joint moments, or that ILEA adapt their running style to use the knee joint more passively [5]. The prosthetic limb also generated greater hip power compared to the control limbs. This correlates to the prolonged hip extension moments observed in ILEA running

with RSPs [3]. The prosthetic limb further produced lower swing phase knee power absorption and hip power generation that can be attributed to smaller inertial properties of the lower limb with the RSP.

Our second hypothesis that increased running speed would be associated with similar increases in peak powers of the intact and prosthetic limbs was accepted. As the demands of running faster increase, the peak joint powers responded accordingly. However, in several cases, the intact limb joints increased power generation and absorption at a greater rate than the prosthetic limb. This suggests that in stance phase, the potential limitations of the prosthesis resulted in greater power output requirements by the intact limb to achieve faster running speeds. In swing phase, the speed demands had a greater impact on the intact limb due to its greater inertial properties. As peak joint powers offer a limited view into mechanical energy requirements of ILEA running, additional study of joint work profiles are needed to further elucidate compensatory mechanisms.

BODY-IN-THE-LOOP OPTIMIZATION FOR THE SELECTION OF PROSTHETIC CONTROL PARAMETERS – A PILOT STUDY

Wyatt Felt, Emily S. Gardinier, Jeffrey Wensman, Deanna H. Gates, C. David Remy

The University of Michigan, Ann Arbor, MI, USA
email: cdremy@umich.edu, web: http://ram-lab.engin.umich.edu/

INTRODUCTION

Like many assistive devices, the BiOM T2 powered ankle-prosthesis (BiOM, Inc., Bedford, MA) has numerous software settings that need to be tuned. Four basic parameters control stiffness and ankle power, while seven advanced parameters control the timing of push-off and other functionalities [1]. Selecting appropriate values for these parameters or those of similar devices can be a challenge. Evaluating many different device settings can be a slow and fatiguing process for the user and the resulting settings might suffer from a subjective bias of the clinician. Therefore, a faster and more objective method for identifying proper device settings would be a valuable tool. *"Body-in-the-Loop" optimization* refers to a process of parameter selection that utilizes physiological measures to drive an algorithmic parameter selection process [2]. The purpose of this study was to determine if such a process could be used to accelerate the identification of metabolically optimal device settings for a powered prosthesis.

METHODS

The proposed process relies on real-time measures of metabolic cost acquired while parameters are continuously varied. We estimate the instantaneous metabolic cost, *x,* using transient metabolic measurements (rather than using "steady-state" measurements [3]). To this end, we represent the relationship between the parameter setting *p,* and the instantaneous metabolic cost, *x,* with a fifth-order polynomial of *p* with a vector of coefficients, λ. Modeling the dynamics of the measured metabolic response, *y,* as a first-order, linear system with inputs, *x,* and a time constant, $\tau,$ yields an estimated series of breath measurements, $\overline{y}^i$. The dynamics of the breath-to-breath oxygen

consumption measures can be written in terms of the breath-number, *i,* and the time between breaths, h_i:

$$\overline{y}^i = \left(1 - \frac{h_i}{\tau}\right)\overline{y}^{(i-1)} + \frac{h_i}{\tau} x^i \left(p^i, \lambda\right)$$

The vector of coefficients, λ, is optimized to minimize the error between a set of predicted breath measurements, $\overline{y}^i$, and actual measurements, $\hat{y}^i$.

$$\min_{\lambda, \overline{y}^1} \; e = \left(\hat{y}^1 - \overline{y}^1\right)^2 + \sum_{i=2}^{n}\left(\hat{y}^i - \overline{y}^i\left(x(\lambda, p^i), \overline{y}^{i-1}\right)\right)^2$$

In this equation, we recursively propagate an initial measurement, $\overline{y}^1$, that is also being estimated.
Figure 1: Using continuous measures of metabolic cost, we identified metabolically optimal parameter settings in a fraction of time needed by traditional methods. The red dots are means energy expenditure from steady-state tests. The green line is the fifth-order polynomial, $x(p, \lambda)$, that was fit to breath measures taken while the parameters were varied continuously.

We applied this process to approximate the metabolically optimal parameters of the BiOM T2 Ankle System for a 59-year-old male with unilateral transtibial amputation. The device was fit and the settings were adjusted by a manufacturer-certified prosthetist. The subject's BMI and walking speed were 28.9 kg/m^2 and 1.16 m/s respectively. Energy use was measured with a portable respirometer (K4b2, COSMED, Rome, Italy).

The BiOM manufacturer allows the power and timing parameters to be varied between 0% and 100%. We tested each parameter independently. While varying the timing parameter, the power was fixed at the prosthetist-selected 57%. Similarly, in the power trials, the timing was fixed at 44%. All other device parameters were fixed at prosthetist-selected settings.

We ran two tests to identify the relationship between the energy expenditure and the parameters. The first test evaluated energy expenditure by averaging several minutes of data at steady-state conditions. The total walking time for each parameter was approximately 48 minutes.

The second test applied the methods of "body-in-the-loop" optimization. The walking time required for these trials was approximately 13 minutes per parameter. In these trials, the dynamics of the metabolic response were first identified by asking the subject to stand at rest for three minutes and then walk for three minutes. The parameters were then varied between 0% and 100% (or vice-versa) over the course of ten-and-a-half minutes. A fifth-order polynomial was used as a surrogate function.

RESULTS AND DISCUSSION

For the power setting, both methods indicated the 100% power setting as the metabolically optimal choice. For timing, the results of the two methods differed slightly. In the "Body-in-the-Loop" optimization, the best-fit 5th-order polynomial predicted the optimal timing parameter to be 22%. A 5th-order polynomial fit to the means of the steady-state measures had a minimum at 28%.
Figure 2: Our method enables us to estimate relationships between device parameters and metabolic cost in real-time, using noisy and dynamically changing measures of energetic cost ($\hat{y}^i$, blue dots). The first part of the experimental trial was used to identify the time constant of the metabolic response. The red line is the best-fit, predicted metabolic response, $\bar{y}^i$.

Though these methods were only tested on a single subject, "Body-in-the-loop" optimization techniques hold promise for improving the selection of parameter settings. They allow for the rapid and objective evaluation of parameter settings without an excessive amount of subject fatigue.

EMULATING CANDIDATE ANKLE-FOOT PROSTHESES TO INFORM PRESCRIPTION

[1,2] Joshua M. Caputo, [2] Peter G. Adamczyk, and [1] Steven H. Collins

INTRODUCTION

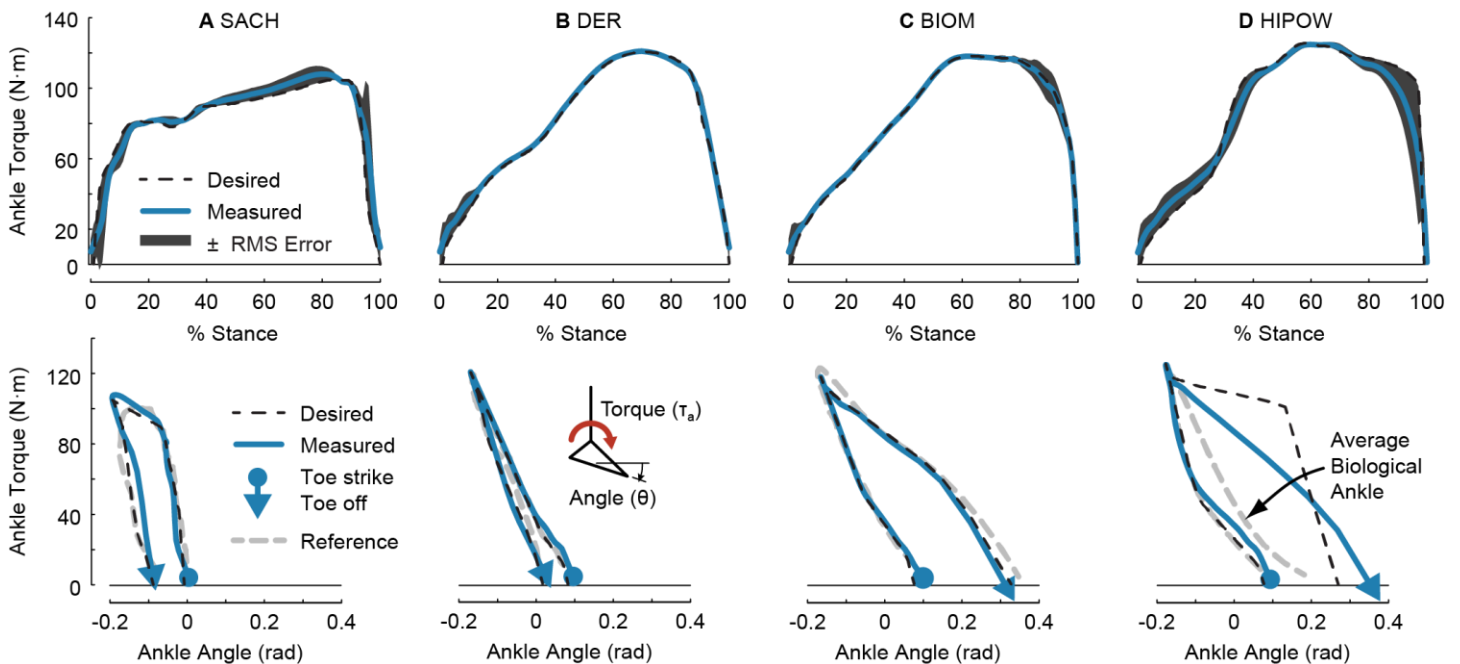
Robotic ankle-foot prostheses can improve walking performance for amputees compared to conventional designs [1], but prescription has been hindered by their high cost and uncertainty about the degree to which individuals will benefit. The typical prescription process cannot well predict how an individual will respond to a device they have never used, as it bases decisions on subjective assessment of an individual's current activity level [2]. We propose a new approach to prescription in which individuals 'test drive' candidate devices using a prosthesis emulator while their walking performance is quantitatively assessed and results are distilled to inform prescription decisions [3].
Figure 1: The emulator consists of a lightweight prosthesis actuated through a tether by a powerful motor and controller. Metabolic and heart rate, maximum walking speed, and user satisfaction are measured to assess the emulated behaviors.


Figure 2: We programmed the behavior of **A** a solid ankle cushioned heel (SACH), **B** a dynamic-elastic response (DER), **C** the BiOM® T2 powered robotic, and **D** a conceptual high-powered robotic (HIPOW) prosthesis. Emulation was performed by joint torque control with the ankle torque vs. angle relationships of commercially-available prostheses as the reference torque. Data presented are from a single representative subject walking at 1.25 m/s on level ground over approximately 150 strides.

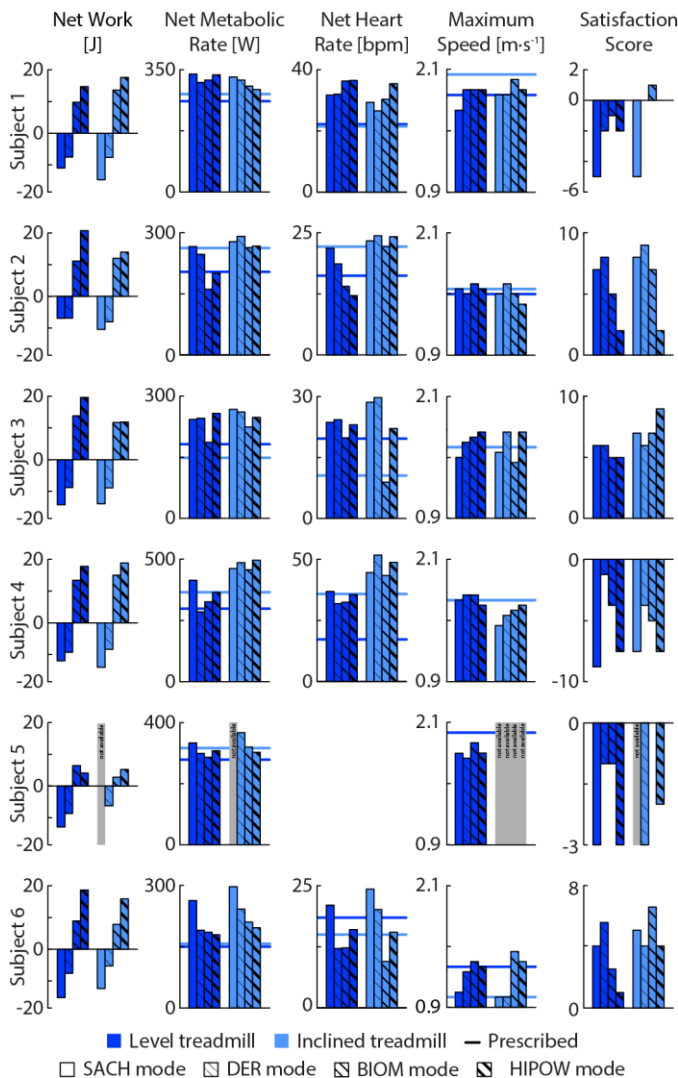
We propose a new approach to prescription in which individuals 'test drive' candidate devices using a prosthesis emulator while their walking performance is quantitatively assessed and results are distilled to inform prescription decisions [3]. By emulating, rather than purchasing and fitting candidate devices, behavior can be changed quickly through a software interface rather than by swapping mechanical components, so users can experience a broader range of devices than is possible using traditional approaches.


Figure 3: Walking performance outcome metrics listed for each subject across different emulator modes and two treadmill incline conditions.

METHODS

To test the viability of the approach, we developed a prototype ankle-foot prosthesis emulator (Fig. 1)

and assessment protocol, leveraging hardware and methods we previously developed [4] for basic science experiments (eg. [5]), and conducted a treadmill walking experiment with 6 unilateral transtibial amputees (♂, K3, aged 49±5 yrs, 15±16 yrs as amputee, 184±15 lbs).

RESULTS AND DISCUSSION

We demonstrated an emulator that closely tracked the ankle torque vs. angle relationships of an array of commercially-available ankle-foot prostheses (Fig. 2). Average RMS torque tracking errors were between 2 and 4% of the maximum ankle torque. Users indicated that emulations were subjectively convincing representations of each device class. We demonstrated a protocol for measuring users' walking performance across emulator modes that discerned individuals' needs using simple quantitative measures (Fig. 3). All unilateral transtibial amputees we tested appeared to benefit from robotic assistance strategies to some degree but with individual subject differences. The five DER users demonstrated potential for improved walking performance and satisfaction with a robotic prosthesis, but were never able to explore this option within the conventional prescription process. The BiOM® T2 user showed benefits from robotic assistance, but only when walking uphill, and always preferred walking in the passive modes. By exploring candidate device behaviors through haptic emulation, prosthesis prescriptions could be objectively justified prior to device purchase and fitting to ensure that users reach an appropriate balance of cost and benefit.

THE EFFECT OF MULI-AXIAL PROSTHETIC STIFFNESS ON ANGULAR MOMENTUM IN PEOPLE WITH TRANSTIBIAL AMPUTATION WALKING OVER UNEVEN TERRAIN

W. Lee Childers, Ryan D. Funderburk, Adam T. Smith, C. Jake Davidson

Alabama State University, Montgomery, AL, USA
email: lchilders@alasu.edu, web: http://www.alasu.edu/biomechanics

INTRODUCTION

Individuals with transtibial amputation face serious challenges when negotiating uneven terrain. Prosthetic foot manufactures have attempted to minimize these challenges by designing prosthetic feet that can deform and adapt to uneven terrain. Feet incorporating "multi-axial" features have been traditionally prescribed to individuals expected to negotiate uneven environments. However, there is limited information on the effect of multi-axial prosthetic ankle stiffness on measures of gait stability.

The purpose of this study was to define the effect of prosthetic multi-axial stiffness on gait stability in people with uni-lateral transtibial amputation. Study results should strengthen the evidence-base of prosthetic/rehabilitation interventions.

METHODS

Eight participants (of twelve recruited) with uni-lateral transtibial amputation secondary to trauma (101 ± 20.5 kg, 1.84 ± 0.14 m, 42.5 ± 13.4 yrs) have completed this IRB approved study.

Participants walked ten times over even and uneven terrain to a metronome (108 bpm). The uneven terrain (Figure 1) consisted of a 7.3 x 0.8m walkway with 80 x 25 x 20 cm blocks specifically placed in a rotating pattern (0˚, 45˚, 90˚, and 135˚). The center of each block was spaced 200 cm apart from each other. A 1 cm thick rubber mat was placed over the uneven walkway reducing visual feedback while making the floor appear even. A track mounted harness system (Solo-step Inc. North Sioux City, SD, USA) was used to safe ambulation over the uneven walkway. A full-body marker (Vicon PlugInGait) in conjunction with an eight camera motion capture system (Vicon Motion Systems, Oxford, UK) recorded limb kinematics. The participant's normal prosthesis and an Endolite Multi-flex foot with four different ankle unit stiffnesses (soft, medium, firm, and locked out) were tested in random order. The ankle design of the Endolite multi-flex foot was used because it consists of a ball and socket joint and stiffness can be controlled by interchanging rubber isolators between the joint's shank and foot sections.

Figure 1: The uneven walkway with part of the mat removed to show the blocks underneath.

Matlab 2013b was used to calculate whole body center of mass based on a 14 limb-segment model [1] and the range of angular momentum about the coronal and sagittal planes when the amputated limb was in stance [2]. Angular momentum was normalized to the participant's mass, velocity, and height [1]. Minimum toe clearance during swing for the amputated limb and stance width variability were also quantified to provide indirect measures of gait stability [3]. A two factor Repeated Measures ANOVA (terrain x ankle) with Bonferroni post-hoc tested statistical significance ($p < .05$).

RESULTS AND DISCUSSION

There were significant effects from terrain and prosthetic ankle for toe clearance, angular

momentum in the coronal and sagittal planes. Stance width variability only demonstrated significant effect between terrains. There were no significant effects related to gait speed (1.06 ± 0.02 m/s), cadence (106 ± 2.4 strides/min), or Froude number (0.14 ± 0.004) indicating these effects were minimized. The locked ankle condition significantly increased the range of angular momentum in both planes when compared with the participant's normal prosthesis and the soft ankle condition (Figure 2). Toe clearance was significantly smaller comparing the normal, soft, and medium ankle stiffnesses to the locked condition (Figure 3). Stance width variability only demonstrated significant effects between terrain but showed a trend toward minimization at the medium stiffness (Figure 3).

The uneven terrain destabilized gait across all measures of gait stability (range of angular momentum, toe clearance, and stance width variability). The locked prosthetic ankle also tended to destabilize gait. There were general trends in the data suggesting that prosthetic ankle stiffness had a greater effect on the uneven terrain. Generally, the softer ankle stiffnesses was related to increasing gait stability over uneven terrain, likely because the softer ankles better allowed the prosthetic foot to alter its orientation and conform to the terrain.

Figure 3: The locked ankle condition significantly increased prosthetic toe clearance compared to the soft and medium ankle stiffnesses. Decreasing the toe clearance or stance width variability indicate an increase in gait stability [3]. * indicates statistical significant difference from the locked ankle condition.

CONCLUSIONS

These data indicate prosthetic feet with multi-axial features will increase gait stability over even and uneven terrain. Therefore, prosthetic users will benefit from the use of prosthetic foot/ankle systems that allow for multi-axial movement. Optimal prosthetic ankle stiffness will be more apparent when ambulating over uneven terrain and softer ankles demonstrate a trend toward more stability; however, more participants need to complete the study before a definitive conclusion can be drawn.

WHOLE-BODY ANGULAR MOMENTUM DURING SLOPED WALKING WITH POWERED AND PASSIVE ANKLE-FOOT PROSTHESES

INTRODUCTION

Sloped walking places increased demand on the ankle joint [1], and results in a greater risk of slipping than level walking due to an increased shear force between the foot and ground [2]. Sloped walking may thus be especially challenging for individuals with transtibial amputation (TTA), who have a greater risk of falling compared to able-bodied individuals (AB) [3]. This increased fall risk is partially attributed to the functional loss of the ankle muscles, which are critical for controlling dynamic balance during walking [4].

Whole-body angular momentum (H) has been previously used to investigate dynamic balance [5, 6], but has not been quantified for individuals with TTA during sloped walking. In addition, powered prostheses (PWR) actively generate torque at the ankle joint, which may affect dynamic balance differently than passive energy storage and return prostheses (ESR). The influence of PWR on dynamic balance during sloped walking is unclear, and thus the purpose of this study was to analyze H during sloped walking while using both powered and passive prostheses.

METHODS

Six adult males with (n=3) and without (n=3) TTA walked on slopes of ±10°, ±5°, and 0°. Individuals with TTA were assessed using their clinically prescribed ESR prosthesis and also with the BiOM (BiOM, Bedford, MA) powered prosthesis. Whole-body kinematics were collected at 120 Hz while participants walked at a fixed walking speed based on leg length.

Kinematic data were filtered at 6 Hz using a 4th order low pass Butterworth filter. A 13-segment inverse dynamics model was used to compute H as:

$$\vec{H} = \sum_{i=1}^{n}[(\vec{r}_i^{COM} - \vec{r}_{body}^{COM}) \times m_i(\vec{v}_i^{COM} - \vec{v}_{body}^{COM}) + I_i\vec{\omega}_i]$$

where n is the number of segments, $\vec{r}_i^{COM}, \vec{v}_i^{COM}$, and $\vec{\omega}_i$ are, respectively, the position, velocity, and angular velocity of the ith segment, $\vec{r}_{body}^{COM}$ and $\vec{v}_{body}^{COM}$ are, respectively, the position and velocity of the body center of mass (COM), and m_i and I_i are the mass and inertia matrix of the ith segment. For each of the three anatomical planes as well as the overall vector magnitude, H was normalized by body height and weight and expressed from 0 to 100% of the left or prosthetic limb gait cycle. Characteristic features (range, mean) of H during the first (0-50%) and second (50-100%) halves of the gait cycle were compared across groups and slopes using a linear mixed effects ANOVA with slope angle and group (AB, ESR, PWR) as fixed effects and subject as a random effect nested within type (AB, TTA). Post-hoc pairwise comparisons were performed when significant main or interaction effects were found, and p-values were adjusted using Tukey's method. All tests used a significance level α=0.05.

RESULTS AND DISCUSSION

Although H was analyzed in each of the three anatomical planes, the primary findings were in the sagittal plane and in the vector magnitude of H during the first half (0-50%) of the prosthetic (left) limb gait cycle (Fig. 2). For all slope conditions, both ESR and PWR resulted in increased range of sagittal-plane H relative to AB (Figs. 1 & 2). In addition, the mean magnitude of H was increased in ESR relative to AB on declines, and was increased in both ESR and PWR relative to AB on inclines. The increased range and magnitude of H in individuals with TTA suggest that it may be more difficult for them to maintain their balance on slopes, since the affected limb lacks ankle muscles

that are important for regulating H [7]. This potential increase in fall risk for individuals with TTA is in addition to the already increased risk of falls on slopes relative to level ground [2].
Figure 1: Normalized whole-body angular momentum (H) trajectories in the sagittal plane (top row) and total vector magnitude (bottom row) for 3 sloped walking conditions.
Figure 2: Mean (±SD) of the range (peak-to-peak value) of sagittal H (top) and magnitude of the H vector over the first 50% of the gait cycle. Significant differences between groups are indicated by '*'.

Few differences were observed in H when using ESR relative to PWR, similar to previous results on stairs [6]. However, one notable difference was that individuals with TTA had increased sagittal-plane range and mean magnitude of H with ESR compared to PWR when walking on a 10° decline. This result suggests that PWR performs more similarly to AB than ESR, potentially because of controlled plantarflexion in early stance and active

plantarflexion in late stance [8]. These functions may help in regulating H during decline walking for individuals with TTA.

All groups had increased sagittal-plane range and mean vector magnitude of H at +10° relative to 0° in the first half of the gait cycle. However, only AB had a decreased mean magnitude of H at -10° relative to 0°, suggesting that individuals with TTA do not regulate H as tightly as AB during decline walking. The risk of falling during decline walking is greater than during incline walking because of differences in the timing of the peak shear GRF [2]. AB may be more tightly controlling H in response to this greater risk of falling [5], which may be difficult for individuals with TTA.

CONCLUSIONS

Differences in H suggest altered control of dynamic balance across different sloped walking conditions, between individuals with TTA and AB, and when using different prostheses. Future work will incorporate additional subjects and investigate the external moment to further understand dynamic balance control.

EFFECTS OF INTENTIONAL EFFORT MANIPULATION ON BALANCE TESTED UNDER A DUAL-TASK PARADIGM

[1] Christopher Neville and [1] Ryan Charboneau

[1] Upstate Medical University, Syracuse, NY, USA
email: nevillec@upstate.edu

INTRODUCTION

Balance is routinely tested in athletes at high risk for mild traumatic brain injury (mTBI, also known as concussion) before the start of an athletic season (baseline testing). Poor performance on baseline tests due to intentional acts or reduced effort may lead to failed injury identification. More precise measurement of balance using inertial sensors may allow improved ability to identify effort related manipulation as well as change due to injury.[1] Additionally, measuring balance while subjects concurrently complete a balance and cognitive test (dual-task) may further uncover effort related changes.[2] Therefore, the purpose of this study was to compare 3 consecutive data sessions collected from a healthy study cohort. The first two data sessions included test-retest data collected as reliability data to represent baseline performance. The third data session was collected after subjects were instructed to simulate being injured following a published "malingering" protocol. It was hypothesized that the third session would be different than the two baseline sessions. Further, it was hypothesized that dual-task tests would identify that injury symptoms were simulated.

METHODS

Twenty healthy college students volunteered to participate in a study where they would be asked to complete a balance assessment on two separate occasions to establish reliability. In addition, 10 of the subjects completed a third session where they acted impaired following a protocol to elicit malingering type symptoms and responses.[3] The balance tests were instrumented with an inertial sensor (Motion Intelligence, Ithaca NY) and tri-axial acceleration data was output at 250Hz for each of the 30-second tests. The balance assessment consisted of 11 common balance test but two tests

were chosen for camparison in the current analysis to address the stated hypotheses. These tests included a balance test in isolation; tandem stance eyes open (TSEO) standing on the floor, and a similar test where the subject stood in the same position but also held a tablet-computer and completed a cognitive test (trail-making Part B: TMB). The first two testing sessions were completed 2 days apart (baseline reliability) while the third data set was collected one week later. Data was output graphically (Figure 1) to identify patterns across the 3 sessions of data. A noted change in the variance of the accelerations between the third (malingering) session and the first two (baseline) sessions prompted calculation of a variance metric. The variance metric was calculated to represent 95% of the variance in the acceleration signal (P95), similar to 2 standard deviations but not assuming a normal distribution. The data was compared between sessions using a repeated-measures ANOVA with an alpha level of 0.05 followed by individual subject comparisons to aid in the interpretation of the ANOVA model in the cohort of 10 subjects. Finally, a ratio was calculated as balance alone (TSEO) divided by dual-task balance (TMB). This ratio was tested between sessions using a t-test.
Figure 1: Histogram of the frequency (number) of Acceleration values observed across the 30-second balance test (TSEO) for 1 subject completing 3 separate sessions (2 baseline-reliability (blue and green), 1 malingering (red))

RESULTS AND DISCUSSION

As expected, for the isolated balance test, TSEO, session 3 was significantly (p<0.01) greater than session 1 or 2 but there were no differences between session 1 and 2 (p=0.73)(Table 1, Figure 1). For the dual-task balance test, TMB, there was again a significant (p<0.01) difference between session 3 and 1 or 2, and no difference between session 1 and 2 (p=0.54)(Figure 2). For the ratio of balance alone (TSEO) to dual-task (TMB) there was a significant (p<0.01) difference between baseline reliability sessions, and session 3 (simulated injury).
Figure 2: Histogram of the frequency (number) of Acceleration values observed across the TMB dual-task test for 1 subject completing 3 separate sessions (2 baseline-reliability (blue and green), 1 malingering (red))

CONCLUSIONS

The purpose of this study was to identify potential effects of simulated injury compared to typical baseline performance. The group comparisons for sessions 1 and 2 suggest good overall consistency allowing good comparisons to simulated injury in session 3. Session 3 results demonstrate that subjects increased the variance of their acceleration by increasing their sway in attempts to simulate injury. The variance was observed to increase in the dual-task balance test compared to the isolated balance test during the baseline session. This may be due to the added cognitive load distracting participants from the balance task or the effect of simply adding upper extremity movement to complete the cognitive test. Interestingly, this was not observed during session 3 while subject simulated injury. It is hypothesized that the added cognitive task makes efforts to act injured more difficult resulting in atypical decreases in sway compared to the isolated balance test. Only 2 of the 10 subjects were able to maintain their efforts to simulate injury by increasing sway during the dual-task test. Additional studies to identify effort related effects are needed but metrics that target acceleration variance show promise over common metrics such as root-mean-square (RMS) which capture average acceleration.[1]

SINGLE AND DUAL-TASK TURNING IN RECENTLY CONCUSSED ATHLETES AND MATCHED CONTROLS: PRELIMINARY RESULTS

email: fino@vt.edu

INTRODUCTION

Typical sports-related concussion symptoms resolve within 7-10 days post-concussion [1]. However, use of challenging motor control tasks indicate that deficits can persist beyond this typical timeframe. For example, concussed athletes have increased medio-lateral (ML) sway during dual-task gait up to two months post-concussion [2]. After being cleared for competition, recently concussed athletes demonstrate greater reorientation variability [3] and greater clearance when circumventing obstacles [4] compared to controls in turning tasks. Other changes to turning mechanics due to concussions and their potential impact on performance and/or injury remain unknown. This study examined turning in recently concussed collegiate athletes and matched controls, after the athletes were cleared to return to play, to examine differences in path curvature and ML inclinations.

METHODS

Four recently concussed athletes (C) and four healthy matched controls (H) were tested a mean (SD) of 23 (2) days after each concussion. The C athletes were cleared 12 (4) days post-concussion. Concussions were clinically diagnosed by Virginia Tech sports medicine physicians. Controls were selected from the same team as each concussed athlete and matched based on position, age, stature and weight. Participants gave written consent and protocols were approved by the Virginia Tech IRB.

Participants walked continuously around a course marked with 1.5 m tall pylons and consisting of straight and non-straight segments with ~90° turns (Figure 1). Participants walked at their normal pace (single task = ST) around the course 14 times, seven

laps in each direction. Participants then repeated the procedure while serially subtracting by sevens (dual task = DT).
Figure 1: Depiction of the 18 m long course. Triangles indicate pylons, and the hexagon indicates the pylon location where motions were tracked.

Kinematic data was sampled at 120 Hz for each lap using four ProReflex (Qualysis, Sweden) cameras located around the middle pylon. Reflective markers were placed over the xiphoid process, approximate T9 vertebra, and on each calcaneus (heel). The upper body center-of-mass (COM_{UB}) location was estimated as the mean of the xiphoid process and T9 vertebral markers. Kinematic data was filtered using a 6 Hz 4th order phaseless Butterworth filter.

The maximum instantaneous curvature of the horizontal COM_{UB} trajectory identified the apex of the turn. Heel contact was identified using the local minima of the heel marker vertical location. The turning stance limb was identified as the heel contact closest to the apex, with the turning stride encompassing one step forward and backward (Figure 2). The ML inclination angle (θ) was calculated as the angle from vertical in the frontal plane from the heel to the COM_{UB} at each heel contact in the turning stride (Pre-Apex, θ_{Pre}, Apex, θ_{Apex}, Post-Apex, θ_{Post}).

Mean curvature and ML inclination angles were compared between groups (C vs. H) using GEE

models with compound symmetry covariance structures across laps. Turning strategy (inside vs. outside stance limb), task (ST vs. DT), velocity of the COM_{UB}, and all group-paired interactions were included in the model as covariates, with significant interactions retained in the final models. A 0.05 significance level was used throughout and analyses were performed using MATLAB^{TM}.
Figure 2: Example overhead view of a turning stride (dotted line) connecting the left-right-left heel contacts around the apex. Black circles show the location of the COM_{UB} at each heel contact.

RESULTS AND DISCUSSION

Summary statistics for each outcome measure are given in Table 1. Significant differences in mean curvature were found between groups ($p = 0.012$), COM_{UB} velocities ($p < 0.001$), and turning strategy ($p < 0.001$). Significant group ($p = 0.002$) and turning strategy ($p < 0.001$) differences were found for θ_{Pre}. The angle θ_{Apex} was significantly different between turning strategy ($p < 0.001$) and task ($p = 0.019$), and the θ_{Post} differed by COM_{UB} velocity ($p = 0.02$), strategy ($p < 0.001$), and task ($p = 0.03$).

Overall, the group differences in curvature and θ_{Pre} support other studies that suggested concussions can affect dynamic task performance, even after athletes return to play [2-4]. Although measured during walking and not competition speed (i.e. running), the lower curvatures found here suggest a potential effect on performance, with recently concussed athletes taking wider, less abrupt turns that may inhibit their ability to respond to competitive demands. Furthermore, the decreased θ_{Pre} suggests delayed anticipation of the turn that may manifest in declined performance and/or increased injury risk. However, it is unclear whether these differences are caused by the neurophysiology of the concussion or are a result of potential detraining during recovery. The increased curvature and θ_{Apex} for outside stance limb compared to inside stance limb agree with a previous report [5].

In summary, these results encourage further research examining the effects of concussions on turning behaviors and on the competitive readiness of athletes returning/recovering from concussions.

EFFECT OF SEX ON RECOVERY OF GAIT BALANCE CONTROL FOLLOWING CONCUSSION

Quinn Peterson, Rachel Klas, David Howell, and Li-Shan Chou

Department of Human Physiology, University of Oregon, Eugene, OR, USA
email: chou@uoregon.edu, web: http://biomechanics.uoregon.edu/MAL

INTRODUCTION

Concussion is an acutely evolving injury that can result in a wide array of functional and neuropsychological deficits, including, but not limited to, clinical signs, physical symptoms, cognitive impairment, and gait balance impairments [1]. The role of sex as an indicator of concussion severity is not well understood but has been hypothesized as a potential risk factor and/or predictor of injury severity [2]. However, a study investigating sex differences in concussion recovery reported no differences in neuropsychological test measures following injury, and no differences in long-term recovery outcomes [3].

Due to anatomical and physiological differences between sexes that may result in differences in sustaining and recovering from concussion, differences in gait balance between female and male concussion subjects can potentially be measured [4]. Therefore, the purpose of this study was to longitudinally examine differences in gait balance impairment between female and male subjects following concussion.

METHODS

38 subjects (14F/24M; mean age: 18.6±3.2 and 17.3±3.2) diagnosed with concussion by healthcare professionals were referred to the lab for the first testing session within 72 hours of injury and returned at approximate time points of: 1wk, 2wk, 1mo, and 2mo post-injury. 38 control subjects matched for age, sex, height, weight, and sport participation were tested in a similar timeline following their initial visit. Concussion symptoms were assessed based on a 22-symptom inventory using a Likert-like scale (ranking each symptom from 0-6) [1].

Subjects walked barefoot along a walkway at a self-selected speed while performing a continuous auditory Stroop test for 8-10 trials. The Stroop test consisted of a recorded voice saying the word "high" or "low" in a high- or low-pitch voice four consecutive times. Subjects were instructed to identify the pitch, regardless if the pitch was congruent with the meaning of the word.

29 retro-reflective markers were placed on bony landmarks and whole body movement was recorded using a ten camera motion analysis system (Motion Analysis Corp., Santa Rosa, CA) at a sampling rate of 60 Hz. Whole body COM position was calculated with a 13-link model [4]. Three dependent variables were identified from each gait cycle: the peak anterior COM velocity (Av), total COM medial/lateral displacement (MLdisp), and average walking speed. Av and MLdisp have previously been reported to provide sensitive detection of gait imbalance in concussion subjects [4].

Three-way mixed-effects ANOVA were used to analyze each of the walking dependent variables and symptom scores in order to determine the effect of sex (female/male), group (concussion/control), and time (72hr, 1wk, 2wk, 1mo, 2mo), and interactions between these independent variables. For all omnibus tests, significance was set at $p < .05$. Follow up pairwise comparisons were examined using the Bonferroni procedure to control Family Wise Type I Error.

RESULTS AND DISCUSSION

For the average walking speed, no significant effect of sex was detected (P = .218), while main effect of group on average walking speed was nearly significant (p = .059). Both concussion and control groups increased average walking speed across the 2-month testing period (time x group interaction, P = .001).

On average, concussion subjects were observed to have significantly greater MLdisp compared to control subjects across the 2-month testing period (main effect of group, $P < .01$; main effect of time, $P = .001$). However, there was no significant interaction or effect of sex found for MLdisp during dual-task walking ($P = .66$) (Figure 1); indicating gait balance impairment for concussion subjects up to 2-months post-injury with no difference between male and female subjects.
Figure 1: Average total medial/lateral displacement in female/male concussion and control subjects across testing time points.

Additionally, no significant differences were observed between male and female subjects for peak anterior velocity ($P = .295$). The peak anterior velocity increased for concussion subjects at each time point across the 2-month testing period, while control subjects showed no significant difference across time (time x group interaction $P < .01$).

On average, all female subjects reported significantly greater total symptom scores than male subjects, regardless of concussion (main effect of sex, $P < .05$) (Figure 2). Symptom scores of male concussion subjects were found to be resolved to the control level between the 1mo and 2mo time points, whereas female concussion subjects did not reach symptom resolution throughout the 2-months of testing. Concussion subjects reported greater symptom scores than matched controls (main effect of group, $P < .001$) and demonstrated significant

decreases in total symptom scores at each visit across the 2-month testing period, while control subject symptom scores did not significantly change during the testing period (group x time interaction, $P<.001$).
Figure 2: Average total symptom score in female/male concussion and control subjects across testing time points.

DISCUSSION AND CONCLUSIONS

The present data suggest similar recovery patterns over time between female and male concussion subjects in terms of balance control during dual-task walking. However, self-report symptom scores were resolved to control levels for male concussion subjects between the 1mo and 2mo time points, whereas female concussion subjects did not reach symptom resolution throughout the 2-months of testing. Females also reported greater total symptom scores throughout the entire testing period. It is likely that females perceive and/or self-report the effects of concussion differently than males.

INTRODUCTION

Concussions can affect balance and stability, making balance assessments an important component of concussion test batteries [1]. The balance error scoring system (BESS) has become the standard field test to identify balance deficits following concussions using a trained clinician to count errors [2]. Instrumenting the BESS with inertial measurement units can produce better diagnostic classification than the traditional "error count" which can be challenging for the clinician [3]. Removing the clinician's error count reduces the challenge of administering the BESS. Furthermore, using publicly familiar IMUs will allow more widespread use when a clinician is not readily available (e.g., youth sports, at-home monitoring). This study compared the traditional BESS error count with the sway measurements of a common smartphone attached with a standard sport armband in healthy young adults.

METHODS

Twenty healthy young males (ages 18-22) previously unfamiliar with the BESS gave written consent and were tested two separate times with one week in between sessions. All protocols were approved by the Virginia Tech IRB. A smartphone (iPhone 5, Apple Inc.) was placed laterally on the upper arm, midway between the elbow and shoulder using a standard smartphone sport armband (Belkin Sport-Fit Armband, Belkin). Participants performed three stances (double, single leg, tandem) on firm ground and on a foam Airex balance pad. Participants were instructed to keep their hands on their iliac crests and maintain each stance for 20 seconds with their eyes closed, returning to that position as soon as possible if they moved their hands, feet, opened their eyes, or lost balance.

A trained sports medicine physician counted BESS errors for each stance [2]. The smartphone calculated sway using tri-axial accelerometers, sampled at 31.5 Hz, and computed the angles between the sensitive axes and the direction of gravity using α, β, and γ, the angles of the resultant acceleration with respect to the local reference frame (Figure 1) [4]. The projection's coordinates (d_x, d_y) were calculated using these angles and the height of the smartphone dz. The circular sway area was calculated using the mean radius of sway and sway velocity was the sway length over time.
Figure 1: Schematic diagram of projected sway using the iPhone accelerometers. Adapted from [4].

Spearman's rank correlation coefficient (ρ) was used to compare all measurements of sway area and sway velocity to the BESS errors overall and separated by ground (firm vs. foam). Interclass correlation coefficients (ICC (2,1)) compared the repeatability of the BESS and sway measurements on each individual from the first to second weeks.

RESULTS AND DISCUSSION

Spearman's ρ between all BESS scores and sway area was 0.86, and 0.85 between BESS scores and sway velocity. On the firm surface, ρ = 0.76 for sway area and 0.77 for sway velocity. On the firm surface, ρ = 0.83 for sway area and 0.79 for sway velocity. ICC values are given in Table 1. Medians and inter-quartile ranges (IQRs) for each measure are given in Table 2.

Table 1: ICC's comparing between weeks.

ICC	All	Firm	Foam
BESS errors	0.01	0.45	-0.27
Sway area	-0.04	0.40	-0.10
Sway velocity	-0.01	0.08	-0.02

Overall, the smartphone based measures showed good (> 0.80) clinical reliability to the BESS scores, especially for a system located on an upper extremity. While the repeatability was poor, the sway area's repeatability was similar to the BESS, and both showed the highest repeatability on firm ground, the most likely surface for BESS tests without a clinician. Because the BESS errors do not take into account movements of the upper body unless an error is committed, it is possible the smartphone based measures of sway area and sway velocity may more accurately represent the postural control of individuals, with differences between methods attributed to discrepancies in the BESS reliability and repeatability [5]. This discrepancy between methods is evident when examining the single leg stance measurements, where large upper body movements resulted in very large sway amplitudes and velocities, but may have only counted as one error. However, this study is limited because the smartphone based measures were not compared to a ground truth (i.e. force plate) and no concussed individuals were tested, limiting conclusions about the clinical classification ability of the sway area and velocity. By placing the smartphone on the upper arm, the measurements were also biased against arm movements, which resulted in large sway amplitudes and velocities, compared to foot movements or opening eyes, which the BESS treats equal to arm movements but produced small sway amplitudes.

CONCLUSIONS

Overall, a common smartphone and sport armband achieved good reliability and comparable repeatability with the BESS, encouraging further studies in clinical and concussed populations to extend the use of smartphone-based balance testing.

THE RELATIONSHIP BETWEEN HEAD ACCELERATION AND HEART RATE VARIABILITY: A POSSIBLE DIAGNOSTIC TOOL FOR HEAD INJURY SEVERITY

INTRODUCTION

Traumatic brain injury (TBI) is one of the leading causes of death in the United States with over 1.7 million people affected annually.[1] Four typical events contribute to the occurrence of TBI including: 1) contact with objects and equipment, 2) falls, 3) motor vehicle accidents, and 4) assault or violent acts.[2] These events suggest vulnerability to TBI for a large segment of the population, including the elderly, due to the high rate of falls they experience. Along with children (0-4 years) and adolescents (15-19 years), adults 65 years of age and older are the most likely group to experience TBI resulting from a fall.[1]

Several neuroimaging techniques are currently used to assess injury severity following a jolt or blow to the head. These include magnetic resonance imaging (MRI) and computerized tomography (CT). Additionally, new techniques are being developed including diffusor tensor imaging and magnetic resonance spectroscopy. The latter are not without shortcomings including both cost and the inability to detect incidence of lesser severe TBI cases.[3]

Heart rhythm is controlled by the sinoatrial node, which is modulated by the parasympathetic and sympathetic branches of the autonomic nervous system. Slight changes in these nervous system inputs result in variations in heart rate. Spectral analysis of heart rate variability (HRV) has been shown to be related to Glasgow coma scale results as well as brain damage severity.[4] Thus, our research team sought to explore the use of a direct biological measurement (HRV) to determine fall injury severity. The purpose of the study was to examine the relationship between HRV and linear head acceleration. Head acceleration was used as a simulation of the magnitude of head impact.

METHODS

Nine apparently healthy male volunteers (175.9±2.4 cm, 75.1±7.3 kg, 25.3±2.4 yrs), with no history of lower extremity injury in the last six months granted institutionally approved written consent to participate. A heart rate monitor (Polar RS800cx; Polar Electro, Kempele, Finland), set to R-R interval mode, was secured to the chest with data transmitted to a wireless receiver secured to the wrist. Sampling frequency was set to 1,000 Hz providing temporal resolution of 1 ms for each R–R period. A plastic helmet with an attached uniaxial accelerometer (PCB Piezotronics Inc. 52456; Depaw, NY) was donned. Bioware software (Kistler 4.0; Amherst, NY; 1000 Hz) was used to measure head vertical acceleration (HA) values.

The experimental protocol consisted of quiet sitting followed by continuous landing. An initial resting heart rate measurement was recorded over 5min. Participants were then instructed to continuously step onto a 45cm platform, step off the platform, and come to rest on the floor "softly". Participants repeated this process over a 5min period as both heart rate and head acceleration were measured. Next, a second 5min resting heart rate measurement was recorded followed by 5min of continuous 45cm step-off landings, this time minimizing the amount of knee flexion upon landing (stiff landing). A final 5min resting heart rate measurement was obtained. Data were extracted over the 5min sample using Polar Pro Trainer 5 software (Polar Electro, Kempele, Finland) and each R-R interval file was analyzed using Kubios HRV Analysis Software 2.0 (Biomedical Signal and Medical Imaging Analysis Group, Kuopio, Finland).

Dependent variables in the time domain included maximum head acceleration (HA), the standard

deviation of R-R intervals (RRsd) and the root mean square (RMSsd) of R-R intervals. Frequency domain measures of power in the low frequency (LF; 0.04-0.15 Hz) and high frequency (HF; >0.15-0.40 Hz) ranges were also extracted. All dependent variables were evaluated using repeated measures ANOVAs ($\alpha = 0.05$) with Huynh-Feldt corrections as necessary. Correlations between HA and the indices of HRV were also computed. All statistical comparisons were conducted using SPSS v22 Statistics software (IBM; Armonk, NY).

RESULTS AND DISCUSSION

There was a significant difference (p=0.001) observed between HA_{soft} (3.05±1.11 g's) and HA_{stiff} (7.61±2.73 g's), which confirmed that participants did distinguish performance between landing conditions, as instructed. There were no significant differences among resting conditions for RRsd (70.9±15.3, 74.8±10.0, 72.6±13.3 ms, for pre-, mid- and final rest, respectively) or similarly for RMSsd (44.2±16.1, 37.2±17.5, 31.4±10.4 ms, respectively). A significant RRsd ANOVA result ($F_{(1,8)}=2.056$, p=0.001, $\eta^2=.836$) was followed up with *post hoc* contrasts using Sidak adjustments. RRsd for both the soft (37.6±9.2 ms) and stiff (32.4 ±8.1 ms) landing conditions were significantly less (p=0.007 and p=0.001, respectively) than any of the resting conditions. RRsd between landing conditions was not significantly different. A similar trend was observed for RMSsd with the source of the significant ANOVA ($F_{(1,8)}=25.24$; p<0.001; $\eta^2=.759$) between both the soft (10.5±5.6 ms) and stiff (9.5±5.0 ms) landings compared to the three resting conditions (44.2±16.1, 37.2±17.5, and 31.4±10.5 ms, respectively).

In the frequency domain, no significant differences were observed among LF or HF measures (Figure 1). Correlations between HA and HRV measures ranged from ±0.162-0.664 with a significant relationship demonstrated between HA_{stiff} and RMSsd (r=-0.664, p = 0.026).

HRV is posited to mirror the control of the cardiovascular system. In the time domain, the measures of HRV (RRsd, RMSsd) significantly decreased with increased HA, with no differences observed in HRV among the rest conditions. Surprising, a similar outcome was not observed at the group level between the soft and stiff landing conditions. There were no observed differences in the frequency domain, perhaps due to lesser agreement between LF and HF measures from the Polar monitor versus a 12-lead ECG.[5] Increased variability in HF for the stiff landing condition (Figure 1), might also have influenced this outcome.
Figure 1. Mean and standard deviation values for frequency domain analysis.

CONCLUSIONS

Results suggest the potential application of HRV as a quantifiable, non-invasive diagnostic measure of head impact severity. Future research should consider head and neck rotational components relative to HRV across a wider range of impact activities, as well as examining LF/HF ratio.

INTRODUCTION

Balance control is a challenging task in many patient populations such as in post-stroke hemiparetic subjects. More than 50% of stroke survivors experience falls within one year post stroke (e.g., [1]). Lack of balance control can lead to physical injuries and long-term disabilities. Thus, it is important to assess dynamic balance using reliable methods in order to detect and treat balance disorders.

Various methods have been used to evaluate balance performance. These methods range from simple clinical scores such as Berg Balance Scale (BBS) (e.g., [2]) and Dynamic Gait Index (DGI) (e.g., [3]) to more comprehensive laboratory-based measures such as margin of stability (MoS) (e.g., [4]) and peak-to-peak range of whole-body angular momentum (H) (e.g., [5]). Further, clinical balance scores are based on discrete score assignments while completing a series of movement tasks, whereas the laboratory-based measures are obtained using whole-body kinematic and kinetic data during walking, often on a treadmill.

A recent study investigated the relationship between clinical balance scores and the rate of change of H in post-stroke subjects and found that a higher rate of change of H during the paretic leg stance was associated with poorer BBS and DGI scores [6]. However, no study has investigated whether the other methods report consistent findings in assessing balance in post-stroke subjects. This information can assist clinicians in selecting the appropriate method to evaluate balance. Thus, the purpose of this study was to assess frontal-plane balance using BBS, DGI, MoS and peak-to-peak range of H in post-stroke hemiparetic subjects and determine if these measures are correlated.

METHODS

Previously collected [7] three-dimensional kinematics and ground reaction force (GRF) data were collected at 100 Hz and 2000 Hz, respectively, while 19 post-stroke hemiparetic subjects (14 left hemiparesis; age: 62 ± 11 years; 6 female) walked on a split-belt instrumented treadmill at their self-selected walking speeds. In addition, BBS and DGI data were collected for each subject.

A 13-segment inverse dynamics model was used to calculate the center-of-mass (CoM) position and velocity for all the body segments. Margin of stability (MoS), which is the minimum distance between the extrapolated CoM and the base of support, was calculated in the mediolateral direction as described in [4]. MoS values were calculated at each step for the paretic foot placement, the nonparetic foot placement and the sum of both legs. Whole-body angular momentum (H) in the frontal plane was calculated as the sum of individual segments angular momenta about the body CoM and was normalized as described in [5]. The peak-to-peak range of H was calculated as the difference between the minimum and maximum values of H over the entire gait cycle.

To determine whether these four measures assess balance performance consistently, correlation analyses were performed. Pearson's correlation analyses were performed between MoS and the range of H using both the mean values across all subjects and the individual step data. Also, non-parametric Spearman's correlation analyses were performed between the clinical balance scores (BBS and DGI) and the laboratory-based measures (MoS and range of H).

RESULTS AND DISCUSSION

Significant correlations were found among all the balance measures (Table 1). BBS was positively correlated with DGI. That is, subjects with a lower BBS also had a lower DGI, indicating poor balance control. Also, MoS (sum from both legs) and the range of H were positively correlated. This was true both for the mean values across all the subjects (Table 1) as well as the individual step data ($r = 0.52$, $P < 0.001$). However, both of the laboratory-based measures (MoS and the range of H) were inversely correlated with the clinical scores (BBS and DGI) (Table 1). In other words, subjects with a higher range of H had a higher MoS (sum from both legs) and lower BBS and DGI scores, indicating poor balance control. These results are consistent with previous studies [5-6]. Further, examining MoS for each foot revealed that only the MoS corresponding to the paretic foot placement was correlated with other balance measures (Fig. 1). Thus, the use of MoS to assess balance performance in stroke subjects should be carefully implemented.

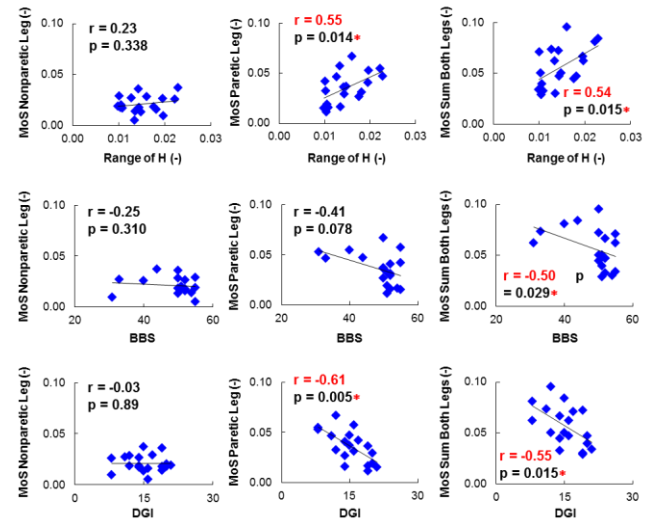
In summary, all measures led to similar conclusions in assessing balance in post-stroke hemiparetic subjects. However, balance being multidimensional, each measure may provide insight about different aspects of balance. The advantage of clinical balance scores is that they provide a simple and quick global assessment which does not require collection and processing of kinematic and kinetic data. However, contrary to the laboratory-based measures, the clinical balance scores cannot provide insight into the mechanisms for maintaining dynamic balance. MoS can provide some insight into foot placement mechanisms, but not the GRFs. Further, it does not account for the segmental moment of inertia and rotational motion that influence dynamic balance. Although a more complex in calculation, whole-body angular momentum can provide insight into how the sum of linear and angular momenta of all the body segments (about the body CoM) can be controlled


Figure 1: Top row shows the Pearson's correlations between normalized margin of stability (MoS) and the range of whole-body angular momentum (H). Middle and bottom rows show the Spearman's correlations between MoS & Berg Balance Scale (BBS) and MoS & Dynamic Gait Index (DGI), respectively. The left, middle and right columns respectively correspond to the MoS for the nonparetic leg, the paretic leg, and the sum of both legs. Significant correlations ($p < 0.05$) are shown in red with '*'

by adjustments in foot placement and generation of the appropriate GRFs. The results of this study can assist clinicians with selecting the most suitable method for assessing balance performance.

INTRODUCTION

Dynamic, overhead body weight support (BWS) systems are often used during gait rehabilitation. By applying an upward force through an overhead lift at a fixed medio-lateral location, some external lateral stabilization will be provided to a subject during walking. Our purpose was to quantify this interaction between BWS and lateral stability during treadmill walking.

Previous research suggests that smaller step widths, and less step width variability are typically observed when walking in a stable environment [1]. We hypothesized that increasing BWS would reduce the requirements for active lateral stabilization when gait speed was held constant. With BWS, we expected to find decreases in step width, step width variability, and minimum lateral margin of stability (MoS). In dynamically similar environments, we did not expect to see significant differences in lateral stability.

To create dynamically similar environments, in which the ratio of inertial forces to gravitational forces experienced during walking were similar across varying levels of BWS, walking speed was varied. Specifically, walking velocity was calculated using a set Froude number (Fr), a factor used to compare motions of different body size, velocity, and gravity. Walking velocities were calculated as:

$$V = \sqrt{\frac{Fr}{gl}}$$

where g is the gravitational constant, and l is the leg length. Fr=0.25 was used for all subjects as it represented the optimal walking speed [3].

METHODS

Eight able-bodied subjects walked on a treadmill with BWS provided by a motorized overhead support system (ZeroG, Aretech, Ashburn, VA). Subjects walked with BWS of 0%, 20%, 40%, and 60% body weight. At each BWS level, a walking velocity, where Fr=0.25, was calculated. These calculated speeds and BWS levels were paired to form a set of *Dynamically Similar* conditions. Each BWS level was also repeated with the absolute speed calculated for 0% BWS, to a form a set of *Speed Matched* conditions. The order of the conditions was randomized. Subjects accommodated to each condition for five minutes, after which data was collected for two minutes.

For each condition, we calculated step width, step width variability, and minimum lateral MoS. Calculation for MoS was adapted from [2], and taken as the minimum difference between the extrapolated center of mass, a measure accounting for both center of mass position and velocity, and the lateral base of support for each step. Statistical comparisons were made in MATLAB (Mathworks, Natick, MA) with a one-way repeated measures ANOVA. Bonferroni post-hoc comparisons were made when the ANOVA indicated there were significant differences between conditions. A p value of ≤ 0.05 was considered statistically significant for all tests.

RESULTS AND DISCUSSION

We found significant differences in step width, step width variability and MoS between conditions (ANOVA, $p < 0.05$; all variables). Step width tended to increase as BWS was increased. Step width was 13% larger during the 60% BWS than the 0% BWS for both the Dynamically Similar (post-hoc, $p<0.001$) and Speed Matched (post-hoc, $p<0.001$) conditions (Figure 1). Step width variability tended to decrease as BWS increased. For both the Dynamically Similar and Speed Match conditions, step width variability was significantly smaller during all levels of BWS when compared to the 0%

BWS condition (post hoc, $p<0.001$) (Figure 2). For minimum lateral MoS, there was only a significant difference between 60% and 0% BWS for the Speed Matched condition ($p<0.001$). During the Speed Matched 60% condition, MoS was 12% larger than during 0% BWS.
Figure 1: Normalized step width changes for dynamically similar conditions (left) and speed matched (right) conditions. Asterisks indicate significance from 0% BWS ($p<0.001$).
Figure 2: Normalized step width variability changes for dynamically similar conditions (left) and speed matched (right). Asterisks indicate significance from 0% BWS ($p<0.001$).

CONCLUSIONS

In both the Dynamically Similar and Speed Matched conditions, subject step width became less variable when subjects were provided with BWS. This reduction in variability suggests that, as we hypothesized, the BWS system may provide lateral stability during gait. However, subjects also adapted wider steps and demonstrated an increased lateral MoS as BWS increased. Both these adaptations are typically observed in destabilizing environments. Subjects' choice to increase step width with BWS was contrary to our hypothesis. It is possible that subjects increased step width with BWS for reasons other than to increase lateral stability. Wider steps may have given subjects greater ability to control their yaw moments that may have been affected by increasing BWS forces. Future research investigating how BWS affects ground reaction forces and joint moments will provide further insight.

Overall our results indicate that overhead BWS effects frontal plane gait kinematics. Reductions in step width variability suggest that the BWS system may provide an external lateral stabilization and decrease the requirements for subjects to actively stabilize. However, increases in step width with BWS suggest that changes in frontal plane kinematics may occur for reasons other than controlling lateral stability. BWS creates a unique environment that needs to be considered before designing therapeutic interventions.

DYNAMIC GAIT STABILITY: THE RECIPROCAL RELATIONSHIP BETWEEN LOWER LIMB AND TRUNK CONTROL IN RESPONSE TO SEGMENTAL LOADING

[1] Shawn M. Beaudette, [1] Timothy A. Worden, [1] Lori Ann Vallis and [1] Stephen H.M. Brown

email: sbeaudet@uoguelph.ca, tworden@uoguelph.ca

INTRODUCTION

For successful walking to occur, the central nervous system (CNS) requires implicit information about the mechanical properties of body segments, including segment masses and moments of inertia [1]. Alterations in segment mechanical properties, such as those induced by an asymmetrically applied mass to a leg segment during walking, have been shown to alter stepping kinematics [2], however, the effect of limb mass reweighting on both upper body and joint (hip, knee, ankle and lumbar spine) dynamic stability remains unknown.

The purpose of this study was to examine the effect of an asymmetrically applied mass to individual leg segments on upper body (combined Head, Trunk and Pelvis segments, termed 'HTP') and lower limb dynamic stability. Furthermore, temporal changes in dynamic stability induced by the segment weighting were examined over the duration of cyclical treadmill walking trials. We hypothesized that distal loading would produce larger instabilities in HTP dynamic stability, while it would stabilize individual joints of the lower limb and lumbar spine due to increased muscular activation. Conversely, we hypothesized that proximal loading would stabilize HTP, while destabilizing joints distal to the applied load. Temporally, we expected both HTP and individual joints to become more stable over time as the CNS adapted to any altered segment properties.

METHODS

Fourteen healthy young adults walked on a treadmill (1.5 m/s; 5 min) while completing three different asymmetrical segment loading conditions (THIGH, SHANK and FOOT) as well as an UNLOADED control trial. The applied masses were 50 % of each estimated individual segment mass [3], and were securely applied to the non-dominant leg for the entire walking trial. Each trial was divided into five, non-overlapping stride epochs (E1, E2, E3, E4 and E5; 50 strides per epoch) to examine the temporal effects of segmental reweighting.

Margins of Stability (MOS) and Local Dynamic Stability (Lyapunov Analysis) estimates were computed from anteroposterior (AP) and mediolateral (ML) HTP velocities to approximate neuromuscular control of the center of mass [4]. Three-dimensional angular joint kinematics were collected, and Lyapunov analyses were performed to obtain estimates of LDS for the lumbar spine, hip, knee and ankle. A two-way repeated measures statistical design was conducted, with the loading conditions and temporal epochs as independent variables. Post-hoc analyses were performed with a Tukey's adjustment, $p < 0.05$.

RESULTS AND DISCUSSION

When examining HTP dynamic stability across the different weighting conditions in the ML direction, MOS demonstrated that FOOT weighting was more destabilizing as compared to the THIGH, SHANK and UNLOADED conditions (Figure 1). Both MOS and LDS detected similar trends, although MOS detected more significant differences between conditions, with proximally applied loads (THIGH and SHANK) being more stable than the UNLOADED condition (Figure 1). Similar trends for both dynamic stability measures were also apparent in the AP direction, with distal weighting being more destabilizing as compared to proximal weighting. This was likely due to the larger accelerations the foot segment experiences; with distal loading being a more challenging perturbation to the control system. Temporally, the only effect on HTP dynamic stability was detected by LDS in

the AP direction, with the first time epoch being less stable than all other epochs.

Figure 2: LDS of the ankle joint for the four weighting conditions (*p < 0.05). Note that a higher LDS (λ_{max}) indicates lower stability.

Temporally, the hip and ankle LDS stabilized over the duration of the trial (independent of which loading condition was applied, including Unloaded). This indicates that the hip and ankle joints may be responsible for the control of adaptation to walking on a treadmill.

CONCLUSIONS

Our results indicate that adding a mass distal to a joint increases the dynamic stability of that joint. Interestingly, the increased stability at the joint level appears at the cost of reduced stability of the HTP segment. We propose that the increased joint stability is the result of increased muscular activation about the joint, which in turn stiffens the leg segments. This stiffness in leg segments presumably changes foot strike patterns, thereby destabilizing HTP MOS measures. Temporally, the ankle and hip joints stabilized over time while walking on the treadmill, indicating that overall HTP stability is achieved via alterations occurring at the joint level.

Figure 1: The effects of segment reweighting on HTP A) MOS and, B) LDS (*p < 0.05). Note that a higher LDS (λ_{max}) indicates lower stability.

For individual joint stability, it was found that a mass applied proximal to a joint had a destabilizing effect as determined by increased LDS. Conversely, masses applied distal to a joint had a stabilizing effect at the joint. As illustrated in Figure 2, the ankle joint was destabilized when the mass was more proximally applied (THIGH and SHANK), and conversely was as stable as the UNLOADED condition when the mass was applied to the foot. Similar spatial weighting effects were also observed at the knee and hip. This may be due to the increased muscular activation about the proximal joints required to stabilize the distally applied load, thereby stiffening each joint and increasing stability.

DOES DYNAMIC BALANCE OF TRANSTIBIAL AMPUTEES CHANGE AFTER A THREE WEEK ADAPTATION PERIOD ON A NEW PROSTHETIC FOOT?

[1]Jenny A. Kent, [1,2]Nicholas Stergiou, and [1,3]Shane R. Wurdeman

INTRODUCTION

Assessment of the suitability of a prosthetic device immediately following delivery to a patient with lower limb amputation is complicated by the ability of an individual to adapt to the device. Forming a judgment on device efficacy before this adaptation has occurred could lead to inappropriate prescription decisions. It is therefore important to understand the changes that may be expected to take place as the individual adapts. Measures that show consistency at baseline with later assessment, regardless of adaptation are valuable for the decision process, providing objective support to currently subjective decision methods.

Balance during walking is of high importance to transtibial amputees [1] and its assessment a fundamental consideration in limb prescription. The margin of stability (MOS) is a measure of dynamic balance that has been adapted from traditional static base-of-support measures to account for the inertial factors associated with center of mass (COM) motion during movement [2]. The velocity of the COM is multiplied by a factor $\sqrt{(\text{leg length/acceleration due to gravity})}$ to obtain the Extrapolated Center of Mass (XcoM). This vector is then added to the vertical projection of the COM onto the ground in the anterior-posterior (AP) and medial-lateral (ML) directions to generate MOS. MOS in the ML direction (MOS_{ML}) is defined as the minimum distance between the XcoM and the lateral margin of the base of support during movement. We defined MOS in the AP direction (MOS_{AP}) as the maximum distance past the base of support that the XcoM is allowed to progress in swing prior to contra-lateral heel strike.

We hypothesized that changes in balance, evident in MOS_{ML} and MOS_{AP} values, over a three week adaptation period with a new prosthesis would differ depending on the individual's prescribed Medicare functional classification level [3]. Specifically, improvements in balance would be exaggerated when adapting to a foot of a lower activity level than the person's functional level, compared to a foot of the correct functional level.

METHODS

21 unilateral transtibial amputees (age 27-76 yrs; height 1.78 (0.81) m; mass 100.6 (18.8) kg; etiology traumatic (n=13), vascular (n=5), other (n=3)) participated in a randomized crossover trial. Participants were tested on two foot components rated 'higher activity' (HA) (i.e. energy-storage-and-return type feet) and 'lower activity' (LA) (e.g. SACH) with order of provision randomized. All subjects were previously categorized as K3 or K4 and appropriately wore high activity feet with their personal prostheses. Prosthesis provision and alignment was conducted by a certified prosthetist.

A new foot component was provided at the initial session (V1) after which participants immediately undertook baseline gait assessment. Movement of the lower limbs was recorded with 27 retroreflective markers (60 Hz; 12 camera Motion Analysis Corp., Santa Rosa, CA, USA) [2]. Each participant completed ten traverses of the laboratory at a self-selected walking speed, with 10-15 steps per leg extracted for analysis. Following a three-week adaptation period, participants returned for a repeat assessment (V2). The foot component was then swapped for an alternative component of a higher or lower activity rating and the process (V1, V2) was repeated with the second foot. The vertical

projection of the midpoint of the pelvis markers onto the floor was used to represent COM [4]. For MOS_{ML} the lateral malleolus marker was used to approximate the lateral base of support. MOS_{AP} was defined as the maximum anterior deviation of the XcoM beyond the base of support defined by the ipsilateral toe marker in terminal swing (i.e. at the point of contralateral foot contact). MOS_{ML} and MOS_{AP} were examined using a three way repeated measures ANOVA (leg x prosthesis x visit) with Fisher's LSD post hoc tests.

RESULTS AND DISCUSSION

With HA, from V1 to V2 the MOS_{ML} on the prosthetic side decreased while sound limb MOS_{ML} increased. Although these changes were not significant, in V2 this resulted in the elimination of the significant inter-limb difference that was apparent at V1. No such change was seen with LA (Figure 1). MOS_{AP} was greater on the sound limb compared to the prosthetic limb on both HA and LA during both visits, although the difference was only significant for LA. Significant increases in MOS_{AP} on both the sound and prosthetic limbs were seen from V1 to V2 on HA but not on LA (Figure 2).

Our hypothesis was refuted given the significant changes in both MOS_{AP} and MOS_{ML} across visits that were greater on average for HA. The changes seen however resulted in a more symmetrical MOS_{ML}, which may suggest reduced favoring of the sound limb, and an increased MOS_{AP}, indicative of a greater balance confidence.

CONCLUSIONS

Changes in dynamic balance indicated by MOS_{ML} and MOS_{AP} occurred over a three week adaptation period on a new prosthetic limb of the individual's prescribed Medicare functional classification level. Our results oppose the use of MOS at initial fitting to assess function on a given device, regardless of the appropriateness of its activity level for the individual.

RELATIONSHIP BETWEEN POSTURAL BALANCE PARAMETERS AND GAIT ASYMMETIES IN UNILATERAL TRANSTIBIAL AMPUTEES

[1,2] Jonathan S. Akins, [1,2] Rory A. Cooper, and [1] David M. Brienza

[1] University of Pittsburgh, Pittsburgh, PA, USA
[2] VA Pittsburgh Healthcare System, Pittsburgh, PA, USA
email: jsa14@pitt.edu

INTRODUCTION

Greater than half of community dwelling amputees are at risk of falling and this rate is more than twice the fall rate among the general community dwelling population (24.7%) [1]. Among amputees that fall, up to 50% sustain a physical injury [1]. Physical injuries are compounded by psychological consequences that include fear of falling and lack of confidence. The causes of falls are complex and numerous fall mechanisms are not readily modifiable (e.g., environment, prosthetic entanglements, and terrain). However, mechanisms such as postural balance and gait are modifiable via rehabilitation and exercise. Previous research has examined inter-limb asymmetries of amputees during postural balance [2] and gait [3], but no known research has determined if correlations exist. The purpose of this study was to explore relationships between medial-lateral (ML) balance parameters and gait asymmetries. We hypothesized that reduced ML balance parameters were correlated with greater gait asymmetries.

METHODS

Unilateral transtibial amputees were recruited and written informed consent was obtained prior to the initiation of study procedures. Lower extremity kinematics and kinetics were measured in a computer assisted rehabilitation environment (CAREN, Motek Medical, Amsterdam, Netherlands) using a conventional gait model.

<u>Quiet Stance</u> Participants stood on separate force platforms with their hands on their hips and attention focused straight forward at a target placed at eye level. Three, 30-second trials were conducted with the mean values of the three trials used for analysis. Parameters were ML center of pressure (COP) excursion, mean ML distance from geometric mean, root mean square (RMS) ML distance from geometric mean, and ML range of COP. ML parameters were selected because they have been associated with future falls [4].

<u>Perturbed Balance</u> Participants stood in the same posture and four linear support surface translations were applied in the horizontal plane − anterior, posterior, towards the prosthetic limb, towards the sound limb. Perturbation magnitude was 2% of the participant's height and was applied with the CAREN's 6 degree-of-freedom motion platform. Three trials were conducted for each direction; perturbation direction and time were randomized. Peak joint moments were calculated within the active force production range (160-400 ms). Response latencies were calculated as the time from onset of platform perturbation (0 ms) to peak ankle and hip moments. The symmetry index was calculated for the ankle and hip: $SI(\%) = (X_S - X_P) / (0.5(X_S + X_P)) * 100$, where X_S is the sound limb and X_P is the prosthetic limb. The mean of three trials was used for analysis and only ML perturbations were analyzed.

<u>Gait</u> Participants walked at a preferred walking velocity in a virtual environment. The scene was a straight trail in the woods with flat terrain; optic flow was matched to walking velocity. After participants performed a 3-minute accommodation task and took a rest break, a 3-minute trial was conducted. Twenty strides were used for analysis. Symmetry of the full normalized gait cycle waveforms were calculated using the method proposed by Kaufman et al., 2012 [2], which uses singular value decomposition. Values of + 1 indicated perfect symmetry between waveforms, 0

indicated no relationship between waveforms, and – 1 indicated perfect asymmetry.

<u>Statistics</u> Spearman's rank correlation coefficients were calculated between ML quiet stance parameters and gait asymmetries, and between ML perturbed balance parameters and gait asymmetries. Statistical significance was set as $P \le .05$ *a priori*.

RESULTS AND DISCUSSION

Ten unilateral transtibial amputees participated: 9 men and 1 woman; 56.3 ± 13.1 years of age; 174.7 ± 11.4 cm; 89.4 ± 14.2 kg; 9.0 ± 5.84 years since amputation; and 6 traumatic and 4 dysvascular amputations.

Decreased mean ML distance, RMS ML distance, and ML range were significantly correlated with increased ankle kinematic and kinetic gait symmetry parameters (Table 1). Decreased quiet stance parameters correspond with better balance and increased symmetry parameters are generally accepted to correspond with better gait, although a debate exists. The correlation between ML quiet stance parameters and ankle gait symmetries support the importance of gait symmetry in unilateral transtibial amputees because previous studies have demonstrated that ML quiet stance parameters are associated with future falls [4]. While Piirtola and Era [4] was a review of prospective follow-up studies with elderly participants, no such study has been performed with the unilateral transtibial amputee population.

Quiet stance parameters were not correlated with knee (r = -.527 − .285) or hip (r = -.515 − -.127) symmetry parameters. Few perturbed balance parameters were correlated with ankle, knee, or hip symmetry parameters and no clear relationships were identified. Gait symmetry index parameters

were generally symmetric (+1) with a few outliers for ankle angle, knee moment, and ankle and hip powers (Figure 1).
Figure 1: Boxplots of gait symmetry index parameters for sagittal plane kinematics and kinetics.

Limitations of this study include a cohort of traumatic and dysvascular amputees and no control group. Matched-control participants are currently being recruiting and tested.

CONCLUSIONS
The importance of gait symmetry in unilateral transtibial amputees is supported by the correlations between ML quiet stance parameters and ankle gait symmetries shown in this study.

FOLLOW THIS FELLOW? FINE, BUT GIVE IT YOUR OWN TWIST.

Paul DeVita, Ph.D.
Department of Kinesiology, East Carolina University, Greenville, NC 27858
Biomechanics Lab on Facebook (more fun than Lab website)

CAREER OVERVIEW

Believe it or not, I was educated: Maplewood Elementary, Memorial Junior High, Walt Whitman High, SUNY at Binghamton and U. of Oregon. All that yet I still can't spel champaign. Since then I have progressed through the ranks at Southern Illinois and East Carolina Universities. I have also been highly active in ASB, of course, and ACSM.

SCIENTIFIC QUESTIONS ADDRESSED

I have worked as a locomotion biomechanist investigating ACL injury, aging, obesity, osteoarthritis, and healthy gait. The common theme throughout is the biomechanical plasticity in locomotion (1) induced by various health issues. Through this work, I learned that while the mechanics of biomechanics provide our methods, the bio of biomechanics provides the mystery. Animals are adaptable, flexible, malleable, compliant, transformable, and ever-so-changeable. Thus we find the not-always-easily-predictable responses humans make to a change in our state, i.e. the mystery of biomechanics.

REFLECTIONS ON CAREER

When starting a career, we think about ourselves and the work we can and will do. Later however, we start to think about other people and how we can assist them in performing the work they can do. We migrate from first to last authors on our papers. I like this because while we should all like our work, we should like our colleagues and students more, especially our students. As we get better at our jobs we contribute more to the professional and personal growth of young people and we must do that with passion and sincerity.

WHAT DIRECTIONS WOULD I GET INTO NOW?

Vertical? Oh, not that kind of direction. Personally, I wanted to be the NY Yankees Biomechanist but this job didn't exist in 1986. Probably still doesn't but it soon will. Biomechanics will not always be dominated by researchers but will one day have practitioners, to use this term. Of course, many biomechanists today work in commercial settings using biomechanics to, "improve performance," of people or things. As I look into the future, I foresee more commercial biomechanics opportunities. Name the industry… sports, film-making, medicine, construction, manufacturing…biomechanists will be employed to explain, exploit, and expand the human movement element. Of course, I love doing biomechanics science and always have. I think however future biomechanists will be employed as both science-creators and science-users and some of the users will have PhDs. Brave new world.

ADVICE FOR YOUNGER SCIENTISTS

- Create hypotheses that are comprehensive, fundamental ideas, not statements of expected results. Write introductions that lead to hypotheses not purpose statements.
- Avoid university service as much as you can. Do not serve on the Library Committee, the Should-Students-Wear-Blue-On-Tuesdays Committee, and most other committees. Do not be exploited by the university to do service tasks unrelated to your science. Provide biomechanics service for your university and for biomechanics (e.g. contribute to ASB). Of course, service is part of the tenure triumvirate and you must perform some activities defined as service but keep them to a minimum and fly under the university service radar.
- **Get some advice from people who have been working for ~8 years. They have been around the block yet are still part of the modern world.**
- Work hard when you are young and energetic.

(1) This phrase developed by my long-time colleague, Tibor Hortobagyi

A Career Path: From Get Smart ... to Getting Smarter

Irene S. Davis

Department of Physical Medicine and Rehabilitation, Harvard Medical School, Cambridge, MA 02138
www.runsnrc.org

CAREER OVERVIEW

I graduated from Sandwich High School, Sandwich, MA with 60 kids that I had spent the majority of my schooling with. I had originally wanted to be an FBI agent, but was denied a summer internship by J. Edgar Hoover because of my sex (no females allowed!). Thus, I took a year off, bought a motorcycle and travelled the US. With a secondary interest in the human body, I then went on to complete a BS in Exercise Science from the University of Massachusetts, a BS in physical therapy from the University of Florida, an MEd in Biomechanics from the University of Virginia and a PhD in Biomechanics from Penn State University. I subsequently accepted a faculty position in the Dept. of Physical Therapy at the University of Delaware. I remained there for 21 years until accepting a position in the Dept. of Physical Medicine and Rehabilitation at Harvard Medical School to develop and direct the Spaulding National Running Center where I now work.

SCIENTIFIC QUESTIONS ADDRESSED

My research has been aimed at understanding the relationship between lower extremity mechanics and overuse musculoskeletal injuries associated with gait. This has included injuries such as stress fractures, patellofemoral pain, iliotibial band syndrome, plantar fasciitis and Achilles tendinitis. A second focus has been on the development and assessment of gait retraining interventions to address abnormal mechanics leading to these particular injuries. While my emphasis has been on injured runners, I have also studied retraining interventions for other populations such as those with knee osteoarthritis and amputations. Two areas of much interest to me are patellofemoral mechanics and foot mechanics, neither of which are very amenable to standard motion analysis techniques. Therefore, I have very recently become involved in studying these mechanics using biplanar videoradiography techniques. Another recent area of exploration is the mobile monitoring of gait. I hope to better understand how mechanics might change out in the natural environment. I am also working to provide realtime biomechanic feedback to alter walking and running mechanics out in the community to improve the reinforcement of new motor patterns.

REFLECTIONS ON CAREER

What I have learned about a career is that it is a professional path that has a beginning, and an initial direction. However, it is dynamic and can be significantly altered by the people you come in contact with and/or who join you along its course. I started out wanting to be an FBI agent – and that course was altered forever with a rejection letter from J. Edgar Hoover.

Thus, I started my undergraduate program without any real direction….and a bit worried. An exercise science course sparked my interest and an advisor who was a physical therapist further influenced my path towards physical therapy. As a rehab physical therapist working with patients with spinal cord injuries, I became intrigued about the biomechanics of patients being able to move their bodies with only 25% of their muscle power. This propelled me to pursue graduate work in biomechanics – another alteration of my professional path. Through my Masters' work, I developed an interest in lower extremity mechanics and sought out a PhD program focusing on this. Being accepted into Penn State University to work with Peter Cavanagh on running mechanics set the primary course for the rest of my career. Wanting to merge my clinical and scientific focuses, my path was set in the direction of understanding the relationship between lower extremity mechanics and injury.

During the first half of my career at the University of Delaware, my goal was to understand the mechanics associated with specific injuries. This provided the justification to then develop

interventions to alter these mechanics to reduce injury risk. This is the work I pursued during the second half of my tenure at UD. However, after over 20 years, I was ready for a new challenge. I wanted to apply our research findings into a clinical environment. I also wanted that clinical environment to be continually shaped by evidence derived from ongoing research. Thus the idea of a clinical and research center focused on running injuries began to develop. Boston was my home and I felt it was the ideal location for such a center, so I began to network in this area. One day, I found myself sitting across from the Chair of Physical Medicine and Rehabilitation at Harvard Medical School, describing my idea for this new center…..and my career path diverged once again to where I am now.

What I have learned is that it is nearly impossible to predict where your career will take you. But, whatever path you take, you should keep it open to new directions.

WHAT DIRECTIONS WOULD I GET INTO NOW?

Dynamic imaging techniques such as ultrasound and biplanar videoradiography are two of the new frontiers in biomechanics. These techniques provide a way to assess muscle action as well as bony motions not possible with current techniques using external markers. This relatively new line of research can provide important new information about musculoskeletal mechanics not possible without these techniques. I also think the time and mobile technology has come to promote the study of mechanics outside the laboratory environment and especially when individuals are not conscious of their gait being observed. These are the types of data that will be the most ecologically valid, and likely the most valuable.

Another area I find fascinating is tissue engineering. While we have progressed in our surgical techniques and implant technologies, nothing takes the place of nature. I believe the closer we come to restoring our natural state, the better our outcomes will be. It is entirely possible that we will soon be growing new joints using biological scaffolds and stem cell technology. This will be an incredibly

impactful and exciting area of future biomechanical research that I believe will be quite fundable.

Finally, I believe strongly in preventative medicine Unfortunately, this is not currently an area with strong funding support. However, if this funding environment changes, I believe this is a critical area of research that biomechanists could contribute significantly to, whether it be in the area of occupational, sports, or clinical biomechanics. Promoting preventative medicine in this way could significantly improve the quality of lives and reduce the remarkably high costs of healthcare.

ADVICE FOR YOUNGER SCIENTISTS

Choose your work carefully and live by the four Ps. Have a noble Purpose, doing something that you are Passionate about. Be Persistent with your approach and Patient with results. Plan a line of research that logically builds progressively. A scattered research history is heavily scrutinized during promotion reviews. Collaborate early and often. Collaborations with those more experienced will help you in your funding efforts. Your research will become so much more dimensional and interesting through collaborations with scientists with skills outside your own area of expertise. Pick your collaborators wisely – you will be working closely with them and there truly needs to be a mutual trust and respect between you. Keep a steady influx of young scientists with new ideas into your lab to keep your research ideas fresh and relevant. Keep an open mind to shifts in paradigms that might shake the core of your current beliefs. Remember that the truth of 10 years ago may not be the truth of today, and the truth of today may not be the truth 10 years from now.

It is a privilege to live an academic life, but it is very easy for it to consume you. In terms of balance, you wear three hats: your professional hat, your family hat and your personal hat. It is difficult to be at your best in all three areas at the same time. Sometimes one or two areas have to take priority. My advice is just not to let any one area go too long without attention. Also, if you feel your plate is full, do not add another responsibility until you eliminate one first. Finally, I have found that it is so important to be able to completely disconnect from your work at times – so work hard, but play hard.

USING BIOMECHANICS TO TRY TO UNDERSTAND THE MECHANISMS OF UNINTENTIONAL INJURIES SO THEY CAN BETTER BE PREVENTED

James A. Ashton-Miller, Ph.D.

Department of Mechanical Engineering,
University of Michigan, Ann Arbor
jaam@umich.edu; webpage: http://me.engin.umich.edu/brl/

EARLY YEARS

I grew up in England with four sisters and a brother in Flax Bourton, a village of 250 near the southwest coast of England. When I was five my mother died unexpectedly after childbirth. It was iatrogenic - a needless death caused by a blood clot due to a doctor ordering too much bed rest. Thankfully, medical practice changed soon after. My father, a surgeon, remarried a Norwegian. At 7 years I was sent to her mother on a small farm in Norway for 6 months to learn Norwegian and attend school. With 6 feet of snow, it was heaven. The local boys introduced me to the joys of gliding down hills on my skiis. They dared me to try their ski jumps, so they could enjoy the inevitable head plant with glee. But the Telemark bindings prevented serious injuries, and I slowly became a passable skier. Back in England I also became an inveterate tinkerer. By age 10 my friend and I had bought two 1929 cars for £1 each. We stripped them to their engine and chassis and had two full-size go carts to race around the neighbor's farm after the crops were in. In school I played soccer and cricket, ran track and cross-country and took up squash. My first real injury was a lumbar intervertebral disc herniation; now a known risk factor for cricket fast bowlers. By 15 I had acquired and rebuilt a 1936 MG PB sports car that would later carry me the 300 miles to college, along with a toolbox that could be needed at any time. After high school a stipend allowed me to study physical education for a year at Romerike Folkehögskole in Norway, where I got certificates as a children's gymnastics, swimming and ski instructor. That was where I learned my first anatomy and physiology, and first heard about biomechanics. Back in England I attended Newcastle University to study mechanical engineering. A senior design class provided my first introduction to biomechanics, and I found the experience of the collaborating with physicians to help patients very gratifying. That was what I wanted to do – apply my engineering to humans. But in 1972 there were only a couple of openings to study biomechanics in the U.K –at Strathclyde University. Surmising that I had a very small chance of being accepted there I never applied and moved to the U.S. to study for a masters degree at M.I.T. in mechanical engineering. I did research on spinal cord injuries. Every winter weekend I raced the Vermont and New Hampshire X-C ski circuit. In 1975 my bride, Kathy, and I moved to Norway so I could improve my X-C racing and she could find her roots. I volunteered as a biomechanical engineer at a University of Oslo orthopedic hospital while Kathy supported us by teaching. Luckily, I was granted a fellowship by the Norwegian government to study the biomechanics of idiopathic scoliosis for a doctorate. In 1980 I happened to see an IBM computer advertisement in a U.S. national newspaper showing how Albert Schultz (a later ASB Borelli winner) had used a computer to model spine scoliosis. By chance he was on sabattical in Gothenberg, Sweden, so I invited him to Oslo to give a seminar. We found common interests and he offered me a job at the University of Illinois at Chicago. In 1983 we were both recruited to the University of Michigan (U-M) in Ann Arbor, where I have worked ever since. It is interesting how job opportunities seemed to materialize at fortuitous times.

REFLECTIONS ON SCIENTIFIC QUESTIONS ADDRESSED

Spine Biomechanics: My doctoral work involved demonstrating that higher vertebral growth rates in children with idiopathic scoliosis than normal.,

measuring the 3-D biomechanical properties of two child spines, and building a 17-vertebra 3-D mathematical model of the child spine stabilized by 144 muscle slips controlled by an optimization algorithm. I used the model to study how different neuromuscular recruitment strategies might affect curve progression risk under gravitational loading. I learned the hard way that complex theoretical models can be almost impossible to validate. I am forever grateful to Al Schultz for teaching me the power of using simple biomechanical models to capture the essence of the behavior of interest, and to Gunnar Andersson for modeling how orthopedic surgeons can effectively collaborate with engineers.

Falls in the Elderly: In the early 1990s Al and I were encouraged by a U-M gerontologist to examine how aging affected balance and gait. We performed some of the first studies of stepping over obstacles. Working with geriatrician Neil Alexander and neuropsychologist Bruno Giordani we studied obstacle avoidance with and without divided attention. With Darrel Thelen as a post-doc, we studied the biomechanics of forward falls and how much age and sex adversely affected rate of ankle torque development. Later doctoral students Kurt DeGoede and Josh Lo helped me analyze optimal fall strategies, both theoretically and experimentally. More recently physiatrist James Richardson and I have studied gait on uneven surfaces, especially in diabetic neuropathy.

Anterior Cruciate Ligament Injuries: About 10 years ago I suggested to a U-M orthopedist, Ed Wojtys, that we figure out which 3-D impulsive loading causes the highest ACL strain during a simulated jump landing. It took three doctoral dissertations (Tom Withrow, Youken Oh and David Lipps) to find the answer. Since then doctoral students David Lipps and Melanie Beaulieu have helped us use that experimental model to demonstrate that, while a single overload can cause an ACL rupture, repeated sub-maximal loading can also cause failure - due to low-cycle ACL tissue fatigue. This is especially true in the presence of femoroacetabular impingement.

Maternal Injuries during Vaginal Birth and Pelvic Floor Function and Dysfunction. A serendipitous meeting with John DeLancey (Obgyn) about 25 years ago over a cadaver led us to meet every Friday morning to try to understand how, why and when women are injured during birth, and why those injuries lead to pelvic organ prolapse and incontinence later in life. Aided by our Pelvic Floor Research Group we have made steady progress. Our data challenge the prevailing dogma that prolapse is caused by a problem with the vaginal wall connective tissue, and hopefully they will lead to improved treatments.

REFLECTIONS ON CAREER

Whether it was orthopedics, geriatrics, physical medicine, gynecology, urology, or neuropsychology it seemed to take about two years to learn enough about the new field to get a good feel for what is and is not possible. I have been privileged to find physicians who are open minded and respectful of what other disciplines can bring to the table to help their patients. Part of the reason I survived on soft money for 40 years, through good and bad funding cycles, is that I purposely diversified my portfolio to spread the risk of failure. I have found that competing for funding to put bread on the table means only submitting one's very best work. Anything else is a waste of time.

ADVICE FOR YOUNGER SCIENTISTS

1) Work on important socioeconomic problems - they are easier to get funded and they will open doors for you. If one's research is not going to make a difference, then move on to a topic that will.

2) Life is too short to work with people you don't respect or who don't respect you, your time, or your efforts.

3) Be considerate of your collaborator's time and give credit where credit is due.

4) The best way to get a collaboration going is to meet every week, come rain or shine, and preferably with an interested student.

REGRETS, I'VE HAD A FEW; BUT THEN AGAIN, TOO FEW TO MENTION – Frank Sinatra

Rodger Kram

University of Colorado Boulder
rodger.kram@colorado.edu; www.colorado.edu/intphys/people/kram.html

CAREER OVERVIEW
• High School (1975-1979): Realized in ~1977 that I could combine my 2 obsessions (running and science) via exercise physiology. Collected my first VO2max data. Biomechanics not yet on radar; ASB only formed 1977.
• Northwestern University (1979-1982) Biology major: Abysmal classroom student (GPA 2.74) but worked in a lab and never lost confidence or fascination with science.
• Penn State University (1982-1985): Lab tech, then M.S. student under Peter Cavanagh. Lived the dream, ran ~80 miles/week while studying biomechanics and energetics of human running.
• Harvard University (1985-1991): Lab tech, then Ph.D. student under Dick Taylor & Tom McMahon. Studied biomechanics and energetics of locomotion in humans, kangaroos, horses and antelope +.
• University of California Berkeley (1992-2000): Post-doc under Bob Full, then Assistant Professor. Studied biomechanics and energetics of locomotion in insects, humans, penguins and elephants.
• University of Colorado Boulder (2000-present): Associate Professor, research evolved towards health related topics (obesity, amputations, aging) and sports related topics (xc skiing, cycling, and as always, running)

SCIENTIFIC QUESTIONS ADDRESSED
What is the biomechanical basis for the metabolic energy cost of legged locomotion in humans and other animals? It's been a tough question; I'm still working on it after 30+ years.

REFLECTIONS ON CAREER
I figured out what I wanted to be when I was just a kid and at key junctures, I audaciously pursued opportunities. I am amazed that I get paid to read, think and tinker/invent things. I am gratified to see young scientists extend (and/or disprove) my ideas. Mentoring grad students and seeing them succeed on their own is my greatest career satisfaction. Good ideas will get you through times of no money better than money will get you through times of no ideas.

WHAT DIRECTIONS WOULD I GET INTO NOW?
Understanding how the brain controls movement is a daunting challenge, one that was quite primitive when I was a student. Merging the new tools of neuroscience (fMRI etc.) and imaging (PET) with biomechanics and energetics seems promising. PET scanning or something better will help us to understand energetics at the muscle level and even more locally. It is impossible to be an expert in every technology. I would pursue collaborations with experts in these techniques who are looking for questions to answer.

NIH etc. funding opportunities can be very frustrating and inefficient. Industry funding can be infinitely faster and the odds are much better. In my mind, grants are means to an end, but some departments view grants as ends in themselves.

WHAT WOULD I DO DIFFERENTLY IF I WERE STARTING AGAIN?
Mistake #1. I was really good at math in high school but I got in over my head in my first college math course. I squeaked by with a C and never took another math class.
Mistake #2. I had been OK at programming in grad school and as a post-doc. But when I was an Assistant Professor, I felt that I was too busy to learn Matlab when it came on the scene. As a result, I've had to depend on my students and post-docs for any serious data processing. Both of these mistakes restricted later options. Learn as much math and computer science as you can, in a formal class or on-line, DIY etc. You'll have a bigger toolbox.

Mistake #3. I am not very patient and I became frustrated by the time involved in writing grants, the delays and low odds of getting NIH funding. I have not applied for NIH grants as PI in many years. That resulted in my grad students doing more TA-ing than their peers (not always a bad thing) and it is why I have not advanced to the rank of Full Professor. Lack of funding has forced me to be more creative, but it also has limited my research to some extent. By writing papers, I have made good use of the time that I could have spent writing grants. But in hindsight, I should not have given up on grants without more fight.

Mistake #4. Also after tenure, I tried to develop a parallel career track developing research tools into clinical devices and growing my own business. That was a disaster. I do not belong in a world where the goal is making money and truth is not valued. It is better to patent and license your practical ideas. A scientist trying to be a businessperson can be as pathetic as a businessperson trying to do science or a fish riding a bicycle.

ADVICE FOR YOUNGER SCIENTISTS
My strengths have always been as an experimentalist and inventor. Although modeling and simulation are now a huge part of biomechanics, there is still plenty of room for clever experiments and equipment design. The best scientific papers develop a model and test it with experiments. Few people are both excellent modelers and experimentalists. Find a collaborator who complements your strengths/weaknesses.

Science can be like being on a whale-watching boat trip. When a whale is spotted off the starboard side, everyone runs to that side, the boat lurches to that direction and only a few people get to see the whale. Government initiatives (RFPs) and new hot areas are like whale sightings. Aging research was a hot area at one point and I avoided it in part because the crowd was all running in that direction. Later in my career, when I had some original ideas percolate up about aging and locomotion, I was able to make significant contributions. In short, pursue your own ideas, don't try to study what someone else says is important.

• Undergrads: If majoring in engineering, take some biology classes and vice versa. Learn to write!
• Grad students: ABR = Always Be Reading high quality scientific papers. Learn to ask important scientific questions and design experiments. Best Dissertation = series of papers published 1 or 2 per year, not a single *magnum opus* published after graduation. You don't get a Ph.D. for surfing the Internet; write your damn paper.
• Post-docs: Become a Reese's Peanut Butter Cup (chocolate + peanut butter) i.e. combine Ph.D. expertise with that of post-doc advisor to become a unique and powerful combination.

Don't take work so seriously. Be intense but make sure to have fun in and outside of the lab. Cultivate a lifetime form of exercise/sport and do it regularly. Many faculty are quite macho/proud about how many hours they work per week and how little vacation time they take. I find that planned vacations result in very productive pre-vacation frenzies of work and vacations result in greater energy and enthusiasm when I return. I get perspective on my work when I am away from it and the creative ideas flow.

HOW OBESITY AFFECTS HIP JOINT CONTACT FORCES DURING WALKING IN CHILDREN

Raymond C. Browning and Zachary F. Lerner

Colorado State University, Fort Collins, CO, USA
email: Zach.Lerner@ColoState.edu web: http://pal.colostate.edu

INTRODUCTION

Obese children are at an increased risk of developing orthopedic disorders of the lower-extremity. At the hip, a strong, positive association exists between pediatric obesity and a reduction in femoral neck anteversion angle and slipped capitol femoral epiphysis (SCFE), the most common hip disorder in children [1, 2]. SCFE is a debilitating condition that results in an inferior-posterior slip of the femoral head relative to the femoral neck along the physis. It has been theorized that altered hip joint loading during daily physical activity (e.g. walking) in obese children may contribute to their increased risk of developing these orthopaedic disorders of the hip [1, 2]. However, it remains unknown how pediatric obesity affects hip joint loads during walking. This gap in the literature limits our ability to evaluate the risk-benefit ratio of walking physical activity on the musculoskeletal system of obese children. *This study sought to determine the effects of pediatric obesity on compressive and shear hip joint contact forces and loading rates during walking.*

METHODS

Kinematic and kinetic data was collected during treadmill walking at 1 m•s^{-1} in 10 obese (BMI$_Z$ > 95%) and 10 healthy-weight (5% < BMI$_Z$ < 85%) 8-12 year-olds. Age, sex, and leg length were similar between groups. We used dual x-ray absorptiometry (DXA) to determine body composition, segment masses, lower-extremity alignment, and femoral neck angle (Fig. 1) and width for each child.

To validate our musculoskeletal model and optimization scheme used to predict muscle forces, we compared measured to predicted axial, mediolateral, and anteroposterior hip joint contact

forces for an individual with an instrumented hip prosthesis walking at 1.08 m•s^{-1} [3]. Predicted loads had similar magnitudes and waveforms. At peak loading, which occurred during early-mid stance, peak axial, anterioposterior, and mediolateral contact force predictions had accuracies of 98.6%, 90.3%, and 85.7%, respectively.

We scaled a generic OpenSim musculoskeletal model to the size of each participant and subsequently specified lower-extremity alignment and segment masses to create a subject-specific model for each child. We used a weighted static optimization approach to estimate the muscle forces that reproduced the measured walking mechanics determined from inverse dynamics, and calculated hip joint contact forces using the joint reaction analysis [4]. To compute compressive and shear forces, we transformed the contact forces from the reference frame of the hip to that of each child's femoral neck (Fig. 1).
Figure 1: Measurement of femoral neck angle (θ) from a representative participant's DXA radiograph (inset) and transformation of the hip joint contact forces.

RESULTS AND DISCUSSION

Obesity affected compressive and shear hip joint loading (Fig. 2). First peak compressive contact forces (N) during stance were 1.8 times greater in the obese vs. healthy-weight participants ($p<0.001$). Similarly, first peak distal and posterior shear forces were 1.8 and 1.5 times greater ($p<0.001$), respectively, in the obese vs. healthy-weight children.
Figure 2: Compressive (top), vertical shear (middle), and anterioposterior shear (bottom) hip joint contact forces in obese (red, solid) and healthy-weight (blue, dashed) children.

Peak compressive and resultant shear loading rates, which occurred during early stance, were 1.47 times (10.15 vs. 6.89 kN•s^{-1}, $p<0.001$) and 1.43 times (4.35 vs. 3.03 kN•s^{-1}, $p=0.002$) greater in the obese vs. healthy-weight participants, respectively.

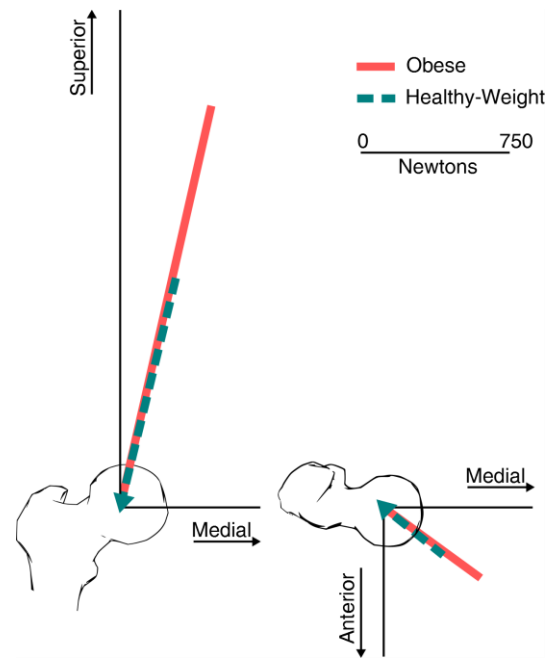
The hip joint contact force load vectors had similar directions but greater magnitudes in both the sagittal and transverse planes for the obese vs. healthy-weight children (Fig. 3). The directions of the applied shear forces (inferior and posterior) are consistent with the direction of femoral head slippage in the SCFE condition (inferior-posterior).


Figure 3: First peak hip contact force load vectors in the sagittal (left) and transverse (right) planes for the obese (red, solid) and healthy-weight (blue, dashed) children.

CONCLUSIONS

Our results of greater compressive and shear forces at the hip during walking in obese children provides biomechanical evidence that altered loading during daily walking physical activity may contribute to their increased risk of developing orthopaedic disorders at the hip. Femoral neck diameter was similar between groups. This suggests that our findings of greater contact forces in the obese children likely represent similarly elevated compressive and shear stresses at the growth-plate. The results of this study may help clinicians weigh the risk-benefit ratio of increased physical activity on the musculoskeletal system in obese children.

FRONTAL HIP POWER ABSORPTION DURING WEIGHT ACCEPTANCE AMONG INDIVIDUALS WITH INCOMPLETE SPINAL CORD INJURY

[1] Lise Worthen-Chaudhari, [2] James Schmiedeler, and [1] D. Michele Basso

[1] The Ohio State University, Columbus, OH, USA
[2] University of Notre Dame, Notre Dame, IN, USA
email: lise.worthen-chaudhari@osumc.edu

INTRODUCTION

During locomotion, power absorption in the lower extremity joints serves to decelerate the center of mass of the body (i.e., brake), prevent joint collapse [1], maintain forward propulsion and provide vertical support [2]. Within the frontal plane of the hip joint, power absorption is prevalent during the weight acceptance (WA) phase of locomotion [3]. Despite the importance of power absorption for functional success, the WA phase of locomotion has received little attention in neurorehabilitation research of locomotor recovery. In addition, frontal plane hip dynamics may play a more important role in WA than previously realized [3,4]. We hypothesized that individuals with incomplete spinal cord injury (iSCI) who had shown substantial gains during prior locomotor training (LT) would evidence persistent deficits in power absorption about the frontal hip during the WA phase of walking.

METHODS

This research was approved by The Ohio State University Institutional Review Board. Two participants with iSCI, who had undergone more than 50 LT sessions by the day of testing, and eight control participants consented to participate. The 2 participants with iSCI had recovered full (blue; Fig. 1) or limited (gold; Fig. 1) community ambulation during LT participation prior to participating in this study, as measured by standard clinical measures such as the 10 meter walk test and the Spinal Cord Injury Functional Ambulation Inventory. Their treadmill walking speeds (0.6 m/s, 0.54 m/s) were similar to the mean speed of the controls (0.64 m/s; representative data at 0.57 m/s shown in green; Fig. 1), although BWS was applied at 30% vs 0% for control. At low speeds, power production about the

frontal hip in controls is not significantly different at 30% and 0% BWS [5].

Kinematic data were collected using a 7-camera system (Vicon, 200Hz), and force data were collected using a split belt instrumented force platform treadmill (Bertec, 1000Hz). Body weight support (BWS) was provided by a hydraulic BWS system and harness. Subjects were asked to walk normally per condition, to look at a target positioned at the head of the treadmill at eye level, and to walk at steady-state speed for approximately 25 seconds per trial. Low-pass filters were applied to kinematic (Butterworth, 1st order, bi-directional, 6Hz) and force (critically damped, 1st order, bi-direction, 10Hz) data. Joint power calculations were performed in Visual 3D (C-Motion, Inc). WA phase was isolated [4], and peak power with corresponding hip ab/duction angle was detected using custom MATLAB software.

RESULTS AND DISCUSSION

Participants with iSCI demonstrated delayed onset of hip adduction (Fig. 1E) and prolonged, exaggerated weight acceptance activity about the frontal hip (Fig. 1F). The end of weight acceptance in controls occurred at 22.8±4.8% of stride (mean±STD), consistent with the representative case in Fig. 1F. At the time of peak power absorption about the frontal hip, participants with iSCI exhibited less hip adduction than did controls (Fig. 1D), with the modestly recovered iSCI participant even exhibiting abduction at this instant in some cases. These aberrant hip motions tend to be distinctly different from those caused by gluteus medius weakness, such as in a Trendelenburg gait, in that the pelvis and hip of the swing leg are elevated rather than dropped (Fig. 1B,C).

Figure 1: Depictions of left side frontal hip function for three functional levels: Normal, Good locomotor recovery, and Modest locomotor recovery following iSCI and LT. (A,B,C) depicts lower extremity position and ground reaction force, (D) plots peak power by corresponding angle for five trials, (E) shows time to WA end, and (F) depicts hip frontal power.

CONCLUSIONS

Individuals with iSCI who have undergone LT show persistent deficits in hip abductor function during the WA phase of gait, as evidenced by prolonged, exaggerated power absorption about the frontal hip in WA. Specific training to address persistent deficits may provide a way to tap into additional potential for neurologic recovery.

KNEE MOMENTS INCREASE MORE THAN GROUND REACTION FORCES INCREASE WITH ADDED LOADS

Rebecca E. Fellin, Shane G. Sauer, Peter N. Frykman and Joseph F. Seay

U.S. Army Research Institute of Environmental Medicine, Natick, MA, USA
email: rebecca.e.fellin.civ@mail.mil, web: http://www.usariem.army.mil/

INTRODUCTION

Soldiers often carry heavy loads (up to 55-kg) while on missions. Soldiers who frequently carry heavy loads are more likely to sustain knee injuries than soldiers who do not often carry heavy loads [1] although the precise mechanisms of injury are unclear. For example, increases in vertical ground reaction force (vGRF) were 5-6 percent bodyweight (%BW) for every 10% increase in relative load, load normalized to %BW [3]. Recent research found that joint moments increased as added load increased [2,3]. However, researchers have not explored the relationship between increases in joint moments compared to increases in relative load. In order to better understand the possible relationship between knee loads and knee injury, a comprehensive analysis of joint moments in the lower extremity and relative load is necessary.

Therefore, the purpose of this study was to compare increases in ground reaction forces and joint moments to increases in relative load. We hypothesized that the ground reaction forces would increase at the same rate as increases in relative load. We further hypothesized that the joint moments would increase at a lower rate than relative load.

METHODS

Thirty male soldiers (20.6 ± 3.1 yrs; ht: 1.77 ± 0.08 m; wt: 84.7 ± 14.4 kg; mean ± SD) volunteered to participate in this study. Only males were included as infantry roles in the Army are limited to males, currently. During an orientation session, subjects walked on an instrumented treadmill at the speed and maximum weight they would experience in the data collection. During the data collection session, subjects were instrumented with retro-reflective markers to track pelvis and bilateral lower extremity motion. Subjects then walked in their combat boots at 3 MPH on the treadmill for 5 minutes following which 30 seconds of data were recorded during 6 load conditions: bodyweight (BW) only, 15-kg, 25-kg, 35-kg, 38-kg and 55-kg. The BW only condition was presented first followed by the 5 loads presented in random order. The 15-kg load was an armored vest, and subsequent loads were weighted vests. Subjects rested for a minimum of 3 minutes between loads.

Kinematic and kinetic data were filtered at 10 and 20 Hz, respectively. Five strides from the right side were selected for analysis. Spatiotemporal parameters, including step rate, stride length and double support time, as well as vGRF, 3D joint angles and moments at the hip, knee and ankle were computed. Knee range of motion (ROM) was calculated as knee flexion angle between footstrike and mid-stance. vGRF was normalized to BW. Joint moments were normalized to body mass. Peak moments in early (0-50%) and late (51-100%) stance were extracted. Variables were averaged across the 5 strides for each condition. Relative load, load normalized to percent bodyweight (%BW), was calculated for each subject. Percent increases compared to BW only values for all variables were computed. To minimize regression bias, BW percentages >70% (11 data points) and outliers (3*interquartile range) were removed from the analyses. Outliers removed were hip extension (1) and knee flexion (1) moments and knee flexion peak angle (2). To identify the sensitivity of variables to load increases, regression analyses for each individual variable (spatiotemporal, knee ROM, and kinetics) with %BW load as a predictor variable were conducted.

RESULTS AND DISCUSSION

As hypothesized, vGRF peaks for loading and push-off increased at a similar rate to %BW increases in relative load, 0.93% and 0.81%, respectively

(Figure 1). Additionally, our hypotheses for hip and ankle moments were supported with increases of 0.65-0.67% in early stance and 0.65-0.77% in late stance for each %BW increase in relative load. Interestingly, knee moments were the most sensitive to increases in relative load. Knee extension moment increased 1.3% for every 1% increase in relative load. A scatterplot of the knee extension moment revealed most data points were above a 1:1 relationship, indicated by the dotted line (Figure 2). Knee flexion moment in late stance increased 0.86% for every 1% increase in relative load.

Figure 2: Knee extension moment increases for added loads. Dotted line is 1:1 relationship. Values >70% relative load removed prior to analyses to minimize bias and no outliers remained.

These findings of similar increases in vGRF peaks to increases in relative load are in contrast to findings of vGRF increases of only half the relative load increase [3]. These differences may be due to load carriage experience of soldiers in our cohort versus civilians and/or due to wearing combat boots compared to what was likely other footwear.

Figure 1: Slopes of regression lines, which compared effects of increases in relative load to percent increases in peak values of kinetic variables over baseline values. All slopes significantly different from zero. Dashed line at 1.0 indicates a 1:1 relationship between increases in relative load and kinetic variables. vGRF=vertical ground reaction force peak, mom=moment peak.

These increases in knee extension moment occurred despite potential mechanisms to decrease the effects of the relative load. For each added %BW of relative load, there was a significant increase in double support time (0.33%). Smaller, yet statistically significant, protective changes occurred in step rate, 0.09%, peak angle for knee flexion, 0.08% and stride length, -0.05%, for each %BW increase in relative load. However, knee ROM did not increase with relative load (slope 0.02%). The lack of change in knee ROM, indicated that the knee musculature appear to share a higher burden of

the increased load, which was previously found between 15-kg and 55-kg loads in this dataset [2].

CONCLUSIONS

Despite adaptive strategies to decrease joint loads in the lower extremity, some joint loads still increased at rates similar to increases in relative load. These data suggest a potential mechanism of why the knee joint is more commonly injured in soldiers who frequently carry heavy loads.

PROSPECTIVE GAIT ANALYSIS OF ANKLE ARTHRODESIS AND ARTHROPLASTY

[1]Shannon M. Pomeroy, [1]Michael E. Hahn, [2]Ava D. Segal, [2]Eric C. Whittaker, [2]Marisa Benich, [2-4]William R. Ledoux and [2,4]Bruce J. Sangeorzan

INTRODUCTION

Historically, the treatment for ankle arthritis has been arthrodesis, which provides a relatively painless and stable joint. However, the diminished joint ROM has been reported to increase the risk for developing distal foot pain [1]. In recent years arthroplasty has become available. With this replacement technique, closer to normal kinematics have been achieved [2]. Both operations have displayed improved gait function, with one retrospective study concluding that patients with arthrodesis were able to walk faster, however, their gait was more asymmetrical than patients with arthroplasty [3].

Although studies have separately examined the effects of each operation on functional outcomes, limited studies have made direct comparisons, with a lack of long-term prospective studies. Thus, in this prospective work, it was hypothesized that post-surgery, there would be improved temporospatial parameters, altered ankle ROM, increased internal plantarflexor moment and increased power in both surgeries. It was further hypothesized that improvements pre- to post-surgery would be greater in the arthroplasty group than in the arthrodesis group, with an increasing disparity over time.
Figure 1. Radiographs of the ankle following (a) arthrodesis and (b) arthroplasty.

METHODS

Twenty-three patients scheduled for surgical treatment of end-stage ankle arthritis were recruited for participation in the study following a surgical decision. Exclusion criteria included having neurologic, metabolic, or orthopaedic lower limb impairment of ambulatory ability, a recent surgical intervention, or systemic inflammatory arthritis. Subjects were stratified based on chosen surgical procedure, either tibiotalar arthrodesis using a screw fixation or standard arthroplasty technique (Figure 1; Table 1). Patients were evaluated prior to surgery (t_0) and at 1, 2, and 3 years post-surgery (t_1, t_2, and t_3). Due to time commitment and relocation, some patients opted out of return visits (Table 2). Each patient engaged in standard rehabilitation protocols [4]. Subject informed consent and Institutional Review Board approval was obtained prior to study initiation.

Table 1. Demographics of patients enrolled; Mean (SD).

	Arthrodesis	Arthroplasty
N	8	15
Sex	2 female; 6 male	8 female; 7 male
Age (years)	55.3 (3.7)	59.4 (7.1)
Side	6 right; 2 left	4 right; 11 left
BMI (kg/m^2)	28.2 (2.1)	31.3 (4.6)

Kinematic and Kinetic Analysis

Three-dimensional marker coordinate data of the affected limb and ground reaction forces were collected for 5 successful barefoot gait trials along a 10-m walkway at self-selected walking speed using previously reported motion capture techniques [4]. Net internal joint forces, moments, and power for the hip, knee, and ankle were subsequently calculated using inverse dynamics. Peak stance phase kinetic values and sagittal plane ankle ROM were extracted and averaged for each subject across trials. Gait velocity (m/s), stride length (m), and cadence (steps/min) were also calculated (Table 2).

A mixed effects linear model was used to compare temporospatial variables, peak kinetics, and ankle ROM between visits for both groups ($\alpha=0.05$). Kinematic and kinetic comparisons included gait velocity as a covariate and changes across time were tested for group effects.

RESULTS AND DISCUSSION

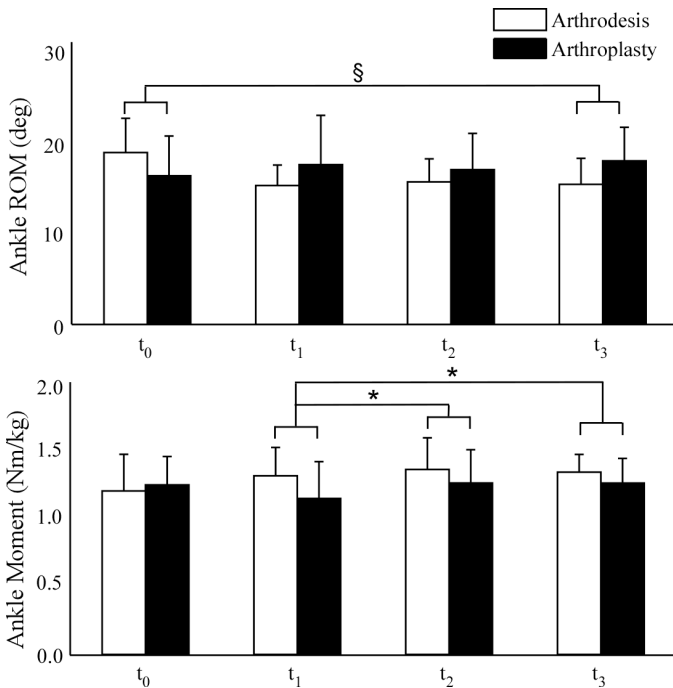
Sagittal plane ankle ROM was significantly affected by surgery type, with a decrease of 4.8° following fusion and increase of 1.9° following arthroplasty at 3-years follow-up (Figure 2; $p<0.01$). Significant pair-wise differences were found for peak internal plantar flexor ankle moment between t_1, t_2 and t_3.


Figure 2: Ankle joint kinematics and kinetics (mean ± standard deviation) pre- (t_0) and post-surgery (*, pair-wise difference between time points, $p<.05$; §, significant change by surgery type, $p<.01$).

Though not statistically significant, many observations were noted which can aid in the interpretation of primary findings (Table 2). Gait velocity stabilized following surgery in arthroplasty patients, however a decreasing trend was found in arthrodesis patients across the 3-year follow-up. Arthroplasty patients displayed decreased peak internal plantar flexor moment and increased ankle ROM with an increasing trend in ankle joint power across the 3-year follow-up. At the same time point, the arthrodesis group produced increased peak ankle, knee, and hip moments along with decreased joint power. It is possible in a fusion patient that the proximal joints become involved due to the complex coupling between knee and ankle with a fixed tibiotalar joint. These observations should be examined further in future studies.

CONCLUSIONS

Outcomes demonstrated that regardless of operation, surgery to address end-stage ankle arthritis is able to improve gait function. However, gait function seems to decline at 3 years post-surgery in arthrodesis patients, with gait velocity reduced close to pre-surgical values. It is plausible that at this time compensations such as increased ankle joint moments with significantly reduced ankle ROM are beginning to compromise surrounding joints [1]. To better explain how gait function is maintained in both groups following surgery a more robust multi-segment foot model is necessary. Future consideration of the current data coincident with recorded physical function in daily activities as well as center of mass movement will afford extrapolation of the mechanisms utilized and resulting quality of life. Presently, the findings provide insight to the ongoing debate regarding surgical outcomes in treating end-stage ankle arthritis, providing data highlighting the beginning stages of altered kinematics and associated risk.

email: mjc73@zips.uakron.edu http://bme.uakron.edu

INTRODUCTION

In 1970, Kapandji proposed the notion that "Viewed as a whole, the plantar vault [of the foot] can be compared with an architectural vault supported by three arches". The three ground supports to which Kapandji was referring occur at the first and fifth metatarsal heads (MTHs), as well as the calcaneus[1]. The present study focused on (i) the existence of a tripod under the foot, and (ii) the ability of neuropathic, diabetic patients to support the arches.

METHODS

Pressure and shear stress data were collected on 29 human subjects: 16 control patients (9M, 7F; Age: 47.6±5.8 years; Weight: 824 N) and 13 neuropathic, diabetic patients (8M, 5F, Age: 61.6±14 years, Weight: 944 N). Each subject walked barefoot across a custom built shear and pressure collection system that is aligned in the center of a 3 m. x 0.6 m. platform[2]. Four steps were analyzed for each subject and all plantar surfaces were divided into ten regions (Figure 1) using custom-written Matlab code. The present study focuses on four of the ten regions: regions 4, 6, 9 and 10 (Figure 1).
Figure 1: Display of shear force directions for regions of primary interest in present study. The green areas correspond to the base of a tripod.

It was hypothesized that evidence of a collapse of a plantar tripod could be demonstrated using the mean shear values in the regions previously listed. In support of the medial longitudinal arch, the differences were determined between mean anterior shear under the first MTH and mean posterior shear under the medial heel. For the lateral longitudinal arch, the differences were calculated between mean anterior shear under the fourth and fifth MTHs and mean posterior shear under the lateral heel. Lastly, for the transverse arch, shear differences were examined between the mean medial shear under the first MTH and the mean lateral shear under the fourth and fifth MTHs. These values were determined for all 116 steps then steps compared between control and diabetic, neuropathic groups.

RESULTS AND DISCUSSION

The presence of peripheral neuropathy correlates with loss of nerve, as well as intrinsic muscle control. Therefore, it was hypothesized that the existence of three arches could be demonstrated using differences in shear values, and moreover that diabetic patients would exhibit greater shear differences due to splaying of their foot (i.e., the tripod) during gait.

The differences in shear forces for each element of the tripod were significant for all three elements of the tripod. The medial longitudinal arch had mean values of 11.5 ± 3.7 kPa and 15.1 ± 5.4 kPa for control and diabetic, neuropathic participants, respectively ($p < 0.01$). The mean values of force differences for the lateral longitudinal arch were 9.3 ± 2.8 kPa and 13.1 ± 4.0 kPa for control and experimental subjects, respectively ($p < 0.01$). Lastly, the mean differences across the metatarsal heads were 17.7 ± 4.6 kPa for the control group and 22.5 ± 9.0 kPa for the diabetic, neuropathic subjects ($p < 0.01$) (Figure 2 and Table 1.)

CONCLUSIONS

This is the first study to examine the relationship between shearing forces on the plantar surface of the foot and each element of "Kapandji's tripod". In our opinion, any diminished ability to maintain these arches would be manifested through slippage of the skin relative to the support surface, and concomitant changes in shearing stresses on the plantar surface of the foot.

Due to the presence of peripheral neuropathy in the diabetic subjects, it was hypothesized that intrinsic muscles would have diminished capabilities to oppose the collapsing of the three arches during gait. The differences were determined between mean anterior shearing forces under the first MTH and fourth and fifth MTHs and the mean posterior shears under the medial and lateral calcaneus, respectively. The same methods were utilized for medial shear under the first MTH and lateral shear under the fourth and fifth MTHs to demonstrate the collapse of the transverse arch. Significantly higher differences were found for the diabetic, neuropathic

subjects along all three arches in comparison to the control subjects. These data not only support the existence of three arches and in turn the tripod theory; but also support the claim that the feet of diabetic subjects with peripheral neuropathy are less capable of opposing the outward shear forces that lead to the collapse of these three arches.

ADAPTATIONS IN LOWER EXTREMITY WORK DUE TO CHANGES IN WALKING SPEED

[1]Anahid Ebrahimi, [2]Saryn R. Goldberg, [1]Steven J. Stanhope
[1]University of Delaware, Newark, DE, USA, [2]Hofstra University, Hempstead, NY

INTRODUCTION

The ability to modulate walking speed is often an important goal for individuals with gait impairments. To aid in developing proper treatments and corrective devices for individuals with impairments, it is important to first understand the gait adaptations of unimpaired individuals ambulating from slow to typical walking speeds. Studying the energetics of the lower extremity allows for causal analysis of movement. While energetics studies have historically been limited to 3 degree-of-freedom (DOF) work calculations of the joints (ankle, knee, and hip), recent literature has supported the use of 6 DOF inverse dynamics work calculations of these joints and the inclusion of a distal foot work term [1].

The objective of this study was to understand the work adaptations of all the lower extremity limb constituents (ankle, knee, hip, and distal foot) that occur in order to increase walking speed. We investigated changes in the 6 DOF work of the limb constituents over slow to typical walking speeds during the stance and swing phases of gait. Furthermore, we quantified the proportional change of the constituents' contributions to the absolute work produced by the limb with increased speed.

METHODS

A subset of the data collected by Goldberg and Stanhope (2013) was used for data analysis [2]. Eight unimpaired adult subjects (height 177 ± 7.5 cm, mass 74 ± 13.1 kg) walked on a calibrated [3] instrumented split-belt treadmill (Bertec, Columbus, OH) at three height-normalized velocities (0.4, 0.6, and 0.8 statures/s). Three-dimensional movement analysis data were collected via a six-camera system (Vicon, Los Angeles, CA). Using Visual3D software (C-Motion, Inc. Germantown, MD), 6 DOF powers of each constituent (ankle, knee, hip, and distal foot) were calculated using methods described elsewhere [4,5]. Stride length was calculated by multiplying the treadmill velocity in meters per second by the

subject's average stride time (heel-strike to ipsilateral heel-strike) in seconds. Positive (negative) constituent work values were calculated for each subject by integrating the positive (negative) portion of the respective constituent power curves over stance and swing phases. Net constituent work was the sum of the positive and negative constituent work for each constituent. Positive, negative, or net limb work was the sum of the positive, negative, or net constituent work values, respectively (e.g., net limb work in Eq. 1). Absolute limb work (W_{limb}^{abs}) was the sum of the positive limb work and absolute value of the negative limb work. Relative work (RW) was the absolute value of each constituent's work divided by the absolute limb work (e.g., relative negative ankle work in Eq. 2). All work values were normalized by body mass and stride length.

$$W_{limb}^{net} = W_{ankle}^{net} + W_{knee}^{net} + W_{hip}^{net} + W_{distal\,foot}^{net} \quad (1)$$

$$RW_{ankle}^{-} = |W_{ankle}^{-}| \div W_{limb}^{abs} \quad (2)$$

Differences in net work and relative work were compared separately across the three walking speeds using several repeated measures ANOVAs with Bonferroni corrections ($p<0.05$) using SPSS software (IBM Corp., Armonk, NY).

RESULTS AND DISCUSSION

Average stride length increased with faster walking speed (mean $\pm$ SD): 0.877 ± 0.153 m, 1.165 ± 0.110 m, and 1.306 ± 0.253 m for 0.4, 0.6, and 0.8 statures/s, respectively. In stance, net ankle work and net distal foot work significantly increased, while net hip work significantly decreased with speed ($p<0.05$) (Table 1). In swing, net hip work during swing significantly increased with speed ($p<0.05$). Net limb work did not differ significantly with speed in stance or swing. Absolute limb work did not significantly differ with faster walking speed: 1.056 ± 0.189 J/kg/m, 1.092 ± 0.170 J/kg/m, and 1.376 ± 0.703 J/kg/m for 0.4, 0.6, and 0.8 statures/s, respectively. The sizes of the pie charts in Figure 1 are relative to the amount of absolute limb work performed at that speed.
Figure 1: Relative constituent work (J/kg/m) as % of absolute limb work across speeds. Slices not labeled are ≤1%. * and ^ indicate a significant difference from 0.4 statures/s and 0.6 statures/s, respectively.

Our findings indicate that while net limb work per distance does not change significantly with increased walking speed, the net constituent work does change. All constituent net work values showed some change with walking speed except for the net knee work. Using the same data set presented here, it was previously shown that peak knee extension moments do not significantly differ with speed [2]. In addition, Figure 1 provides a unique analysis of the proportional change in constituent work relative to absolute limb work with speed, separated by the phase of the gait cycle in which the relative constituent adaptations occur. In stance, the positive ankle and negative distal foot work contributions increased while the negative ankle contribution decreased with faster speeds, supporting trends seen in previous literature [5]. Interestingly, as speed increased, the knee and hip generated less relative positive work in stance. Conclusions must be limited to unimpaired individuals walking at slow to typical walking speeds. Future studies will characterize work across a broader range of gait intensities, including faster walking conditions.

CONCLUSION

The net limb work did not change significantly with speed, while net constituent work did change (except at the knee). Relative constituent work helps identify the extent of individual joint adaptations and where in the gait cycle they occur to enable unimpaired persons to walk at faster speeds.

SYSTEMS ENGINEERING APPROACH TO IDENTIFYING CORE CONTROL STRATEGIES IN INDIVIDUALS WITH AND WITHOUT LOW BACK PAIN DURING A NOVEL UNSTABLE SITTING TASK

[1] Bradley S. Davidson and [2] Sheri P. Silfies

[1] University of Denver, Denver, CO, USA
[2] Drexel University, Philadelphia, PA, USA
email: bradley.davidson@du.edu, web: www.du.edu/biomechanics

INTRODUCTION

Individuals with recurrent and chronic low back pain (LBP) have impaired core neuromuscular control [1,2], which may influence recurrence of symptoms [3,4]. Understanding differences in core neuromuscular control between healthy individuals and those with LBP will help advance clinical assessment and in planning rehabilitation interventions. We propose that insight into neuromuscular control within LBP is gained within a multi-joint task that requires coordination and stabilization of all musculoskeletal elements by the central nervous system. Prior characterization of neuromuscular control in patients with LBP has produced inconsistent findings. Most analyses have focused on a single parameter within neuromuscular control (e.g. proprioception, muscle timing) or neglected the dynamic interdependence between key musculoskeletal elements (e.g. trunk, pelvis).

The objective of this investigation was to implement an assessment of overall system function by applying a well-established system identification paradigm to a novel seated dynamic stabilization task. We used this approach to characterize differences in performance and motor control strategies of the trunk and pelvis system between patients with LBP and healthy controls.

METHODS

Six patients with current low back pain (average: pain 4.8 ± 2.2 [NPRS, 0-10]; disability $27.3 \pm 8.6\%$, [Oswestry, 0-100%]) and six age and gender matched healthy controls participated in the investigation (8/12 female, average age 36.8 ± 15.1 years). Each participant performed four trials of a dual control task on an unstable seat that required them to simultaneously: 1) maintain upright sitting and 2) tilt the seat to match a target. The seat was attached to a sphere that rolled without slipping on a force platform. Weight of the lower extremities was counterbalanced so that the participant was in a neutral configuration (vertical trunk and horizontal thighs). Targets were based on center of pressure (COP) repositioning, which were achieved by reconfiguration of the trunk and pelvis from neutral (Fig. 1). Each participant received real-time visual feedback of the COP on a computer monitor during all portions of the task.
Figure 1: Neutral configuration and reconfiguration (dotted lines) of trunk and pelvis (left) required to reposition COP on targets (right).

Within a single trial, eight targets 35mm away from the neutral COP in eight directions (0º, 45º, 90º, 135º, 180º, 225º, 270º, 315º) were sequentially displayed on the monitor (Fig. 1). For each target, the participant started in the neutral position, and was instructed to "move directly toward the target as quickly and accurately as possible, pausing on the target." Force platform data were collected at 2400 Hz during the entire trial, filtered (piecewise-linear), and used for subsequent analyses.

To characterize neuromuscular control for each

participant, we performed 2nd-order nonparametric system identification on time series data to identify three system coefficients (Fig. 2). The input, $U(s)$, was a series of eight step functions equivalent to the eight targets at 35mm from neutral, and the output $Y(s)$ was the series of recorded COP trajectories within a trial (Fig 2a).

Validity of the model structure was assessed for each participant with a leave-one-out cross validation (% accuracy) for the four trials. Representative coefficients were averaged across the four trials, and mean coefficients were compared across groups using two-tailed t-tests.

RESULTS AND DISCUSSION

The 2nd-order model structure provided high accuracy for both groups (Control Group: 94.2(1.0)%, LBP group 93.4(1.2)%). The participant-specific models demonstrated clear differences in performance between the groups (Fig. 2b), which were reflected by differences in two of the three identified coefficients (Table 1).

Table 1: Mean (SD) coefficients identified for each group. Asterisk indicates group difference ($P<0.05$).

Coefficient	Control Group	LBP Group
a_0	1.09 (0.38)*	0.68 (0.17)
b_0	1.53 (0.28)	1.56 (0.35)
b_1	1.10 (0.38)*	0.69 (0.17)

Interpreting these changes within the context of classical second order systems analysis provides coarse insight into strategy and performance of the LBP group. Lower a_0 in the LBP group compared to control group indicates an overall lower system gain and corresponds with the slower rise time to the target observed in the COP traces. Higher b_1 in the control group compared to the LBP group indicates more damping, which may be necessary to limit the overshoot during a faster target acquisition strategy.

Our approach represents a unique paradigm compared to past systems approaches because the trunk and pelvic reconfiguration for each target is initiated by executive command (internal perturbation). Previously applications in the low back used externally applied perturbations with a
Figure 2: a) 2nd-order system with coefficients. b) Simulated responses to the target task using participant-specific models (blue: healthy; red: low back pain)

fixed pelvis [5,6] and identified mechanical properties of the trunk segment alone.

Nonparametric analysis is an appropriate first step, but cannot identify performance of individual system components and limits our interpretation to general differences between groups. In future work, we will develop a parametric analysis that considers parameters needed in neuromuscular control to complete the target task.

CONCLUSIONS

Nonparametric system identification was used to establish differences in neuromuscular control between LBP and control groups. This foundation will allow us to develop analyses that lead toward a more comprehensive understanding of neuromuscular control in the context of assessment of and rehabilitation for LBP.

INFLUENCE OF INPUT DEVICE, WORK SURFACE ANGLE, AND TASK ON SPINE KINEMATICS DURING SIMULATED OFFICE WORK

INTRODUCTION

Modern software and touch technology have enabled tablets to perform nearly all the advanced functions of desktop computers. Their mobility allows tablets to be versatile across industries and favoured in off-site and non-traditional office settings. Being a stand-alone device, tablets provide users with location mobility and the ability to perform tasks in standing or sitting postures with ease. Contemporary equipment, such as an adjustable work surface slope, is often used in conjunction with tablets and other input devices, adding to an increasingly complex workstation environment. The type of work task heavily influences trunk posture [1] as well as the location of the device due to viewing angle [2]. Changing these elements of a work surface slope may facilitate a closer interaction and proper viewing angle between the device and the user resulting in the maintenance of neutral spine postures. The purpose of this study was to analyze the kinematics of the cervical and lumbar spine segments during simulated computer tasks using a desktop computer and a tablet, on both a sloped and horizontal work surface.

METHODS

Fourteen participants (6 male and 8 female) volunteered for this study. Three-dimensional kinematics of the cervical and lumbar spine were sampled at 32 Hz using a motion capture system (Optotrak Certus, NDI, Waterloo, Canada). Participants sat for 1-hour at a hybrid sit-stand workstation with a work surface that could vary slope from 15° to horizontal (Focal Upright Furniture, New York, USA). The adjustable foot platform and height of the seat-pan was modified to match the participant's height, and to position the

participant's thigh-to-trunk angle at 135°. The session was separated into four randomized 15-min conditions: horizontal-computer, horizontal-tablet, sloped-computer, and sloped-tablet. A 2nd generation iPad was used (Apple, Cupertino, CA, USA). Within each condition, participants completed three 5-min tasks: reading (READ), emailing (MAIL) and filling out a form on a device from a paper copy (FORM). Cervical and lumbar median angles and range of motion (ROM) (10th to 90th%ile angles) were extracted from amplitude probability distribution functions (APDF) calculated from the angle data. All outcome measures were entered into a three-way general linear model with three repeated factors of device (TABLET/ PC), desk (HORIZONTAL/ SLOPED), and task (READ/ MAIL/ FORM).

RESULTS AND DISCUSSION

There was a significant main effect of task on cervical spine posture (p=0.0008). The FORM task produced the greatest median neck flexion angle (20.3 ± 2.5°) compared to the MAIL (14.2 ± 2.5°) and READ (11.8 ± 2.7°) tasks. A table-by-device interaction effect (p=0.0228) showed higher cervical flexion angles in TABLET conditions that were more influenced by the change from HORIZONTAL to a SLOPED work surface than the same tasks performed on a PC (p=0.0228) (Table 1). A three-way interaction was seen for cervical spine ROM between table, device, and task (p=0.0212). There was a device-by-table interaction effect for all tasks (MAIL: p=<0.0001; FORM: p=0.0005; READ: p=0.0332). Participants experienced more neck flexion when using a tablet on a horizontal versus a sloped work surface, which has been found in previous studies and was consistent for both devices [2,3]. Extreme neck flexion angles have been associated with the flexion

relaxation phenomenon (FRP). Even though participants were free to either hold or place the tablet on the table, participants assumed a posture resulting in more neck flexion when interacting with a HORIZONTAL work surface, demonstrating participants do not choose a neutral posture under these conditions. The FRP may have similar implications for pain development in the cervical spine as it does in the lumbar spine. The degree of neck flexion is highly influenced by task and the degree of tablet tilt by means of viewing/gaze angle (0° or 15°). To mitigate this viewing issue, external devices should be used if interacting with tablet on a non-sloping surface to prevent high cervical flexion angles.
Figure 1: Relative lumbar median spine angle with respect to a neutral posture between tasks while using a desktop computer and tablet. Note: (*) signifies a significant difference.

A device-by-task interaction ($p=0.0061$) was observed for relative lumbar spine angles (Fig. 1). FORM ($p=0.0106$, 35.3 ± 3.4°) and READ ($p=<0.0001$, 34.2 ± 3.5°) resulted in greater lumbar spine flexion while using a PC compared to a TABLET (READ: 31.9 ± 3.4°; FORM: 32.1 ± 3.5°). A main effect of task ($p=0.0242$) was found for lumbar spine ROM. This finding was accompanied by a trend towards significance in the lumbar spine ROM for the main effect of device ($p=0.0592$). This increase in lumbar flexion while using a PC was likely due to the lack of mobility compared to the TABLET, which can be moved closer to the participant while they were using it. The influence of task on posture cannot be ignored as the physical properties of the task, (layout and tools) heavily determines the postures users adopt [4]. Differences are hypothesized to be due to the requirement of either direct finger contact or mousing to complete the tasks.

CONCLUSIONS

Based on the task specific responses of spine postures, when selecting a device one should consider the physical nature of the task and the work surface adjustability. Working with a TABLET on a HORIZONTAL work surface slope resulted in high amounts of cervical flexion. Therefore, when possible, external aids such as a monitor arm and keyboard should be used to reduce flexion and facilitate a neutral posture if a tablet is the primary device used to complete tasks.

INTRODUCTION

We present physical ergonomics assessment of typical tablet device usage. Tablet devices are becoming widespread and often even displace personal computers and laptops. However, while physical ergonomics of PCs and laptops was extensively studied in the past, there is only little knowledge of ergonomics of tablet devices. In particular the user assessment is complex due to portability of tablets, which allows a variety of tablet locations, orientations and holds which can be adopted by users. The purpose of this work was to identify typical postures, set of recruited muscles and health risks related to the tablet interaction.

Few previous works [1, 2] have measured head and neck posture, or wrist and shoulder posture of tablet usage, however they used predefined set of tablet hold configurations. They extracted joint angles directly from locations of markers attached to anatomical landmarks, which ignores such sources of error as marker drift during movement, joint displacement, or absence of skeletal anatomy. In contrast to this in our work we do not assume a particular posture for interaction and ask participants to take a pose and hold the tablet as comfortable for them. We record motion of the whole human body and analyze biomechanical indices simulated using an anatomically-correct musculoskeletal model.

METHODS

For the analyses we have used the dataset created by Bachynskyi et al. [3]. The data comes from 40 participants (26 males and 14 females) recruited on the local university campus. Mean age is 24.9, height 171.4 cm, and weight 67.4kg. The participants were asked to perform a repetitive target selection task on an iPad-sized and shaped surface. Targets were of 12 types depending on the

size and approach angle, and participants performed 50 target selections in each condition. During the tasks the participants used sitting postures which they have considered comfortable, without constraints from the experimenter. 12 cameras of PhaseSpace Impolse motion capture system have tracked 38 active markers attached to all body segments of a participant at 480 Hz. To record main external forces acting on a user, the chair and platform under the feet were equipped with 8 force sensors collecting data at 125 Hz.

The data was pre-processed by custom Matlab scripts. Biomechanical simulation was performed in an open source software OpenSim [4] with a commercial musculoskeletal model of the Full-Body[1]. The outputs generated by Inverse Kinematics, Inverse Dynamics and Static Optimization are further consolidated into the single dataset. This allows fast and simple analysis of frame-level and aggregated data. The dataset contains posture and moment values for 109 joints, forces and activations for 236 muscles covering the whole human body.

We use Matlab and an interactive visualization tool [5] to perform analyses on the data. We compute average postures of each joint and compare it to movement ranges and neutral postures. Postures close to extreme are considered as health risk after prolonged use. Further, we consider average and peak joint moments. High values of average joint moments pose health risk after prolonged use; high peak moments can lead to an injury even in short interaction. We consider peak muscle forces, as a factor that can lead to a muscle or tendon injury. High average muscle forces lead to muscle stress and fatigue. In our analyses we focus on the body segments the most affected by the tablet usage: upper back and neck, shoulder and arm supporting the tablet, and shoulder and arm interacting on the

---

[1] http://www.musculographics.com

device. The most extreme value at each segment defines health risk for the whole segment.

RESULTS AND DISCUSSION

The results show that the typical posture selected for interaction with a tablet is incorrect and has high risk for users' health. In particular, the posture of upper back and neck is stressful and impose serious risk: average neck flexion differs by 42.6° from the neutral pose. Average and peak joint moments are also high for the neck which can lead to both RSI after prolonged use, or to an acute injury in neck joint. Average muscle forces are moderate which means that muscles are not actively recruited to support head and will not suffer from fatigue, however the peak muscle force is high, and can lead to injuries in neck extensor muscles.

Average elevation angle of the supporting shoulder is slightly larger than neutral zone, so the joint angle is not extreme, but muscles can fatigue after relatively short period. Average joint moment at shoulder is high which can lead to RSI after prolonged use, however peak joint moment is moderate, as result an acute injury is less probable. Average muscle force is high, as a result muscles will fatigue relatively fast. Peak muscle force is also high which can lead to a muscle strain. The elbow joint is in the neutral zone. Average joint moment is low and peak moment is also low. Average muscle force and peak muscle force are high for some muscles, however, there are redundant muscles with similar action which can be recruited if necessary, for example biceps can generate force if brachialis

is fatigued. There is no such reserve for shoulder muscles to recruit in the case of fatigue.

Average shoulder elevation of the interacting arm is in the neutral zone. Average and peak joint moments are moderate, average moment is 35% lower than the moment of the supporting shoulder. Average muscle forces and peak muscle forces are only slightly lower than in the supporting shoulder, however the set of recruited muscles is different and there is more variability in recruitment. As a result the muscles of the interacting shoulder can be fatigued, but much slower than in the supporting shoulder. Average elbow flexion is 110.4°, which is at the border of neutral zone. Average and peak joint moments are moderate. Average muscle forces are low, but peak muscle forces are still high for some muscles. There is more variability in muscle groups of the interacting arm. This adds to more balanced usage of the musculature without exhaustion of a particular muscle.

The largest risks of tablet interaction in the typical postures are related with bad neck posture and fatigue of the supporting shoulder muscles.

INTRODUCTION

Musculoskeletal injuries in the workplace delimit corporate productivity and individual worker performance health. Work-related claims involving the low back and shoulder are designated as a "high impact" claim group, representing over one third of all lost time claims and almost half of all lost time benefits [1]. Upper extremity use during manual materials handling (MMH) tasks is quite variable and can be affected by whole body postures; previous research has not quantified the biomechanical exposures associated with sitting and standing during MMH tasks. Understanding the physical demands associated with task performance in seated and standing positions will facilitate the development of schedules to rotate between these configurations. The purpose of this research was to determine if differences in workplace configurations between seated and standing postures creates changes in joint moments or local body discomfort levels during MMH tasks.

METHODS

Twenty right-handed males (22.5±2.2y, 1.79±0.07m, 79.5±9.06kg) and twenty right-handed females (22.3±1.9y, 1.64±0.07m, 61.2±8.78kg) performed 4 MMH tasks: a 40N static push, a 40N static pull, a weighted bottle transfer set at 15% of the participant's maximal arm elevation strength, and a light assembly task. All tasks were completed once each while both seated and standing. Seat height was set so that sagittal hip, knee and ankle joint angles were all 90°. Three-dimensional motion was tracked using reflective markers placed over bony landmarks and recorded at 50 Hz using eight VICON MX20 optoelectric cameras with VICON Nexus software (VICON Motion Systems, Oxford, UK). During the push and pull tasks, force outputs were measured using an AMTI 6-DOF force transducer (MC3A, AMTI MA, USA) rigidly fixed between a D-shaped handle and a MOTOMAN HP-50 robotic arm (Motoman Robotics Division, Yaskawa America, USA), and sampled at 1500 Hz. Ratings of local body discomfort were measured on a 100mm visual-analog scale, with participants indicating local body discomfort in 18 body sections before collection and after each MMH task. Local joint moments at each time sampled were calculated for the wrist, elbow, shoulder, and low back joints. Amplitude probability distribution functions (APDFs) of the X, Y and Z components of each joint were then calculated and a joint trade-off index was used to examine potential inter-joint loading differences (Eq. 1):

$$TOI = \frac{NM_{standing_i}}{NM_{isitting_i}} \tag{1}$$

where TOI = trade-off index, $NM_{standing}$ = resultant joint moment at the 0.9 APDF level for joint i in standing, $NM_{sitting}$ = resultant joint moment at the 0.9 APDF level for joint i in sitting. Joints with trade-off values greater than 1.0 within a task represented significant increases in joint loading in standing compared to sitting. A mixed model ANOVA was used to assess differences in joint loading and body discomfort ratings. Two within subject factors (MMH task, workspace configuration) and one interaction factor (task*configuration) with a between subject factor of gender were used in the analysis with post-hoc testing to confirm significant differences at p<0.05. All statistical analyses were performed using JMP 10.0 software (SAS Institute, Cary, NC, USA).

RESULTS AND DISCUSSION

Joint trade-offs between sitting and standing occurred at the wrist, elbow, and shoulder for most MMH tasks. These differences appeared in both wrists in the push and pull tasks, the left wrist in the transfer task, and the right shoulder during the push task (Table 1). Low back trade-offs were below

1.00 in the push, pull and transfer tasks, indicating decreased moments in sitting compared to standing. No joint experienced a significant sit-stand trade-off in the assembly task.

Figure 1. Local body discomfort changes between sitting and standing in the assembly task. Blue regions indicate decreased discomfort when moving from sitting to standing, while red regions indicate an increase.

Differences in local body discomfort were primarily discriminated by task, but also by the task*configuration interaction. Interaction effects were observed in the shoulders, mid back, right lower back, and shank/foot sections (p<0.0244), with most areas decreasing when moving to standing. Post-hoc testing indicated decreased discomfort in the left shoulder (60%), right shoulder (21%), left mid back (88%), right mid back (76%) and right low back (58%) in standing. Shank/foot discomfort increased by 273% and 609% for left and right sides, respectively (Figure 1).

Trade-off effects were primarily observed in the wrists and low back across the MMH tasks. When

standing, wrist load increased and low back load decreased. Within the same MMH task, wrist flexion was often increased while standing, resulting in greater net moments [2]. This trade-off resulted in net moments 8.2 times greater in standing, however this large change was likely due to the small absolute values of the wrist joint moments. Despite the small hand loads, resultant wrist moments in sitting and standing postures had differences of up to 4.17Nm. This magnitude represents over 30% of mean population wrist strength, and warrants consideration in industrial design [3]. Low back trade-offs appeared in the push, pull, and transfer tasks, with decreased moments in standing compared to sitting. Greater low back flexion in sitting increased joint moments, which agrees with previous work [4].

Most body regions experienced increased discomfort in sitting, however seated postures were not universally worse. Foot/shank discomfort increased in standing, and is likely attributable to the rest provided to the lower limbs in sitting.

CONCLUSIONS

Future recommendations regarding upper extremity and low back mechanical exposures during MMH tasks should consider placing workers in standing postures to minimize musculoskeletal loading. The task*configuration interactions identified in this study should be considered in the development of workspaces and tasks, in which musculoskeletal risks are generally reduced while standing.

INFLUENCE OF JACKHAMMER WEIGHT ON HAND-ARM VIBRATION TRANSMISSION

Blake Johnson, MS, Naira Campbell-Kyureghyan, PhD, Wilkistar Otieno, PhD, Kristian O'Connor, PhD

email: john2742@uwm.edu

INTRODUCTION

To better understand the onset of Hand Arm Vibration Syndrome, the biodynamic responses of the hand-arm system (HAS) to vibration have been extensively studied. The transmissibility of vibration has often been investigated as a way to quantify the biomechanical response to a vibration stimulus (1). Previous laboratory research has identified that vibration attenuates in the structures as it moves up the HAS (2). Resonance frequencies have also been identified for the hand to be in the range of 16-40 Hz and for the upper arm in the range of 8-12 Hz (3, 4). The previous research has helped identify important characteristics of hand-arm vibration (HAV) from a frequency perspective. However, no study attempted to investigate the affect of the weight of the vibrating tool on the vibration transmission.

The goal of this research is to quantify the vibration transmission in the HAS while operating two different weights of jackhammers (JH). It was hypothesized that the reduction in weight of the lightweight jackhammer will increase the amplitude of the vibration transmission to the hand-arm. The findings of this research will help to better understand how the weight of a vibrating tool contributes to the transmitted HAV.

METHODS

Eight JH operators (7 males and 1 female) with experience ranging between 3-20 years participated in this study. The average weight and height of the operators were 85(±24) kg and 167(±10) cm, respectively. All operators signed an IRB approved consent form before participating in the study.

Two pneumatically powered JHs were selected for this study: 40.8 kg conventional (CJH) and 27.2 kg lightweight (LJH). Each subject broke a 91cm x 91cm section of 15cm thick reinforced concrete twice in a random order, once with the CJH and once with the LJH. The operators were required to break along specific diagonal lines to control for task variation. No other instructions were given to the operators to allow for normal use of the JHs.

Jackhammer accelerations were recorded on the handle using a Biometrics W4X system and S2-G10-MF accelerometers (Nexgen Ergonomics, USA). The same system was used to collect accelerations on the hand. Accelerations on the forearm and upper arm were measured using Delsys Trigino wireless sensors (Delsys, USA). The placement of the accelerometers on the hand-arm was done in accordance with the ISO standard 5349 part one (Figure 1). All accelerometer data was collected at 500 Hz and processed using Vibration Analysis Toolset software (Nexgen Ergonomics, USA), high pass filtered at 4 Hz and root mean squared. Dominant frequencies were found through a power spectral density analysis of each trial. Transmission was calculated as the difference in acceleration between source and hand-arm segment.
Figure 1: Sensor locations and directions of the axes

Grip pressure was measured with an FSA 24 sensor pressure glove (Vista Medical, CA). The overall sum of all grip pressure sensors was calculated at each step. The average grip pressure during JH operation was then calculated for each trial.

A paired t-test was performed on the results to compare the different weighted JHs. The alpha value for significance was set at 0.05.

RESULTS AND DISCUSSION

There were no differences in average acceleration magnitude measured on the handle between the JHs (p=0.422). In both weight cases an increase in the vector summed acceleration magnitude from the source to the hands was measured (19% for CJH and 28% for LJH), while a reduction at the forearm (36% for CJH and 43% for LJH) and upper arm (72% for CJH and 71% for LJH) was observed (Figure 2). The overall increase in hand acceleration is due to the increases in acceleration amplitude in the X and Y axes (Figure 3). It has been previously found that vibration transmissibility increases in these axes as frequency increases, up to 2.5 times the input acceleration from 16–50 Hz (5). The reductions found at the forearm and upper arm could be due to the attenuation of vibration at the joints and tissues. Similar reductions were found by Adewusi et al (6).
Figure 2: Overall change in acceleration from source
Figure 3: Change in acceleration from source per by axis

On average the increase in hand acceleration in the case of the LJH was 1.67 times greater than the CJH (Figure 2) (p=0.023). This difference between JH weight acceleration transmission could be attributed to the operating frequency. The LJH has a dominant

frequency of 22 Hz versus 19 Hz for the CJH. It has been previously found that as the vibration frequency at the hand increases, the transmissibility increases as well, peaking at 35 Hz (5). No differences in acceleration of the forearm and upper arm were found due to the two weights of JHs (p=0.803 and 0.293).

Another explanation for the differences in acceleration transmission to the hand could be the differences in grip pressure between the JH weights. Although grip pressure differences were observed (0.46 MPa CJH and 0.40 MPa LJH) the differences were not statistically significant (p=0.126). Note that higher relative grip pressures were measured for the LJH, indicating that more control was exerted. It is therefore possible that more motion was allowed for the CJH, leading to some of the vibrational energy being directed into inertial effects of the JH instead of transmitting to the hand.

CONCLUSIONS

JH weight was found to affect acceleration transmission to the hand, with the LJH exhibiting greater transmission than the CJH. Differences in dominant frequency and relative grip pressure may explain the observed differences in JH-hand acceleration transmission. The current study further supports previous findings of increasing vibration transmission at the hand above the ISO standard considered frequency range of 16-20 Hz, and therefore the current weighting used in the standard might not accurately reflect the risk for the hand (5).

A NOVEL MULTIPLE COMPARISON PROCEDURE FOR FUNCTIONAL DATA: THE EFFECT OF FITNESS- AND MOVEMENT-CENTRIC EXERCISE ON TRUNK POSTURE AMONG FIREFIGHTERS

INTRODUCTION

Among firefighters, overexertion accounts for over one third of all injuries, with 40% of those injuries affecting the low back region [1]. Approximately 50% of overexertion injuries have a specific cause of 'lifting', typically resulting from inadequate help or procedure during heavy lifting [1]. In addition to this high occurrence rate, overexertion-related injuries are associated with high compensation costs: in medical cost alone, the average overall per-claim mean was $1,973 whereas the overexertion injury mean was $3,458 [1]. Since the job demands of fire-ground operations cannot be modified or predicted easily, increasing firefighters' capacity via exercise may be the key to reducing low back injuries. Two approaches can be used to train firefighters [2]: i) primarily emphasizing movement outcomes (fitness-centric) and ii) emphasizing both the way the movement was completed and its outcomes (movement-centric). It is hypothesized that movement-centric exercise would provide additional benefit since an individual's injury risk is determined by their capacity and how this capacity is utilized. For instance, risk of injury may not change if an individual adopts postures that increase the tissue load.

There have been several methods used to examine time-varying (functional) data, including principal component analysis (PCA) and fractal analysis [3]; however, the difficulty of these methods lies in interpretation of the results and examination of local differences in curves, respectively. Herein, a novel statistical method − namely, the parametric bootstrap-based minP procedure with Welch's t-test, was used to investigate whether each group's average response differs from another and where in time the difference becomes significant [4]. This multiple comparison procedure also provides simultaneous overall and pairwise comparison adjusted p-values without any discrepancy in the conclusion between the two. Therefore, the objective of this study was to use this statistical method to analyze the phases of symmetrical lifting or lowering tasks where statistically significant differences may occur among different exercise interventions with professional firefighters.

METHODS

Fifty-three career firefighters (males) from the Pensacola Fire Department (Pensacola, FL, US) were included in the analyses. All participants were free of any activity-limiting health conditions and were randomly separated into three groups: fitness-centric exercise group (FIT; N = 16), movement-centric exercise group (MOV; N = 22), and control group (CON; N = 15). Each intervention group participated one of two 12-week exercise programs and were coached by accredited strength and conditioning coaches. Coaches provided different instructions and feedback according to the objectives of each group: FIT group was given extrinsic feedback to maximize the performance outcomes (i.e. improving the physical fitness scores) and MOV group was given intrinsic feedback to improve physical fitness while maintaining quality of coordination and control of movement. There were no restrictions on activities outside of this program for all groups.

To examine the effect of the two exercise programs, a symmetrical lifting and lowering task, simulating manual material handling was performed before and after the 12-week interventions. Four task conditions were performed in order of increasing demand: low load, low velocity (LLLV); low load, high velocity (LLHV); high load, low velocity (HLLV); and high load, high velocity (HLHV). In low and high load conditions, 6.8 and 22.7 kg weights were used, respectively. In high velocity conditions, participants were instructed to complete each trial as fast as they were comfortable with. In each condition, three repetitions of lift and lower trials (bending down to lift a crate from the floor to

the upright posture and back to the floor) were performed with rest in between. Three-dimensional kinematics of the trunk, pelvis, and upper and lower extremities were captured using a 10-camera Vicon motion capture system (Vicon, Oxford, UK) at 160 Hz using Vicon Nexus Motion Capture software (Version 1.5, Vicon, Oxford, UK). Post-processing was performed using Visual3D software (Version 4, C-Motion, Inc., Germantown, MD, United States). The kinematic data were low-pass filtered (Butterworth, 4th order, zero-lag, 6Hz cutoff) and the trunk angle was calculated with an Euler rotation sequence of flexion/extension, abduction/adduction, and axial rotation. Each phase (lift and lower) was normalized by time, and a curve produced by taking the difference between the pre- and post-intervention measure was used in the statistical analysis. Parametric bootstrap based minP procedure with Welch's t-test was performed for statistical analysis [5]. Welch's t-test was used since the group variances were unequal in this study. Parametric bootstrap with 1000 resamples was used to better control the familywise error rate [6].

RESULTS AND DISCUSSION

Significant or trending towards significant sagittal motion (flexion/extension) differences between CON and FIT/MOV groups were observed mainly in the lowering phase (Table 1). CON and FIT groups were significantly different in the LLLV condition in the middle (40-60%) of lowering phase (p = 0.041) (Figure 1). Trending towards significant (p < 0.10) differences were seen in the lowering phase (HLHV, LLHV, LLLV) and the lifting phase (HLHV) between CON and MOV groups, in which the largest difference occurred at the beginning through mid-phase (30-60%) of the trial. In all conditions and phases, the MOV group adopted more favorable (less flexed) trunk posture following the exercise program. In a study examining the kinematics of lifting and lowering, horizontal displacement during lowering has been shown to be larger (further away from the trunk) than during lifting due to the anterior momentum of the load [7],

indicating increased risk of injury. Therefore, a reduction in trunk flexion in the middle of the lowering phase, where horizontal displacement is reaching its peak [7], can be considered a favorable adaptation to minimize tissue load on the low back. Although there was no significant difference between FIT and MOV groups (p > 0.10), the difference between MOV and CON was trending towards significantly different in half of the conditions, indicating that MOV may yield better "transfer" of training. There were no significant differences between the groups in transverse (axial rotation) and frontal plane motion (abduction/adduction). Future studies will include examining variability between groups using a similar statistical method.
Figure 1: Mean (solid) and 95% simultaneous confidence band (dotted) of each group difference in the LLLV lowering phase. Shaded area indicates where the significant difference occurred between CON and FIT (p < 0.05).

A BOOTSTRAPPING METHOD TO ACCESS THE INFLUENCE OF GENDER ON PROBABILITY OF TRIPPING AS A FUNCTION OF OBSTACLE HEIGHT

[1] Christina R. Garman, [1] Christopher T. Franck [1] Maury A. Nussbaum, [2] Michael L. Madigan

[1] Virginia Tech, Blacksburg, VA, USA
[2] Texas A&M University, College Station, Texas, USA
email: rossic@vt.edu

INTRODUCTION

Tripping accounts for an estimated 53% of falls among older adults [1]. The most common measure for characterizing the probability of tripping is the minimum foot clearance (MFC) during swing. A decrease in the central tendency (i.e. mean/median) of MFC, or an increase in MFC variability, are both associated with an increased probability of tripping [2-4]. These indirect measures of probability of tripping can lead to ambiguous results, though, when both increase or decrease simultaneously. Moreover, median MFC and MFC IQR are positively correlated [3], indicating concurrent increases or decreases in both are to be expected.

The purpose of this study was to determine the probability of tripping using a method that avoids this ambiguous situation, and to demonstrate how this method can be used to compare this probability between groups of interest. This method was used to investigate differences in the probability of tripping between females and males, based upon reports of elevated risks of falling and sustaining a fall-related injury among females [5].

METHODS

Forty males and forty females completed 16 trials walking along a 10 m walkway at a self-selected speed. All participants wore the same brand of athletic shoes, to which were attached three reflective markers. A Vicon MX T10 motion analysis system (Vicon Motion Systems Inc., LA, CA) was used to sample marker positions at 100 Hz. MFC was determined using a method adopted from Startzell et al [6].

MFC values from all trials were used to create trip probability curves that indicated how the probability of tripping varied as a function of the height of a potential tripping obstacle (Figure 1). For potential tripping obstacle heights ranging from 0 - 7 cm, in increments of 2 mm, each MFC value was dichotomized as either a trip (if the potential obstacle height was greater than MFC) or a non-trip (if the potential obstacle height was equal to or less than MFC). The percentages of trips at each obstacle height were then computed, serving as an estimate of the probability of tripping versus obstacle height.

A statistical bootstrapping technique was used at each potential obstacle height to determine whether the probability of tripping differed between females and males. The first step was to randomly reassign participant group labels (i.e., male or female) to each participant's 16 MFC values. A probability curve was then created for each group, and the difference in trip probability between groups was calculated at each potential obstacle height. This process was repeated a large number of times (100,000 in our analysis) to obtain a distribution of differences at each potential obstacle height that would occur if group assignment was random. The second step was to examine the position, within the distribution of differences, of the actual observed difference in probability of tripping between groups. This was done to determine if this difference was statistically significant at a level of $\alpha=0.05$. A multiplicity correction was used to avoid inflation of type I errors. As such, if the difference was positioned in the outer 0.14% of the distribution, then the difference in trip probability between groups was considered statistically significant ($\alpha=0.0014$). The percentage of the distribution of differences outside of the actual observed difference yielded a bootstrap p-value. This second step was performed at each potential obstacle height to determine the specific heights at which the probability of tripping differed between females and males.

Group differences identified from this statistical bootstrapping technique were compared with group differences identified using the traditional measures of median MFC and MFC IQR and mixed-factor analyses of covariance (ANCOVA). Analyses were performed using JMP v7 (Cary, North Carolina, USA).

RESULTS AND DISCUSSION

The probability of tripping was higher among females across a range of obstacle heights (1.2-4.4 cm), while both median MFC and MFC IQR were lower among females (Figure 1).
Figure 1: Trip probability curve and median/IQR MFC. Differences in trip probability between groups are indicated by a solid vertical line, and differences in median/IQR are indicated by bold. Note: m=male, and f=female

This technique identified clear gender differences in the probability of tripping versus obstacle height despite ambiguous results from the ANCOVA analysis in that both median MFC and MFC IQR were both lower among females. Furthermore, characterizing the probability of tripping as a function of obstacle height provides additional information on how individual factors may affect the probability of tripping. For example, results suggest that trip probability does not differ between males and females unless obstacle heights are greater than 1.2 cm (Figure 1). Such information may be helpful in establishing safety guidelines.

Two limitations to the method presented here warrant mentioning. First, this method focuses on foot clearance at the instant that MFC occurs even though a trip could occur at other instances during the swing phase. Second, unlike an ANOVA based upon median/mean MFC and/or MFC IQR, the current method cannot incorporate measures of covariance, or statistically control for the effects of other variables, when evaluating an independent variable of interest.

In conclusion, a pragmatic method is reported to characterize the probability of tripping as a function of obstacle height, and which can identify effects of factors not identifiable by the commonly used ANOVA analysis using MFC central tendency and variability

SEX-SPECIFIC DIFFERENCES IN LOWER EXTREMITY JOINT POWER DURING A SINGLE-LEG HOP TEST IN HEALTHY ADULTS

[2,6]Rachel L. Tatarski, [2,6]Joshua Hoffman, and [1-6]Timothy E. Hewett

INTRODUCTION

Females are typically at greater risk for musculoskeletal injury compared to their male counterparts. Often, this increased risk is attributed to modifiable risk factors such as strength and neuromuscular movement patterns. Females use quadriceps-dominant movement strategies, whereas males use hip extensor dominant movement strategies [1,2]. This quadriceps-dominant movement strategy puts females at greater risk for knee injury. Thus, determination of which females are a greater risk of knee injury is an important goal for health care professionals such as athletic trainers, physical therapists, and physicians.

Functional tests such as the single-leg hop are often used in physically active populations to test for risk of injury or deficits due to injury. Asymmetry between limbs in hop distance is usually the outcome of interest, but this measure does not take into account sex-specific movement strategies. Moreover, the distance hopped is likely related to the power generation strategy during the take-off phase of the hop and could serve as another measure of function. Therefore, the purpose of this study was to compare the power generation strategies between healthy males and females. We hypothesized that females would display a quadriceps-dominant strategy, while males will display a hip-extensor-dominant strategy.

METHODS

Sixteen subjects volunteered to participate and provided written informed consent (n = 8 females; n = 8 males). To measure whole body kinematics, each subject was fitted with 55 retro-reflective markers to define joints and segments. Markers were tracked in 3-dimensional space using 12 Motion Analysis cameras. Ground reaction forces were measured using 4 imbedded Bertec force plates. Data were analyzed using Motion Analysis Cortex, Visual3D, and MatLab. To measure the take-off phase of a single-leg hop for distance, subjects were instructed to begin the movement on the force plate with their foot lined up with a tape measure. Subjects were instructed to hop as far as they could forward on one leg and stick the landing. The distance of the hop was measured at the location of the heel. Subjects were allowed to practice the hop twice on each leg and then performed two successful trials per leg. A trial was considered successful if the subject only used one leg to push off and land. Pearson's product-moment correlation was used to assess the relationship between power generation and hop distance. *Student's t*-test was used to test for significant differences between sexes. The alpha level was set to 0.05, *a priori* to determine significant results.

RESULTS

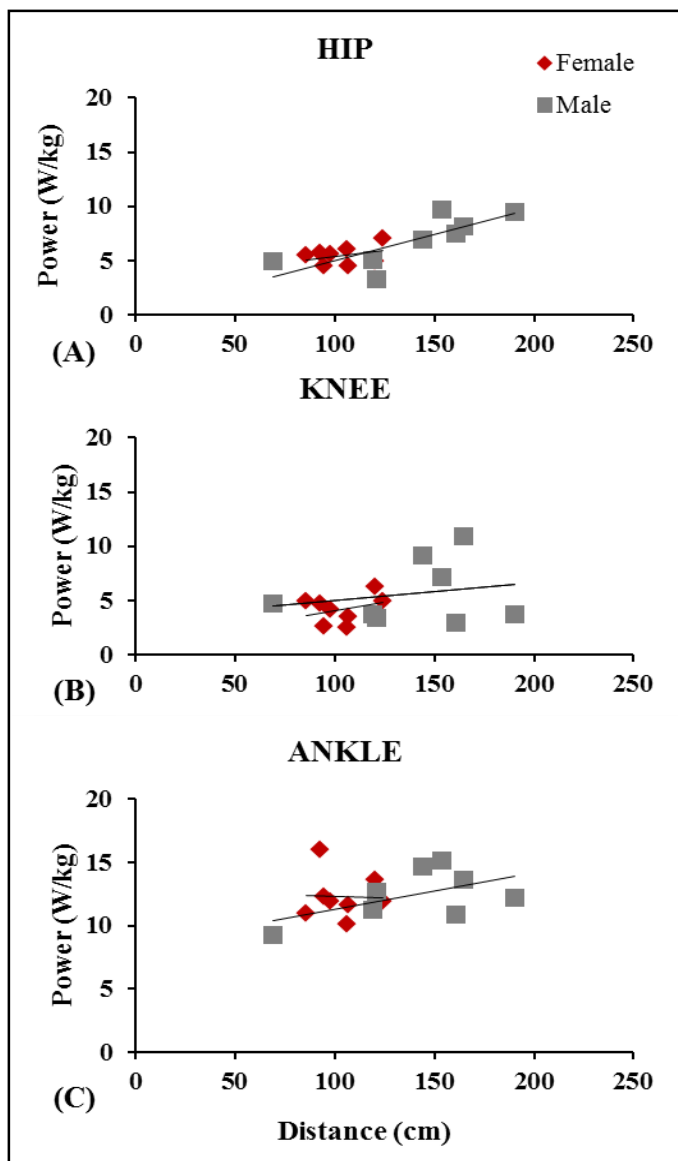
Overall, there was a strong, positive correlation between peak total lower extremity joint power and hop distance ($r = 0.60$). Males demonstrated a stronger relationship between peak total joint power and hop distance ($r = 0.58$) than females ($r = 0.24$). In addition, males hopped significantly farther than females (Table 1). For either hip or ankle excursion, there were no significant differences between sexes; however, males had significantly more knee excursion than females (Table 1). Peak hip power accounted for ~60% of the variance in hop distance in males, but only ~13% of the variance in hop distance for females (Figure 1A). Peak knee power accounted for ~4% of the variance in hop distance in males and ~11% variance in hop distance for females (Figure 1B). Peak ankle power accounted for ~29% of the variance in hop distance for males and~1% in females (Figure 1C).


Figure 1: Relationships between single-leg hop distance and peak joint powers between males and females (A = hip, B = knee, C = ankle).

DISCUSSION

The findings from this study confirm our hypothesis that males would use a hip-extensor strategy for power generation during a single-leg hop, while females would rely on a quadriceps-dominant strategy. These sex-specific differences in performance are similar to previous findings in functional tests such as the drop vertical jump [3]. However, it is interesting to note that the data from our female subjects showed a clustering trend, while the data from our male subjects were more varied. The lower R-squared values for the female subjects is likely due in part to the clustered nature of this data. However, exponential transformation did not affect this pattern. Individual variation between female subjects may also account for this low association.

CONCLUSIONS

Overall, females tended to use less total lower extremity excursion, instead females utilized a more upright posture and thereby limited the power-generating function of their muscles. Furthermore, females tended to use a quadriceps-dominant strategy, whereas males used a hip-extensor strategy to perform the task. Since a quadriceps-dominant strategy is a known risk factor for knee injury, an easy, simple and straightforward test such as the single-leg hop may be a useful tool to assess injury risk in this population.

INTRODUCTION

Anterior cruciate ligament (ACL) injury rates are 4-8 times greater in female athletes than their male counterparts.[1] As female athletes are at increased risk of ACL injury compared to males, it is important to understand the underlying mechanics that contribute to this sex bias. The purposes of this investigation were to employ a robotic manipulator to simulate male and female kinematics from athletic tasks on cadaveric specimens and to identify sex-based mechanical differences relative to the ACL. The primary hypothesis tested was that simulations of female motion would generate higher ACL loads associated with greater ACL injury risk than simulations of male motion when executed on the same cohort of cadaveric specimens. A second hypothesis tested was that female motion simulations would exhibit greater ACL strains than male motion simulations.

METHODS

A 6-degree-of-freedom robotic manipulator articulated 19 cadaveric lower extremity specimens from 12 unique cadaveric donors of mixed sex (9 males; 3 females, age = 47.9 ± 7.0 years; mass = 832 ± 190 N) through simulations of *in vivo* knee kinematics that were recorded from male and female sidestep cutting and drop vertical jump tasks (DVJ).[2] A six-axis load cell aligned with the mechanical axis of the tibia recorded joint forces and torques at the joint center point, while differential variable resistance transducers implanted on the anteromedial bundle of the ACL recorded ligament strain. Univariate ANOVA was used to evaluate statistical significance of mechanical simulations between genders ($\alpha < 0.05$).

RESULTS AND DISCUSSION

Peak ACL strain during a simulated DVJ was 6.27% and 6.61% for the female and male models, respectively ($P = 0.86$; Table 1). For the sidestep cut peak ACL strain was 4.33% and 7.57% for the female and male models, respectively ($P = 0.21$). Female simulations exhibited lower peak lateral joint force during the DVJ and lower peak anterior joint force, lateral joint force, and external joint torque during the sidestep cut compared with male simulations ($P < 0.05$; Figure 1).

ACL strain was only different between sexes at peak knee flexion during sidestep cutting. The sidestep cut simulations exhibit peak flexion angles of approximately 62° and 50° for the male and female, respectively. This indicated that the only significant gender differences in ACL strain occurred at a position where the ligament is likely unloaded or minimally loaded.[3] Further, the female motion did not generate higher joint loads compared to the male motion. The simulations performed were relative to controlled athletic tasks

Table 1: Peak ACL strains observed at various stages of landing phase during sex-specific simulations of DVJs and sidestep cutting.

	Landing Phase	First 50 msec	Initial Contact	Peak Flexion
DVJ				
Male	6.6	3.7	3.7	6.0
Female	6.3	4.5	4.2	5.0
Sidestep Cut				
Male	7.6	4.8	4.8	6.4*
Female	4.3	4.1	4.1	2.4*

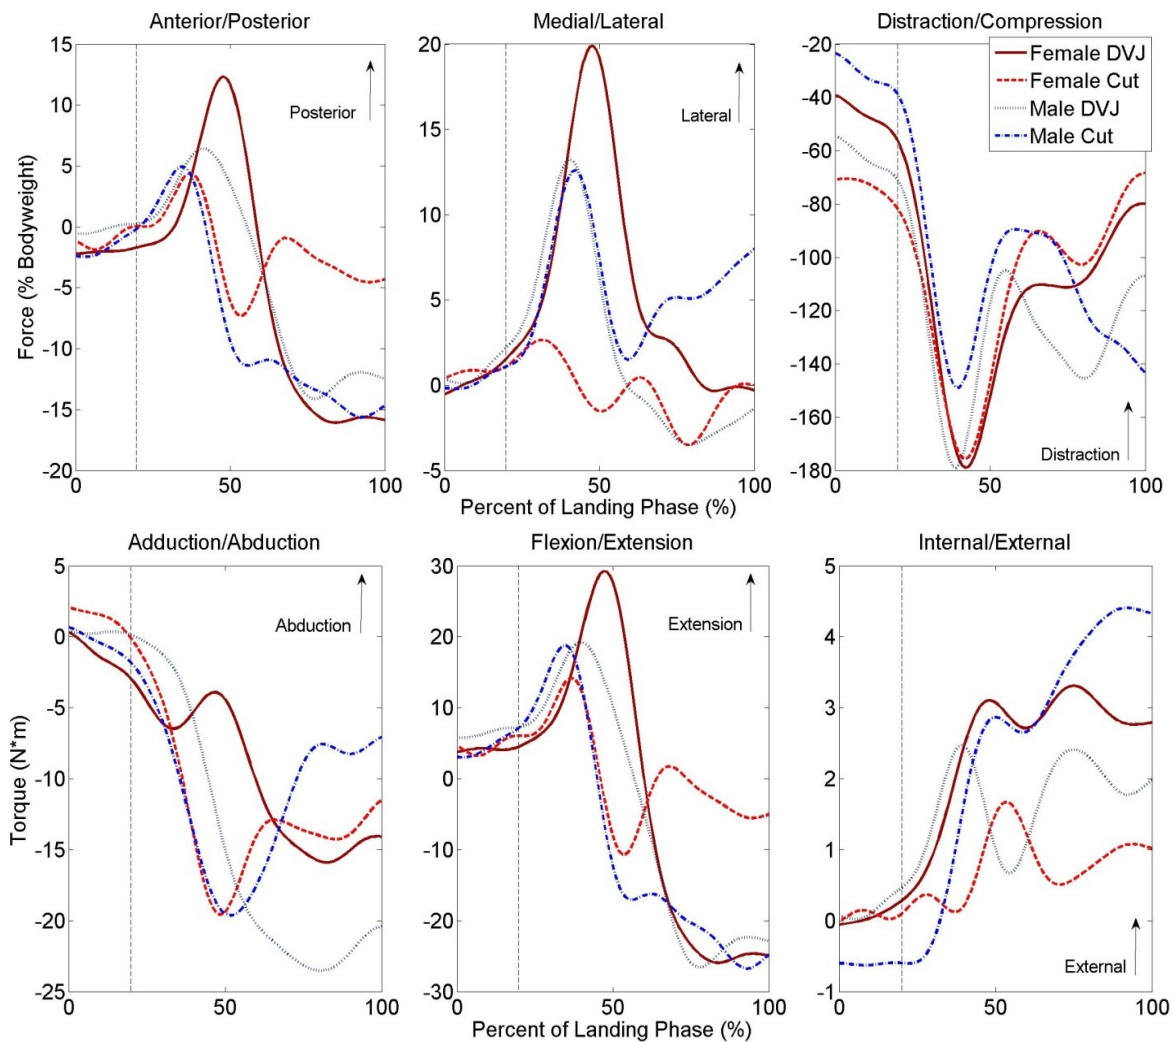
* statistically significant difference between sexes ($P < 0.05$)


Figure 1: Displays the population average force (top row) and torque (bottom row) measured at the tibiofemoral joint in response to simulated male and female DVJ and sidestep cut articulations. The vertical, dashed line represents the approximate cutoff for the first 50 msec after initial contact, where ACL injuries are most likely to occur.

with minimal perturbation to the athlete and no injuries. In this setting, the male and female simulations exhibited minimal mechanical differences; however, more rigorous activities that offer greater perturbation and exhibit additional sex-based loading differences.

CONCLUSIONS

The sex-based loading and strain differences noted do not appear to explain the increased rate of ACL injures observed in female athletes for the athletic tasks simulated, assuming parity of ligament properties between sexes. Therefore, additional perturbation is likely necessary to invoke the mechanical differences that lead to higher rates of ACL injury in female populations. In the current

Investigation, data indicated that, during the performance of regulated athletic tasks, sex-specific movement patterns exhibit similar levels of ACL strain. As such, the rehabilitation and prevention of ACL injuries should be similarly focused on known risk factors across sexes.

Climbing Direction, Number of Contact Points and Gender Influence Recovery from Ladder Falls but not Glove Use

[1] Erika M. Pliner, [2] Na Jin Seo and [3] Kurt E. Beschorner

[1] The University of Wisconsin-Milwaukee, Milwaukee, WI, USA

[3] The University of Pittsburgh, Pittsburgh, PA, USA
email: beschorn@pitt.edu

INTRODUCTION

Ladder falls account for 16% of fatal falls and 8% of non-fatal falls [1]. Injuries from ladder falls are severe, but can be prevented from safer ladder climbing practices and proper ladder climbing training [2]. Previous research has investigated the effects of gloves on grasping ladder rungs in hopes to improve ladder climbing practices [3, 4]. High friction gloves were found to increase the maximum gripping force when the rung is forcibly pulled from their hand [3]. Also, more muscle activity is needed to stabilize the rung with low-friction gloves [4]. However, these studies only considered the interaction between the hand and the rung, which may be an over-simplification of ladder recovery.

Other risk factors for ladder falls may include gender, utilizing 3 points of contact and climbing direction. For example, differences in strength across genders [5] may alter recovery risk. Three points of contact is a common safety suggestion and requirement of OSHA. Lastly, falls have been observed more frequently during egress of mining equipment than ingress suggesting that ladder descent may be more difficult than ascent [6]. A paucity of objective data exists regarding how each of these factors impacts recovery from a ladder fall event.

The purpose of this study was to quantify the impact of gloves, 3-point contact, gender and climbing direction on recovery after a ladder perturbation.

METHODS

Thirty-five (10 female, 25 male) healthy participants between the ages of 18 and 29 were recruited for this study. IRB approval and written informed consent were obtained prior to testing. All participants were equipped with standardized attire, footwear and a safety harness that was equipped with a load cell to measure the support force (1000 Hz). Forty-seven reflective markers were placed on participant's anatomical landmarks to record their kinematic data (100 Hz), including the hands, feet, and the anterior/posterior superior iliac spines.

Participants climbed a vertical 12-foot custom-designed ladder. The ladder was equipped with strain gauges and load cells to estimate forces placed on several of the ladder rungs. The fourth rung on the ladder was designed such that the rung could be released under the participants' foot electronically. The armed rung was programed to release when the contralateral leg stepped off of the previous rung. This timing corresponds approximately to when subjects typically slip [7], leaving the hands as the primary means of recovery. Each participant experienced six simulated ladder missteps corresponding to three glove conditions (bare hands, high friction gloves and low friction gloves) and two climbing directions (ascent and descent). Participants performed between five and eight baseline trials before each perturbation to minimize anticipation. The order of gloves and climbing direction were randomized.

A participant's ability to recover was based on the force supported by the safety harness. The harness force was normalized to the participant's body weight and calculated as the peak harness force between the start of fall and end of fall time points. The start of fall was the point in time the fourth rung was triggered to release. The end of fall was the point in time of the first minimum of the mid-hip joint center's vertical displacement after the start of fall. Hip joint centers were calculated based on the pelvic markers [8]. The number of body to ladder contact points at the start of fall was visually determined from kinematic data. Point of contact varied between two point contact (2 Pt, 1 hand and 1 foot) and three point contact (3 Pt, 2 hands and 1 foot). An ANOVA was performed with gender, climbing direction, point of contact and glove

condition as independent variables and harness force as the dependent variable.

RESULTS AND DISCUSSION
Females had higher harness forces than males ($p < 0.001$). Descending perturbations resulted in higher harness forces ($p < 0.001$). Participants who had three point contact with the ladder at the start of fall had lower harness forces ($p < 0.05$). Glove condition did not affect harness force (Figure 1).
Figure 1: Average harness force normalized to body weight for males (M) vs. females (F), ascend (A) vs. descend (D), 2-point contact (2 Pt) vs. 3-point contact (3 Pt) and bare hand (BH), high-friction (HF) vs. low-friction (LF).

The discrepancy between males' and females' ability to recover may be due to physiological factors. Young male adults typically have higher upper body strength [5] than female adults, which may have assisted their ability to recover from a fall.

The difference in harness forces of ascending and descending perturbations may be due to the momentum of the body at the time of perturbation. Ascending the ladder may provide climbers with more time to respond since downward falling will be delayed and downward fall velocity is reduced. Thus, descending a ladder may be a more hazardous task than ascending a ladder, which may explain the higher injury rates reported during the egress process over the ingress process on mining equipment [6].

The finding that 3 points of contact enhances recovery is largely consistent with safety practices that promote utilizing three points of contact at all times on ladders. Less supporting points of contact will increase the required reaction load at each contact point, which may be too much for a single

hand after losing the support foot. It should be noted that few subjects maintained 3 points of contact during the whole climbing process (40%) and that the number of points of contact was just assessed at the moment of perturbation onset. Thus, the results of this study indicate that utilizing 3 points of contact when the body is most vulnerable to a slip (i.e., just after foot off [7]) may be sufficient to reduce fall risk.

Surprisingly, no effects were found between gloves and harness forces. Increased force capability from high friction gloves may not necessarily translate to better recovery during full body recovery. One potential reason for this finding may be that other factors (positioning of the hands, personal strength) may be more important than the maximum pull strength when an actual fall event is occurring.

CONCLUSIONS
This study found that fall risk was higher for female participants than male participants, for descent than ascent and when only 2 extremities are contacting the ladder compared with 3 extremities. Gloves did not affect recovery. This study suggests that ladder safety should prioritize maintaining three points of contact over glove use. Also, this study suggests that additional protection may be needed during ladder descent and for female ladder climbers.

THE LUMBOPELVIC RATIO DURING TRUNK FLEXION: THE EFFECTS OF AGE, GENDER AND MOTION PACE

[1]Milad Vazirian, [1]Iman Shojaei, [1]Anuj Agarwal and [1]Babak Bazrgari

[1] University of Kentucky, Lexington, KY, USA
email: milad.vazirian@uky.edu

INTRODUCTION

The prevalence of low back pain (LBP) increases with aging. Given the projected increase in the number of older individuals at workplace, management of occupational LBP will require an understanding of the reason(s) behind such increase in risk of LBP with aging [1]. A recent study by Tafazzol et al. [2] has shown that a reduction of lumbar contribution to a given angle of trunk flexion, as reflected in a reduction of lumbopelvic ratio (LPR), was associated with an increase in spinal loads. The objective of this study was to quantify age-related changes in LPR under fast and slow trunk flexion motions. On the basis of the suggested relationship between the LPR and spinal loads, it was hypothesized that, for a given task, the LPR of older versus younger individuals and faster versus slower motion paces will be smaller.

METHODS

Sixty individuals participated in the study after completing a consenting procedure approved by the University of Kentucky IRB. Participants were grouped in five age ranges of 22-28 (11 male and 7 female), 32-38 (7 male and 7 female), 42-48 (3 male and 6 female), 52-58 (4 male and 6 female) and 62+ (4 male 5 and female) years old with respective mean (SD) stature (cm) of 172 (1.9), 171 (1.8), 170 (2.3), 173 (4.2) and 171 (2.7) , and respective mean (SD) body mass (kg) of 69 (2.5), 72 (3.4), 77 (5.2), 81 (3.7) and 71 (4.2). Each participant attended two data collection sessions during which they completed three repetitions of slow and three repetitions of fast trunk flexion-extension tasks. Participants started each task from the standing posture and bent forward to reach their maximum comfortable trunk flexion, and then returned to the upright posture. The paces of trunk flexion for fast and slow motions were self-selected and participants were instructed to remain in full flexion posture for 5 s during the slow tasks. The thoracic and pelvic relative rotations from the upright standing posture were measured using two inertial-magnetic sensors (Xsens Technologies, Enschede, Netherlands) attached to the subject's back at the levels of T12 and S1. Lumbar flexion during each task was estimated as the difference between the measured thoracic and pelvic rotations. Finally, the LPR, was calculated as the ratio of lumbar flexion to pelvic rotation at the instant of full trunk flexion. Kinematics data were collected by a sampling rate of 50 Hz and were low-pass filtered using a fourth-order, bidirectional, Butterworth filter with cutoff frequency of 6 Hz. Repeated measures analysis of variance (ANOVA) was conducted to determine the effects of age and gender (i.e., between-subject factors) as well as flexion pace (i.e., within subject factor) on the maximum values of thoracic and pelvic rotations along with corresponding lumbar flexion and the LPR.

RESULTS AND DISCUSSION

The maximum thoracic rotation did not change with age (p=0.433) or gender (p=0.395), but was larger (p<0.001) during the fast vs. slow flexion tasks (Table 1).

Table 1: Mean maximum thoracic rotations along with 95% confidence interval for the slow and fast tasks (all values are in degrees)

Pace	Mean	95% Confidence Interval	
		Lower Bound	Upper Bound
Slow	82.9	79.4	86.4
Fast	95.8	92.4	99.1

The pelvic rotations increased with age (p<0.001), pace of task (p<0.001) and was larger (p<0.001) in females vs. males. (Table 2).

In contrast to the pelvic rotation, the lumbar flexion decreased generally with age (p=0.003). However, it was larger in the males than females (p=0.017), and similar to the thoracic and pelvic rotations, was found to increase with pace of task motion (p<0.001). (Table 3).

Table 2: Mean maximum pelvic rotation along with 95% confidence interval for each age group, gender and pace (all values are in degrees)

Age	Mean	95% Confidence Interval	
		Lower Bound	Upper Bound
22-28	24.0	20.0	28.1
32-38	26.4	21.9	30.9
42-48	29.3	23.4	35.3
52-58	35.3	29.9	40.7
62+	40.4	34.3	46.6
Male	26.7	23.1	30.9
Female	35.5	32.5	38.6
Slow	26.5	24.3	28.7
Fast	35.6	33.1	38.0

Table 3: Mean lumbar flexion along with 95% confidence interval for each age group, gender and pace (all values are in degrees)

Age	Mean	95% Confidence Interval	
		Lower Bound	Upper Bound
22-28	60.4	56.0	64.9
32-38	65.2	60.4	70.1
42-48	59.5	53.1	66.0
52-58	51.9	46.0	57.8
62+	52.0	45.9	58.1
Male	60.9	57.1	64.6
Female	54.7	51.4	58.0
Slow	55.9	53.3	58.5
Fast	59.7	57.1	62.2

The main effects of age, gender and pace on the LPR were all significant (P<0.001). Specifically, the LPR was smaller under fast versus slow trunk motions, older (>40 years old) versus younger (< 40 years old), and female versus male participants. There was an interaction between the pace and age, however, the slow motion was associated with a higher LPR in all age groups, although with highly different values.

Our results concur with earlier findings of reduction in lumbar range of flexion with aging [4].

Furthermore, on the basis of the suggested relationship between the LPR and spinal loads [2], our results suggest that older versus younger individuals and females versus males may experience larger spinal loads when doing the same flexion-extension task. Given the important role of mechanical loading in development of LBP, it is likely that the adopted lumbopelvic motion by older individuals to perform physical activity put them at higher risk of lower back injury as compared to younger individuals. It is also important to mention that LBP patients demonstrate a smaller LPR during trunk flexion as compared to asymptomatic individuals [4]. Future investigation of whether such differences in LPR, and potentially in the lower back biomechanics, between people with and without LBP is a cause or consequence of LBP can further enhance our understanding related to etiology of LBP among older individuals.

Table 4: Mean LPR along with 95% confidence interval for each age group, gender and pace

Age	Mean	95% Confidence Interval	
		Lower Bound	Upper Bound
22-28	2.998	2.538	3.458
32-38	3.038	2.529	3.546
42-48	2.273	1.600	2.946
52-58	1.733	1.118	2.347
62+	1.368	.729	2.006
Male	2.754	2.361	3.147
Female	1.809	1.465	2.154
Slow	2.620	2.280	2.959
Fast	1.944	1.740	2.148

THE EFFECT OF EXERCISE TRAINING ON SHOULDER JOINT POSITION SENSE

Yin-Liang Lin and Andrew Karduna

University of Oregon, Eugene, OR, USA
email: yinliang@uoregon.edu, web: http://karduna.uoregon.edu/

INTRODUCTION

The central nerve system uses proprioception to help coordinate muscle activity around the shoulder to provide dynamic stability during movement. Impaired proprioception has been found to be associated with shoulder injuries [1].

Exercise is an important part of shoulder rehabilitation, but the effect of exercise on proprioception is still controversial [2, 3]. To our knowledge, no study has focused on training rotator cuff and scapular muscles, which are the dynamic stabilizers of the shoulder. The purpose of this study is to investigate the effect of rotator cuff and scapular muscle strengthening exercise on the shoulder joint position sense.

METHODS

Twelve healthy subjects were recruited (4 males and 7 females, 18 – 26 years old). They received exercise training three times per week for four weeks, with an average during of 30 minutes per session. All training sections were supervised to ensure compliance with the training protocol. The exercise protocol contained six exercises, including full can, prone full can, external rotation in sidelying, diagonal exercise, push up with plus, and push up on exercise ball. The training consisted of three sets of 10 repetitions using variable resistance: one set at 50% of the 10-repetition maximum (RM), one at 75% of the 10 RM, and one at 100% of the 10 RM.

JPS was tested with an active position reproduction test before and after the exercise training. A magnetic tracking device (Polhemus Liberty, Colchester, VT) was used to measure scapular, humeral and thoracic kinematics. Subjects wore a head mounted display, which provided visual cues for the target position and blocked the visual feedback on the arm position. A custom written LabVIEW program (National Instruments, Austin, TX) guided subjects to move their arm to a specific target elevation of the humerus with respect to the thorax in scapular plane (Figure 1).

After the subject had maintained the arm in the target position for one second, the display turned completely black, thus removing all visual feedback. Subjects held their arms for two seconds, memorizing the target position. Then subjects were instructed to return to the rest position. After three seconds, subjects were prompted with another verbal cue to return to the target position. The subjects indicated when they believed they had reached the target by pushing a button on a wireless presenter remote with their contralateral hand [4].
Figure 1. The white bars indicate the target. The red bar represents the humerothoracic elevation angle. The green bars indicate if the arm deviates from the scapular plane

Three target positions were presented: humerothoracic elevation angles of 50°, 70°, and 90°. This study focused on humerothoracic elevation, glenohumeral elevation, and scapular helical angles. Percentage errors were calculated by dividing the errors between the reposition angle and target angle by the reposition range of motion. The

error of the scapular helical angles was calculated from the rotational matrix at the reposition with respect to the target position. The scapular range of motion is calculated from the rotational matrix at the reposition with respect to rest position. Constant errors (CE) and variable errors (VE), which were calculated from percentage errors, were used to represent joint position sense. A two-way repeated measures ANOVA was used to examine the changes after the training.

RESULTS AND DISCUSSION

Figure 2 and figure 3 show the CE and VE of humerothoracic elevation, glenohumeral elevation and scapular helical angles before and after exercise training. No significant interaction was found in CE and VE in three joints. There was a significant main effect in angle found in both CE and VE in three joints, indicating that when the target angles increased, the CE and VE decreased.

There was no significance difference after the exercise training in humerothoracic and glenohumeral elevation angles. The errors of humerothoracic and humerothoracic elevation demonstrate similar patterns. Significant difference in CE before and after exercise training was found in scapular helical angles, with CEs decrease after the training.

CONCLUSIONS

Although the overall shoulder and glenohumeral joint position sense did not change, scapular joint position sense improved after the exercise training of rotator cuff and scapular muscle. The exercise may be important for the control of scapula.

HOW HUMANS USE VISUAL OPTIC FLOW TO REGULATE STEPPING MOVEMENTS

INTRODUCTION

Visual optic flow is critical for regulating walking [1]. Healthy humans walking on a motorized treadmill (no optic flow) maintain approximately constant stride speeds (S_n) at each stride, n [2]. Subjects allowed deviations in stride length (L_n) and time (T_n) to persist across strides, but rapidly corrected deviations in S_n. In contrast, during overground walking, fluctuations in L_n, T_n, and S_n all exhibit strong persistence [3]. Optic flow provides information about *motion* (i.e. speed) [4]. Differences in optic flow may explain these different experimental results. Here, we determined how humans alter stride-to-stride stepping control by systematically removing or altering optic flow in a virtual (VR) walking environment.

METHODS

Twenty healthy adults (10M/10F; age 19-34) walked on a motorized treadmill at fixed speed (v_w). They were presented 5 optic flow conditions: static VR scene (STA), blank screen (BLK), and VR scene with optic flow speed either matched to (MAT), slower (SLO), or faster (FAS) than v_w. Whole-body kinematic data were recorded to compute time series of L_n, T_n, S_n, and absolute treadmill position, P_n.

During treadmill walking, all [T_n, L_n] combinations that equally achieve the same speed (i.e., $L_n/T_n = v_w$) define a Goal Equivalent Manifold [2] (Fig. 1). Deviations tangent to the GEM (δ_T) do not affect speed (v_w), while deviations perpendicular to the GEM (δ_P) do affect speed (v_w) (Fig.1). Time series of δ_T and δ_P fluctuations relative to the GEM were also computed.

Means and standard deviations were computed for each time series. Detrended Fluctuation Analysis (DFA) was used to compute exponents, α, that quantified the degree of statistical persistence / anti-persistence in each time series. Smaller α indicate

greater likelihood of correcting stride-to-stride deviations on the next stride (i.e. greater *control*) [2].
Figure 1: Goal Equivalent Manifold (GEM, $L_n/T_n = v_w$) for walking, showing example [T_n, L_n] data (each dot represents one individual stride n) [2].

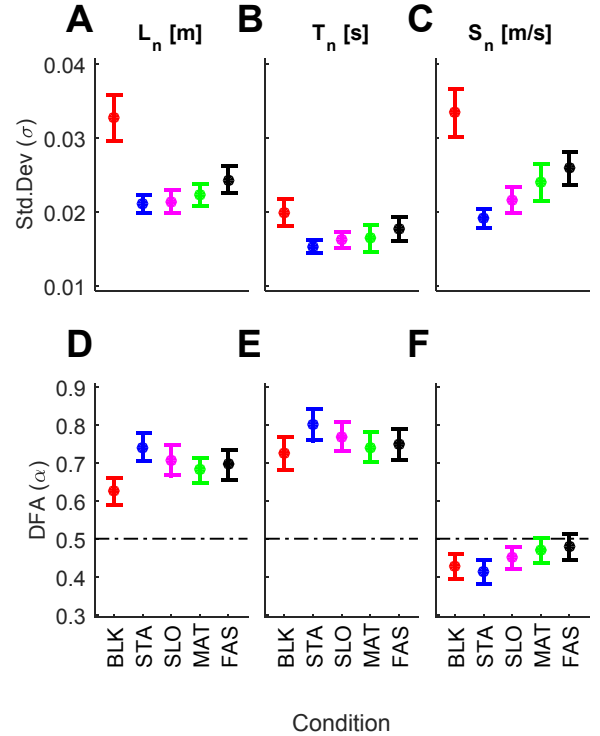
RESULTS


Figure 2: Variability (σ) and Statistical Persistence (α) of Stride Parameters (L_n, T_n, S_n).

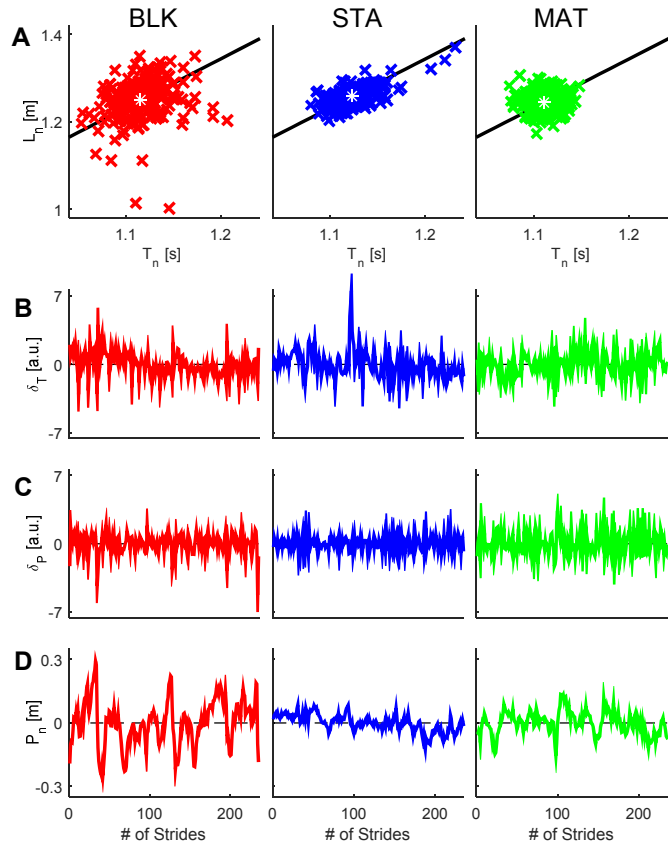
Across conditions, participants exhibited stride-to-stride statistical persistence (i.e. $\alpha \gg \frac{1}{2}$) in both L_n (Fig. 2A) and T_n (Fig. 2B), suggesting weaker control of these deviations. Anti-persistence (i.e. $\alpha < \frac{1}{2}$) was observed in S_n across all conditions (Fig. 2C). During BLK, participants exhibited significantly increased variability for all three stride parameters (Fig. 2A-C), and L_n was less persistent compared to the other conditions (Fig. 2D), indicating greater control [2].


Figure 3: Example $[T_n, L_n]$ and time series data for typical subject for BLK, STA, and MAT conditions.

In the BLK condition, participants exhibited qualitatively more variance in all directions (Fig. 3A). In the STA condition compared to the MAT condition, participants exhibited more variance along and less variance perpendicular to the GEM (Fig. 3A).

Participants exhibited greater variability for δ_T than for δ_P deviations across all conditions (Fig. 4A-B). For the STA condition, variance ratios ($\sigma(\delta_T)/\sigma(\delta_P)$) were highest and ($\sigma(P_n)$) was lowest. Participants exhibited greater statistical persistence for δ_T than for δ_P and strong persistence of P_n across all conditions

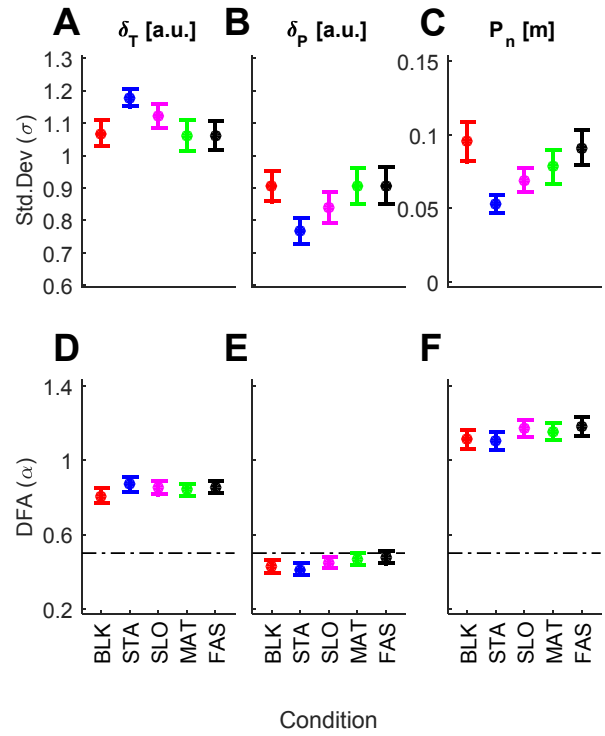
(Fig. 4D-F). No significant differences were found for statistical persistence of δ_T, δ_P, or P_n (Fig. 4D-F).


Figure 4: Variability (σ) and Statistical Persistence (α) of both δ_T and δ_P deviations and absolute position (P_n).

DISCUSSION AND CONCLUSIONS

Participants did not adopt stepping control strategies observed during overground walking [3]. However, manipulating optic flow did significantly alter walking variability and how that variability was regulated. Lack of a visual reference (BLK) lead to significantly greater movement variability. However, the level of stride-to-stride control remained similar for these healthy young adult subjects.

PROXIMAL-DISTAL DIFFERENCES IN MOVEMENT SMOOTHNESS REFLECT DIFFERENCES IN BIOMECHANICS, NOT NEURAL CONTROL

[1,2]Steven K. Charles, [1]Layne H. Salmond, and [1]Andrew D. Davidson

[1]Mechanical Engineering and [2]Neuroscience, Brigham Young University, Provo, UT, USA
email: skcharles@byu.edu, web: neuromechanics.byu.edu

INTRODUCTION

Smoothness is a hallmark of healthy movement and has the potential to be used as a marker of recovery in rehabilitation settings. However, while much past research has focused on how the neuromuscular system plans and controls shoulder and elbow movements (reaching), which are remarkably smooth, little is known about the smoothness of wrist rotations despite the importance of wrist rotations in everyday life. Because the smoothness of wrist rotations has not been characterized, it cannot be used as a marker for diagnosis and evaluation. This study examined the smoothness of wrist rotations in comparison to the known baseline of reaching movements. We found that wrist rotations are significantly less smooth than reaching movements, and that this difference reflects differences in the low-pass filtering properties of the shoulder/elbow vs. the wrist joint.

METHODS

Ten young, healthy subjects were asked to perform 15-degree wrist rotations and 14cm reaching movements in eight different directions at fast, medium, and slow speeds (300, 550, and 900ms durations, respectively). Position data were recorded using trakSTAR (Ascension Technologies, Milton, VT), low-pass filtered and differentiated to get velocity, acceleration, and jerk, and individual movements were extracted as the portion of each movement continuously above 10% of the maximum speed. The smoothness of each individual movement was quantified using two measures: the ratio of the integrated square jerk of the movement to that the corresponding minimum-jerk trajectory, and the number of maxima in the speed profile. To compare the smoothness between factors (joint, speed, target, and direction), we performed on both measures mixed-model ANOVA with subject as a random factor.
Figure 1: Position and velocity of typical reaching movements (top) and wrist rotations (bottom). Actual movements (blue and cyan) are compared to corresponding minimum-jerk trajectories (pink). Green and red open circles indicate the start and stop of movements (based on 10% of maximum speed).

RESULTS AND DISCUSSION

Position and velocity data of representative fast reaching movements and wrist rotations are shown in Figure 1. Comparing the velocity plots in Figure 1 suggests that wrist rotations were less smooth than reaching movements. Indeed, our analysis showed that 1) wrist rotations were significantly less smooth than reaching movements ($p \leq 0.005$; Figure 2), 2) smoothness decreased significantly as speed decreased ($p < 0.0001$; Figure 2), and 3) wrist rotations exhibited a pattern of smoothness that varied significantly between targets and outbound/inbound movement directions ($p < 0.0001$; not shown).

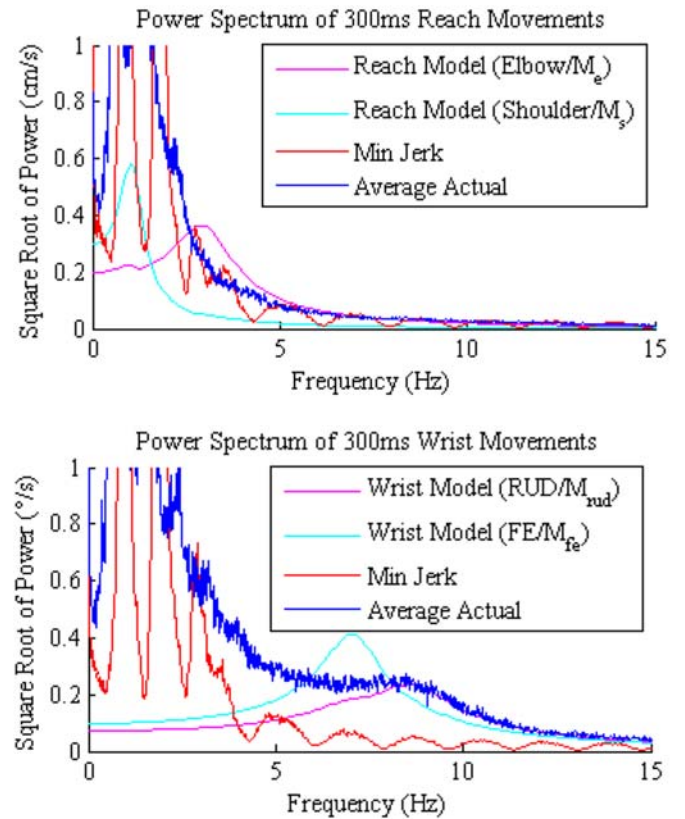
We further investigated potential causes for these findings. The cause behind the first finding was explored by testing whether the observed difference in smoothness between wrist rotations and reaching movements was due to differences in mechanical, muscular, neural, or protocol-related properties. To investigate the cause behind the third finding, we tested whether differences in wrist smoothness between directions was due to anisotropy in the musculoskeletal dynamics of the wrist or anisotropy in movement duration. Prior studies revealed for reaching and finger movements that faster movements are smoother, so we relied on these studies for an explanation of the second finding.
Modeling the power spectra of the shoulder/elbow and wrist revealed that the bandwidth of the wrist is significantly larger than that of the shoulder and elbow, and that there is considerable power in the bandwidth of the wrist that would be low-pass filtered in reaching movements, indicating that at least some of the difference in smoothness between wrist and reaching movements is due to differences in mechanical properties (Figure 3). Differences in muscular, neural, or protocol-related properties (signal-dependent noise, proprioceptive acuity, and the speed requirements of the task, respectively) do not appear to be capable of causing the observed difference in smoothness between wrist and reaching movements. Differences in wrist smoothness between movement directions reflects differences in movement duration between directions.


Figure 3: Power spectrum of reaching movements (top) and wrist rotations (bottom). The spectra of actual movements are shown in blue, while the spectra of corresponding minimum-jerk trajectories are shown in red. Superimposed on the power spectrum plots are scaled versions of the magnitude responses (cyan and pink). The power spectrum of the wrist shows considerable power above 4Hz that is not required by the task (hinted by the fact that the minimum-jerk spectrum drops off). Assuming that the input to reaching movements has a similar bandwidth, the power in the 4-10Hz band could not pass through the shoulder/elbow, resulting in smoother movements.

Figure 2: Wrist rotations were found to be significantly less smooth (higher jerk ratio) than reaching movements. For wrist rotations and reaching movements, slower movements were significantly less smooth than faster movements.

BETA FREQUENCY SENSORIMOTOR CORTICAL OSCILLATIONS DURING ANKLE PLANTARFLEXION ARE RELATED TO SPATIOTEMPORAL GAIT KINEMATICS

[1]David J. Arpin, [2]Elizabeth Heinrichs-Graham, [2]Tony W. Wilson & [1,2]Max J. Kurz

[1]Munroe-Meyer Institute, University of Nebraska Medical Center, Omaha, Nebraska
[2]Center for Magnetoencephalography, University of Nebraska Medical Center, Omaha, Nebraska

INTRODUCTION

Numerous investigations have examined the kinematics and kinetics of human locomotion; however, few have attempted to explore how the brain is involved in the control of the gait biomechanics [1,2]. A prior study that used electroencephalography (EEG) has shown that there are changes in the sensorimotor cortical oscillations in the beta-frequency (15-30 Hz) range during gait [2]. While identifying that beta oscillatory activity is likely involved in the control of gait is insightful, we still have a substantial knowledge gap in our understanding of how they are linked with control of the lower extremity muscular force production during gait. This information is imperative as we strive to develop brain computer interfaces (BCI) that can be used to control robotic exoskeletons for gait.

The ankle plantarflexors are responsible for producing approximately 80% of the total power during gait [3]. As such, the ankle plantarflexors are largely responsible for the forward progression of the center of mass, and have a direct impact on the sustainment and change of the walking speed. Therefore, understanding how the sensorimotor cortex is involved in controlling the ankle joint musculature may provide further insight on the cortical processes involved in controlling gait. The purpose of this investigation was 1) to assess sensorimotor cortical activity at the beta frequency range during performance of an ankle plantarflexion motor task, and 2) to determine if there is a relationship between sensorimotor cortical activity in the beta frequency range during the ankle plantarflexion task and the spatiotemporal kinematics of gait.

METHODS

Nine adults (Age = 25 $\pm$ 3 yrs.) performed an isometric ankle plantarflexion target matching task. Custom Labview software was used to collect and display the isometric forces measured from an isokinetic dynamometer at 1 kHz (Biodex Inc., Shirley, NY). The amount of torque generated was graphically displayed on a large monitor as a single box that moved vertically depending on the amount of torque the subject applied to the foot pedal. The experimental paradigm involved the subjects matching and holding their isometric force at a target torque that was at 20% of their maximum. 60 target matching trials were performed, with each trial consisting of 5 s of isometric torque generation followed by a 10 s rest period where the subject's gaze was fixed on a cross. A 64 channel EEG system was used to concurrently measure the somatosensory cortical activity during the ankle plantarflexion task at 1 kHz (Advanced Neuro Technology, Enschede, Netherlands). Artifact-free epochs for each electrode were transformed into the time-frequency domain and averaged over the respective trials to generate plots of the mean spectral density. The data were then normalized by dividing the power value of each predetermined time-frequency bin by the respective bin's baseline power, which was calculated as the mean power during the baseline period. This normalization procedure allowed power changes to be visually discerned in the individual electrodes. A linearly-constrained minimum variance vector beamformer algorithm was used to reconstruct the electrical neural signals that generated the observed power changes. The images were derived from the cross spectral densities of all combinations of EEG electrodes within the beta frequency, and the solution of the forward problem for each location on

a grid specified by input voxel space. The source power in these images was normalized per subject using a separately averaged pre-stimulus noise period of equal duration and bandwidth. Task effects were analyzed using one-sample t-tests to identify brain areas with significant beta activity. The participants additionally walked across a digital mat at their preferred and fast-as-possible walking speeds in order to assess their gait spatiotemporal kinematics (GAITRite, CIR Systems Inc., Sparta, NJ). Each walking condition was repeated twice and an average was used for the final analysis. For the correlation analysis, the amplitude of the peak voxel for the task effect was extracted from each participant's beamformer output image. Spearman rho rank order correlations were subsequently performed between the peak amplitude and the respective spatiotemporal kinematics.

RESULTS AND DISCUSSION

A representative plot of the time frequency components for the electrode located over the leg motor region (e.g., Cz) is shown in Figure 1A. Inspection of this plot reveals substantial beta frequency activity was present during the ankle plantarflexion task. The beamformer results indicated that the source of this beta activity resided within the leg area of the precentral and postcentral gyri (p<0.000005; cluster-corrected; Fig. 1B).

There were strong correlations between the strength of activity within the peak sensorimotor voxel and the spatiotemporal gait kinematics. For the preferred walking speed, a strong negative correlation was found between the strength of beta neural activity and the cadence (r = -0.67, p = 0.05). During the fast-as-possible walking speed, we found strong negative correlations between the strength of beta sensorimotor cortical activity and the walking speed (r = -0.78, p = 0.01) and cadence (r = -0.87, p = 0.01). This indicated that stronger cortical activity at the beta frequency was related to faster walking speed and quicker cadence. We additionally found a strong positive correlation between the strength of the beta somatosensory cortical activity and step width (r = 0.67, p = 0.05), suggesting that stronger beta activity was related to a narrower step width.
Figure 1. A) Group average time-frequency plot for the electrode located over the leg motor region (Cz) **B)** Beamformer image of the task effect for the 16-22 Hz response from 750-950 ms. The movement related beta-frequency changes are in blue (pre- and postcentral gyri).

Our results show that there is an increased amount of sensorimotor cortical activity at the beta frequency while performing an ankle plantarflexion force task. These results are aligned with prior investigations that have noted that the beta oscillations may be linked with the control of the lower extremity musculature [4]. More importantly, our results show that there are strong correlations between the amount of beta activity within the somatosensory cortices that are involved in the control of ankle plantarflexion musculature and the gait spatiotemporal kinematics. This implies that the beta frequency oscillations previously noted from the EEG collected during gait may reflect the control of the ankle musculature [2]. Based on our strong correlations, we suspect that monitoring the beta frequency oscillations within the leg region of the somatosensory cortices may provide an innovative index for BCI that use robotic exoskeletons to control the ankle plantarflexion force production during gait.

OUTCOME MEASURES FOR HAND AND LEG FUNCTION NATURALLY REVEAL LATENT DOMAINS OF STRENGTH, LIMB COORDINATION, AND SENSORIMOTOR PROCESSING

[1] Emily L. Lawrence, [1]Sudarshan Dayanidhi, [1]Guilherme Ceasar,
[1]Susan M. Sigward, [1]Francisco J. Valero-Cuevas

[1] University of Southern California, Los Angeles, CA, USA
email: ellawren@usc.edu

INTRODUCTION

The International Classification of Functioning, Disability and Health (ICF) construct by the World Health Organization emphasizes clinical assessments related to body structure and function, activity, and participation [1]. But the question remains whether and how individual outcome measure relate to—and reveal—these latent functional domains. We developed a multidimensional approach to examine the interactions among available outcomes measures to reveal latent functional domains in both hand and leg function.

METHODS

Sixty-six healthy older adult participants (38F, 28M, 66.1±11.6yrs, range: 45-88yrs) consented to perform upper extremity outcome measures with their dominant hand. Thirty-seven healthy young adults (18F, 19M, 24.7±2.7yrs, range: 18-30yrs) completed the lower extremity outcome measures with their self-reported dominant leg.

The upper extremity measures included six outcome measures: Grip, Key and Precision Pinch strengths, Box and Block test (BBT), Nine Hole Pegboard test (NHPT) and the Strength-Dexterity test compression force (SD_F). The lower extremity measures included ten outcome measures from five assessment tools: Vertical Jump (VJ), Y-balance (YBT), center of pressure variability (COP) during Single Limb Hop and Balance (SLHB) and Single Limb Balance (SLB) tests, and the Lower Extremity Dexterity (LED) test). In [2] we describe how the compression forces in the SD and LED tests quantify the maximal instability that can be controlled.

We used principal components analyses (PCA) to examine whether and how the associations among outcomes measures reveal latent functional domains. We limited our analyses to the PCs that sufficed to capture ≥ 75% of the total variance for both datasets.

RESULTS AND DISCUSSION

In the upper extremity, the 1st PC shows that measures of hand strength are the leading factors. The 2nd PC is dominated by measures of upper limb coordination (BBT and NHPT with inverted scales, hence the negative correlations). The 3rd PC has sensorimotor processing (SD_F) as the sole contributor (Fig. 1).

In the lower extremity, the 1st PC contains outcome measures requiring more strength for successful performance (VJ and YBT), with moderate, positive correlations with SLB COP_{AP}, and COP_{ML}. The 2nd and 3rd PCs featured measures of coordinated lower limb ability (SLHB and SLB). Interestingly, while the associations between SLHB and SLB COP variables were positive in the 2nd PC, they were negatively associated in the 3rd PC. Moreover, in the 3rd PC, LED compression force (LED_F; a measure of maximal instability that can be controlled) was positively correlated with dynamic balance variables (SLHB), but LED force variability (LED_{RMS}) was more closely associated with static balance variables (SLB). The 4th PC revealed that outcome measures of sensorimotor processing (LED_{RMS} and LED_F) were highly, positively correlated with each other and no other measure (Fig. 2).

Hand and leg functions are inherently multidimensional [1]. The ICF construct offers a language and a framework for quantifying health
Figure 1: Latent domains of hand function. The scaled loadings for the first three PCs are shown. For ease of comparison, the outcome measures were ordered on a continuum of decreasing strength requirement. Strength-related measures are on the left, sensorimotor measures are on the right, and measures of limb coordination are between them.

Figure 2: Latent domains of leg function. The scaled loadings for the first four lower extremity PCs are shown.

and disability. But the link to real-world tasks (e.g., clinically practical outcome measures) is less developed, reducing its utility. The strong and distinct associations and dissociations that emerged naturally among outcome measures reveal—to our knowledge for the first time—three distinct latent functional domains: strength, limb coordination, and sensorimotor processing.

By mapping commonly used functional assessment tools to latent functional domains of hand and leg function, this work critically extends the meaning and utility of the ICF. Strength and sensorimotor processing fit within the structure and function category; and limb coordination fits within activity (reach to grasp, mobility, and balance) and participation (necessary for work, play, and everyday activities) categories.

Importantly, these distinct domains emerged naturally from the data, for both hand *and* leg function despite the obvious evolutionary, anatomical, and functional differences. Despite, also, of the fact that strength is often required in combination with limb coordination for activity and participation, and sensorimotor processing and limb coordination are needed to perform everyday tasks such as in-hand manipulation and maintaining balance.

We present an integrative approach to quantifying hand and leg function that draws from multiple areas including biomechanics, neuroscience, and general well being. Our novel approach of mapping outcome measures to latent domains of hand and leg function provides a critical new perspective for basic science and clinical research: It enables the design of research studies and treatment modalities to target each of the latent domains of function using available outcome measures.

CONCLUSIONS

When assessing one's the level of hand or leg function, it is particularly important to acknowledge their multidimensional nature—and explicitly consider each outcome measure as it relates to these three latent domains of function. Our novel approach enables a clearer view into the underlying physiological mechanisms that enable, impair, or restore ability in everyday life.

PREGNANCY INDUCED ADAPTATIONS IN INTRAMUSCULAR EXTRACELLULAR MATRIX OF RAT PELVIC FLOOR MUSCLES

Marianna Alperin[1] and Richard L. Lieber[2,3]

INTRODUCTION

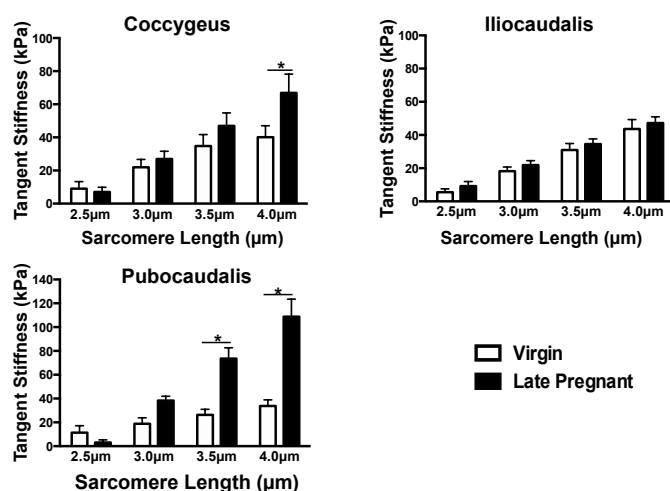
Birth trauma to pelvic floor muscles (PFMs) is a major risk factor for pelvic floor disorders. Modeling and imaging studies suggest that demands placed on PFMs during childbirth exceed their physiologic limits; however many parous women do not sustain PFM injury [1]. Skeletal muscle extracellular matrix (ECM) supports muscle fibers and determines muscle stiffness. Adaptation during pregnancy of most pelvic tissues results in substantial stiffness decrease in preparation for delivery. However, the effects of pregnancy on structural and mechanical properties of intramuscular ECM in PFMs have not been investigated. This may have significant implications for understanding the pathogenesis of PFMs birth injury caused by mechanical strain. In this study, we sought to determine if pregnancy induces adaptations in the PFM ECM in a rat model.

METHODS

Coccygeous (C), Iliocaudalis (IC), and Pubocaudalis (PC) were harvested from 20 3-months old Sprague-Dawley virgin and late-pregnant rats. Stiffness was determined at a bundle level, which reflects mechanical behavior predominantly due to ECM. To establish if parallel changes occur in muscles outside of the PFM, we also examined a hind limb muscle, tibialis anterior (TA). Custom apparatus was used to test 3 bundles from each muscle [2]. Baseline parameters, including cross-sectional area, were measured. A stress-relaxation protocol consisted of increasing sarcomere length (L_s) by 0.25 µm/stretch and relaxing for 3 min, after which force and L_s were recorded. Bundles were stretched until failure or to L_s of 4.0 µm. Force was converted to stress and tangent stiffness was calculated as the slope of the stress-L_s curve between 2.5 and 4.0 µm. Tissue was processed for quantification of total collagen content using spectrophotometric hydroxyproline assay and elastin content using enzyme-linked immunosorbent assay. Collagen crosslinks (Hydroxylysyl Pyridinoline (HP), Lysyl Pyridinoline (LP), Pentosidine (PE)) were determined by HPLC system, as previously described [3]. Data were compared between groups using two-way ANOVA with Tukey's *post-hoc* testing. Linear regressions were performed to determine correlations between measured parameters. Significance was set at $p < 0.05$, all values are reported as mean ± SEM.

RESULTS

Pregnant rats demonstrated significantly greater stiffness in C and PC when compared to virgin controls, with 66.86±11.33 kPa *vs.* 40.09±6.95 kPa ($P<0.05$) in C and 108.74±14.77 kPa *vs.* 33.78±5.13 kPa ($P<0.0001$) in PC at L_s of 4µm (*see Figure*). IC stiffness was unchanged ($P>0.05$). Total collagen content was significantly increased in the ECM of all PFMs in pregnant rats relative to virgin controls. Elastin content, on the other hand, remained unchanged (*see Table*). Analyses of enzymatic collagen crosslinks revealed a differential response of individual PFMs, with significant decrease in HP in PC and LP in C in pregnant rats. On the contrary, PE levels were significantly elevated in all three PFMs in pregnancy (*see Table*). When muscle stiffness was plotted against biochemical parameters examined, there were no consistent significant correlations. Importantly, biomechanical and biochemical changes observed in the PFMs, were not present in the TA.

Figure: Tangent stiffness of pelvic floor muscles in virgin and late-pregnant groups, measured as mean ± standard error of the mean.


CONCLUSIONS

In contrast to other pelvic tissues, the total collagen content of intramuscular ECM and PFM stiffness does not decrease in pregnancy. Instead, pregnancy induces a significant rise in the ECM collagen and stiffness in PFMs. The above adaptation has the potential to shield PFM fibers from excessive mechanical strain during parturition. Pregnancy results in decrease in enzymatic collagen crosslinks in C and PC, while significantly escalating non-enzymatic crosslinks in all PFMs. It remains unclear which biochemical components of PFMs ECM dictate tissue stiffness.

INTRODUCTION

In the US, approximately 200,000 women have surgery to repair prolapse annually with a cost to society that exceeds 1 billion dollars per year. Anterior vaginal wall prolapse, clinically known as cystocele, is the most common form of pelvic organ prolapse and has the highest rate of recurrence.

Dynamic magnetic resonance imaging (MRI) studies have revealed that anterior compartment prolapse is highly correlated with loss of apical support provided by cardinal and uterosacral ligament (1). There are also connective tissues attaching the mid-portion of the vagina laterally to the pelvic floor sidewalls providing "paravaginal support" (2). In addition to the connective tissue attachments, studies have also revealed levator ani muscle damage in women with prolapse. Women with prolapse are 4 times more likely to have the visible damage to the levator ani muscle than women with normal support (3). Sometimes there is a loss of muscle substance but the overall shape of the muscle remains intact. In other instances, gross distortion of the muscle origin occurs (4) presumably due to avulsion of muscle from the pubic bone.

Each of these observations concerns a particular aspect of anterior vaginal wall support and failure. To integrate these observations into a single disease model, we developed a series of biomechanical models from 2D lumped parameter model to 3D finite element models seeking to understand the interactions between different support elements.

METHODS

We first developed a simple 2D lumped parameter model of anterior vaginal wall support (5) (Figure 1). This model simulated anterior vaginal wall deformation in the mid-sagittal plane and provided an important insight on the interaction between muscular support to the anterior vaginal wall provided by the levator ani and apical connective tissue support provided by the cardinal and uterosacral ligaments. Then we developed a 3D finite element model with paravaginal support and deformable posterior compartment to study the interaction between connective tissue impairment and levator ani muscle impairment based on intact nulliparous anatomy (6). Most recently, a series of three finite element models (unilateral model, bilateral model and normal model) have been developed to investigate the effect of the structure distortion caused by the avulsion of pubococcyesus muscle on pelvic floor support. Then the sensitivity analysis were performed using a using a 2^3x3 factorial design in Abaqus 6.8 [TM] to assess all possible combinations of site impairments as shown in Figure 2. Anterior vaginal wall descent was been evaluated at point Aa and apex relative to a hymenal reference plane. The relative theoretical contributions of those four types of impairment to the descent of anterior vaginal wall have been quantified as their effect on Aa and apex decent, which were determined by calculating the their main effect, an aggregate measure that estimates the overall impact on the dependent variable by comparing all of the models.

RESULTS

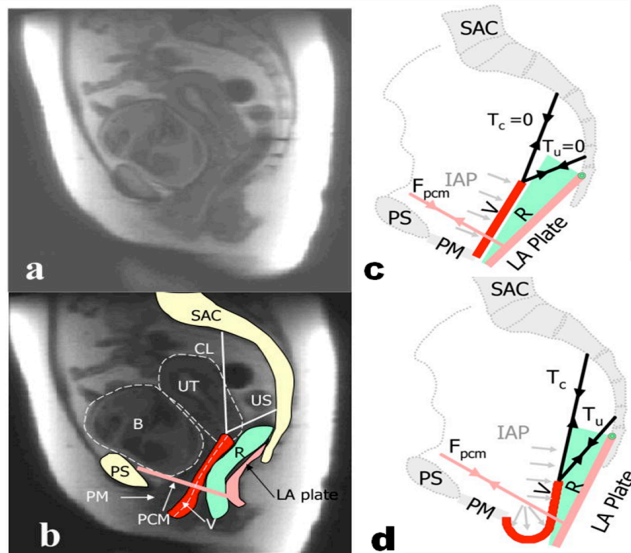
In all generations of biomechanical models, we were able to generate the cystocele similar to what observed clinically. Cystocele size was sensitive to abdominal pressure and impairment of connective tissue and muscle. Figure 3 shows the example simulation results from the most recent models and the sensitivity analysis of how the cystocele size is sensitive to four different types of the impairments.


Figure 1. 2D lumped parameter model of anterior vaginal wall support. **A**: mid-sagittal MR image. **B**: modeled elements . *C:* loading lumped parameter model a with normal muscular support; **D:** loaded biomechanical model with defective muscular support. Pubovisceral muscle: PCM ; PS: pubic symphysis; SAC: sacrum; PM: perineal membrane; LA plate: levator plate; R: rectum; V: vagina; CL: cardinal ligament spring; US: uterosacral ligament spring; B: bladder; UT: uterus. IAP: intra-abdominal pressure.
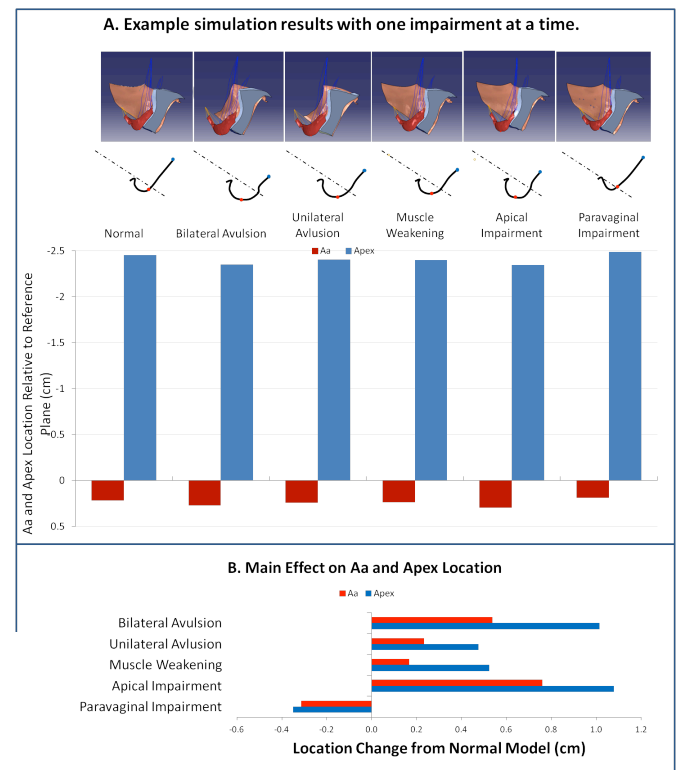
Figure 2. Left panel shows the unilateral defect finite element model resting geometry in oblique view where the right pubococcygeal muscle is missing including: AVW: anterior vaginal wall; PCM: pubococcygeus muscle; PRM: puborectalis muscle; ICM: iliococcygeus muscle; PV: Paravaginal support; PM: perineal membrane. Four different impairments were selected as independent variables and the levels of impairment used in sensitivity analysis showed in the table. Aa and apex locations (the red dots) and their distance from reference plane used as dependent variables.


Figure 3. Panel A. Example simulation results with one impairment at a time. Panel B. Result of sensitivity analysis shows the main effect of four impairments on Aa, and Apex of anterior vaginal wall location deviated from normal model.

CONCLUSIONS
Apical support and the bilateral levator ani muscle avulsion are most influential parameters in the anterior vaginal wall descent.

RESOLVING THE SURFACE DETECTION CHALLENGE IN NANOINDENTATION OF SOFT MATERIALS FOR APPLICATIONS IN REPRODUCTIVE TISSUE MECHANICS

Amy J. Wagoner Johnson and Jie Wei

Department of Mechanical Science and Engineering,
University of Illinois at Urbana-Champaign, Urbana, IL USA
email: ajwj@illinois.edu

INTRODUCTION

Instrumented nanoindentation (NI) is increasingly used to characterize the mechanical properties of soft materials, including tissues. IN is attractive because testing is done on small samples, for example a tissue biopsy. Further, the testing process itself is non-destructive, leaving tested samples available for other analyses such as by histology. NI also has the potential to measure local properties of heterogeneous soft tissues. This capability is valuable both from a basic science and a clinical perspective. Accurate characterization of local properties, as compared to bulk measurements, allows for the development of more accurate computational models, which can help to understand and diagnose a range of clinical pathologies as well as to monitor treatment. We are particularly interested in characterizing the local properties of pregnant and non-pregnant cervix tissue, especially in the context of assessing risk for preterm birth and for developing better computational models of the pregnant cervix and surrounding tissue structures.

While NI has potential for measuring soft tissue properties, there are major challenges that must be addressed before it can be widely used. The most significant challenge is surface detection. Without accurate surface detection, the indentation test often begins with the probe already at some unknown depth, h_i, below the sample surface (Fig. 1). If this is not taken into account, the value used for the contact depth, h_c, is incorrect and therefore the calculation of the sample Young's modulus, E_s, can be grossly inaccurate (Eqn. 1 and 2).

Here, we present and validate a new approach to overcome the surface detection limitation for soft materials during NI. Use of this approach will make it possible to use NI to characterize the local mechanical properties for cervix and other reproductive tissues, as well as for a range of other soft materials.
Figure 1: Schematic of the indentation at the initial unknown depth, h_i, and the final depth, h_{max}. The apparent h_{max} is measured, and h_i is calculated using the MIM approach. A schematic of the load-indentation response is shown (right).

METHODS

Polyacrylamide gels with nominal Young's modulus of 19kPa and 49kPa were prepared for uniaxial compression tests and for NI. The moduli obtained from the bulk compression tests were used as the standard for comparison to those obtained by NI. Compression tests were carried out on a Bose Biodynamic Test system and the modulus was

$$S = \beta \frac{2}{\sqrt{\pi}} \frac{E_s}{(1-v_s^2)} \sqrt{\pi(2Rh_c + h_c^2)} \tag{1}$$

$$h_c = h_{max(actual)} - \varepsilon \frac{P_{max}}{S} \tag{2}$$

$$h_{max(actual)} = h_i + h_{max(apparent)} \tag{3}$$

$$h_i = \frac{S_m^2(h_{max(apparent)-n} - \varepsilon \frac{P_{max-n}}{S_n}) - S_n^2(h_{max(apparent)-m} - \varepsilon \frac{P_{max-m}}{S_m})}{S_n^2 - S_m^2} \tag{4}$$

calculated from the linear portion of the stress-strain curve (N=3). Samples for NI were cast with a flat surface using a custom mold, and affixed to a glass dish petridish. Two samples of each stiffness were tested via NI, and indents were performed on five different spots for each sample. The method described below requires at least two indents to different maximum depths for each spot. The modulus determined using both test methods was compared using an unpaired t-test with significance of p<0.05. These were also compared to the modulus determined using the standard Oliver-Pharr approach (Eqn. 1 and 2)[1].

Our approach uses a multi-indent method (MIM), to determine h_i, which allows us then to accurately calculate the modulus. The important parameters used in MIM are shown in Fig. 1.

According to the Oliver-Pharr model[1] Es, is determined from the stiffness, S, obtained from the linear portion of the load-indentation curve on unloading (Fig. 1), the radius of the probe, R, the sample poissons ratio, v_s, a geometric constant, β, and the depth of contact, h_c. Depth of contact depends on the maximum load, P_{max}, and corresponding maximum indentation depth, h_{max} (Eqn. 2). ε is a constant that depends on the tip geometry and is 0.75 for a spherical tip[2], used here. The actual maximum indentation depth (Eqn. 3), $h_{max(actual)}$, is the sum of the initial unknown indentation depth, h_i, and the apparent maximum depth, $h_{max(apparent)}$, obtained from the load-indentation data (Fig.1). Using the MIM approach two indents of different depths, indent m and n, are made on the same spot. S_m and S_n are the stiffnesses determined for each indent, m and n. By squaring each and taking the ratio, we can solve for h_i, the result of which is shown in Eqn. 4, which relates to h_c through Eqn. 2 and 3. From this we can then determine the sample modulus (Eqn. 1).

RESULTS AND DISCUSSION

Results show that the modulus measured by uniaxial compression tests and the modulus obtained using the MIM approach are in excellent agreement. In contrast, if the initial indentation depth, h_i, is not taken into account and the standard Oliver-Pharr method is used, the modulus is as much as twice the value obtained by MIM and compression tests. The modulus obtained in this way is significantly different (p<0.0001) from those obtained by compression tests and using MIM (Fig.2).
Figure 2: Results show excellent agreement between the Young's modulus determined by compression tests and the MIM approach, while results from the standard Oliver-Pharr model give inaccurate results.

CONCLUSIONS

We developed a multi-indent method (MIM) based on the Oliver-Pharr model that solves the major limitation of NI: the challenge in detecting the sample surface for soft materials. The excellent agreement between the Young's modulus obtained from compression tests and that obtained by MIM validates the approach and demonstrates the error associated with the standard Oliver-Pharr approach for soft materials. Thus, MIM provides a much more accurate way of assessing the modulus of soft materials. We are currently adapting MIM to test pregnant and non-pregnant rat cervix for applications in preterm birth.

INTRODUCTION

Animal models can be best utilized to study for POP, immunological responses of mesh implants, biomechanical characteristics of these meshes over time, and the time-dependent tissue-mesh interaction [1]. A variety of animal models, including non-human primates, rodents, murine, rabbit, etc., has been used in the past decade for studying POP and surgical implantation of meshes/grafts. Recently, scientists have projected sheep as an ideal large animal model for biomedical research due to their similar fetal size, comparative anatomy, being best suited for surgical procedures, ease of handling, and economical advantage. Therefore, in order to establish sheep a rigorous animal model, it is important to understand and evaluate the biomechanical characteristics (*in vitro* and *in vivo*) of sheep pelvic floor tissues.

METHODS

Samples for *in vitro* biomechanical testing (biaxial mechanical testing and ball burst testing) were obtained from a local abattoir. Nulliparous Rambouillet-Suffolk breed female lambs of 9-11 months old (weighing 110-135 lbs) were chosen. For this study, we compared the biomechanical characteristics of sheep pelvic floor tissues namely vagina, bladder, broad ligament, and rectum (n = 8 per group). Biaxial mechanical testing was carried out as per previously established protocols [2]. For biaxial testing, the excised sheep tissue (vagina, bladder, rectum, or broad ligament) was dissected into ~20 mm x 20 mm square samples, with one edge of the sample aligned along the longitudinal direction and the other edge aligned along the circumferential (or transverse) direction. Four black markers were placed on the tissue specimens for tracking local deformation (using CCD camera). Tissue specimens were securely connected to each actuator arms of the biaxial device using custom designed hooks, which were attached to 000 size polyester sutures (4 hooks per edge). Specimens were then preloaded up to 1 gram, preconditioned ten times, and subjected to an equibiaxial stress of 15 kPa. Maximum stretches of the specimen, in both directions, were analyzed to reveal the tissue extensibility. Ball burst testing (Fig. 3) was carried out by a scaled American Society of Testing and Materials (ASTM) standard ball-burst apparatus. The testing apparatus used a stainless steel ball of 12.7 mm diameter, and the sample surface area was set at ~1013.41 mm^2 (ASTM Test Method D3787). Specimens for ball burst testing (~28 x 28 mm) were mounted between two metal plates with a 19.05 mm diameter hole and ruptured at a rate of 10 mm per minute. Data from ball burst tests were processed to obtain max load (g) and max displacement (mm) for the respective tissues.

In vivo biomechanical testing was carried out on live nulliparous lambs (n=3; Katahdin-Dorpers breed; about 9 months old and 120 lbs.) using a novel balloon based insertable probe (Patent US 20140275841 A1) [3]. All animal experiments were performed by a Diplomate of American College of Veterinary Surgeons (ACVS), as per IACUC protocol number 12-088. Once inserted into the vaginal tract, the probe was inflated to 100 cm H_2O (~1.5 psi), and the corresponding vaginal wall displacement in both axes (anterior to posterior, and left to right) was measured in millimeters.

RESULTS AND DISCUSSION

Biaxial testing of these sheep pelvic tissues was performed to reveal the anisotropic behavior of these materials. Anisotropic behavior at 15 kPa was

found to be highest in vagina, followed by rectum, broad ligament, and finally bladder (Fig.1 A-D). For all four pelvic tissues, the longitudinal direction was found to be more extensible than the circumferential (or transverse) direction. For vaginal tissues, the average stretch was 1.18 ± 0.08 mm/mm (longitudinal) vs. 1.02 ± 0.01 mm/mm (circumferential); whereas, for bladder tissues the longitudinal direction was found to be slightly more extensible than the circumferential direction (1.35 ± 0.09 mm/mm vs. 1.31 ± 0.13 mm/mm). Similarly, for ball burst tests, max load was highest for vaginal tissue, whereas max displacement was highest for rectum tissue (Fig.1 E-F).

With biaxial testing under physiological range, we observed a marked difference in the mechanical behavior of the sheep vaginal wall tissues in their respective loading directions (Fig.1 A). This observation, however, is in contrast to a previously published study, which reports sheep vaginal tissue as isotropic material and less extensible beyond physiological range [4]. The *in vivo* data further indicates that, under physiological loading conditions, sheep vaginal tract can accommodate stretching in either direction by virtue of its microstructural organization. Similarly, *in vivo* human biomechanical measurements of female patients with vaginal wall prolapse have shown a greater degree of structural compliance and a reduced elastic behavior [1]. Under the influence of hormone and other biochemical factors, we expect to observe an altered compliance (or dilation) from the *in vivo* biomechanical measurements in the vaginal tract of prolapsed sheep, and perhaps an altered elastic behavior as well.

CONCLUSIONS

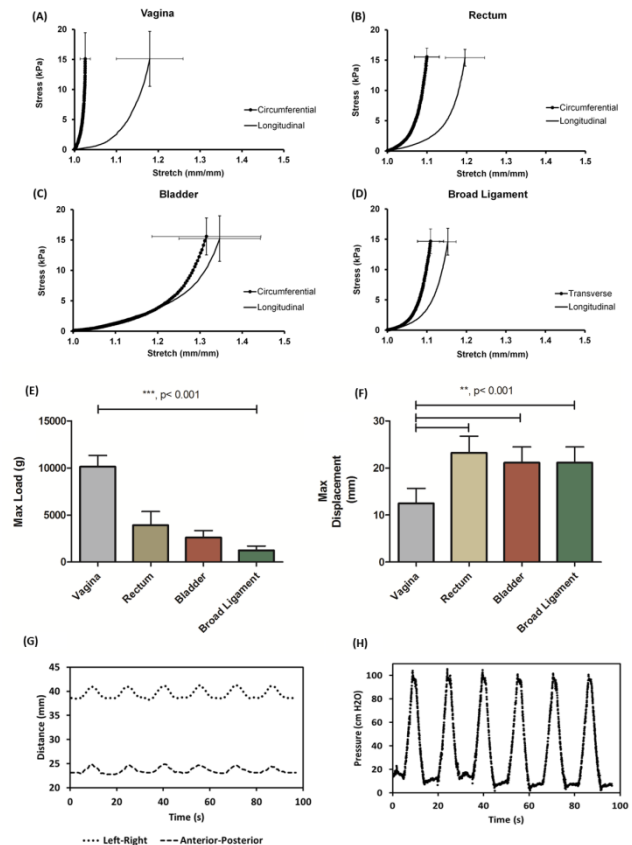
We have developed a baseline protocol for in vitro and in vivo biomechanical characterizations of sheep pelvic tissues/vaginal tract. Sheep have similar supporting structures for the pelvic organs and their structural and mechanical properties share similarities with humans [1]. Furthermore, sheep are advantageous for surgical research owing to their size, anatomy, and relatively quick prolapse timeline. These commonalities make sheep the ideal vehicle for advancing our knowledge of pelvic prolapse.


Figure 1: *In vitro* and *in vivo* biomechanical testing results of sheep pelvic floor tissues. Biaxial mechanical testing results of vagina (A), rectum (B), bladder (C), and broad ligament (D) shows the anisotropic characteristics of each tissue. Ball burst test results of these pelvic floor tissues are shown as Max load (E) and Max displacement (F) parameters. Displacement (G) and Pressure profiles (H) of *in vivo* biomechanical testing of sheep pelvic floor, obtained by the insertable probe is shown here.

INTRODUCTION

This study addresses the open question on which factors influence clinical complications related to insertion of prosthetic meshes for hernia and pelvic organ prolapse (POP) repair. The material itself (usually a polymer such as polypropylene) has been proven to be "biocompatible", e.g. [1]. However, *mechanical biocompatibility*, related to the ability of implants to display a mechanical behavior compatible with its function and favoring its integration in the surrounding native tissue [2], is an important factor which is not determined only by the chemical composition of the implant material. It recently became clear that the deformation behavior of meshes in a physiological range, also called "comfort zone" [3], is of major importance and it is suggested that implants designed to mimic biomechanical properties of the area of application are advantageous.
Figure 1: Finite element model simulation of stresses during valsalva after the sacrocolpopexy procedure.

However, the definition of a reasonable physiological range of loads in-vivo, thus serving as a basis to evaluate experimental results and providing a design target for future meshes, still remains an open challenge, since corresponding in-vivo measurements are currently not feasible. Additionally, the surgical technique and implant handling strongly influence the mechanical behavior of the implant in-vivo.

We use extensive experimental testing and data analysis to evaluate the mechanical biocompatibility of mesh implants [4]. Finite element modeling is employed in order to qualitatively analyze the influence of mesh properties and surgical technique based on an exemplary case of the Valsalva maneuver after a sacrocolpopexy procedure (Fig. 1).

METHODS

Experimental protocol: Nine different mesh types were investigated. Each mesh type was tested in eight different configurations:
 2 (uniaxial tension OR biaxial tension) x 2 (dry OR embedded) x 2 (0° OR 90° direction)
Experiments with uniaxial tension and biaxial tension (realized as uniaxial strain test) were performed on the same tensile test machine. Test piece dimensions were selected to generate a free area of 30mm x 15mm (uniaxial) and 50mm x 15mm (biaxial). Each specimen was loaded to a maximum of 30% nominal strain (loading rate of $\sim 10^{-3} s^{-1}$) and unloaded back to a pre-force threshold of 0.01 N for 10 cycles. Local strains were extracted optically in the center of the specimen with the aid of an image analysis algorithm.
Finite Element Modeling: The FE model was originally developed in the group of M. Brieu [5] and has been modified for the present application. It

is based on MR images and consists of the homogenized pelvic floor muscle structure, the vaginal stump after hysterectomy and a Y-shaped mesh system attached to anterior and posterior vaginal wall as well as the sacrum. Material laws of muscle and vaginal canal are taken from the literature [5,6]. Two meshes were simulated, one stiffer (Dynamesh® PRS) and one softer (Dynamesh® Endolap) with material laws (2nd order reduced polynomial hyperelastic) fitted to our experimental data. Valsalva pressure is applied to the pelvic muscle sheet. In order to investigate the influence of surgical technique, a pre-stretch of 10% is applied to the upper mesh arm, simulating the surgeon pulling the mesh before fixing it to the sacrum.

RESULTS AND DISCUSSION

The mechanical properties of mesh implants show large variation, depending on their knitting pattern, weight, area density and state of loading. In fact, one cannot simply infer properties of the knitted mesh from the source material or pore size and weight. Rather, implants need to be analyzed as a structure. The specific stress and/or strain, at which experimental data is interpreted in terms of mechanical biocompatibility plays another major role. This poses the question of meaningful corresponding physiological reference values (Fig. 2).

Our simulations of the specific exemplary case of Valsalva after the sacrocolpopexy procedure show however, that surgical technique strongly influence the in-vivo structural behavior. By simply pulling the upper mesh arm before attaching it to the sacrum, the mechanical response of the mesh can be altered. An initially soft mesh can become much stiffer and the stresses and strains experienced by the mesh and underlying vaginal tissue strongly increased. Furthermore, the techniques used to attach the mesh to the vaginal wall determines the local interaction of mesh and tissue.

These results indicate the relevance of quantitative biomechanical studies in order to define guidelines for mesh manufacturing and surgical techniques, improving the performance of implants.

THE EFFECT OF FETAL MEMBRANE PRESTRETCH ON CERVICAL LOADING DURING PREGNANCY

INTRODUCTION

Preterm birth (PTB), defined as birth before 37 weeks of gestation, is a major healthcare problem around the world [1]. The dominant structural and material factors that lead to premature rupture of membranes and/or early cervical shortening, major risk factors for PTB [2], are unknown. This study analyzes what role the fetal membrane (FM) may play in the progression of cervical dilation by simulating intrauterine pressure (IUP), membrane-uterus-cervix interactions, and varying levels of membrane *in vivo* prestretch in a finite element (FE) analysis. We constructed an FE model based on an idealized anatomical geometry at term and utilized experimentally-supported material models [3-5] to calculate the loads and stretches in the fetal membrane, uterus, and cervix. We demonstrate that the fetal membrane's *in vivo* stretch level affects its contribution to load sharing, which in turn dictates the loading experienced by the cervix and lower uterine segment.

It is hypothesized that the mechanical failure of tissues supporting the fetus plays a role in PTB. The soft tissues surrounding the fetus are equipped to grow, remodel, stretch and remain intact during the course of gestation. Then at term, in a reversal of their previous role, these tissues allow for delivery of the baby. The uterus contracts, the FM ruptures, and the cervix shortens and dilates. If the remodeling events of these tissues are mistimed, the load-bearing capability could be compromised, leading to PTB.

The contribution of each organ to load sharing is dependent on the material characteristics of the particular tissue and the amount of prestretch in an organ after its growth and remodeling process. Evidence suggests that the FM grows until the 2nd trimester [6], then stretches over the rest of pregnancy to accommodate the enlarging amniotic cavity. Additionally, the area stretch of the FM at term has been measured to be 1.7 by comparing ultrasonic intrauterine area and post-delivery membrane area [7], and IUP has been reported to be 2.66kPa at baseline uterine tone at term (between contractions) [8]. Lastly, we know that the material response of the FM is nonlinear [3]. Given these lines of evidence, we provide a preliminary FE framework to explore the consequences of FM prestretch. We demonstrate that the load-sharing between the LUS, cervix, and FM at term is largely influenced by the amount of FM prestretch.

METHODS

We created an idealized 3D model (Fig. 1) of the uterus, cervix, and fetal membrane using Trelis Pro 15 (csimsoft, LLC, 2015). The uterus was represented by 1/8 of a spherical shell section with an inner diameter of 10cm and a wall thickness of 1cm. We defined the cervix to be a cylindrical tube with an outer diameter of 3cm, an inner diameter of 1cm, and a length of 3.5cm. Since the amnion is the primary load-bearing component of the fetal membrane, we modeled it as a spherical shell section with a thickness of 0.1mm. Its outer diameter in the reference configuration was parameterized in this study in order to investigate two different levels of *in vivo* stretch. The final mesh contained 6688 hexahedral elements with a mean volume of 7.6mm^3. We used a fiber composite material with neo-Hookean ground substance for the uterus and cervix. The cervical model was fitted to mechanical tension and

compression tests of full-term pregnant cervical tissue specimens [4,5]. The uterine material properties were chosen as in [4]. An Ogden material model based on equibiaxial tensile loading of human amnion was employed for the fetal membrane layer. A frictionless sliding interface was defined between the exterior surface of the membrane and the interior of the uterus and cervix. The model was assembled and solved using FEBio 2.2.6 (http://febio.org/).
Figure 1: Quarter model of the idealized LUS (red), cervix (magenta) and two different membrane reference states (blue and green).

We analyzed two states of prestretch: no prestretch and the prestretch corresponding to a baseline *in vivo* IUP. To achieve the latter, we scaled the membrane in its reference state such that it would come into contact with the un-deformed uterus and cervix when subjected to the *in vivo* IUP of 2.66kPa reported by Buhimschi [8]. For comparison purposes we consider also the IUP of 8.60kPa, which represents the peak value during contractions in the second stage of labor.

RESULTS AND DISCUSSION

An increased membrane prestretch resulted in a stiffer membrane response and reduced mechanical loading of the cervix. Increasing the membrane prestretch from 1 (no prestretch) to 1.08 (corresponding to an area stretch of 1.17) decreased the stretch at the cervical internal os from 1.25 to 1.1 at an IUP of 8.60kPa (Fig. 2).

This preliminary investigation suggests that FM prestretch is an important contributing factor to the mechanical loading that occurs in pregnancy. Future work will seek to reconcile these simulations with literature studies on FM area change and *in vivo*

stretch state. We will also refine the amnion material model to include fiber dispersion and the ability to parameterize fiber orientation, and work toward improved uterine muscle modeling.
Figure 2: Cervical stretch levels for IUP at baseline and contraction level under two assumptions for membrane prestretch state. Membranes hidden for stretch state visibility.

CONCLUSIONS

Our model demonstrates that the fetal membrane's *in vivo* stretch level affects its contribution to load sharing, which in turn dictates the loading experienced by the cervix and lower uterine segment. The membrane and its *in vivo* loading state should not be ignored in future studies of pregnancy biomechanics.

INTRODUCTION:

Mechanical output of the lower-limbs during gait is modulated in response to changing environmental demands. For example, at steady speed on level ground, the majority of positive work is performed by the ankle and hip over a range of walking and running speeds (1). On an incline during walking (2) and running (3), joint power contributions are re-distributed, with the hip becoming the predominant source of net work to raise the center of mass against gravity. Our aim was to characterize the distribution of positive and negative mechanical power output across the lower-limb joints in walking and running up and downhill in order to guide design of assistive devices (i.e., exoskeletons and prostheses). We hypothesized that the hip would dominate mechanical energy generation needed to go uphill and the knee would dominate mechanical energy absorption needed to go downhill at steady speed.

METHODS:

3D lower-limb kinematics and kinetics were collected on eight subjects across 5 walking (1.25 m/s; -15%, -10%, 0%, 10%, 15% grade) and running (2.25 m/s; -10%, -5%, 0%, 5%, 10% grade) during 7 minute trials. Using inverse dynamics analysis we computed joint moments and powers for the ankle, knee, and hip in each condition and computed average positive and negative power pie charts including both limbs following (1).

RESULTS AND DISCUSSION:

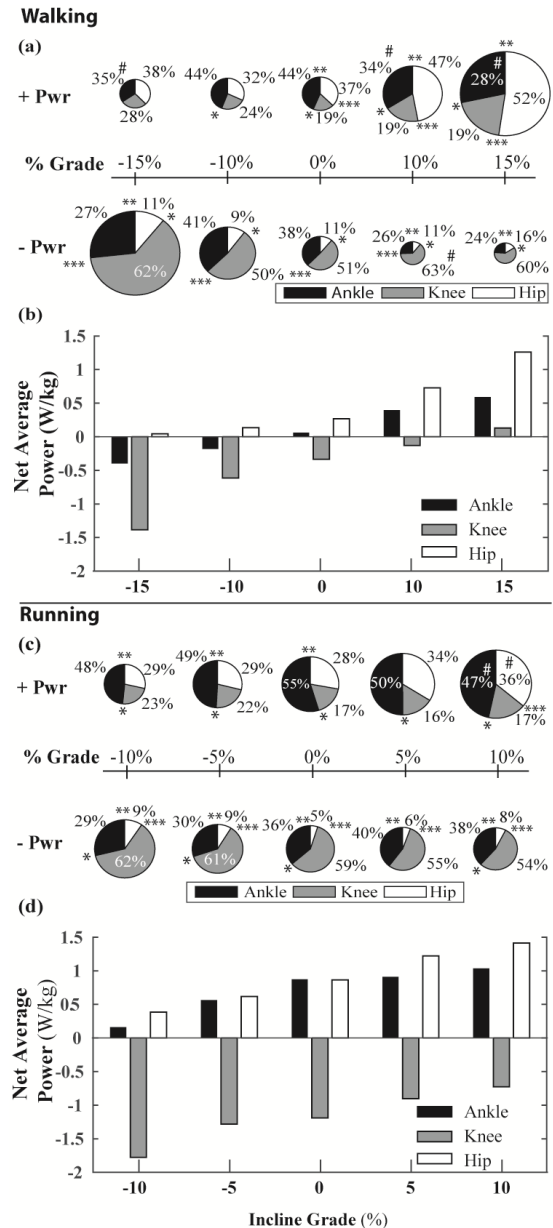
The distribution of joint power and work output among the ankle, knee, and hip depended on both surface gradient and gait. During walking, positive work shifted from the ankle to hip with increasing grade while the knee was the dominant source of negative work across all grades (Fig. 1a). Net work followed similar trends. On inclines, the majority of net work was performed at the hip, while on


Figure 1: (a) Percent distribution of average positive and negative lower-limb joint power for **(a)** walking (1.25 m/s) and **(c)** running (2.25 m/s) over a range of grades. The area of each pie is normalized to the average positive power at level grade for walking (1.02 W/kg) and running (3.66 W/kg). A significant change (p<0.05) in the individual joint's percent work distribution compared to level walking or running is marked by a hash sign (#). A significant difference (p<0.05) in pairwise comparisons between percent joint work at a given grade is marked by a *(Hip to Knee), ** (Knee to Ankle), and *** (Ankle to Hip). Net average power of each joint across grade conditions for **(b)** walking and **(d)** running.

declines the largest source of net work was the knee (Fig. 1b).

During running, the ankle was the dominant source of <u>positive</u> work and the knee was the dominant source of <u>negative</u> work across all grades (Fig. 1c). The hip did very little negative work during running, and was therefore the dominant source of <u>net</u> work during incline running (Fig. 1d).

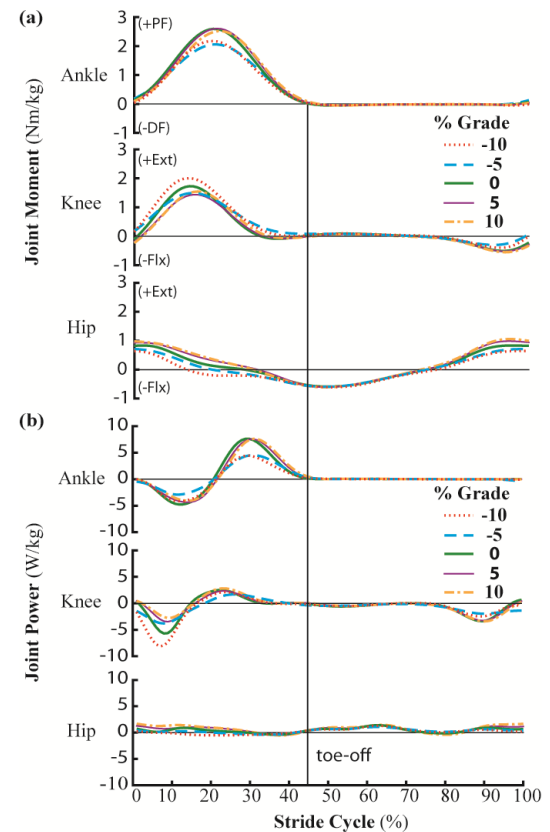
Time series plots show the redistribution of joint moment and power over the stride cycle for walking (Fig. 2) and running (Fig. 3). Again, the general trend was a shift in positive power to the hip with increasing incline, while the knee was the primary site of negative work (i.e. absorption). Changes in ankle positive power were predominately seen at push-off (~60% stride), with changes in the knee negative power and hip positive power coming in initial stance.
Figure 2: Normalized time series plots of the joint moments (a) and powers (b) during walking across grades. Data shown are a group mean over one complete stride defined with 0% and 100% = heel-strike of same limb.


Figure 3: Normalized time series plots of the joint moments (a) and powers (b) during running across grades. Data shown are a group mean over one complete stride defined with 0% and 100% = heel-strike of same limb.

These results support our hypothesis and the previous work of others (1,2,3) that for uphill locomotion, the hip is an important source of net mechanical energy generation. In addition, we have demonstrated that the knee is the predominant source of absorption during both walking and running downhill-highlighting a strong opportunity for energy harvesting during downhill gait. Interestingly, during uphill running, the ankle joint remains an important contributor to overall positive work, making it an ideal site for assistance with simple exoskeletal devices. Future work will be directed at assessing the mechanical and metabolic effects of assistive devices in similar conditions of increased mechanical demand.

INTRODUCTION

Uphill and downhill walking are fundamentally different biomechanical tasks than level-ground walking, as evidenced by altered electromyography (EMG) signals [1] and kinematics and kinetics [2]. However, it is unknown how muscles work in synergy to achieve altered biomechanics on slopes. Musculoskeletal modeling and simulation can be used to estimate the forces and function of individual muscles during movement, and have provided important insight into muscle functional roles during level-ground walking [3, 4]. However, these tools have not been applied to sloped walking. Thus, we sought to use musculoskeletal modeling and simulation to characterize muscle function during walking on uphill and downhill slopes.

METHODS

Thirteen healthy adult subjects (9 male, 4 female) walked on an instrumented treadmill at 1.25m/s and 0° ±3°, ±6°, and ±9°. Ground reaction forces (GRFs) (1500 Hz, Bertec Corp.), whole-body kinematics (100 Hz, Vicon Inc.), and EMG signals (1500 Hz, Noraxon) from eight muscles on each leg were collected. Joint angles were computed using an inverse kinematics algorithm and low-pass filtered at 6 Hz in Visual3D (C-Motion, Inc.). GRFs were also low-pass filtered at 6 Hz to maintain consistency between signals [5].

Subject-specific musculoskeletal models were created in OpenSim 3.1 [6] by scaling the segment lengths and total mass of a generic model with 23 degrees of freedom and 92 Hill-type musculotendon actuators. Passive torques were added to each joint to represent forces from ligaments and soft tissues [7]. A residual reduction algorithm was used to improve dynamic consistency in the simulations between the measured kinematics and GRFs. A computed muscle control algorithm was used to solve the muscle redundancy problem and determine muscle excitations that produced the experimental walking kinematics while minimizing the sum of squared muscle excitations at each time step. Muscle excitations were constrained based on EMG signals from the lower limbs. For each subject, three gait cycles per slope were simulated, resulting in a total of 273 simulations.

After the simulations were generated, left leg muscle contributions to the acceleration of the body center of mass (COM) were determined with an induced acceleration analysis using a rolling without slipping kinematic constraint between the foot and the ground [8]. The induced accelerations in the treadmill reference frame were analyzed by calculating the mean parallel (braking/propulsion), normal (perpendicular to the treadmill), and mediolateral accelerations induced by each muscle group during early (0-30% gait cycle) and late (30-60% gait cycle) stance. A linear mixed effects ANOVA was performed ($\alpha=0.05$) with slope as a fixed effect and subject as a random effect. When a significant slope main effect was found, post-hoc pairwise comparisons ($\alpha=0.05$) were performed using Dunnett's test to compare sloped to level-ground walking.

RESULTS AND DISCUSSION

Nearly all ANOVAs indicated a significant slope main effect, demonstrating that muscle function is greatly affected by both uphill and downhill slopes. The major contributors to acceleration in the parallel and normal directions were the rectus femoris (RF), vasti (VAS), hamstrings (HAMS), gluteus maximus (GMAX), and biarticular plantarflexors (BPF) (Fig. 1). The hip abductors were the primary contributors to mediolateral accelerations, but the accelerations in this direction were small and had fewer significant results.

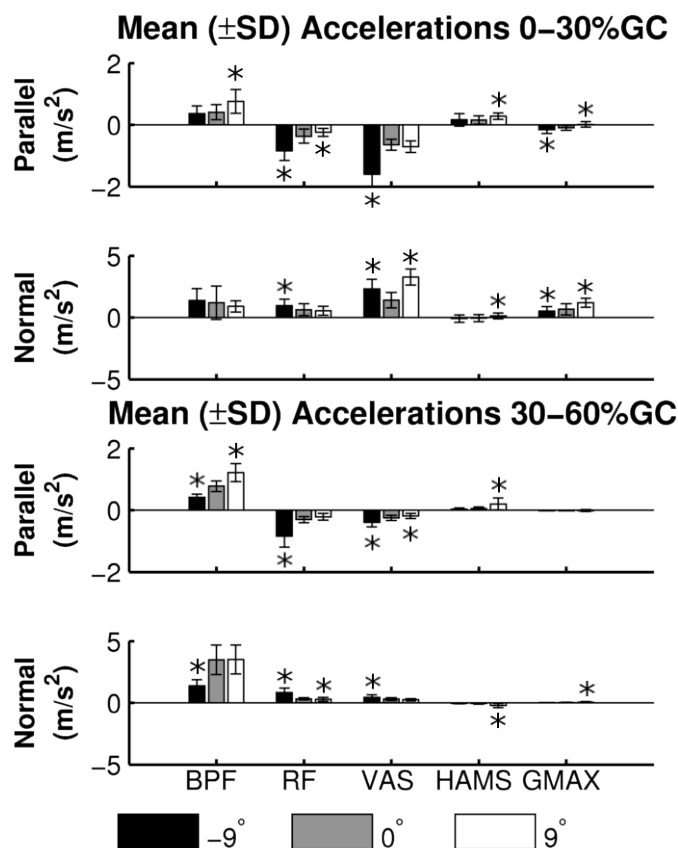
In the parallel direction, RF and VAS were major contributors to braking on downhill slopes. RF provided braking throughout stance, while VAS contributed during early stance. The greater braking from RF and VAS compared to level-ground walking was consistent with greater knee extensor moments previously observed on downhill slopes [2]. On uphill slopes, HAMS and GMAX had an increased contribution to propulsion during early stance compared to level-ground walking. BPF, which primarily delivers energy to the leg to initiate swing in level-ground walking [3], provided increased body propulsion during late stance on uphill slopes. The greater propulsion from HAMS, GMAX, and BPF on uphill slopes was also consistent with greater hip extensor and ankle plantarflexor moments [2].


Figure 1: Mean (±SD) contributions of left leg muscles to body center of mass acceleration during 0-30% (top two plots, early stance) and 30-60% (bottom two plots, late stance) of the left leg gait cycle (GC), in the directions parallel and normal to the treadmill. * indicates a significant difference compared to 0°.

In the normal direction, VAS provided greater upward acceleration (away from the treadmill) of the COM during early stance on uphill and downhill slopes compared to level ground, which was consistent with previous observations of increased knee extensor activity on uphill and downhill slopes [1]. HAMS provided greater upward acceleration in early stance, but only on uphill slopes. During late stance on downhill slopes, BPF provided less upward acceleration, suggesting a reduced need for energy delivered to the leg for swing initiation compared to level-ground walking [3]. RF provided greater upward acceleration in late stance, which was consistent with greater muscle activity [1].

CONCLUSIONS

This study described the specific functions of major muscle groups during uphill and downhill walking. In particular, the ankle plantarflexors and knee extensors provided the largest accelerations to the body COM during all walking conditions, and provided even greater accelerations during uphill and downhill walking. These results can serve as a baseline for identifying functional deficits in impaired populations and aid in the analysis of devices that are intended to replicate muscle function, such as prosthetic feet.

UPHILL WALKING ENHANCES THE RETENTION OF A NEW STEPPING PATTERN LEARNED ON A SPLIT-BELT TREADMILL

[1] Jonathan S. Calvert, Carly J. Sombric, and Gelsy Torres-Oviedo

[1] University of Pittsburgh, Pittsburgh, PA, USA
email: jsc53@pitt.edu, web: http://www.engineering.pitt.edu/MARGroup/Home/

INTRODUCTION

Stroke patients often possess an asymmetric walking pattern that affects their mobility and quality of life. Promising studies have shown that patients can correct their gait asymmetries after walking on a split-belt treadmill, which forces their legs to move at different speeds [1]. Thus, there is an interest for enhancing the duration of these positive effects after split-belt walking. We hypothesize that the duration of the walking pattern learned on the split-belt treadmill is modulated by the forces experienced at the subjects' feet (i.e., ground reaction forces) during split-belt walking. To test this, we assessed the retention of adaptation effects after split-belt walking when healthy subjects walked uphill or downhill, which are conditions that naturally modulate ground reaction forces during walking.

METHODS

Twenty healthy volunteers (12 men, mean age 25.2±5.4) participated in the study. The subjects were divided among three groups: flat, uphill, and downhill walking. The three groups walked on a split-belt treadmill (Bertec), in which one leg moved at 0.5 m/s and the other leg moved at 1.5 m/s (3:1 belt speed ratio) for 600 strides. Subjects also walked on the treadmill when the two belts moved at the same speed (1 m/s) before and after the split-belt condition. Kinematic data were recorded in all groups with a motion tracking system (Vicon) via reflective markers placed bilaterally on the trunk and legs. In the uphill and downhill groups, the treadmill was inclined to a 15% grade before, during, and after split-belt walking.

We used the kinematic data to compare the walking pattern of the three groups when the two belts were moving at the same speed before and after split-belt walking. To accomplish this, we computed in each group their asymmetry in 1) step length, 2) step position, and 3) step time, which are measures known to adapt independently during split-belt walking [2]. We evaluated the extent of adaptation effects (i.e. after-effects) on these outcome measures by comparing their average values before split-belt walking and the initial steps (i.e., average of the first 5 steps) after split-belt walking. We also compared the decay of adaptation effects across the three groups. To this end we computed the number of steps that subjects took before their walking pattern returned to baseline behavior after the split-belt perturbation was removed.

The raw kinematic data was extracted from Vicon and processed in MATLAB. Step length asymmetry, step position asymmetry, and step time asymmetry were calculated as defined in previous split-belt adaptation studies [2]. Values from pre-split-belt walking were subtracted from the post-split-belt walking values to assess how well the subjects retained the new walking pattern. Divergence from baseline walking was defined as the points at which the asymmetry was greater than two times the standard deviation of the baseline walking data. A one-way ANOVA with Tukey post hoc analysis was used to determine if there were differences between the walking conditions ($\alpha=0.05$).

RESULTS AND DISCUSSION

Figure 1 shows the step length, step position, and step time asymmetries after split-belt walking. The uphill group had step length and step position

asymmetries that were significantly different to those of the other two groups. However, the step time asymmetry was not significantly different across groups. Additionally, the flat and downhill groups were not significantly different among any of the asymmetry values.
Figure 1: The average step length, step position, and step timing asymmetries immediately following the adaptation period. The uphill group is significantly different for step length and step position, but not step timing. Asterisks indicate statistical significance.

Additionally, subjects in the uphill group took longer to return to baseline values in the spatial parameters than the temporal parameters. Specifically, subjects in the uphill group took an average of 60 steps to return to baseline values for step position asymmetry vs. 49 and 21 steps in the flat and downhill groups, respectively. Conversely, all groups took an average of 15 steps to return to step time asymmetry baseline values.

Uphill walking significantly increased the retention of the new walking pattern in the spatial domain, but not the temporal domain. Previous studies have shown that slope walking in humans may require specialized neural control strategies [3]. Therefore,

the increased retention of spatial parameters after split-belt walking may be due to a different motor control strategy than what is used during flat split-belt walking.

This increase in after-effects in step position and step length, but not step time, in the uphill condition suggests that split-belt walking on an incline could enhance the correction of spatial asymmetries via split-belt walking. An increase in the retention of spatial adaptation effects is important because stroke patients often have larger deficits in one domain than the other [4]. Therefore, it is pertinent to identify ways to adapt spatial and temporal asymmetries independently.

CONCLUSIONS

Overall, this study shows that we able to increase the effects in the spatial domain during and after split-belt walking in healthy controls by inclining the treadmill. This increase in spatial parameters may be useful in creating individualized rehabilitation for stroke patients who have a large spatial asymmetry. In future studies, stroke patients will be tested with this paradigm to see if these results transfer across populations

INTRODUCTION

Stair ascent is a critical task for mobility independence in daily living. However, stair ascent can be biomechanically challenging, requiring an individual to simultaneously propel the center-of-mass horizontally and vertically [e.g., 1] while also controlling mediolateral motion and modulating leg swing to avoid contact with the intermediate step [e.g., 1]. While the plantarflexors, knee extensors and hip abductors have been identified as important contributors to stair ascent, it remains unclear how the individual muscles function in synergy to accomplish this task. The purpose of this study was to develop a three-dimensional muscle-actuated forward dynamics simulation of unimpaired stair ascent to determine the contributions of individual lower-extremity muscles to the biomechanical subtasks of vertical propulsion, horizontal propulsion, mediolateral control and leg swing. Such an analysis will provide additional insight into muscle function and coordination in stair ascent and help guide the development of effective, targeted rehabilitation programs aimed at improving an individual's ability to ascend stairs.

METHODS

A three-dimensional muscle-actuated forward dynamics simulation of stair ascent was generated to emulate group-averaged experimental kinematics and ground reaction forces (GRFs) for 27 unimpaired subjects. To develop the simulation, the musculoskeletal system, foot-ground contact and muscle force generation were modeled based on previous work [e.g., 2] and dynamic optimization was used to identify the muscle excitation patterns for 38 Hill-type musculotendon actuators that minimized the difference between the simulated and experimental kinematics and GRFs. To identify the contributions of individual muscles to the biomechanical subtasks of stair ascent, previously-described GRF decomposition, induced acceleration and segment power analyses were performed [e.g., 3]. The 38 individual muscles were combined into 15 muscle groups for analysis based on similar functional and anatomical classification [4].

RESULTS AND DISCUSSION

The optimization framework identified a set of muscle excitations that successfully emulated the experimental kinematics and GRFs. In addition, the timing profiles for the optimized muscle excitations compared well with published EMG data [1] and the primary contributors to the subtasks of stair ascent were identified (Table 1).

The vasti (VAS) and plantarflexors (SOL and GAS), which were the primary contributors to vertical propulsion in the first and second halves of stance, respectively, generated vertical power to the trunk and ipsilateral leg (Fig. 1: Vertical Power). The hamstrings (HAM) opposed vertical propulsion in the second half of stance by absorbing vertical power from the legs, although they did redistribute some of that power to the trunk to propel it upward.

Gluteus maximus (GMAX) and HAM, the primary contributors to forward propulsion in the first and second halves of stance, respectively, generated horizontal power to both legs while simultaneously transferring power from the trunk to the legs (Fig. 1: Horizontal Power). SOL contributed to braking in the first half of stance by absorbing horizontal power from the ipsilateral leg while rectus femoris (RF) contributed to braking in the second half of stance by absorbing horizontal power from both legs, although some of this power was transferred to the trunk to propel it forward.

VAS, the primary contributor to lateral control in the first half of stance, absorbed power from the

trunk and transferred some power from the trunk to the contralateral leg (Fig. 1: Mediolateral Power). While this decelerated the trunk's lateral motion, it accelerated the contralateral leg's medial motion which accelerated the overall body laterally. The anterior compartments of gluteus medius and minimus (GMEDA), the primary contributor to medial control in the first half of stance, generated power to the trunk and initially transferred some power from the ipsilateral leg to the trunk prior to generating power to the ipsilateral leg. While this accelerated the trunk laterally, it also decelerated and then accelerated the ipsilateral leg's lateral and medial motion, respectively. During the second half of stance, most of the power distributed by the muscles was very small (not shown).

During pre- and early swing, iliacus (IL) generated power to the ipsilateral leg and transferred power from the trunk to the ipsilateral leg (Fig. 1: Net Power). In contrast, VAS absorbed power from the ipsilateral leg and transferred power from the ipsilateral leg to the trunk. During late swing, tibialis anterior (TA) generated power to the ipsilateral leg while SOL absorbed power from the ipsilateral leg in preparation for contact with the ground.

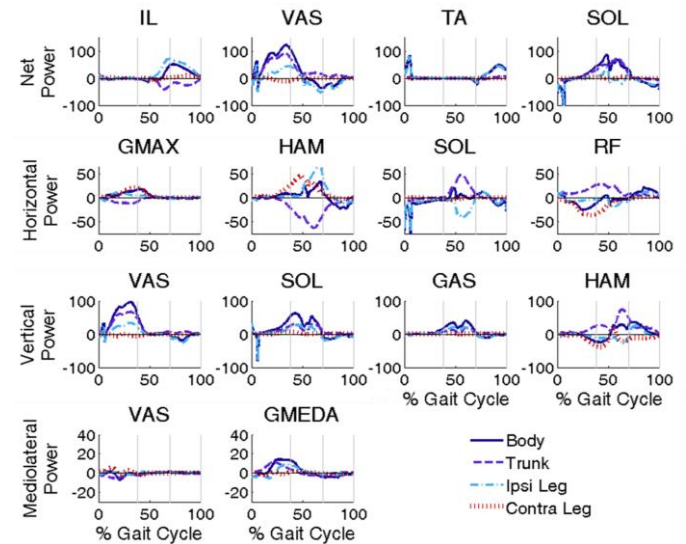
The plantarflexors, knee extensors, hip extensors and hip abductors were found to work in synergy to accomplish the biomechanical subtasks of stair ascent, with additional contributions from the dorsiflexors and hip flexors to leg swing. By understanding the function and coordination of these muscle groups, targeted rehabilitation programs can be designed to improve an individual's ability to ascend stairs.


Figure 1: Net, Horizontal, Vertical and Mediolateral mechanical power distributed to the body, trunk, ipsilateral leg and contralateral leg by the primary muscle contributors to the biomechanical subtasks of stair ascent.

BIOMECHANICAL CHANGES DURING STAIR CLIMBING AT THE KNEE, HIP, AND TRUNK AFTER TOTAL KNEE ARTHROPLASTY

Jacqueline Lewis, Gregory Freisinger, Laura Schmitt, Robert Siston, and Ajit Chaudhari

The Ohio State University, Columbus, OH, USA
email: lewis.1127@osu.edu

INTRODUCTION

Osteoarthritis (OA) is the most common cause of disability in the United States and its prevalence continues to increase [1]. Total knee arthroplasty (TKA) is used to treat end-stage knee OA and is generally considered successful; however, patients with OA and TKA tend to have decreased stair climbing performance compared to healthy adults [2].

Peak knee adduction moment (pKAM) provides an estimate of the balance between the medial and lateral compartments of the knee. Higher pKAM is associated with medial compartment knee OA but is typically reduced to match those of healthy controls after TKA [3]. Peak knee flexion angle (pKFA) and peak knee flexion moment (pKFM) are typically less in knee pathology populations compared to healthy controls [4]. Increased trunk lean is seen in OA and TKA populations and is thought to decrease demand at the quadriceps, but may also increase demand on the hip extensors [5, 6].

Although these abnormal kinematic and kinetic patterns are well defined in knee OA and TKA populations, it remains unknown whether TKA alters the biomechanics from the preoperative status, or if a patient's pre-TKA biomechanical adaptations persist after TKA. We hypothesized that the biomechanical variables would change after TKA to more closely match those of heathy controls. Specifically, pKFA and pKFM would increase, while pKAM, trunk lean, peak hip flexion angle (pHFA) and peak hip flexion moment (pHFM) would decrease after TKA.

METHODS

20 patients (7M / 13F, age: 59.4 ± 6.1 y, mass: 92.0 ± 14.3 kg, ht: 1.7 ± 0.1 m) with predominantly medial compartment osteoarthritis were recruited by three orthopedic surgeons at The Ohio State University Wexner Medical Center and provided IRB-approved informed consent. All participants underwent a primary TKA, using a posterior stabilized (PS) prosthesis. (Zimmer, NexGen LPS Flex; Warsaw, IN). Biomechanical assessments were completed approximately 1 month before and approximately 6 months following surgery.

During the biomechanical assessment, each patient performed stair ascent and descent trials foot over foot on a custom made 3-step staircase (tread depth: 25.5 cm, tread height: 20 cm). The first two steps of the staircase were attached to force plates (Bertec 4060-10; Columbus, OH) embedded in the floor to capture stair climbing ground reaction forces at 1500 Hz. A modified point-cluster marker set in conjunction with a functional hip joint center was used to calculate lower extremity kinematics for the involved limb (10 Vicon MX-F40; Oxford, UK). Marker and force data were filtered with fourth order low-pass Butterworth filters at a cutoff frequency of 6 Hz. All moments were expressed as externally applied to the joint of interest and were normalized by body weight times height. Forward trunk lean angle was calculated using the vector created by the markers placed on the 10th thoracic and 7th cervical vertebrae relative to global vertical axis in the sagittal plane.

Only 17 of the 20 study patients (6M / 11F, age: 59.5 ± 6.5 y, mass: 91.8 ± 14.2 kg, ht: 1.7 ± 0.1 m) were able to descend the staircase foot over foot. Paired t-tests were used to test for a difference between each variable of the involved limb during stair ascent and descent, before and after TKA.

RESULTS AND DISCUSSION

During both stair ascent and descent, pKAM significantly decreased after TKA (Table 1), suggesting that TKA results in a more equally distributed load between the medial and lateral compartments. Although there was a significant change in pKFA and pKFM during stair ascent, the change was a decrease, which contradicted our hypothesis (Table 1). Hip biomechanics and trunk lean during both stair ascent and descent, and sagittal plane knee biomechanics during stair descent did not change after TKA (Table 1).

The results of this study suggest that many biomechanical adaptations utilized by patients with knee OA persist after TKA. It is possible that these biomechanical adaptations persist due to neuromuscular adaptations learned during the progression of OA that are not easily changed. Quadriceps strength deficits are still visible six months after TKA, and therefore, the trunk lean and hip extensors may still be used to compensate for quadriceps weakness. Clinicians should be aware of these potential adaptations when a patient increases stair climbing speed, and may want to focus on decreasing trunk lean during stair climbing, thereby decreasing the role of the hip extensors, and increasing the role of the knee extensors. This could promote more normal knee biomechanics and ultimately improve stair climbing ability after TKA.

In addition to the measurement and estimation limitations associated with optical motion capture, force platforms and inverse dynamics, a potential limitation of this study is the fact that all participants received a PS prosthesis. Changes in femoral rollback have previously been observed with PS designs [5], but the *in vivo* functional consequences of altered femoral rollback remain an avenue for future investigation.

CONCLUSIONS

TKA using a PS prosthesis yielded sagittal plane stair climbing biomechanics that were not different from the biomechanics observed before surgery. The only result that supported our hypothesis was in the frontal plane where pKAM did decrease after TKA, indicating that intraoperative realignment and soft-tissue balancing corrected the varus deformity associated with medial compartment OA. Clinicians may want to focus decreasing the amount of trunk lean in patients with TKA to promote more normal kinematic and kinetic patterns. Further analysis is needed to differentiate between biomechanical adaptations used by patients with OA that persist after surgery and those that form due to the surgery itself.

INTRODUCTION

Rehabilitation following total hip arthroplasty (THA) is designed to reduce the impairments associated with the surgery and to optimize overall functional recovery. It is common for lower extremity muscle strength training to be a focus of rehabilitation as strength deficits can decrease overall function. Through the use of rehabilitation, investigators have reported improvement in muscle strength in the first six months of recovery compared to preoperative values. Typical strength gains ranged from 0-30%, with more common gains of 15-20% [1]. While strength deficits relative to the uninvolved side may persist, early stage strength gains may be beneficial to long-term function and in reducing the loading experienced by the implant.

The strength of the hip abductor muscle group is an important predictor of overall function following THA. This may be due to its influence on the internal joint contact force (JCF), where excessive forces associated with muscle weakness [2] can lead to loosening of the implanted components and overall functional deficits [3]. Targeting deficits in this muscle group may improve functional recovery following surgery. However, the relationship between hip abductor strength and JCF has not been fully investigated, particularly during tasks with high muscle demand. Additionally, identifying which abductor muscles have the most impact on JCF can direct rehabilitation strategy and inform surgical approach. The purpose of this study was to investigate the effects of simulated increases in hip abductor strength following rehabilitation on JCFs during stair descent.

METHODS

Five patients who had undergone THA (2 M, 3F; age: 63±7.5 yrs; BMI: 27.5±2.0) participated in a laboratory testing session that consisted of lower extremity maximum isometric strength tests and a stair descent task from a height of 20 cm as part of a larger study. Subject-specific musculoskeletal models were created by scaling a model that included detailed hip musculature [4] to segment dimensions and mass. Additionally, the subject-specific muscle maximum isometric strength values of each model were scaled to minimize differences between model-predicted and measured preoperative maximum isometric joint torques in hip flexion, extension, and abduction as well as knee flexion and extension.

A baseline forward dynamic simulation of each subject performing the stair descent was constructed using their corresponding subject-specific model to predict JCFs at the ankle, knee, hip, and low back. The hip abductor muscle strength for gluteus medius (glut med), gluteus minimus (glut min), anterior section of the gluteus maximum (glut max), tensor fasciae latae (tfl), piriformis (piri) and gemellus (gem) were then increased relative to baseline in a probabilistic framework using the advanced mean value method [5]. A range of possible strength increases was simulated with a mean of 15% and a standard deviation of 5% to result in a ±3σ range of 0-30% of possible increase in abductor muscle strength.

The output range of peak JCF at each joint was generated by calculating the values with 0.5% (lower) and 99.5% (upper) probability. Muscle strengths were individually varied to calculate sensitivity factors from the advanced mean value method, which quantify the relative impact of increased strength of each muscle on the peak JCF.

RESULTS AND DISCUSSION

Simulated hip abductor strengthening resulted in peak JCFs at lower and upper probabilities that

were reduced relative to baseline for all five patients at the hip (18.9-23.8±16.5%) and knee (20.5-23.8±11.2%). Four of the five patients had reductions at the ankle (7.1-8.5±11.3%) and low back (3.5-7.0±5.3%) with one patient demonstrating no change. Reductions at the ankle and low back were smaller than the hip and knee, but demonstrate the ability of the hip abductor group to influence loading at these joints in some patients (Table 1). The large variability in percent reduction in JCF was associated with preoperative strength. In general, patients with weaker preoperative strength resulted in the greatest reductions in JCF in response to simulated strengthening.

Simulated strengthening resulted in a redirection of JFCs at the lower extremity joints as demonstrated by changes to the force components. The largest differences occurred in the vertical component at each joint and accounted for 82.5±13.1% of the JCF reductions, on average (Table 1).

The two posterior sections of the gluteus medius had a 20.3% greater effect on low back JCF than any other joint, while the anterior section had 46.3% greater effect on knee JCF than any other joint.

The smaller muscles (tfl, gem) had the greatest influence overall for the relative increase in hip strength. Knee JCFs demonstrated sensitivity factors of 0.24±0.8 and 0.26±0.8 for the tfl and gem, respectively, and were the highest of any muscle-joint relationship. However, sensitivity factors varied between subjects, likely due to differences in anthropometry and stair descent kinematics that can influence moment arm and muscle mechanics.

CONCLUSION

Simulated strengthening of the hip abductor muscle
Figure 1: Sensitivity factors for hip abductor muscles with respect to ankle, knee, hip and low back joint contact forces.

group produced reductions in JCF when muscle demand was high, which indicates that targeting this muscle group in early THA rehabilitation may lead to higher overall patient function with reduced JCF on the implant. In addition, JFC was most sensitive to simulated strengthening in what may be considered minor muscles of the hip, and may play an important role in surgical approach and rehabilitation planning.

INTRODUCTION

Chemotherapy-induced peripheral neuropathy (CIPN) is a neurotoxic side effect of several classes of common chemotherapy agents including taxanes. CIPN is associated with a decreased quality of life due to symptoms including pain and impaired function [1]. Similar to peripheral neuropathies in other populations, an increased risk of falling has been observed in patients with CIPN that suggests underlying balance deficits are likely present [2,3]. However, it is unknown how these balance deficits progress as patients proceed through chemotherapy. Establishing the natural history of postural instability in this population may elucidate balance parameters that are able to identify patients early in treatment who are likely to subsequently develop severe symptoms. Improved ability to quantify the effects of CIPN may also better enable researchers to evaluate and develop effective interventions that have remained elusive to date.

The purpose of this pilot study was to establish the feasibility of implementing quantitative, objective balance measures into the clinical setting. We proposed to gain insight into the natural history of postural instability in breast cancer patients being treated with taxane-based chemotherapy.

METHODS

At the time of analysis, 29 breast cancer patients (f/m = 28/1; age = 47.1 ± 11.2 years; mass = 75.1 ± 20.3 kg; height = 1.64 ± 0.08 m) being treated with taxane-based chemotherapy for the first time had been accrued for this study after providing IRB-approved informed consent.

Patients were assessed at 5 timepoints: within 1 month of starting chemotherapy (timepoint 1), at the beginning of subsequent chemotherapy cycles (timepoints 2-4), and 1-3 months after completing their chemotherapy regimen (timepoint 5). At each visit, patients filled out patient-reported outcomes and performed balance and gait tasks. All data was collected by trained clinical research coordinators in the clinic where the patients were receiving treatment. Balance tasks consisted of quiet standing with eyes open (1 trial for 30 sec), quiet standing with eyes closed (1 trial for 30 sec), limits of stability (1 trial), functional reach with foot (5 trials for maximum distance), and functional reach with hand (3 trials for maximum distance), as shown in Figure 1.
Figure 1. Standing balance tasks collected in the clinic. A. Quiet standing; B. Functional reach with foot; C. Limits of stability; D. Functional reach with hand.

Quiet standing consisted of patients standing as still as possible with their arms relaxed at their sides. The limits of stability task involved patients leaning forward, backward, left, and right as far as possible without losing their balance or picking their feet off of the balance plate. For the functional reach with foot task, patients were asked to balance on their left foot and push a slider as far as possible with their right foot in a single controlled motion. For the hand reaching task, patients reached with a locked elbow and closed fist along a graduated poster with

both feet flat on the balance plate. Foot measurements and standardized positioning enabled estimation of each patient's boundaries of support.

Center of pressure (CoP) data was collected during all balance tasks through a Bertec BP5046 balance plate. A custom LabVIEW interface was developed to guide clinical personnel through the protocol and collect CoP data. Processing of balance data was performed through custom Matlab scripts with all CoP data low-pass filtered at 20 Hz using a 4th order Butterworth filter. Preliminary analysis of the data was performed using linear mixed model least squares means for repeated measures to estimate changes in balance parameters over time.

RESULTS AND DISCUSSION

The results of this pilot study support the feasibility of implementing balance measures into a clinical setting to quantify postural instability in breast cancer patients. Testing in the clinic was performed without interfering with normal operations. At the time of analysis, patients were at varying stages of the study with more than half of the patients having completed timepoint 4. Five of the 29 patients dropped out of the study (n=4 after timepoint 1, n=1 after timepoint 2). The preliminary results presented here are for the quiet standing with eyes closed task at timepoints 1-4 using 95% confidence ellipse area of CoP trajectory. Progressive increases in ellipse area were observed, as shown in Figure 2.
Figure 2. Least squares means ± standard error of 95% ellipse area during eyes closed task.

An increase in ellipse area was observed as early as timepoint 2. Changes between timepoints are presented in Table 1.

Table 1. Change in 95% confidence ellipse area from timepoint 1 during quiet stance with eyes closed.

Timepoint Comparison	% Change from Timepoint 1	p-value
1→2	40%	0.046
1→3	37%	0.058
1→4	97%	0.004

Higher 95% confidence ellipse areas have been associated with balance deficits [4]. The changes observed in this pilot study suggest that patients become progressively less stable as they continue through chemotherapy treatment. This result is consistent with a loss of proprioception and/or vestibular acuity. Further analysis will be conducted after completing testing of the breast cancer cohort including comparing changes in balance measures with changes in patient-reported CIPN symptoms. Future research will evaluate this approach in other cancer populations as well as in a larger sample of breast cancer patients to further assess the scope of these findings.

CONCLUSIONS

Balance testing in the clinical setting with trained clinical personnel was conducted in this pilot study, which supports the feasibility of this approach. Preliminary analysis showed a progressive increase in 95% confidence ellipse area during quiet stance with eyes closed.

BALANCE CONTROL DURING REACTIVE STEPPING: THE EFFECT OF INCREASED PASSIVE TRUNK AND HIP STIFFNESS

Tyler B. Weaver and Andrew C. Laing

INTRODUCTION

Age-related changes in the control of the trunk and hips may be one factor influencing fall-risk in older adults. Previous research suggests that older adults exhibit greater trunk stiffness compared to young adults [1], with abnormal trunk movement after a perturbation [2]. Increased trunk stiffness could help to resist gravitational effects, but it could also inhibit compensatory movements after a balance perturbation. Therefore, it is of interest to determine how increased passive stiffness of the trunk and hips influences balance control during a reactive forward step. It was hypothesized that increased passive stiffness would result in detriments during a reactive step, inferred through changes in the centre of mass (COM) displacement and ground reaction forces.

METHODS

Sixteen young adults participated in the study (mean (SD) age: 22.5 (2.5) y; height: 1.70 (0.10) m; mass: 68.4 (9.7) kg). Balance perturbations were applied using a tether-release paradigm, which required participants to react with a forward step and hold their final position for ten seconds. Separate tethers attached to each hip allowed for three perturbation directions to be applied: 1) forward; 2) forward-left rotation; 3) forward-right rotation. Starting foot-position for all participants was standardized to 50% of hip-width. All participants assumed an initial lean position equivalent to 15% of body weight, monitored in real-time. Instructions were provided to participants to lean forward as one rigid segment above the ankles with their arms crossed over their chest, and to let the tethers and harness support their body weight.

Three-dimensional kinematics were collected using a four-bank Optotrak Certus system (NDI, Waterloo, ON) at 100 Hz, and used to calculate the whole body COM position via an 11-segment model in the anterior-posterior (AP) and medio-lateral (ML) directions. Forces from each reactive step were measured using a floor-mounted force platform (AMTI, Watertown, MA) at 2000 Hz. Passive stiffness was increased using a rigid, plastic "corset" which crossed the hips and extended upwards to the xiphoid process. Movement was restricted in both the sagittal and frontal planes.

First, a point of equilibrium, referred to as the 'restabilisation' point, was calculated as the point when the COM velocity waveform entered and remained inside an amplitude bandwidth bordered by two standard deviations of the mean velocity during the last two seconds of the trial [3]. In order to calculate the maximum COM displacement after a step, the 'restabilisation' point established after foot-contact was subtracted from both the maximum global AP and ML COM values observed after foot-contact. To compare the size of 'restabilisation' displacement between the corset and no corset conditions, the starting COM position (prior to the onset of a tether-release) was also subtracted from 'restabilisation' point for each condition to

determine if differences existed between conditions regarding where participants established their new equilibrium after foot-contact (referenced to their COM position at the start of the trial).

Accordingly, the following dependent variables were calculated: 1) maximum AP and ML COM displacement after foot-contact (as defined above) ($COM_{MaxDisp}$); 2) the size of AP and ML COM 'restabilisation' displacement, referenced to the COM start ($COM_{RestabSize}$); 3) AP and ML ground reaction forces at the maximum COM position after foot-contact (GRF). For all metrics means and standard deviations (representing within-subject trial-to-trial variability) were computed and compared. Standard deviation was included as a measure of variability as existing research has reported that variability is larger in older adults [4].

RESULTS AND DISCUSSION

AP COM Movement: AP $COM_{MaxDisp}$ was 36% larger (i.e., forward) with the corset (7.3 cm) vs. without (5.3 cm) ($p=0.002$). The corset also caused AP $COM_{MaxDisp}$ to be 28% more variable compared to the no corset condition ($p=0.015$).

In the AP direction, $COM_{RestabSize}$ was influenced by a corset x perturbation direction interaction ($p<0.001$). Post-hoc analysis revealed that for both the forward-left and forward-right perturbations the $COM_{RestabSize}$ was smaller with the corset vs. without (left: $p=0.003$, 26% smaller; right: $p=0.007$, 25% smaller). AP $COM_{RestabSize}$ was also 22% more variable with vs. without the corset ($p=0.049$).

ML COM Movement: ML $COM_{MaxDisp}$ was not different ($p=0.689$) or more variable ($p=0.918$) between corset and no corset conditions. Further, in the ML direction, $COM_{RestabSize}$ was not statistically different ($p=0.126$), although the corset mean (3.6 cm) was 65% smaller than the no corset mean (10.2 cm) (i.e., smaller = closer to the step leg). ML $COM_{Restabsize}$ was not more variable with vs. without the corset ($p=0.767$).

AP Ground Reaction Forces: AP GRFs were 31% smaller with the corset, compared to without ($p=0.004$). However, AP GRF variability was not different between corset conditions ($p=0.657$).

ML Ground Reaction Forces: ML GRFs were influenced by a corset x perturbation direction interaction ($p=0.031$), where for a forward-right perturbation, the corset condition resulted in a 16% larger ML GRF, with no difference for the other two perturbation directions. The ML GRFs were not more variable with or without the corset ($p=0.315$).

Overall, balance control after foot-contact is influenced by increased passive trunk\hip stiffness. With the corset, participants adopted an AP 'restabilisation' point which was closer to the pre-perturbation AP COM position. Perhaps the stiffness resulted in less trunk flexion during this period with the end result of COM being located more posterior. This may also explain the reduced AP GRFs which were used by participants after foot-contact. In the ML direction, the almost 7 cm mean difference in COM_{Restab} suggests that while wearing the corset, participants adopted a 'restabilisation' point closer to their step leg. Interestingly, when maximum ML COM values were referenced to the starting ML COM position, the corset resulted in 35% greater ML COM movement towards the step leg ($p=0.036$) compared to the no corset condition.

To conclude, increased passive trunk/hip stiffness influences balance recovery after foot-contact. However, researchers should be cognisant of how different methods of reporting COM movement can influence their results. Moving forward, research is needed to determine how increased stiffness influences balance after foot-contact in older adults.

IMPROVING NEUROPATHIC GAIT AND BALANCE VIA SENSORY SUBSTITUTION

INTRODUCTION

Peripheral neuropathy (PN) is a condition characterized by nerve impairment in the distal extremities. PN can result in debilitating problems with balance and walking, putting these patients at an increased risk of falls [1]. A class of medical technologies termed "sensory substitution systems" (SSS) aims to utilize neuroplasticity — the capacity of the central nervous system to rewire neural pathways — to restore lost sensory function. The goal of a SSS is to collect information on behalf of a deficient sensory modality and convert it into a form that can be perceived by the patient [2].

Orpyx Medical Technologies Inc. has developed a SSS to replace lost sensory function in the feet. As the user walks, plantar pressures are measured in real time by insoles worn in the shoes. The magnitude and spatial position of the plantar pressures are wirelessly transmitted to a belt worn around the subject's lower back. Motors within the belt vibrate in correspondence with each pressure sensor to create a mapping of the feet on the back.

We hypothesized that after four weeks of training with this novel SSS device, subjects would exhibit improvements in gait and balance parameters, and further, that any changes in gait and balance would then disappear after a four-week washout period without the device.

METHODS

Eight individuals diagnosed with PN were recruited (6 male, 2 female; 69.3 ± 9.6 years). All participants provided written informed consent in accordance with the University of Calgary's Conjoint Health Research Ethics Board. Each subject made six visits to the Human Performance Lab for periodic gait and balance assessment (Table 1).

Table 1: Timeline of assessments

Stage	Time (Weeks)
1. Familiarization	-1
2. Baseline	0
3. Mid-Training	2
4. Post-Training	4
5. Mid-Washout	6
6. Post-Washout	8

Each subject was initially fitted for the device and familiarized with the measurement protocols before actual testing. After baseline measurements at the subsequent visit, subjects were given the SSS device to take home for a four-week training period. They were requested to use it actively (ambulating) at least one hour per day with no upper limit to its use. Subjects returned the device after the post-training session, and were not exposed to it for the ensuing four-week "washout" period.

Balance was assessed through distance travelled by the center of pressure (CoP) during quiet standing. Ground reaction forces were recorded on a force plate sampling at 2400 Hz (Kistler Instruments AG). Subjects executed three different postural conditions (eyes open, narrow stance, eyes closed) for each of two device conditions (power on, power off). Gait was assessed through stride frequency and its variability in the form of coefficient of variation (CV). Subjects walked a 44m path twice for each device condition (on, off) while wearing a set of instrumented insoles that recorded plantar pressures at 100 Hz (Pedar-X, Novel). A training effect was

defined as a significant interaction between time and device condition in a two-way ANOVA.

RESULTS AND DISCUSSION

For the eyes closed balance task, the CoP path length was significantly shorter while standing with the device in the on condition compared to the off condition across all time points ($F=11.9$, $p<0.03$). There was no significant training effect (improvement over time) for balance (Fig. 1).
Figure 1: Normalized changes in CoP path length over time while standing with eyes closed.

Across all time points, the CV of stride frequency was significantly smaller while walking in the on condition compared to off ($F=21.7$, $p<0.01$). In addition, the mean stride frequency was significantly higher while walking in the on condition compared to off ($F=12.1$, $p<0.02$). There was no significant training effect of the device for stride variability during walking (Fig. 2).
Figure 2: Changes in coefficient of variation of stride frequency over time while walking.

There were significant differences between on and off conditions independent of time, which suggests this device can elicit instantaneous improvements in balance and gait. More stable balance was observed in shorter CoP path lengths while standing with eyes closed. Without visual feedback and with their own feedback from the feet compromised, subjects may have been primed to consciously detect the vibration response to large shifts in balance and perform appropriate postural corrections. Improved gait was evidenced by reduced variability in stride parameters as well as increased cadence, which are both associated with healthier walking in PN [3]. Changes in stride frequency during walking could be explained by locomotor rhythm entrainment to the oscillating left-right vibration signal.

It was anticipated that improvement in balance and gait would be the product of training, i.e. differences between the on and off conditions would change over time. Variability in training factors could explain why the instantaneous effects of the device were not enhanced through training. Subjects wore the device for 1-8 hours per day across a variety of activities. Moreover, the spatial position of the device may have been inconsistent due to potential mediolateral and crainiocaudal movement relative to the subjects' bodies. The subject pool also featured a wide degree of PN severity (from 1-8 on the MNSI-B and 0-10 on the NDS inventories) and a range of PN etiologies, including diabetic, idiopathic, and chemotherapy-induced PN [4].

Users of this sensory substitution device exhibited instantaneous improvements in gait and balance. More regimented protocols are required to better assess its training effects over time. Manipulating locomotion and posture through augmented sensory feedback has broad potential applications in gait rehabilitation and skill acquisition.

POSTURAL CONTROL CHANGES ASSOCIATED WITH ANKLE-FOOT ORTHOSES IN INDIVIDUALS WITH PERIPHERAL NEUROPATHY

Kimberly E. Bigelow and Kurt Jackson

University of Dayton, Dayton, OH, USA
email: Kimberly.bigelow@udayton.edu

INTRODUCTION

Peripheral Neuropathy (PN) affects an estimated 8% of individuals aged sixty-five and older living in the community and up to 26.4% of those with Type II diabetes [1,2]. Individuals with PN often experience problems with balance and mobility and are more likely to fall [3]. Recently there has been some evidence that the use of ankle-foot orthoses (AFOs) may provide augmented feedback to individuals with sensory loss due to PN [4,5]. Developments in the design and manufacture of AFOs further this potential. Newer anterior shell carbon composite AFOs are lightweight and provide a large surface area of tactile contact over much of the shank. The limited work done to date in individuals with PN has largely concentrated on the effect of AFOs on static balance, with limited research focusing on dynamic aspects of balance and mobility. This seems especially important to consider because of the potential tradeoffs with regard to mechanical restrictions of the AFOs. Because of this, the aim of this study was to examine the effect of AFOs on individuals with PN on measures of posturography and clinical assessments of balance and mobility. It was hypothesized that AFOs would results in improved quiet-standing balance but would negatively impact tasks requiring leaning, rapid stepping, and other quick and dynamic movements.

METHODS

Twelve subjects with PN, who had not previously used AFOs, participated in this study (mean age: 75.1±7.4, mean body mass index: 28.7±5.1). These subjects were screened to ensure significant sensory loss in the feet/lower legs (mean sensory threshold: 5.59±1.03, mean vibration values: 0.98±1.41 on a scale of 0 to 8). For the aim of the study, individuals were excluded if sensory loss was accompanied by notable deficits in range of motion or strength.

Participants were assessed in two conditions: while wearing non-articulated, rigid anterior shell carbon composite AFOs bilaterally (ToeOFF, Allard USA, Rockaway, NJ, USA) and while not wearing the AFOs (typical function). The order of these conditions was counterbalanced to reduce potential ordering effects. For the AFO condition, participants were guided in a series of brief exercises to become familiar with the AFOs.

In each condition, individuals underwent the same set of assessments. First, participants completed a quiet-standing posturography protocol. Participants stood on the force plate for 20 seconds at a time in four test conditions: eyes open and closed on the firm plate, and eyes open and closed on a foam pad placed on the plate. Each test condition was repeated three times, and anterior-posterior (A/P) and medial-lateral (M/L) center of pressure (COP) was collected. Participants then completed a Limits of Stability task on the flat plate, leaning as far forward, backward, left, and right as possible using an ankle strategy. A/P sway range, M/L sway range, and mean velocity were calculated for quiet-standing trials and averaged across the three trials of the same condition. A/P sway range and M/L sway range were calculated for Limits of Stability.

Clinical balance and gait assessments that required more dynamic movement were then conducted. Participants completed the Mini Balance Evaluation Systems Test (Mini-BESTest), walking speed assessment, and the Timed Up and Go (TUG). These assessments include tasks that an individual would regularly do in everyday life such as: standing up from a chair, rising on toes, compensatory stepping, and dynamic gait.

Paired t-tests were done to compare the with and without AFO conditions for the posturography measures, the gait speed assessment, and the TUG. Wilcoxon signed rank test was used to compare results of the Mini-BESTest. A significance of 0.05 was used for all testing.

RESULTS AND DISCUSSION

For the quiet-standing posturography assessments, statistical differences were found in the eyes closed, flat plate condition for both A/P sway range (p=0.012) and M/L sway range (p=0.047). In both cases, participants exhibited reduced sway ranges, indicating improved postural control in the AFO condition. Additionally, all parameters associated with eyes open on the firm plate, eyes closed on the firm plate, and eyes open on the foam pad revealed a similar, albeit non-statistically significant trend of reduced and slower sway while wearing the AFOs. The eyes closed, foam pad condition proved to be quite difficult for both AFO conditions. 8 of 12 subjects lost balance on at least one eyes closed, foam trial, limiting the ability to draw conclusions.

The findings of the quiet-standing assessment seemed to support that AFOs were helpful for individuals with sensory impairment. The Limits of Stability results, however, showed a significant reduction in anterior-posterior sway range when the AFOs were worn (146.78±29.6 mm without to 128.03±27.2 mm, p=0.000). This suggested that the AFOs provided mechanical rigidity that restricted how far an individual was able to lean. This has potential implications for tasks such as reaching into a high cabinet safely without losing balance.

The clinical and gait assessments results indicated no statistically significant differences in the mean values for the AFO versus non-AFO condition for any of the outcome measures. Individual performance, though, was quiet variable with the AFOs providing meaningful improvements to some and being detrimental to others. For example, on the Mini-BESTest, two individuals had scores that exceeded the minimal clinically important difference score of 4 points when they wore the AFOs (+4 points and +8 points), but the performance of another two was reduced by more

than the minimally important change value (-6 pts. And -5pts.). This suggests that these individuals experienced changes that would likely have functional implications and that for some individuals these changes associated with wearing the AFOs were positive, whereas for others they could be quite detrimental.

This work suggests that while AFOs may provide additional tactile feedback that improves standing balance, the mechanical restrictions associated with the brace may introduce additional trade-offs. The results of the clinical assessments, in particular, seem to suggest that different individuals may respond differently to AFOs. Future work should seek to determine the characteristics of those who benefit more from the AFOs than others and evaluate whether these differences lessen with time, use, and/or familiarization. Future work should also explore whether the sensory benefits seemingly observed in quiet-standing transfer to a reduction in fall incidence in individuals with PN.

CONCLUSIONS

Anterior-shell carbon fiber AFOs were found to significantly improve quiet-standing balance in individuals with peripheral neuropathy, especially when vision was compromised. Performance on tasks that required more dynamic movement was more variable with no group significant differences.

INTRODUCTION

Postural control and balance are two important factors to humans in performing activities of daily living (ADL). In the past two decades, studies [1] have shown that light touch (contact force less than 1N) of fingers on fixed surfaces can reduce postural sway during quiet standing and walking for people with or without dysfunction of sensory systems. With the help of additional sensory information from biofeedback, individuals with neurological impairments may improve their balance in ADL, which eventually can lead to enhanced quality of life. Recently, a portable sensory augmentation device was developed [2]. However, the efficacy of the device is not studied yet.

In this study, we examined whether augmented sensation at the fingertip via a newly developed portable sensory augmentation device (SAD) can modulate quiet standing postural sway. A closed-loop control strategy was implemented in this system for postural control. Furthermore, it is not known if the effect of sensory augmentation in balance enhancement depends on the availability of sensory modality. The objective of this study is to examine the effect of augmented sensation at the fingertip due to SAD on quiet standing balance of healthy young adults for various sensory modalities. It is hypothesized that augmented sensation enhances quiet standing balance more effectively when more sensory modalities are removed.

METHODS

Fifteen healthy young adults (four females and eleven males; mean age ± s.d.: 26.4 ± 5.6 years) with neither neurological nor musculoskeletal impairments participated in this study. Subjects were asked to stand quietly on a force plate (OR6, AMTI, Watertown, MA) under three conditions of availability of sensation: i) eyes-open (EO), ii) eyes-closed (EC) and iii) tilting head backwards with eyes closed (ECHU). Subjects put SAD on their right index finger (Fig. 1a). A belt enclosing an inertia measurement unit (IMU) (MPU-9150, InvenSense Inc., San Jose, CA) and an embedded control unit (myRIO, National Instruments, Austin, TX) was wrapped around waist of subjects (Fig. 1b). The details of SAD and control unit can be found at [2].
Figure 1: a) SAD, b) experiment setup

The experiments consisted of two parts: 1) practice session, and 2) main session. In the practice session, subjects were instructed to stand quietly on a force plate under three conditions of availability of sensation (EO, EC, and ECHU). The purpose of the session was to calibrate IMU by computing subject's reference angle while quietly standing, and to familiarize the subject with the testing environment. In the main session, subjects were asked to stand quietly on a force plate for 30s, with 10 repetitions for each sensory modality condition (EO, EC, ECHU) and SAD condition (on vs. off). Subjects were unaware of the function of SAD. Force plate data and pitch angle were sampled at 1kHz and 500Hz, respectively. Two-minute rests were given every five trials to avoid muscle fatigue.

SAD contactor was controlled by a position control where angular velocity of contactor was proportional to the angular deviation of pitch angle from the reference angle [2]. For example, when subject leaned forward (or backward) during quiet standing, the contactor rotated clockwise (or

counterclockwise) so that the fingertip pad was stretched backward (or forward). This way, the subject was provided augmented sensory feedback of his/her postural sway.

From the force plate data, center of pressure (COP) was computed. From COP data, several traditional parameters such as maximum distance (*MaxDist*), range (*Range*), and mean frequency (*MeanFreq*) in anterior-posterior (AP), medial-lateral (ML) directions were computed [3].

To study the effect of availability of sensation and SAD on quiet standing balance, a two-way repeated measures ANOVA was performed. Level of significance was set to $\alpha=0.05$ (SPSS, v21, Chicago, IL).

RESULTS AND DISCUSSION

Availability of sensory information significantly affected balance. *MaxDistAP*, *MaxDistML*, *RangeAP*, and *RangeML* indicated that postural sway was the smallest when all sensory information was available (EO), followed by when vision was lacking (EC), and followed by when both vision and vestibular information was deprived (ECHU) in both AP and ML direction (Table 1). These results agreed with previous studies that removing sensory information or challenging balance significantly increased postural sway [4].

Sensory augmentation due to SAD significantly affected balance. *MeanFreqAP* and *MeanFreqML* significantly decreased when sensory augmentation was provided (Table 1). *MeanFreq* is proportional to ratio of *Total Excursion* to *Mean Distance* or equivalently to ratio of *Mean Velocity* to *Mean Distance* [3]. This result suggests that sensory augmentation from SAD can reduce effective postural way that cannot be captured by the mean values of postural sway.

Our hypothesis that the effect of sensory augmentation due to SAD will be more prominent when less sensory modality was available was also supported. *MaxDistAP* and *RangeAP* had significant interaction effects between sensory availability and SAD. This interaction came from the fact that for EO/EC condition, SAD increased the mean values of *MaxDistAP* and *RangeAP* whereas for ECHU condition, SAD decreased the mean values of *MaxDistAP* and *RangeAP*.

One possible explanation is that sensory information during EO/EC conditions was enough to make stable balance whereas sensory information during ECHU condition was not enough to make stable balance so that additionally provided sensory augmentation could help improve balance.

Limitation of this study was as follows. Since SAD used position control and subject's reference angle kept changing over time during experiment, the quality of sensory feedback could be suboptimal. One possible solution would be applying velocity-based control where the reference angle does not affect the performance of SAD.

CONCLUSIONS AND FUTURE WORK

The efficacy of the developed sensory augmentation system via skin stretch feedback is evaluated. Our results indicate that the presence of additional sensory input helped maintaining balance when both visual and vestibular inputs were removed, substantiating our hypothesis. Future works include to 1) develop velocity-based controller (derivative control) and change the approach of obtaining the subject's reference angle, and 2) recruit groups of patients with impaired sensory systems to compare the quiet standing performance with normal subjects.

RECOVERY FROM HIP ABDUCTOR FATIGUE DURING STANDING IS INFLUENCED BY THE PRESENCE OF LOW BACK PAIN

Daniel Viggiani and Jack P. Callaghan
Department of Kinesiology, University of Waterloo, Waterloo, ON, Canada

INTRODUCTION
Muscle fatigue and pain are two factors often associated with musculoskeletal injury. Both muscle fatigue and pain are task-dependent[1], therefore the specific interactions between muscle fatigue and pain will differ based on how fatigue and pain are generated. However, previous research approaches examining the fatigue-pain interaction have used methods that are rarely encountered outside of laboratory settings. This study's purpose is to determine how the pain developed during prolonged standing, interacts with a type of fatigue that is also frequently encountered in workplace settings – repetitive low-level muscular activity. The hip abductor muscle group was chosen as it is both relevant to postural control[2] and the pain pathway[3] reported during prolonged standing.

METHODS

Thirty participants (15 female) completed two, 2-hour standing sessions. During one of the sessions, participants performed a side-lying repetitive leg-raising exercise using their dominant leg just prior to the start of standing; the other session was used as a control session with participants completing 2 hours of prolonged standing work. The order of the sessions was randomized.

Surface electromyography (EMG) of bilateral gluteus medius was measured continuously while participants were standing. Raw EMG data was linear enveloped and expressed as a percentage of maximal isometric voluntary contraction. The normalized EMG data was used to compute cocontraction indices between the left and right gluteus medii[3]. Self-reported levels of pain for the low back were recorded using 100 mm visual analog scales (VAS) prior to the start of and every 15 minutes during standing. VAS scores were used to classify participants as pain (PD) or non-pain (NPD) developers using a 10 mm minimum threshold based on control data[3,4]. Participants were asked to maximally abduct their dominant leg against isometric resistance provided by a tethered cuff positioned just above their femoral condyles. These abduction contractions (ABCs) occurred at time points 0, 1, 2, 3, 5, 10, 15, 30 minutes and every 15 minutes thereafter during the standing work. Force measures from the ABCs were normalized to a baseline ABC completed at least 5 minutes prior to the start of each standing session. The difference of normalized strengths between the control and fatigue sessions was then computed.

Paired t-tests were performed on cocontraction indices and ABCs with pain group as the independent variable. A mixed-model ANOVA with a within factor of session and between factor of pain group was performed on VAS scores.

RESULTS AND DISCUSSION

Twelve of 30 participants were classified as PDs (8 female) based on VAS scores. PDs had a trend of smaller cocontraction indices during the first 15 minutes of standing in the fatigue session (591.9 ± 777.9 %MVC) compared to the control session (854.4 ± 1216.9 %MVC; p = 0.0736). PDs also reported lower peak low back pain during the fatigue session (Figure 1), having a peak pain reduction of 8.6 mm (SD = 5.0 mm; p < 0.0001). Only 3 out of 12 PDs reported pain below the 10 mm threshold and as a whole, the PD group was still experiencing clinically significant levels of pain while standing[4]. There was no difference in NPD pain reporting between control and fatigue sessions (mean difference: -0.7 mm; SD = 3.3 mm; p = 0.3096).

PDs had greater strength differences between control and fatigue sessions than NPDs at time points 30 minutes (p = 0.0313), 105 minutes (p = 0.0264) and 120 minutes (p = 0.0111; Figure 2). In the last 30 minutes of standing, PDs had a trend of

greater strength losses while standing while NPDs were able to recover strength losses (Figure 2).
Figure 1: Peak low back pain reported by participants during the control and fatigue dates.

CONCLUSIONS

Using fatigue to alter the PD hip abductor activity patterns reduced their low back pain during standing, but NPDs responses were unaffected. This implies that the hip abductor muscle group is one of multiple potential causes of the low back pain in prolonged standing. It appears as though PDs did not recover force as well as NPDs after a fatiguing exercise, however PDs reported less low back pain during the two hours in which they were recovering from fatigue. Prolonged standing in itself may introduce

muscle fatigue in PDs but not NPDs based on differences in muscle activation patterns[3], and may place this group at a higher risk for incurring low back injuries while standing[1].

STRIDE-TO-STRIDE CONTROL OF TREADMILL WALKING IN HEALTHY ELDERLY

INTRODUCTION

Intrinsic noise is ubiquitous to all biological systems and [1] and increases with age [2]. This contributes to increased gait variability as we age [3]. Increased gait variability also prospectively predicts increased fall risk in the elderly [4]. However, it is not known if such correlations are *causal*: i.e., if variability predicts fall risk *because* it indicates deleterious changes in locomotor *control*, or if it reflects "just noise".

Young healthy humans exploit redundancy to regulate variability [5,6] in walking [7] (Fig. 1). Here we determined whether healthy elderly exploit redundancy in the same way, in spite of the increased biological noise [1,2] that naturally accompanies aging.

METHODS

Young adults walking on a treadmill do *not* tightly regulate fluctuations in stride length (L_n), time (T_n), or position, but instead try to maintain speed, v, at each stride, n [7]. All $[T_n, L_n]$ combinations that equally achieve this goal (i.e., $L_n/T_n = v$) define a "Goal Equivalent Manifold" [6,7] (Fig. 1). *Goal equivalent* tangential deviations (δ_T) do not affect v. Only *goal relevant* perpendicular deviations (δ_P) do.

17 young (YH) and 17 older (OH) healthy adults each walked on a treadmill for 2 trials of 5 min each at each of 5 speeds [3]. 3D movements of their feet were recorded (Vicon, Oxford Metrics, Oxford, UK) to compute time series of L_n, T_n and stride speeds (i.e., $S_n = L_n/T_n$), as well as time series of δ_T and δ_P fluctuations relative to each GEM ([7]; Fig. 1).

Means and standard deviations were computed for each variable. We used Detrended Fluctuation Analysis (DFA) [6-8] to compute exponents, α, that quantified the degree of statistical persistence / anti-persistence in each time series. Smaller α are predicted

by controllers that rapidly *correct* stride-to-stride deviations and thus reflect greater *control* [6-8].
Figure 1: Stride lengths (L_n) vs. times (T_n) for a typical subject, showing the GEM ($L_n/T_n = v$) and scalar deviations δ_T and δ_P relative to the GEM [6,7].

We also extended our computational model of these stepping control strategies [7] to quantify how *independently* varying the noise and degree of control effort in our model would reflect observed behavior.

RESULTS
Figure 2: Variability of stride parameters (L_n, T_n, & S_n) for Young (YH) and Older (OH) healthy adults.

Elderly subjects took shorter (p = 0.02) and faster (p < 0.001) steps than young, but maintained the same

speeds (p = 0.57) [3]. Our elderly also exhibited significantly greater variability (p < 0.04) than young subjects for all stride variables quantified (Fig. 2).

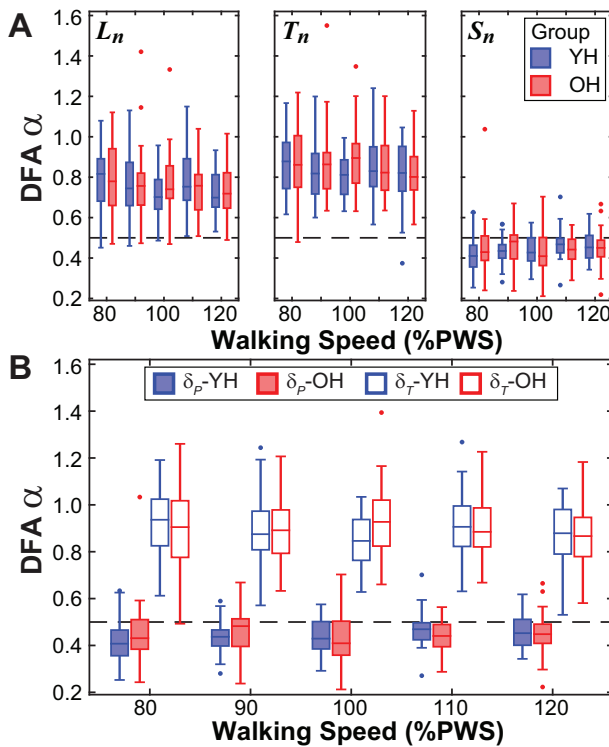
However, despite their greater variability (Fig. 2), OH subjects exhibited no differences (p = 0.52) in the relative *shapes* of their variability distributions within the [T, L] plane (not shown). These OH subjects likewise exhibited no differences in statistical persistence (α) for fluctuations in any of the stride parameters (all p > 0.56; Fig. 3A) or for fluctuations with respect to the GEM (p = 0.86; Fig. 3B).


Figure 3: DFA exponents (α) for stride parameters (**A**) and GEM variables (**B**) for YH and OH adults.

In our model (Fig. 4) increasing only intrinsic noise [1,2] produced greater variability, but no changes in statistical persistence (Fig. 4A), consistent with our experiments (Figs. 2-3). Conversely, manipulating only the degree of *control* led to minimal changes in variability, but substantial shifts in DFA α (Fig. 4B). This was contrary to our experiments, but fully consistent with theoretical expectations [6-8].

DISCUSSION AND CONCLUSIONS

These healthy elderly exploited the available [T_n, L_n] redundancy to maintain ~constant walking speed at

each stride in the same way as young subjects (Fig. 3) [7]. They exhibited the same degree of stride-to-stride control [5,6] despite increased variability (Fig. 2; [3]). We emphasize these were very *healthy* elderly who had not yet fallen and did not yet walk slower than our healthy controls. Thus, age-related increase in neuronal variability [2] alone may not indicate degraded neuromuscular *control*.

AGE-ASSOCIATED REDISTRIBUTION OF RELATIVE JOINT MOMENT ANGULAR IMPULSES IS ROBUST TO STRIDE LENGTH MANIPULATIONS

Harsh Buddhadev, Ann L. Smiley-Oyen and Philip E. Martin
Iowa State University, Ames, IA, USA
email: harshb@iastate.edu

INTRODUCTION

Compared to young adults, older adults display higher relative joint moment and power contributions at the hip and lower contributions at the ankle joint at any given speed of walking [1]. DeVita and Hortobagyi [1] speculated age-related decline in plantarflexor muscle strength is one cause for redistribution of joint moments observed in the elderly. Two recent studies [2,3] demonstrated that systematically increasing stride length (SL) at a fixed walking speed resulted in higher peak and average net joint moments and powers at the ankle and lower values at the hip in young adults. Allet et al. [3] suggested differences between young and older adults in joint moment contributions may originate in SL and cadence differences between the two age groups. However, both studies [2,3] used only young adults as participants.

There is a need for further assessment of the relationship between SL and distribution of effort across the ankle, knee, and hip during walking in young and older adults. The purpose of the study was to determine if age-associated differences in distribution of joint moment impulses are robust to SL manipulation. Hypotheses: 1) Older adults demonstrate a proximal redistribution (i.e., lower ankle and higher hip and knee contributions) compared to young adults, and; 2) longer strides are associated with higher ankle and lower hip relative contributions in both older and young adults.

METHODS

Participants were 16 healthy young (8 males and females; age, 25.3 ± 4.3 yrs; height, 172.0 ± 6.6 cm; mass, 66.1 ± 8.9 kg) and 18 older adults (8 males and 10 females; 71.8 ± 5.8 yrs, 170.7 ± 9.4 cm, 74.4 ± 16.3 kg), who were free from conditions that can affect normal walking. Reflective markers (n=21) were placed on anatomical landmarks of the participant's pelvis and right lower extremity. Participants completed three successful overground walking trials at 1.5 m·s^{-1} ($\pm 3\%$) under three SL conditions (preferred SL, preferred SL -10% of leg length (LL), preferred SL +10% LL) conditions. Three dimensional marker positions and ground reaction forces were sampled synchronously at 100 Hz and 500 Hz, respectively.

A three-segment sagittal plane inverse dynamics model was used to estimate net joint forces and moments at the ankle, knee and hip. Segment inertial properties were predicted using methods outlined by Vaughan [4]. Average extensor joint impulses normalized to body mass were calculated over the stance phase of a gait cycle for ankle, knee, and hip as described previously [2]. Based on total average extensor impulse (computed as a sum of all three average joint extensor impulses), relative impulse at the three joints were computed as a percentage of the total. A 2 x 3 repeated measures ANOVA examined the effects of age and SL on ankle, knee, and hip average and relative extensor impulses. Significant differences were considered at $p < 0.05$.

RESULTS AND DISCUSSION

For average joint impulses, a main effect was observed for knee impulse, which was greater for older compared to young adults. The total average joint moment impulses and average ankle, knee, and hip moment impulses increased as SL increased (Table 1). These results were in partial agreement with Allet and colleagues [3], who reported higher average ankle and knee impulses, but not hip impulses, for longer SL's. In partial agreement with our first hypothesis, older adults generated lower ankle and higher knee relative angular impulses compared to young adults. However, relative hip impulse was not different for young and older adults (Figure 1). In contrast to our second hypothesis,

relative ankle impulse decreased and knee impulse increased as SL increased. Relative hip impulse was unaffected by changes in SL.

These data suggest that average and relative joint impulses could change as a function of SL in both young and older adults. However, the age-associated distal-to-proximal redistribution of relative joint impulses is yet apparent as stride length was manipulated at a fixed walking speed. These findings imply that age-associated distal-to-proximal redistribution may not originate from differences in SL's chosen by young and older adults as suggested by Allet et al. [2]. Dynapenia, reduction in torque and power generating ability of the lower limb muscles, especially in the plantarflexor muscles may one of the factors underlying to the age-associated redistribution of relative joint moment impulses as suggested by previous studies. Strengthening exercises aimed at improving power in the lower limb muscles, especially the plantarflexors, may help to improve and sustain walking abilities in older adults.

CONCLUSIONS

Relative joint moment impulses displayed an age-associated distal-to-proximal redistribution (i.e., lower ankle and higher knee contributions) when SL's was manipulated at fixed walking speed. With increase in SL, relative ankle moment impulses reduced and knee moment impulses increased. Dynapenia of lower limb muscles may the mechanism contributing to the distal-to-proximal shift. Thus, strengthening exercises aimed at improving power in the lower limb muscles may help to improve and sustain walking abilities in older adults.

Figure 1: Relative joint extensor impulses (%) as a function of age and SL during the stance phase of walking at 1.5 m·s^{-1}. Older adults exerted lower relative ankle (*p*=0.000) and higher relative knee (*p*=0.003) impulses compared to young adults. Relative ankle impulses decreased (*p*=0.000), knee impulses increased (*p*=0.000), and hip impulses were unchanged (*p*=0.632) as SL was increased. These relative extensor impulse data were computed over the stance phase at a walking speed of 1.5 m·s^{-1}.

THE EFFECT OF FATIGUE ON KNEE MECHANICS IN OLDER ADULTS: DOES PHYSICAL ACTIVITY MATTER?

Jocelyn F. Hafer, Jane A. Kent, and Katherine A. Boyer
University of Massachusetts Amherst
email: jhafer@kin.umass.edu

INTRODUCTION

Aging is often associated with a change in gait mechanics and it is possible that these changes contribute to the incidence of knee osteoarthritis (OA), a mechanically mediated, age-related disease. Differences in gait mechanics between healthy young and older adults appear to follow a similar trend as differences between healthy older adults and older adults with knee OA [1]. Given the potential importance of gait mechanics for maintenance of joint health, there exists an urgent need to understand the factors that contribute to age-related changes in gait mechanics.

Compared with young adults, older adults have lower baseline knee extensor strength and greater muscle fatigue during rapid, high-velocity dynamic contractions. As the knee extensors are prime movers in gait, fatigue accumulated throughout the day in these muscles could result in changes in gait mechanics. The purpose of this study was to determine whether a bout of treadmill walking induces knee extensor fatigue and changes in knee mechanics in healthy older adults. Because habitual physical activity (PA) is a potential mediator of knee extensor strength in aging, we also examined the effect of usual PA level by comparing the responses to treadmill walking in sedentary and highly active older adults. We hypothesized that the treadmill protocol would induce a larger drop in knee extensor power as well as larger changes in knee mechanics in older sedentary adults compared with older runners.

METHODS

Healthy adults aged 55-75 with BMI <25 were recruited in two groups: those who ran ≥15 miles/wk, and those who were sedentary (<150 min of moderate to vigorous PA per week). Participants completed baseline gait and strength testing, a 30 minute bout of treadmill walking (30MTW), and post-30MTW gait and strength testing.

Gait testing consisted of motion capture of 5 strides of right-sided overground walking data at each participant's preferred walking speed. Joint kinematics were calculated using the point cluster technique, which allows for calculation of joint rotations as well as translations at the knee [2]. Externally referenced moments were calculated using inverse dynamics and normalized to body mass and height. Knee extensor (KE) concentric and eccentric power were assessed at 90, 180, and 270°/s using an isokinetic dynamometer (Humac Norm, Cybex). KE isometric strength was assessed at 60° of knee flexion.

After baseline gait and strength testing, all participants completed the 30MTW at their preferred overground speed. This protocol, which includes 3 1-minute "challenge" periods during which the grade is increased to 3%, has been shown to induce knee extensor fatigue in older women [3]. Pre- to post- 30MTW changes in KE power and strength (%), as well as changes in knee mechanics relevant to knee OA (knee flexion at heel strike, peak knee flexion during loading response, peak knee adduction angle, anterior femoral displacement at heel strike, anterior femoral displacement during loading response, peak knee flexion moment, and peak knee adduction moment) were calculated. Paired t-tests were used to compare changes within groups in KE power pre- to post-30MTW. Unpaired t-tests were used to compare changes in power and knee mechanics between groups post-30MWT. T-tests were one-tailed as we hypothesized a larger drop in KE power and a larger increase in knee mechanics variables in sedentary older adults. Due to the preliminary nature of the current results, significance was set at $p \leq 0.10$. Effect sizes were calculated for unpaired tests at a 95% confidence level.

RESULTS

Currently, participants include 6 runners (2 female), 62.8±4.3 years, BMI 22.6±1.6 kg/m^2 and 3

sedentary older adults (1 female), 64.7±3.1 years, BMI 23.13±2.1 kg/m². KE power data were excluded for one runner due to a strong learning effect from pre- to post- strength testing. Average preferred walking speed and stride length normalized to height for the runners and sedentary adults were 1.4±0.1 m/s, 0.9±0.1; and 1.4±0.1 m/s, 0.8±0.1, respectively.

In response to the 30MTW, sedentary older adults displayed a significant drop in eccentric muscle power at 270°/s while older runners had decreases in eccentric KE power at 270 and 180°/s and in concentric KE power at 270°/s. For eccentric power at 270°/s and for isometric strength, the drop was larger in sedentary older adults compared to runners, with effect sizes of 1.14 and 0.87, respectively (Figure 1).

For knee mechanics outcomes in response to the 30MTW, the sedentary group showed an increase in peak knee adduction angle and peak knee adduction moment, while these variables decreased in the runners. Effect size calculations indicated larger increases in sedentary older adults than runners in peak knee flexion and femoral anterior displacement during loading response, as well as in peak knee flexion moment (Table 1).

CONCLUSIONS
In response to the 30MTW, older sedentary adults displayed a larger decrease in eccentric KE power at 270°/s as well as in isometric strength compared with older runners. In addition, runners displayed a significant decrease in KE power at high eccentric

and concentric contraction velocities (Figure 1). These findings demonstrate that both inactive and active older adults experience measurable muscle fatigue in response to a bout of walking comparable to daily activity.

Sedentary older adults had larger increases in most of the knee mechanics variables in response to the 30MTW as compared to older runners. The finding of larger increases in peak frontal plane variables are particularly relevant to knee joint health, as frontal knee malalignment and increased knee adduction moment have been tied to higher risk of knee OA [4]. This shift in knee mechanics in sedentary older adults follows the direction of differences observed between older asymptomatic adults and older adults with knee OA [1] and may indicate that these individuals are at risk of accumulating cartilage damage as they fatigue through daily activity. Our results suggest that maintenance of vigorous habitual PA may protect older adults from changes in gait mechanics induced by muscle fatigue.

INCREASED LATERAL FOREFOOT PRESSURE REGULARITY IN OLDER ADULTS IS INDEPENDENT OF GAIT VELOCITY

INTRODUCTION

Aging is a non-homogenous degeneration of biological processes ultimately leading to a loss of physiologic complexity [1]. As we age, the foot bone and ligament structural properties are altered leading to changes in plantar pressure distributions [2]. In addition, plantar soft tissue in older adults displays increased stiffness and an altered response to changing impact velocity [3]. Older adults walk with a conservative gait pattern [4] and one out of three present with a foot deformity [5]. Moreover, studies investigating the effects of aging on plantar pressure distributions have found decreased peak pressures in the heel and medial foot masks in older adults [6]. The regularity of peak pressures, within a spectrum of walking velocities, can provide insight into the preferred loading behavior and potential gait differences due to aging.

If a movement is too regular, it lacks the flexibility to adapt to an external perturbation whereas, a highly irregular movement is uncoordinated. Either of these extreme conditions are a potential mechanism for gait abnormalities among older adults. The theory of optimal variability proposes that there exists an ideal range of variation in the inherent fluctuations during movement that is advantageous to human performance and describes healthy movement patterns [7]. Optimal variability models the complexity and predictability (i.e., regularity) of a time series; moderate levels of predictability and high complexity are key components of a healthy physiologic process.

The primary goal of this research was to identify alterations in peak plantar pressure variability due to aging and walking velocity. Specifically, we aimed to quantify the amount and temporal structure of peak pressure variability under distinct anatomical regions of the foot during consecutive stance cycles.

It was hypothesized that older adults would present with a decreased amount of variability (as measured by standard deviation (SD) and coefficient of variation (CV)) and increased regularity (as measured by sample entropy (SampEn) of peak pressures in the lateral forefoot due to changes in foot structure and a reduction in medial pressures but not lateral in older adults [3, 6]. Secondly, it was hypothesized that, for both groups, the amount of variability would decrease and the temporal structure would become increasingly regular at faster walking velocities due to increased effects of inertia on foot roll over dynamics.

METHODS

Ten healthy young adults (25.8y±2.7) and 10 healthy older adults (75.1y±6.7) participated in this study. A clinical foot evaluation was conducted in order to document foot deformities and anthropometric measurements were obtained. Subjects were then fitted to a control shoe (Dart VI, Nike) with a pair of pressure sensitive insoles (PedarX, Novel Electronics) inside. Subjects were given a 5-10 minute period to adapt to the footwear and treadmill. During this time self-selected walking speed (SSWS) was determined. Subjects then walked on the treadmill for 10 minutes for three different speed conditions (3 minutes rest between trials) while plantar pressure data was collected. The first trial was always the SSWS condition. The following two speed conditions were randomized to either ±20% of the SSWS.

The pressure insole was masked into 7 anatomic regions (Figure 1). The amount and temporal structure of peak pressure variability in the right foot was used for comparisons. Regional peak pressure SD, CV, and SampEn (r=0.25, m=2) was calculated from 400 consecutive steps (N). SSWS was compared between groups using an

independent t-test. The SD, CV, and SampEn of the regional peak pressures were compared using a 2x3 repeated measures ANOVA (2 groups x 3 speeds). If a dependent variable violated assumptions of sphericity, a Greenhouse-Geisser correction was reported.
Figure 1: Plantar pressures were masked into the following regions for analysis: R1) Heel, R2) Lateral mid-foot, R3) Medial mid-foot, R4) Lateral metatarsals, R5) First metatarsal, R6) Lateral toes, and R7) Hallux.

RESULTS AND DISCUSSION

The SSWS of older adults was significantly reduced as compared to the younger group (p=0.02). A main effect for group was found in the SampEn of the lateral metatarsal region, R4, ($F_{2,36}$ =17.79, p=0.001) indicating a significant increase in the lateral forefoot regularity in older adults. This result partially supports the first hypothesis. It was also hypothesized that there would be decreases in the SD and CV in the lateral forefoot, however, no changes were identified. This is not unexpected, as temporal structure of variability measures have been shown to discriminate between groups when amount of variability cannot [7]. Despite insignificant findings, other lateral regions trended towards regularity in older adults. A group effect was nearly detected in the SampEn of the lateral mid-foot, R2, ($F_{2,36}$=3.95, p=0.06) and lateral toes, R6, ($F_{2,36}$=3.2, p=0.09). Increased sample size may improve significance in these regions.

A main effect for speed was found for the SD of the lateral mid-foot, R2, ($F_{1.39,25.05}$=14.1, p<0.001) and the medial mid-foot, R3, ($F_{1.29,23.29}$=3.98, p=0.049). In addition, a main effect for speed was found in the CV of the heel, R1, ($F_{2,36}$=14.1, p<0.001), lateral mid-foot, R2, ($F_{1.43,25.7}$=8.79, p=0.003), lateral metatarsals, R4, ($F_{2,36}$=6.48, p=0.004), lateral toes, R6, ($F_{2,36}$=9.32, p= 0.001). These variables were all decreased in the fast velocity compared to both of the other conditions. The slow speed was significantly increased from both other conditions in the lateral mid-foot, R2, SD and for CV in the heel and lateral mid-foot, R1 and R2. These results support part of the second hypothesis, however, no main effects for speed were found in SampEn. Mean pressure increased with higher velocity resulting in the amount of variability, SD and CV, to decrease. However, SampEn is independent of the mean and depends on the fluctuations in the behavior from step to step. It is possible that the ±20% SSWS was an insufficient perturbation to one or both of these populations.

A significant interaction was found in the CV of the hallux, R7, ($F_{2,36}$=4.33, p=0.021). Both groups demonstrated a decrease in CV from slow to the fastest speed; however, in young adults reduction in CV from SSWS to +20% was significantly greater. This is likely attributed to similar variation but reduced pressure in older adults.

CONCLUSIONS

These results suggest increasingly repetitive peak pressures under the lateral metatarsals in older adults. Increasing regularity indicates an adaptive process to gait that allows older adults to gain consistent sensory information from the environment. These findings indicate that amount of variability is more sensitive to changing gait velocity. These results support findings from other studies that the amount and temporal structure of variability provide different information [7]. This may have further implications for elderly persons with foot pain, diabetic ulcers, or at risk for falls.

Visual Perturbations, but not a Cognitive Challenge, Induce an Increase in Muscle Co-Activation during Gait in Healthy Old Adults

Carrie A. Francis, Jason R. Franz and Darryl G. Thelen

University of Wisconsin-Madison, Madison, WI, USA
email: carrie.francis@wisc.edu, web: http://uwnmbl.engr.wisc.edu/

INTRODUCTION

Old adults are often at greater risk of falling during locomotion. Age-related declines in integration and quality of sensory feedback likely contribute to fall risk. Our recent studies show that old adults rely more on vision to inform balance control during gait [1-2]. This visual reliance may compensate for age-related declines in quality of somatosensory and vestibular feedback [3-4]. Alternatively, changes in executive function may alter the integration of sensory information and planning motor actions [5]. Fear of falling may also contribute to greater fall risk by leading old adults to limit physical activity, compounding losses in strength and coordination [6]. Moreover, increases in antagonist muscle co-activation – a presumably protective mechanisms to stiffen the joints, often seen in old adults – may be an indicator of fear of falling or a sign of disrupted balance [7]. Better understanding of the way that sensorimotor changes with age affect balance during gait may allow earlier detection of fall risk and improved intervention strategies.

To this end, a number of studies have investigated biomechanical differences in gait between healthy old and young adults, often focusing on gait variability. In these studies, age-related differences in gait variability are enhanced by making walking more challenging. However, there is little consensus on the challenge to use with approaches including physical and cognitive (dual-task) challenges and sensory manipulation. In this study, we investigated changes in leg muscle activation patterns in old and young adults walking normally, with a visual perturbation, and while performing a dual task (serial 7 subtractions).

Based on kinematic findings with these tasks [2], we hypothesized that when healthy old and young adults walked normally or with a dual task, the two groups would exhibit similar muscle activation patterns. We further hypothesized that old adults would perceive visual perturbations as a greater threat to balance than young adults, which would be reflected in an increase in muscle co-activation.

METHODS

Twelve healthy young (23.6 ± 3.9 years) and ten healthy old adults (71.0 ± 4.4 years) walked on a treadmill facing a semi-circular screen showing a speed-matched virtual hallway (Fig. 1a). Subjects walked at their preferred overground speed on a treadmill and completed a 3-minute trial for each of three conditions: normal walking, visual perturbations, and a dual task.
Figure 1. a) A subject walks on an instrumented treadmill while watching a virtual hallway. b) The sum of sinusoids used to produce mediolateral perturbation of the virtual hallway.

During the visual perturbation, the virtual hallway rotated continuously in the mediolateral direction according to the sum of two sinusoids (0.135 and 0.0442 Hz) with 0.175 m amplitudes (Fig. 1b). For the dual task, subjects performed serial 7 subtractions starting at a given three-digit number.

We collected lower limb kinematics and bilateral EMG from five muscles - medial hamstrings (MH), vastus lateralis (VL), medial gastrocnemius (MG), soleus (SL), and tibialis anterior (TA). EMG data were band-pass filtered (1 – 350 Hz), rectified, and then low-pass filtered with a 10 Hz cut-off to obtain activation envelopes. EMG data were partitioned into gait cycles identified from the kinematic data. Subjects' EMG data were averaged over each trial and normalized to the root-mean-square for the normal trial. Left and right EMG were then combined and group averages computed. Using a repeated measures ANOVA, we compared EMG signals from five periods of the gait cycle: loading response (0-10%), mid-stance (10-30%), terminal stance and pre-swing (30-60%), initial swing (60-73%), and terminal swing (87-100%) [7].

RESULTS AND DISCUSSION

Muscle activation patterns did not differ between healthy old and young adults during normal walking, and only exhibited minor differences in the dual task condition. Young adults increased TA activity during the loading response of the dual task. Young adults' TA activity was also greater than that of old adults during loading response and terminal swing. Previously observed gait changes in healthy adults under dual task conditions is mixed, but some studies suggest that young adults are more likely than old to prioritize gait in an attention-dividing condition [5].

Substantial aging effects were observed in visually perturbed gait, with old adults increasing activation of the quadriceps, hamstrings and plantarflexors. Specifically, compared to normal walking, old adults increased MH and VL activity during terminal swing and increased MH, VL, and SL activity during mid-stance. Compared to young adults, old adults had higher MH and VL activation during terminal swing, loading response, and mid-stance, and higher MH activation in terminal stance and pre-swing. Changes in old adults' upper leg muscle activations during visually perturbed walking were consistent with greater antagonist muscle co-activation, presumably to stabilize the leg during contact. Since the physical demands of walking during the visual trial were not altered, the increases in old adults' muscle activation would seem to be an attempt to compensate for a

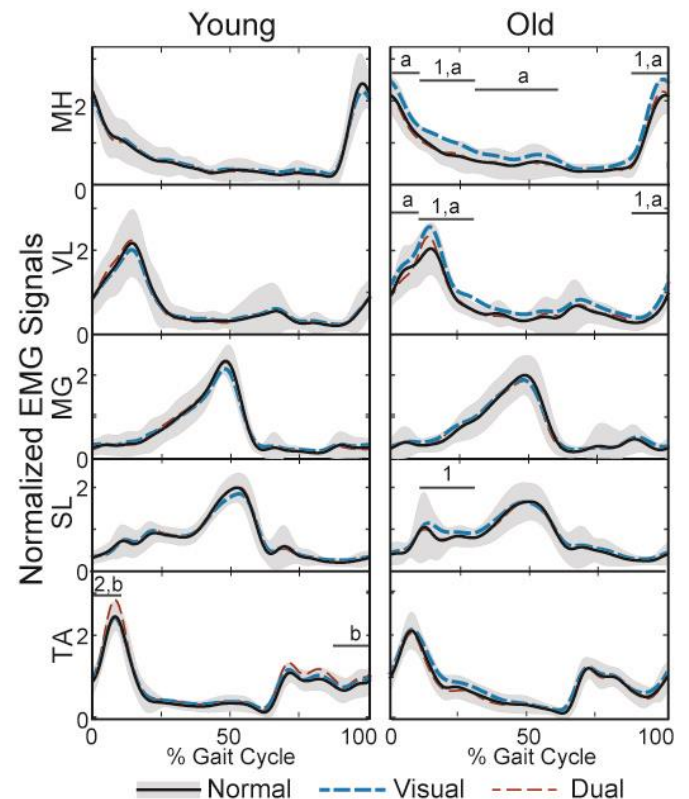
perceived threat to their balance from a decline in the quality of the visual information provided.


Figure 2: Mean ± standard deviation EMG activity for normal walking in each group plotted with mean activity for challenge trials. Significant differences are denoted: Visual vs. Normal (1), Dual Task vs. Normal (2), Age Effect-Visual (a), Age Effect-Dual Task (b).

QUANTIFYING PERFORMANCE AND EFFECTS OF LOAD CARRIAGE DURING COMPLETION OF A WINDOW OBSTACLE USING AN ARRAY OF WIRELESS INERTIAL SENSORS

INTRODUCTION

Warfighter performance is inherently challenging to quantify due to the complex tasks that warfighters perform, variations in technique, the environments in which warfighters operate, and limited knowledge of measures that truly characterize task performance beyond simple success or failure. Occupational physical performance tests, or obstacle courses, are one approach to assess the effects of fatigue and/or load on warfighter performance [1, 2]. Unfortunately, measures of the total time to complete an obstacle course or time required to complete each obstacle are typically the only quantitative metrics obtained from such tests.

Advancements in inertial measurement unit (IMU) technology make it possible for researchers to unobtrusively measure body segment kinematics in real-world environments. In this study, we utilized an array of wireless IMUs to measure the movements of subjects completing a window obstacle as quickly as possible, both with and without external load. Our objectives were: 1) to quantify changes in performance due to load, 2) to quantify changes in subject movement and 3) to identify performance metrics. We hypothesized that carrying external load would: increase the time required for subjects to complete the obstacle, decrease the ranges of motion of the pelvis and torso (due to effects of armor [3]), and decrease the angular velocities of the torso and pelvis (due to increased inertia).

METHODS

We tested 30 subjects (11 females, 19 males; age = 20.8±2.6 years; body mass = 75.4±11.1kg; height = 1.75±0.08m; mean ± standard deviation). The University of Michigan IRB approved the study,

and all subjects gave informed consent. Subjects completed an outdoor obstacle course both with and without a 20.5kg load (body armor and tactical assault panel); the order of trials (load or no load) was random. Subjects carried a mock-rifle (3.4kg) in both load conditions. The window obstacle is a freestanding wooden wall with a 0.91m×0.91m opening 1.22m off of the ground. Subjects approached the window and used any technique they chose to pass through the window as quickly as possible. The subjects then repeated the process, going through the window in the opposite direction.

We secured eight wireless IMUs (Opal, APDM, Inc.) to each subject's feet, shanks, thighs, sacrum, and torso. Each IMU contains a 3-axis accelerometer, angular rate gyro, and magnetometer; a proprietary Kalman filter estimates the directions of gravity and magnetic north relative to sensor-fixed axes. Subjects performed calibration movements prior to testing, allowing us to deduce body segment-to-sensor alignments in post-processing. Sacrum accelerations were resolved in an inertial frame and integrated to obtain vertical velocity of the sacrum. Peaks in the vertical velocity signal revealed the jump up onto and down from the window, which identified the time required for a subject to complete the window obstacle (Fig. 1) without a stopwatch or timing gates. Orientations of the torso and sacrum-mounted IMUs relative to gravity and magnetic north were used to calculate medial-lateral (ML), anterior-posterior (AP), and heading (rotation about vertical) ranges of motion for both the torso and pelvis.

We focused our analysis on 12 candidate performance metrics: total time through window (performance), 3-D ranges of motion for the torso and pelvis, and mean angular velocity magnitudes of the feet, shanks, thighs, pelvis and torso. We used

paired t-tests with a Bonferroni correction (α = 0.05/12 = 0.004) to test for significant differences between loaded and unloaded conditions.
Figure 1: Representative plot of vertical velocity of the sacrum versus time. The shaded region highlights the time interval that the subject is completing the obstacle.

RESULTS AND DISCUSSION

Load carriage resulted in a significant increase in the total time through the window (mean diff = 1.81s, t=3.67, p=0.001), consistent with other studies that demonstrate that external load decreases obstacle course performance [2]. Subjects reduced their pelvis heading angle range of motion when carrying load (mean diff = -12.35deg, t=-4.06, p<0.001) but did not significantly alter ML and AP ranges of motion of the pelvis or torso ranges of motion. The largest changes in torso and pelvis orientation typically occurred when subjects passed through the window opening. The decrease in pelvis heading angle range of motion with load indicates that subjects chose to keep their pelvises more in line with the direction of travel through the window while keeping other movements relatively unchanged from the unloaded condition. All segment mean angular velocity magnitudes decreased significantly with load carriage (t<-8.77, p<0.001 for all segments). While we expected torso and pelvis mean angular velocities to decrease due to increased inertia when carrying load, we were surprised to find that lower limb segment angular velocities also decreased, as no mass or inertia was added to the lower limbs.

Larger values of mean segment angular velocity magnitudes were correlated to higher performance (faster times); Fig. 2 illustrates this relationship for the torso. A power-law provides a good fit to the data (R^2=0.74); other segments exhibit a similar relationship. This result indicates that faster moving subjects (larger mean segment angular velocities) are able to complete the obstacle more quickly. Performance in other obstacles is likely also correlated to measures of segment angular velocity.
Figure 2: Total time to complete the window obstacle versus torso mean angular velocity magnitude.

CONCLUSIONS

Load carriage significantly reduces performance on a window obstacle, reducing the speed at which subjects move (segment angular velocities) and altering pelvis range of motion. Subject technique varies widely, and therefore it is possible that additional load effects may be revealed by considering subject technique. We also plan to continue to work with this data set to reveal common strategies that our subjects used to negotiate the window obstacle through the use of a cluster analysis or principal components analysis.

INTRODUCTION

Slips, trips and falls are among the leading causes of fireground firefighter injury [1]. With several sizes of compressed air tanks available and fire departments tending towards larger, extended duration tanks, changes in body kinematics are anticipated. This study investigated the effects of self-contained breathing apparatus size and design as well as fatigue from simulated firefighting activities on balance during a functional balance test [2].

METHODS

Thirty firefighters (29 male) used each of four self-contained breathing apparatuses (SCBA): standard cylinders providing 30, 45, and 60 minutes of air when breathing at 40 L/min (S30, S45, S60); and a low-profile prototype (P45, 45-minute) (MSA, Inc.; Murrysville, PA, USA). The functional balance test (FBT) used a ground-level balance beam with a raised platform on each end. A trial consisted of walking across the balance beam to the opposite raised platform and then returning to the starting position. Subjects performed two trials each with and without a light-weight bar across the middle of the balance beam at 75% of the subject's height. Subjects were instructed to move at fireground pace, which is common fire service terminology for moving quickly but safely.

FBT performance was quantified by completion time (sec) and error count – minor (MI) and major (MA). MI included not turning within a 24" × 24" marked space on either platform or contacting the overhead bar. MA included walking off the beam or knocking the bar off its supports. To quantify overall performance, a unit-less performance index was calculated for each trial: *PI = completion time + MI + 2*MA*. Thus, a lower PI is considered to be a better performance.

FBT trials were performed before (pre) and after (post) subjects completed an exercise protocol in a heated environmental chamber (47°C, 20% humidity) consisting of two minutes each of four simulated firefighting tasks, with two-minute rests between tasks, such that the total time for one bout was 16 minutes. The firefighting tasks were stair ascent and descent, hose advance, floor search, and ceiling pull [3]. During separate visits, subjects completed one bout (1B), two bouts with a five-minute break (2B), or back-to-back bouts in the chamber (BB). Repeated-measures ANOVAs assessed time, MI, MA, and PI for three comparison groups based on SCBA characteristics or fatigue ($\alpha = 0.05$):

    CG1) SCBA size (S30_1B, S45_1B, S60_1B)
    CG2) SCBA design (S60_1B, P45_1B)
    CG3) Bouts of exertion (S60_1B, S60_2B, S60_BB)

Subjects were binned into groups based on years of firefighting experience for additional analysis.

RESULTS AND DISCUSSION

Analysis of time, error counts, and PI indicated that there are variations in FBT-crossing ability as a result of SCBA size/design and extended duration of firefighting activities.

The CG1 analysis investigated increasing size of SCBA with one bout of activity. A significant increase in minor errors (p=0.001) was observed with the addition of an overhead bar, as well as an

increase in time (p<0.001). There was a significant increase in PI as SCBA size increased, especially for the condition with a bar overhead (Fig. 1, p<0.001). These results suggest that firefighters may have difficulty moving quickly and carefully with larger capacity tanks, increasing fall risk [4]. Binning subjects into experience groups revealed a main effect of experience for minor error counts (p=0.04). Post-hoc analysis showed that inexperienced firefighters made fewer MI than subjects with intermediate firefighting experience (Table 1, p=0.03). This trend indicates that novice firefighters may be more careful in FBT performance than intermediate ones.

Table 1: Average minor error counts for all 1B test conditions with a standard SCBA (S30, S45, S60). Subjects binned based on years of experience.

Experience Group	Years of Experience	Average MI Count (±SE)
Novice (n=9)	0.5 − 2	0.08 ± 0.07
Intermediate (n=12)	4 − 10	0.32 ± 0.06
Advanced (n=9)	16 − 25	0.21 ±0.07

The CG2 analysis sought to determine whether the low-profile prototype P45 would be helpful for avoidance of an overhead obstacle. The P45 was comparable in weight to the S60. No significant difference was found in MA because the counts were so low. PI dramatically decreased from S60 to P45 with the bar overhead, showing improved balance (Fig. 1, p=0.008).
Figure 1: Performance index relative to SCBA size and obstacle presence (used in CG1 and CG2). Standard error bars are shown.
Figure 2: Comparison of varied exercise duration with the S60 SCBA. Standard error bars are shown.

The CG3 analysis varied bouts of exercise using the S60 SCBA. An interaction effect between period and bouts was observed for PI (Fig. 2, p=0.002), showing an increased PI after longer duration of exercise. This suggests that being fatigued following BB exercise may lead to a decrease in obstacle-crossing performance.

CONCLUSIONS
These data demonstrate that changes in SCBA size/design and exercise duration can significantly affect functional balance in firefighters. Larger SCBAs may result in a loss of balance and increased mistakes when crossing obstacles, resulting in an increased risk of injury. These findings should be considered by fire departments using larger SCBA with extended duration of firefighting.

INTRODUCTION

Load carriage systems (such as backpacks) are typically designed to interface with the user directly. In many military applications, duty requirements often dictate that load carriage systems be worn over body armor. This change in load-user interface often results in a decrease in load stability. In many military career fields, such as special forces/special ops, load stability can directly affect performance and survivability, particularly during tactical engagements. The two most viable solutions to maximize load stability when an external load is worn over body armor is to develop an integrated armor/load carriage system, or modify the existing load carriage systems to provide a more stable load-user interface. While development of an integrated armor/load carriage system is ongoing, there remains many load carriage and armor systems already in use that may benefit from a redesigned user interface to maximize load stability when being worn over armor.

The purpose of this study was to quantify backpack motion relative to the user/armor system at two treadmill walking speeds, and determine the magnitude of load stabilization offered by an integrated 'bolster' system under these conditions.

METHODS

Backpack-experienced subjects (14 men, Mean ± SD: 32±7 yrs, 177.6±4.4 cm, 78.3±10.1 kg) were fitted with body armor and a pack frame onto which was mounted a 60 lb military backpack. Subjects then performed a 3-5 minute walking warm-up session in order get accustomed to the treadmill and ensure they were able to comfortably perform at the two required walking speeds (3 and 4 mph) while carrying the required load used in the study.

At each of the two walking speeds, the subjects carried the load with and without an integrated bolster system attached to the pack, for a total of four test conditions. The integrated bolster system was attached to the pack frame and served to increase contact area laterally between the load and armor system. The load remained unchanged across all testing conditions. In addition to the armor system and pack load, subjects were required to carry an M-16A2 'Rubber Ducky' rifle (i.e., simulating carrying a rifle on patrol), which weighed another 4.1 kg. The four test conditions (two walking speeds and two bolster conditions) were counterbalanced across subjects. Each trial lasted three minutes in duration, with data sampled and averaged over five strides 30 second prior to the end of each trial. A three minute rest period was provided between trials.

Linear and angular measures of motion were quantified for both the armor system and the load (backpack). Angular measures of motion included lateral (side-to-side) and anterior/posterior (front-to-back) changes in angular orientation measured directly using two 2-D inclinometers, one attached to the front plate of the armor system, and the second attached to the back of the pack. Linear measures of motion consisted of vertical, lateral, and forward linear acceleration measured using two 3-D accelerometers attached directly to each of the inclinometers on the armor system and pack. Each measure of motion was averaged over five strides and evaluated for significant differences across conditions using a multivariate 2-factor repeated measures analysis of variance ($\alpha=0.05$).

RESULTS AND DISCUSSION

All measures of linear and angular motion increased for both the pack and armor system as walking speed increased from 3 to 4 mph. With the exception of vertical acceleration, pack motion was always greater than motion of the armor system. Pack angular motion in the lateral direction was twice as much as that associated with the armor (14.1 vs 6.7 degrees respectively, p<0.001), and 25% greater (14.7 vs 11.9 degrees respectively, p<0.001) in the forward direction. Linear measures of pack motion were 81% (p<0.001) greater than armor motion in the lateral direction, and three times greater in the forward direction (p<0.001). This difference between pack and armor motion was more pronounced as walking speed increased from 3 to 4 mph. The greatest increases in pack motion as speed increased were seen in the side-to-side angular motion (56% increase, p<0.001), and lateral (89% increase, p<0.001) and forward (87% increase, p<0.001) acceleration. Motion (acceleration) of the pack and armor system in the vertical direction were very similar at the lowest walking speed, and increased by the same magnitude (~60%) as speed increased to the highest walking speeds. This was the only measure tested that was similar for both the pack and armor system across conditions (p=0.577).

Use of the integrated bolster system was most effective at reducing pack motion at the higher walking speeds, particularly in the forward and side-to-side directions (both linear and angular measures). Pack motion was reduced by 11% (p=0.010) for side-to-side angular motion, 20% for lateral acceleration (p=0.027), and 7% for forward acceleration (p=0.024) at the fastest walking speed (4 mph). Little difference was seen in pack motion when the bolster system was used at the slowest walking speed. The integrated bolster system had little influence on vertical acceleration (p=0.805) or angular pack motion in the front-to-back direction (p=0.555). This result is not surprising as the bolster system is located on the lateral aspects of the pack/load system and, as such, has very little potential to affect motion in the vertical or forward direction.

CONCLUSIONS

The results of the current study show that both pack and armor system measures of motion increase as walking speed increases, with pack motion increasing to a greater extent than armor motion for almost all measures. The use of an integrated bolster system was found to decrease the amount of pack motion, particularly at faster walking speeds. The highest walking speed tested in the current study was just under the walk/run transition speed for most subjects. Given the observed increase in pack motion associated with increased walking speeds, it is logical to assume that these increases in pack motion would be exaggerated once walk/run transition speed is exceeded and that the integrated bolster system may be even more effective at reducing pack motion with speeds exceeding the walk/run transition.

PHYSIOLOGICAL AND BIOMECHANICAL CHANGES
DURING EXECUTION OF THREE LOAD CARRIAGE PARADIGMS

INTRODUCTION

The effects of prolonged load carriage on military populations are not well characterized. Research evaluating the effects of prolonged marching by soldiers carrying an external load has focused on energy cost and not alterations to gait mechanics. Epstein et al. [1] hypothesized that fatigue of skeletal muscles alters gait biomechanics and that this change is the proximal cause of increased energy cost over time when carrying heavy loads. Patton et al. [2] maintained that several mechanisms are probably responsible for the rise in energy cost with prolonged load carrying and proposed, as Epstein et al. [1] did, that a factor of particular importance is a reduction over time in mechanical efficiency due to altered biomechanics. Changes in energy cost and in gait biomechanics that might be associated with long-duration load carriage have critical implications for successful execution of military operations by dismounted soldiers. The purpose of this study was to measure kinematic changes over time associated with three increasingly difficult prolonged load carriage paradigms, while concurrently measuring oxygen consumption ($\dot{V}O_2$).

METHODS

Eleven U.S. Army soldiers (Age, 23 ± 3 years; Ht, 178.6 ± 6.5 cm; Wt, 83.1 ± 9.0 kg; $\dot{V}O_{2peak}$, 49.1 ± 4.3 ml·kg^{-1}·min^{-1}) walked on a treadmill at 1.35 m·s^{-1} for 2 h on three nonconsecutive days. On each occasion, the soldiers were tested on a different one of 3 march paradigms: I — 6-kg load, 0% grade; II — 40-kg load, 0% grade; III — 40-kg load, 4% grade (Table 1). $\dot{V}O_2$ data (CPET, COSMED, Chicago, IL) were collected for 2 min at the beginning of the march and then every 30 min (5, 30, 60, 90, and 120 min). A mean was obtained over each 2-min recording period and the data were normalized to the individual's body mass (ml·kg^{-1}·min^{-1}). Kinematic data were also collected at the beginning of the march and then every 30 min via a 12 camera motion capture system (Oqus, Qualisys AB, Gothenburg, Sweden). Joint angles were calculated [minimum, maximum, range of motion (ROM), in degrees] for the ankle, knee, hip and trunk and averaged over 5 consecutive strides (Visual3D™, C-Motion, Inc., Germantown, MD). Single two-way, repeated-measures analyses of variance (ANOVAs) were performed to assess the effects of the 3 march paradigms and elapsed march time. In those instances in which an ANOVA yielded a significant effect ($p < .05$), post hoc analyses were performed with a Bonferroni correction applied.

RESULTS

The $\dot{V}O_2$ analysis yielded a significant interaction ($p < .001$) between march paradigm and time on the march. $\dot{V}O_2$ increased significantly from paradigm I through III, revealing increasing levels of exertion. Steady state energy expenditure was achieved early in the march with paradigm I, whereas $\dot{V}O_2$ increased as time progressed for paradigms II and III (Table 1).

Table 1: Mean (SD) $\dot{V}O_2$ (ml·kg^{-1}·min^{-1}) normalized to body mass for each paradigm and time on the march.

Paradigm (Load, Grade)	2-h March	Time (min)				
		5	30	60	90	120
I: 6 kg, 0%	13.07 (1.27)$_A$	13.03 (1.09)$_A$	13.13 (0.98)$_A$	13.05 (1.11)$_A$	13.06 (1.42)$_A$	13.07 (1.20)$_A$
II: 40 kg, 0%	17.37 (1.73)$_B$	16.71 (1.46)$_A$	16.82 (1.94)$_{AB}$	17.46 (1.71)$_{AB}$	17.56 (1.51)$_B$	18.3 (1.81)$_C$
III: 40 kg, 4%	23.86 (1.68)$_C$	22.84 (1.45)$_A$	23.42 (1.50)$_A$	23.86 (1.41)$_B$	24.40 (1.51)$_B$	24.76 (1.99)$_B$
In each row, means for Time that do not share the same subscript differed significantly in post hoc tests ($p < .05$).						

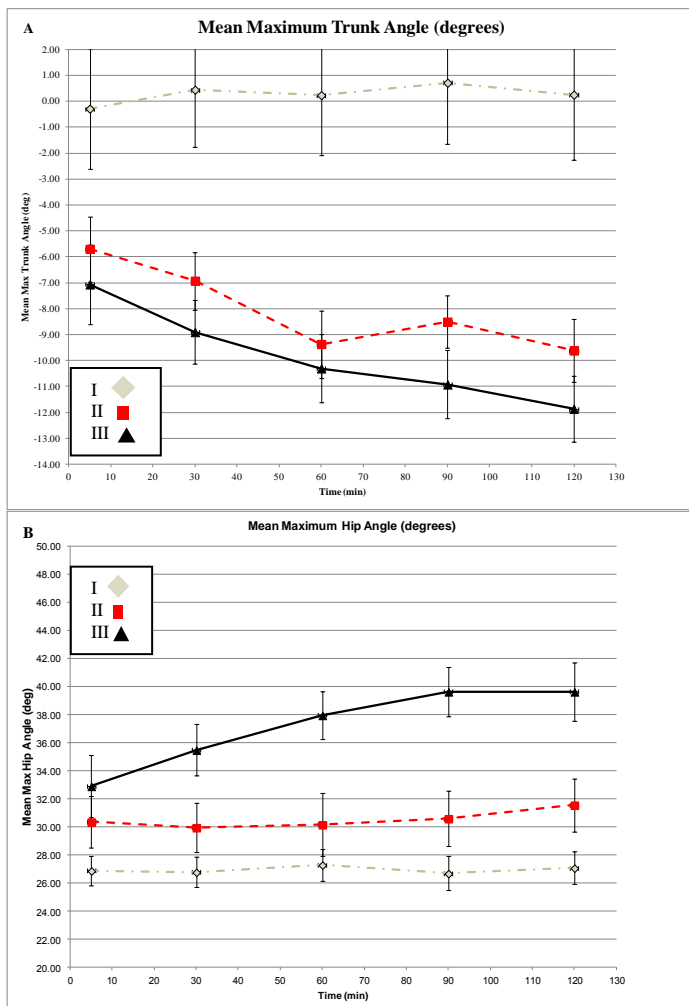
There was a significant main effect of paradigm on ankle ($p < .001$), knee ($p < .02$), and hip ($p < .001$) ROMs. Paradigm III differed significantly from paradigms I and II in post hoc tests, with higher ankle and hip and lower knee ROM (Table 2). There were significant paradigm by march time interactions for maximum trunk ($p < .001$) and hip angles ($p < .05$). As the march progressed, there was little change in these maximum angles for paradigm I, whereas paradigms II and III revealed increased flexion (Figure 1).


Figure 1: Means (*SE*) for paradigm by march time interactions on the **(A)** maximum trunk angle and **(B)** maximum hip angle measures.

DISCUSSION

A particular focus of this investigation was the alteration in gait biomechanics that previous researchers [1, 2] hypothesized was the proximal cause of the increases in the energy cost of load carrying. In consonance with the earlier findings, the results of this study showed increases in $\dot{V}O_2$ as march time increased when the heavier (40 kg) load was carried (paradigms II and III). In addition, analysis of kinematic data in the current study supported the hypotheses of Epstein et al. [1] and Patton et al. [2] insofar as changes in gait kinematics were obtained for the more strenuous march paradigms. As time on the march progressed, maximum trunk and hip angles reflected an increased flexed posture with the heavier load (paradigms II and III) compared to the lighter load (paradigm I). Joint angles for paradigm III, when compared to I and II, also differed significantly, with higher ankle and hip and lower knee ROM.

CONCLUSIONS

These study results demonstrate an association between the increases in energy cost and changes in biomechanics. Changes in energy cost and in gait biomechanics that are associated with long-duration load carriage have critical implications for successful execution of military operations by dismounted soldiers. The higher metabolic costs are likely to have a negative effect on efficient completion of a march and success in undertaking subsequent tactical operations. In addition, alterations in gait biomechanics over time may increase the probability of musculoskeletal injury.

Effects of Load Carriage and Surface Inclination on Slip and Trip Risks

Ehsan Rashedi, Hema Bhatt, and Maury A. Nussbaum

Virginia Tech, Blacksburg, VA, USA
email: nussbaum@vt.edu

INTRODUCTION

Slips, trips, and falls continue to be significant occupational safety concerns, and causes of occupational injuries and fatalities in the workplace and daily activities. While extensive gait research has focused mainly on level walking, less evidence is available for inclined surfaces. The latter is particularly important since walking on inclined surfaces increases the risk of instability and slips, due to the generation of higher shear forces.

Diverse work environments (e.g., construction and agriculture) require load carriage during walking on inclined surfaces. However, few studies have assessed the risks of slips or trips in such conditions. To our knowldege, this is the first study that specifically investigated different methods of load carriage without the use of packs or other assistive devices and the influence of walking on inclined surfaces. We hypothesized that surface inclination, load carriage method, and load magnitude would significantly affect biomechanical parameters related to the risks of slipping or tripping.

METHODS

Twenty participants (gender balanced), with no self-reported musculoskeletal disorders, completed the experiment after giving informed consent (procedures approved by the VT IRB). Respective means (SD) for age, stature, and body mass were 26.1 (3.3) yrs, 167.9 (7.4) cm, and 72.3 (9.0) kg. Each participant walked in 12 different loaded conditions (e.g., Fig. 1). The 12 conditions involved all combinations of: 1) three *surface inclinations* (SIs): level, up and down a 20° incline, 2) two types of *Load Carriage* (LC): on head and posterior load carriage (on upper back), and 3) two *Load Magnitudes* (LM): medium (7.5 kg) and heavy (15 kg) loads. Dependent variables were step length (SL), walking velocity (WV), required coefficient of friction (RCOF), heel contact velocity (HCV), and minimum toe clearance (MTC), each of which were normalized to values from additional no-load conditions.

Consistent shoes were provided to the participants, and 18 passive retro-reflective markers were placed over bony landmarks to track segmental kinematics using a 9-camera system (Vicon Motion System Inc., Los Angeles, CA, USA). Kinematic data were recorded at 120 Hz, and low-pass filtered with a cutoff frequency of 5 Hz. Ground reaction forces were sampled (960 Hz) from two force platforms (AMTI OR6-7-1000, Watertown, MA, USA), and low-pass filtered at 12 Hz.

Separate repeated-measures analyses of variance were performed to assess the effects of SI, LC, and LM on each normalized dependent measure, with *post hoc* comparisons done using Tukey's HSD. Student t tests were used to compare conditions to the relevant no-load conditions. All statistical analyses were conducted using JMP Pro 11 (SAS Institute Inc., Cary, NC), and statistical significance was determined when $p < 0.05$.

RESULTS AND DISCUSSION

All dependent measures were significantly affected by SI (Table 1), with substantial effects in some cases (Fig. 2). Compared to the level walking, SL decreased by 5.3% going uphill, while WV and HCV respectively decreased by 2.4 and 10.4% going downhill. There were 7.4 and 6.4% decreases in RCOF during downhill and uphill walking, respectively. MTC during downhill walking was 8.9% larger than in level walking. Main effects of LC and LM were only significant on WV. Normalized WV was 1% lower when carrying the heavier loads, while it was 2% higher carrying the load on the back. During level walking, RCOF was

larger for on head versus posterior load carriage (~5%).

RCOF and HCV are the main parameters associated with friction demand during human gait [1]. A slip event can be initiated when the required friction demand exceeds the available friction. In all surface conditions, RCOF increased relative to the no-load condition, especially during level walking (~9.3%), indicating a higher risk of slip initiation. An increase in HCV has been considered to increase the likelihood of slip-induced falls [2]. Similar to previous work [1], HCV decreased with load carriage, and is likely related to adoption of slower gait (~3.8%). However, the decrease in WV was not as large as the decline of HCV, which was more pronounced in downhill walking. Specifically, WV decreased by 5.3%, while HCV decreased by 13.6%, and which might indicate adoption of safer gait to decrease slip risk during the most risky condition (walking downhill). Decreased MTC increases trip risk, and which may increase the risk of fall-related injuries [3]. While carrying a load, MTC decreased during uphill (~0.9%) and flat (~3.3%) walking, and suggests a higher trip risk.

Overall, SI was the most influential factor in this study. Except for WV, use of different LMs did not significantly affect any of the dependent variables. Similarly, the main effect of LC method (i.e., on head versus posterior load carriage) was only significant on WV. Considering RCOF, LC method was mainly influential while walking over the flat surface. In summary, interventions to decrease the risk of slips, trips, and falls while carrying a load on different surfaces may focus more on *Surface Inclination*, rather than the *Load Magnitude* or the *Load Carriage* method.

Table 1: Summary of ANOVA results (*p* values) for main and interactive effects of SI, LC, and LM.

	SI	LC	LM	SI×LC	SI×LM	LC×LM
SL	**<0.0001**	0.19	0.48	0.39	0.65	0.82
WV	**0.0013**	**0.0132**	**0.0170**	0.08	0.21	0.94
HCV	**0.0033**	0.31	0.15	0.06	0.70	0.94
RCOF	**<0.0001**	0.28	0.40	**0.0053**	0.61	0.50
MTC	**<0.0001**	0.15	0.52	0.41	0.63	0.88

A CLINICAL PERSPECTIVE ON PROSTHETICS

[1] Francois. J. Van Der Watt
[1] LIM Innovations, San Francisco, CA, USA
email: fvanderwatt@liminnovations.com, web: www.liminnovations.com

INTRODUCTION

To better understand the capabilities of wearable active and passive leg prostheses, it is important to gain a perspective of the history of these devices. Thus, I will provide a general overview of lower limb prosthetic devices that will cover prosthetic device development since World War II [1] as well as the functional and clinical limitations of these devices for people with lower limb amputations. I will also present an introduction to present day micro-processor controlled devices and powered prosthetic devices for different levels of amputation. Sport or activity specific devices will also be discussed as many people with lower limb amputation require prosthetic devices that can improve their sport performance as well as allow them to lead an active lifestyle that would not be possible with conventional prosthetic devices.

TECHNOLOGY

Following WWII, the need for prosthetic devices grew substantially due to injuries sustained in the war. This dramatic increase in service members with amputations facilitated rapid development of lower limb prostheses. To understand the potential functional benefits or drawbacks of these devices, I will establish a timeline of the advancements made in prosthetic devices and the technological development of prostheses up to today (Fig. 1). Further, I will discuss the role and contribution of the Department of Veterans Affairs (VA) in the development and research of prosthetic devices.

CURRENT PROSTHETIC DEVICES

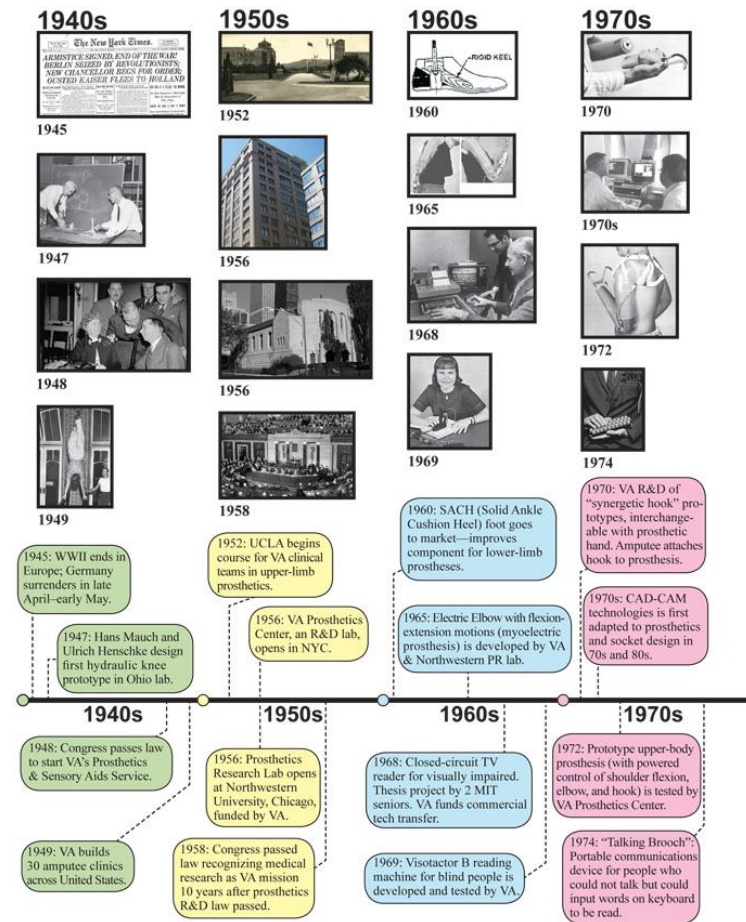
Current day commercially available prosthetic devices and components have the potential to improve locomotion and function for people with a leg amputation. Examples of these prostheses and components include microprocessor controlled (MPC) and powered controlled (PC) prosthetic devices, the C-Leg by Otto Bock (Germany), the


Figure 1. Chronology of Department of Veterans Affairs (VA) Optimization Study.

Figure 2. Power Knee (Össur)

Rheo Knee and Power Knee (Fig. 2) by Össur (Iceland), the BiOM T2 System Foot (Fig. 3) by BiOM (USA) and the Proprio Foot by Össur

(Iceland) [2-5]. Sport specific prosthetic devices like the Cheetah foot (Fig. 4) by Össur can improve activity specific sport performance and I will discuss the implications for future development of these activity specific devices.

Figure 3. BiOM T2 Foot (BiOM)

Figure 4. Cheetah Foot (Össur)

FUTURE DEVELOPMENTS

Clinical indications for future developments are needed in the functioning of prosthetic devices. The future functional and outcome requirements of the amputee population should be considered in developing the next generation of prosthetic devices that include a powered driven or a passive prosthetic device. Considerations for integrated prosthetic devices to include the socket system will also be discussed. Integrated systems can include various levels of micro processing function and communication of control mechanisms in the complete prosthetic device. A brief discussion will follow of the future development and research of

neuro-integrated and osseo-integrated (Fig. 5) prosthetic devices.

Figure 5. Osseointegration

CONCLUSIONS

The history of prosthetic device development post WWII up to present day provides an important context for current devices. The advancement of technology and the role in prosthetic device development to improve function and outcomes for the lower limb amputee will be presented. The clinical considerations will be discussed in the development of the next generation of advanced prosthetic devices for the lower limb amputee population. The continued need for sport performance for amputee athletes and the role of prosthetic devices used in human performance will demonstrate the need for improved future prosthetic device design and development.

ANKLE-FOOT PROSTHESES FOR IMPROVED BALANCE AND STABILITY DURING STANDING AND SLOPED WALKING

[1-2] Andrew Hansen, [1] Eric Nickel, [3] Jonathan Sensinger, [1-2] Stuart Fairhurst,
[1] Steve Morin, [1] Sara Koehler-McNicholas, [1-2] John Ferguson

[1] Minneapolis VA Health Care System, Minneapolis, MN, USA

[3] University of New Brunswick, Fredericton, New Brunswick, Canada
e-mail: Andrew.Hansen2@va.gov

INTRODUCTION

Many persons with lower-limb amputations have low balance confidence, which is associated with reduced mobility and social activities [1]. Persons with amputations also fall at a high rate [2, 3]. The circumstances that lead to falling and reduced balance confidence are not well understood. However, differences in biomechanics between physiologic and prosthetic ankle-foot systems for different functional tasks (e.g. standing) and walking conditions (e.g. sloped terrain) suggest advancements that may improve future outcomes.

The physiologic ankle-foot system conforms to a curved effective rocker shape for level walking and to a flat effective rocker shape for standing and fore-aft swaying [4]. Our measurements of over forty prosthetic feet commercially available in the 2000s suggest that designs were focused on providing good function for level walking, with less focus on standing function. Roll-over shapes of prosthetic feet tested had radii much closer to that of the able-bodied ankle-foot system during walking than during standing and fore-aft swaying.

The physiologic lower-limb system adapts for uphill and downhill walking, with a net "dorsiflexion" of the leg's effective rocker shape for uphill slopes and a net "plantarflexion" of the effective rocker shape for downhill slopes [5]. Many prosthetic feet provide good function for level walking. However, most do not alter their characteristics for walking on sloped surfaces. The systems that do adapt their function for sloped walking often have delays associated with the use of sensors to estimate the surface slope, or they utilize damping that removes energy from the system.

Our group's development efforts in ankle-foot prostheses have been focused on improving balance and stability during standing and sloped walking. Improving balance and stability of lower-limb prosthesis users during standing and sloped walking may lead to increased balance confidence, reductions in falling, and increased participation in life activities (e.g. family, work, and community).

METHODS

Our group has recently developed a bimodal ankle foot-system [6] that provides a curved effective rocker shape for walking and a flat effective rocker shape for standing (Fig. 1). The bimodal ankle-foot system has an automatic switching circuit that utilizes a gyroscope to determine whether the user is walking or standing. A smartphone application can be used to manually control the ankle when the automatic mode is not desired.
Figure 1: (Left) Bimodal ankle in walking mode (top) and standing mode (bottom). (Right) Effective shapes for walking, standing, and swaying for able-bodied persons (top) and for the bimodal ankle (bottom).

Our group has also been working on ankle-foot prostheses that adapt their equilibrium-point by allowing the foot to "find" the walking surface under a low stiffness, and then engaging a higher stiffness element at foot flat [7]. This "EquiFoot" approach provides adaptation to walking slopes on every step of walking and has been demonstrated with mechanically passive prototypes (Fig. 2).

Figure 2: (Left) Photograph of the EquiFoot adaptable ankle-foot prosthesis. (Right) The EquiFoot at "foot flat" on different slopes (i.e., the time used to set the equilibrium-point of the ankle).

RESULTS AND DISCUSSION

Our group has built working prototypes of both the bimodal and EquiFoot ankle-foot prostheses and has conducted limited pilot testing in the laboratory. Results from mechanical testing of the bimodal ankle demonstrate that the standing mode provides a rocker radius that is above the center of mass of the body, creating a mechanically stable system [6].
Figure 3: Effective rocker radii for able-bodied, bimodal, and single-axis prosthetic feet. The bimodal ankle provides a stable base for standing.

Testing of the bimodal ankle-foot system with one person with transtibial amputation demonstrated improvements in balance when using the system in standing mode compared with walking mode. The subject also commented that it was the most stable he had felt during standing since his amputation.

Three persons with transtibial amputations have provided feedback on the EquiFoot prototype shown in Fig. 2. For all subjects, the ankle torque versus ankle angle curves were shifted toward dorsiflexion for uphill walking and toward plantarflexion for downhill walking. Subjects commented that it was more comfortable and took less exertion to walk on sloped surfaces with the EquiFoot compared to their usual non-adaptable prosthetic feet.

Current work on these projects includes further development toward commercially-viable ankle-foot prostheses as well as human subjects testing in the laboratory. Future work will include technology transfer and long-term clinical testing to determine if use of these systems will lead to increased participation in life activities.

INTRODUCTION

Lower limb amputees typically expend 10-30% additional metabolic cost to walk depending on gait speed and amputation level as compared with able-bodied individuals. Many also experience significant gait asymmetry, lower back pain, slower walking speeds, reduced activity levels, and overuse injuries on their unaffected limb.

An intelligent, powered ankle prosthesis has been developed that provides the user with a fully powered and properly timed push-off, picks the toe up in the swing phase, and provides a more natural and energy efficient gait to below the knee amputees. The Ruggedized Odyssey Ankle (ROA), Fig. 1, utilizes a compliant actuator to store the natural braking energy just after heel strike, while a small lightweight motor adds additional energy to the step[1].

Table 1 lists important properties of the ROA device. These performance specifications are made possible by the uniquely tuned ankle spring, the energy store and release actuation scheme, and our continuous (non-state based) gait controllers [2]. Our control scheme examines the phase plane of the tibia's angular velocity and elevation angle to determine a proper actuator position. An actuator position surface was previously developed in terms of walking gait percent and stride length [2]. This surface was recently adapted to include running gait, Fig. 2.

Table 1: ROA Specifications

Mass of Device (kg)	2.5
Maximum Dorsiflexion (deg)	26
Maximum Plantarflexion (deg)	38
Peak Ankle Torque Output (Nm)	190
Max Output Power @ Ankle (W)	1,100

Figure 2: Actuator Position Surface; Illustrates the Walking, Transition, and Running Regions.

METHODS

Pilot data have been collected from two otherwise healthy and high functioning unilateral transtibial amputees, Table 2**.** Ankle angle, moment and power information were derived from embedded sensors on ROA. Video recordings were made from several of the sessions. Prior to data collection, each participant

wore ROA and walked or ran on the treadmill at various speeds while the device's timing and power were tuned. After completion of the tuning procedure adequate time was allowed for the participant to gain familiarity with the device. This included walking and running over ground.

Table 2: Specification for the two male participants of the pilot study.

Sub #	Weight	Age	K-Level	Affliction
001	72 (kg)	58	K4	Transtibial
002	84 (kg)	36	K4	Transtibial

RESULTS & DISCUSSION

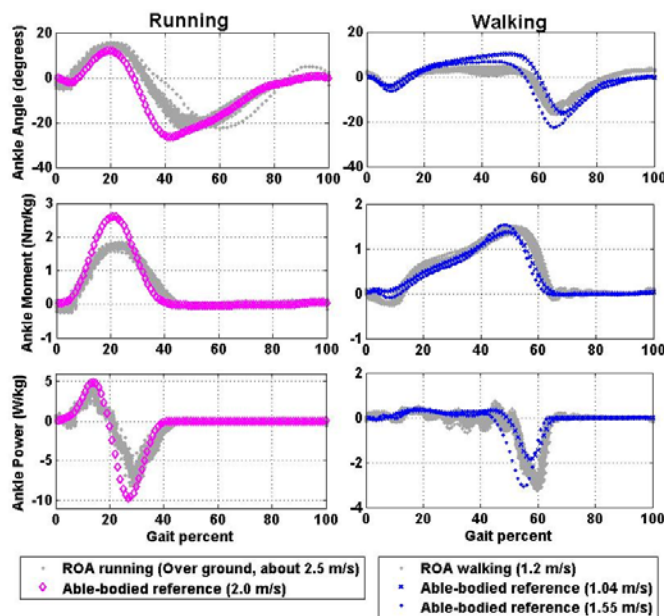
Fig. 3 (left) compares ROA treadmill running (Subject# 001) from 1.6 to 2.5 m/s (3.6 to 6 mph) to able-bodied treadmill running data[3] at 2.0 m/s (4.5 mph). This figure demonstrates that the kinematics and kinetics supported by ROA have similar characteristics as able-bodied gait. The ROA walking data, Fig. 3 (right), were collected on the treadmill at 1.2 m/s (2.7 mph), while the able-bodied comparison data is for treadmill gait at 1.04 m/s (2.3 mph) and 1.55 m/s (3.5 mph). Measured ankle


Figure 3: Ankle Angle, Normalized Moment and Power of ROA during Running and Walking for Subject# 001 Compared to Able-Bodied Data

angles, moments and powers are comparable to the able-bodied data.

Fig. 4, illustrates the average kinematics and kinetics over 18 treadmill walking steps for subject 002 at 3.3 mph. Ankle range of motion, moment and power

have shape, timing and amplitude characteristics of able-bodied norms.

CONCLUSION

Initial testing of ROA shows a strong correlation with able-bodied kinematics and kinetics for both walking and running gaits. Future work will focus on clinical trials to fully understand how powered ankle systems affect amputees from a whole-body perspective and to identify the amputee groups that will benefit the most from the technology.

PROSTHETIC LIMBS THAT REDUCE THE ENERGY COST OF WALKING TO BELOW NON-AMPUTEE LEVELS ARE POSSIBLE BUT HARD TO DISCOVER

Steven H. Collins

Carnegie Mellon University, Pittsburgh, PA, USA
stevecollins@cmu.edu, http://biomechatronics.cit.cmu.edu

INTRODUCTION

This symposium addresses the question: Can active or passive prosthetic legs augment performance in people with amputation? In terms of reducing the energy cost of locomotion, all signs point to 'yes'. In principle, walking at constant speed on level ground requires no energy input. In practice, both powered [1] and unpowered [2] ankle exoskeletons can reduce the energy cost of unimpaired human walking to below normal levels. Powered prostheses can reduce the energy cost of walking compared to passive devices [3, 4] and passive prostheses can allow the same cost of transport as for unimpaired controls [5]. Ankle-foot prosthesis controllers can even reduce the energy used for active balance [6]. It is likely that powered, semi-active and unpowered prostheses will eventually lead to more economical gait than possible with biological legs.

Despite these positive signs, we cannot predict now the formula for success. Many devices expected to augment gait, powered or passive, have failed. The benefits of powered prostheses, and their effects on gait mechanics, have not been consistent [4], and many studies have found performance deficits with passive prostheses. Some amputees experience lower metabolic rate or increased satisfaction with emulations of robotic prostheses, while others respond better to emulations of passive devices [7]. Net work performed during ankle push-off might be responsible for the benefits of active prostheses, where present, but has not been studied in isolation from other prosthesis features. In non-amputee subjects wearing amputation-simulating boots, increasing prosthetic ankle push-off work in isolation leads to decreased metabolic rate [8], but only if push-off occurs late in stance [9] and without hypothesized reductions in center of mass work.

In this presentation, we will review recent studies that address the theme of augmenting locomotor performance and present the results of a new study intended to isolate the effects of ankle push-off work on the energetics of amputee walking [10].

METHODS

Participants with unilateral, trans-tibial amputation (N = 6, 47 ± 6 yrs, 1.79 ± 0.04 m, 88 ± 8 kg) with congenital (N = 1) or traumatic (N = 5) causes, at least one year post amputation (1-45 yrs) provided written informed consent to a protocol approved by the Carnegie Mellon Institutional Review Board.

Subjects wore an ankle-foot prosthesis emulator [11] in place of their prescribed foot. This tethered, robotic device can apply higher mechanical power than mobile prostheses or the biological ankle joint, without varying other prosthesis features such as mass, stiffness or contact geometry. We applied seven push-off conditions in which net ankle work ranged from -2 to 8 times of the value observed during normal walking at 1.25 m·s^{-1}. Mechanics during the lead-up to push-off were held constant. Subjects underwent three acclimation days, three training days, and one collection day.
Figure 1: Metabolic rate was not significantly affected by net ankle-foot prosthesis push-off work on average.

We measured lower-limb joint mechanics, muscle activity, center of mass mechanics, and metabolic rate, and performed ANOVA to test for an effect of push-off work on each outcome. We fit quadratic relationships between net ankle work and metabolic rate on average and for each subject.

RESULTS AND DISCUSSION

On average, work input from the prosthesis did not affect metabolic rate (Fig. 1; P = 0.2; R^2 = 0.03). Effects were inconsistent between subjects (Fig. 2). Negative, low, or moderate net ankle work seemed to minimize metabolic cost in most cases, and no subjects trended towards lower metabolic rate with higher push-off work. Only one subject had lower metabolic rate than with their prescribed foot, achieved at about zero net work. Subjects also preferred medium-low net work (P = $3 \cdot 10^{-4}$).

Push-off work affected some mechanics and muscle activity outcomes during the period of active push-off, but with inconsistent implications for metabolic rate. With increasing push-off work, prosthesis-side hip work decreased (H3; P = $8 \cdot 10^{-5}$), prosthesis-side negative knee work increased (K3; P = $6 \cdot 10^{-4}$), and intact biceps femoris activity decreased (P = $3 \cdot 10^{-4}$). Contrary to predictions based on simple dynamic models of walking, increased trailing-limb push-off work did not reduce leading-limb collision work.

CONCLUSIONS

Augmenting gait is not simple. Net work input is thought to be responsible for reduced metabolic rate with powered prostheses, but humans are complex and it is very doubtful that this is the only factor. Subtle mechanical details may have unexpected

effects on, e.g., muscle-tendon dynamics. Details of prosthesis control may also be important, and can reduce or increase energy cost without changing average work input [6]. These and other aspects of prosthesis function are most efficiently studied in experiments with versatile emulator systems [11], which allow single factors to be isolated, rather than comparisons of multi-featured devices.

It is certain that individual differences play an important role in selecting user-optimal device characteristics, illustrated here by the range of responses to increased push-off work. Optimization on an individual basis is challenging for many reasons, but is possible [12] and will be critical to augmentation of amputee locomotion.

OPTIMIZING LEG PROSTHESES FOR WALKING AND RUNNING: CAN WE AUGMENT PERFORMANCE?

[1]Jana R. Jeffers, [1]Owen N. Beck, [1]Paolo Taboga & [1,2]Alena M. Grabowski

INTRODUCTION:

Recent technology incorporates stance-phase power into prosthetic ankles for walking. These powered prostheses generate net positive work by utilizing a motor and battery, could restore full function to people with an amputation [1], and thus may inhibit the sedentary lifestyle adopted by many people with leg amputation using passive prostheses [2]. However, previous studies suggest powered prostheses cannot replicate biological ankle joint function on uneven terrain [3]. Accordingly, we hypothesize that powered ankle-foot prostheses will require robust control to restore biomechanics and metabolic demands during up- and down-hill walking.

Specialized carbon-fiber running-specific prostheses (RSPs) emulate the spring-like function of tendons during level-ground steady-speed running and allow considerable elastic energy return [4]. However, passive-elastic RSPs cannot generate mechanical power, vary stiffness, or dorsi-flex to allow foot-ground clearance during leg swing. Because RSPs cannot adapt, the biomechanics of people with a leg amputation are asymmetrical [5], yet metabolic costs may be comparable to those of non-amputees [6]. Optimizing RSP mechanical properties, such as stiffness and height, could improve symmetry, metabolic demands, and performance. We hypothesize that RSPs that elicit symmetrical biomechanics will decrease metabolic costs during running and increase top sprinting speeds in athletes with unilateral leg amputation, and that less stiff RSPs will decrease metabolic costs during running and taller RSPs will increase top sprinting speed for athletes with bilateral leg amputations.

METHODS:

Walk: 3 males with unilateral transtibial amputation were fit with the BiOM and walked 1.25 m/s on a dual-belt force treadmill (Bertec Corp., USA) at 7 slopes (0°, ±3°, ±6°, ±9°) while we measured kinetics and kinematics (Vicon, USA). We optimized the BiOM tuning for level ground (LVL) and at each slope (ADJ) by iteratively changing tuning parameters until prosthetic ankle joint biomechanics matched those of non-amputees within 1 SD. We measured metabolic rates (Parvo Medics, USA) for 5 min during standing and walking at each slope for LVL and ADJ. We calculated net cost of transport (CoT) with a standard equation and by subtracting standing from walking CoT from the last two minutes if each trial.

Run/Sprint: A certified prosthetist fit 9 runners with unilateral (7 M; 2 F), 3 runners with bilateral (3M), 3 sprinters (2M, 1F) with unilateral, and 3 sprinters with bilateral (3M) transtibial amputations with three different RSP models (RSP1, RSP2, and RSP3) at the manufacturer recommended and ±1 stiffness categories, and at the manufacturer recommended height and ±2 cm; 15 combinations of RSP model, stiffness category, and height.

Runners performed 5 min trials on a force treadmill (Treadmetrix, Park City, UT) at 2.5-3.0 m/s while we measured ground reaction forces (GRFs) and metabolic rates. Sprinters performed sets of trials on the force treadmill while we measured GRFs. Sprinters started each set of trials at 3 m/s, speed was incremented 1 m/s until they approached top speed, then smaller speed increments were employed until subjects reached top speed, which occurred when sprinters could not maintain their position for ten consecutive strides.

RESULTS AND DISCUSSION:

Walk: BiOM ankle net work values for ADJ were within one S.D. of non-amputee values at ±3° and +6°. Net CoT was not different at ±3°, ±6°, or ±9° (p=0.39-0.96) in ADJ versus LVL (Fig. 1). Net CoT was higher for subjects with an amputation compared to non-amputees at -6° and -9° (p<0.05).
Figure 1: Average (±SD) net CoT at 1.25 m/s on up- and downhill slopes with the BiOM tuned for each slope (ADJ) and level ground (LVL), compared to non-amputees.

<u>Run:</u> Runners with unilateral amputations had 4.2-5.2% lower CoT using one RSP model compared to the other two ($p<0.01$), 1.3% lower CoT with -2 cm ($p=0.02$) (Fig. 2), and asymmetrical peak vertical GRFs correlated with higher CoT ($p<0.01$). Runners with bilateral amputations had 5.1% lower CoT with -1 RSP stiffness category ($p<0.01$).

<u>Sprint:</u> Sprinters with unilateral amputations had 8-11% faster top speeds using two RSP models compared to one model ($p<0.005$). For one model, -1 stiffness category increased top speed 5% ($p=0.02$), while -1 cm increased top speed 7% ($p<0.001$). Sprinters with bilateral amputations increased top speed 0.06 m/s with -1 cm RSP height ($p<0.001$) (Fig. 3).

CONCLUSIONS:

<u>Walk:</u> Tuning the BiOM for each slope resulted in normative ankle biomechanics, but no differences in metabolic cost compared to level-ground tuning. The BiOM did not augment performance. Thus, future research is needed to better understand ankle biomechanics and metabolic costs on slopes.

<u>Run/Sprint:</u> Reducing RSP height and peak vertical GRF asymmetry reduced metabolic costs for runners with unilateral leg amputations. Reducing RSP stiffness category reduced metabolic costs for runners with bilateral leg amputations. Faster top speeds were achieved by shortening contact time, and increasing peak vertical GRF in sprinters with unilateral leg

amputations. Surprisingly, shorter RSPs improved top speed in sprinters with bilateral leg amputations. Thus, optimizing RSP mechanical properties improved performance in athletes with leg amputations.

CHARACTERIZING FLUOROSCOPY BASED KINEMATIC ACCURACY BASED ON PULSE WIDTH AND VELOCITY

Arin M. Ellingson, Joseph D. Mozingo, Dixon J. Magnuson, Mark W. Pagnano, and Kristin D. Zhao

Mayo Clinic, Rochester, MN, USA
email: zhao.kristin@mayo.edu

INTRODUCTION

Fluoroscopic imaging has become an increasingly popular method to investigate total knee arthroplasty (TKA) kinematics non-invasively. Briefly, 3D implant models are aligned with 2D image projections, and optimized via an edge-detection algorithm (Fig. 1). Prior studies aimed to assess the accuracy of this shape-matching technique, though largely ignore the importance of fluoroscopic imaging parameters [1, 2]. A particularly sensitive parameter in dynamic applications is the pulse width, or exposure time per frame, which if too long may lead to blur (Fig. 1F) and subsequent degradation in image edge quality. This phenomenon has been anecdotally described previously [3]. However, to our knowledge, no studies have quantified the errors associated with increased pulse widths and movement velocity. *Therefore, the purpose of this study was to assess the accuracy of 6 degree-of-freedom TKA kinematics as pulse width and flexion velocity were systematically varied*.

METHODS

One intact, fresh-frozen cadaver right leg was acquired from the Mayo Clinic Bequest Program. Femoral and tibial total knee replacement components (Triathlon® Knee System, Stryker Orthopaedics, Mahwah, NJ, USA) were implanted by an orthopedic surgeon. A portion of the knee was left partially exposed to facilitate digitization of landmarks to establish local anatomical coordinate systems.

The femur and tibia were secured in a custom apparatus that allowed for unconstrained knee flexion at a manually guided rate. The knee was centered in the imaging volume created by the 48 cm flat-panel Multi-Diagnost Eleva C-arm single-plane x-ray system (Philips Medical Systems, Best, Netherlands) perpendicular to the primary plane of bending. X-ray images were acquired at 30 Hz (63 kV, 160 mA). Infrared marker sets were
Figure 1- Workflow of 2D/3D Shape Matching. Left: 3D TKA models aligned with silhouette when initially fully extended (**A**) and fully flexed (**B**). **Middle:** Silhouette of 1ms pulse width at initial position (**C**) and position of maximal flexion velocity (**D**). **Right:** Silhouette of 16ms pulse width at initial position (**E**) and at maximal flexion velocity (**F**).

attached to bone pins that were embedded in the femur and tibia. 3D kinematics were simultaneously acquired using an Optotrak Certus (Northern Digital Inc., Waterloo, Ontario, Canada) and subsequently downsampled to 30 Hz. The rotation rate was varied between 50°/s, 100°/s, 225°/s for pulse widths of 1ms, 8ms, and 16ms.

An open source model-based tracking program was used to manipulate the position and orientation of 3D CAD models of the femoral and tibial components, such that model edges were coincident with edges of the projected silhouettes on the radiograph (JointTrack, University of Florida, Gainesville, FL, USA). Following manual placement, poses were optimized with a built-in simulated annealing algorithm [4]. Relative orientation was defined using Euler angles (Z-X-Y sequence; flexion/extension, abduction/adduction, external/internal rotation) [5]. The 3D position and orientation of the tibia relative to the femur were determined for all frames of each trial and the limits of agreement were defined using a Bland-Altman technique.

RESULTS AND DISCUSSION

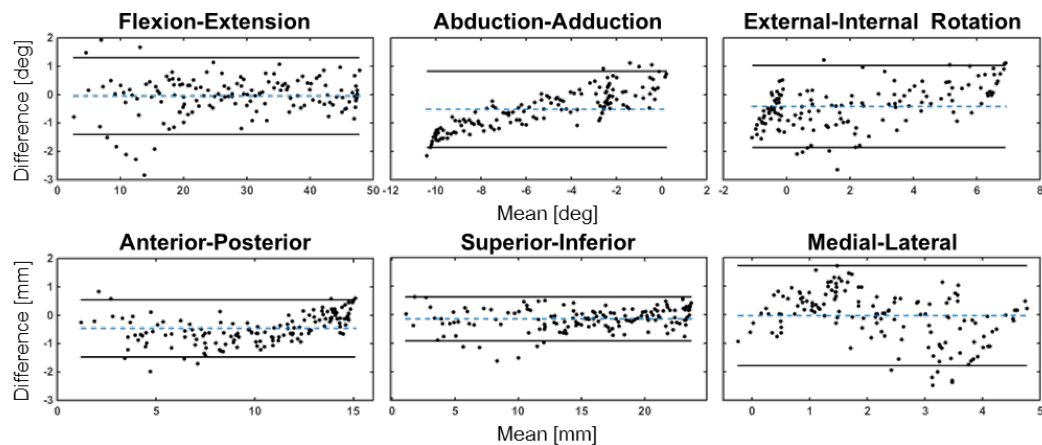
The average kinematic differences between the optoelectric and fluoroscopic methods for the


Figure 2: Bland-Altman plots. Demonstrate agreement in kinematic measures between fluoroscopic and optoelectronic methods for 1ms pulse width, 50/s rotation rate trial. Each point represents the mean and difference of relative joint angles (top row) and translations (bottom row) between each method, at a given frame. The dashed and solid lines are the mean difference between methods, and the 95% confidence intervals respectively.

optimal 1ms pulse width was 1.2° and 0.6 mm or less for all trials (Table 1). Figure 2 depicts a Bland-Altman plot demonstrating the agreement between the two kinematic collection techniques. A linear trend was only detected in the abduction rotation (R^2=0.73). The overall largest mean differences were in abduction-adduction across trials, but varied in translation.

Comparable mean differences and agreement were observed for the 8ms pulse width – less than 1.2° and 0.8mm (Table 1).

The 16 ms pulse width yielded the greatest mean differences, which were intensified during the most dynamic flexion activity. The mean rotational and translational differences were nearly double (2.0°) and triple (1.6mm) those from 1ms, respectively. Furthermore, the agreement between the systems, represented by the confidence interval, also increased dramatically for the 16ms pulse width.

CONCLUSIONS
In conclusion, this work defines the accuracy of our fluoroscopy system in conjunction with a 2D/3D shape-matching protocol for TKA models, which

was well below previously acceptable levels [2]. This provides a basis for future trials investigating TKA kinematics *in vivo.*

Additionally, the importance of pulse width and velocity should not be overlooked for future studies – greater than 1ms pulse widths should be used cautiously and pulse widths of 16ms and greater avoided. This parameter has proven to be a sensitive metric in the quantification of joint motion via fluoroscopy and must be identified and reported in future studies.

DYNAMIC TRACKING INFLUENCED BY ANATOMY IN PATELLAR INSTABILITY

INTRODUCTION

Excessive lateral patellar tracking leading to instability is most common with the knee near full extension. Anatomical factors that are considered contributors to instability include a lateralized tibial tuberosity, trochlear dysplasia, and patella alta. The current study evaluates the influence of these anatomical factors on dynamic in vivo patellar tracking as a function of flexion angle in knees experiencing patellar instability.

METHODS

Eight patients with recurrent instability who had not undergone a previous patellar stabilizing osteotomy were included in the IRB-approved study. Each patient participated in a dynamic CT scan (Aquilion ONE, Toshiba Medical Systems) as part of clinical evaluation. The scans were performed during extension against gravity from a flexed position to full extension over 10 seconds [1]. Computational models of the femur, tibia and patella were reconstructed from 5 to 7 volumes of images spanning the extension range. Shape matching techniques were used to represent each position of knee extension with a single model of each of the three bones. [1, 2].

Patellar tracking was correlated with anatomical parameters. Patellar lateral shift was measured in terms of the bisect offset index as the portion of the patellar width lateral to the deepest point of the trochlear groove (Fig. 1). The measurement was made within a plane perpendicular to the long axis of the patella with the lateral direction defined by the femoral posterior condylar axis. Patellar lateral tilt was measured as the angle between a line along the medial-lateral axis of the patella and the

posterior condylar axis. Trochlear dysplasia was measured in terms of lateral trochlear inclination as the angle between the lateral trochlear ridge and the posterior condylar axis. The tibial tuberosity to trochlear groove (TT-TG) distance was measured as the lateral distance from the deepest point of the trochlear groove to the patellar tendon attachment on the tibial tuberosity. Patella alta was characterized by the Caton-Deschamps index as the ratio of the distance from the superior-anterior aspect of the tibia to the distal point of cartilage on the patella and the length of the cartilage surface along the patella. All measures of patellar tracking and anatomy were quantified using an automated algorithm. Based on previous studies, errors for measures of tilt and lateral trochlear inclination are on the order of $1°$, errors for TT-TG distance are on the order of 1 mm, and errors for bisect offset index and Caton-Deschamps index are on the order of 0.05 [1, 2].
Figure 1: Measures of anatomy and patellar tracking.

Patellar tracking was related to the anatomical parameters using stepwise multivariable linear regression analyses, with $p < 0.15$ required to enter.

The data was separated into flexion angles less than and greater than 20°, based on the approximate angle at which the patella starts to engage the trochlear groove.

RESULTS AND DISCUSSION

At flexion angles less than 20°, bisect offset index was primarily correlated with lateral trochlear inclination, with the relationship with TT-TG distance also significant (Table 1). Lateral tilt was significantly correlated with lateral trochlear inclination. At flexion angles greater than 20°, bisect offset index was significantly correlated with only TT-TG distance. Lateral tilt was significantly correlated with only lateral trochlear inclination. Caton-Deschamps index was not significantly correlated with tracking. The relationships between tracking and anatomy were stronger at flexion angles < 20°. Additional assessment of the relationship between patellar tracking and anatomy with loading conditions more representative of those that produce instability is warranted.

CONCLUSIONS

The results indicate that the relationship between dynamic patellar tracking and knee anatomy in patients with patellar instability varies with the flexion angle. Near full extension, where the patella is most likely to dislocate, patellar tracking is strongly correlated with trochlear dysplasia. Lateral position of the tibial tuberosity has a weaker correlation with patellar lateral shift over all flexion angles. Understanding the relationship between anatomy and tracking helps clinicians assess the risk of recurrent instability and plan effective surgical treatment options.

INTRA-OPERATIVE FRAGMENT TRACKING FOR ARTICULAR FRACTURE REDUCTION

Andrew M. Kern, Steven A. Long, Geb W. Thomas and Donald D. Anderson

INTRODUCTION

Restoring a joint surface to its original state is the primary goal in the surgical treatment of articular fractures. This is done to minimize articular contact stress and to restore the joint contact mechanics. Despite surgeons' best efforts, the articular reduction is often less than perfect.

Visualizing fracture reduction intra-operatively is a challenging task. It requires constructing a mental 3D model working from 2D images. 3D-to-2D computational registration algorithms have been used to deduce the 3D pose of objects from 2D images[1,2]. Computer hardware has recently become sufficiently powerful to provide near-real-time performance with these algorithms. Foundational work for an intra-operative, markerless, fragment tracking system is presented here. The system allows for the position and orientation of individual bone fragments to be derived, in near-real time, using intra-operative 2D fluoroscopy images.

METHODS

The basis of the markerless fragment tracking system is iterative comparison of digitally reconstructed radiographs (DRRs) computed from pre-op CT scan data to intra-operative fluoroscopic images. The poses of individual bone fragments are varied *in silico* to maximize the agreement between the real and synthetic images. The system has three separate components: image segmentation, DRR generation, and pose optimization (Fig 1).

The pre-op CT image is pre-processed for DRR generation by converting the Hounsfield Units (HU) to linear attenuation coefficients (μ cm^{-1}). A semi-automated, watershed-based, image segmentation is performed to uniquely identify individual fragments in a label map. A sub-volume is created for each bone fragment by using the label map to tightly crop a bounding box around each region (Fig 2).
Figure 2. 2D radiograph of calibration frame taken from WBCT (A). CT image reconstructed by the WBCT (B). Segmentation of the surrogate bone fragment along with bounding box defining its subvolume (C). Subvolume containing bone fragment after removal of background (D).

In order to obtain real-time feedback for intra-operative use, a DRR algorithm was written in CUDA C++ for use on a graphics processing unit (GPU). After initialization, DRRs are computed by approximating the integral of X-ray attenuation along the path between the source and each pixel on a detector[3]. Within this framework, the pose of the virtual detector unit, soft-tissue, and bone fragments (sub-volumes) can be varied independently to change each subsequent DRR.

Similarity between the DRR and an intra-op fluoro image is computed using normalized cross correlation (NCC). When multiple images from different views are involved, the NCC from each view is combined into a single similarity metric[2].

$$Similarity = \log \prod_{i=0}^{n} (1 - NCC_i)$$
Figure 1. Intra-operative fragment tracking begins with a pre-operative CT, which is segmented and preprocessed. Each individual fragment pose is identified in an optimization loop. Final result...

The position and orientation of each bone fragment is then varied to minimize the similarity metric and thereby deduce the 3D pose of each fragment.

The DRR algorithm and pose estimation were tested using a prototype weight bearing CT (WBCT) scanner (Curvebeam), where a series of 2D cone beam images (0.38x0.38 mm pixels) are used to reconstruct a 3D CT volume (0.37x0.37x0.37 mm voxels). A surrogate bone fragment (Sawbones, Vashon Island, WA) was placed within a device that allowed the precise spatial manipulation (within 3 μm and 5 arc minutes) in all 6 degrees of freedom. One neutral pose, 3 translated poses, and 2 rotated poses were imaged. The bone fragment, segmented from the neutral pose CT data, was aligned to orthogonal 2D images from the poses using an optimizer to minimize the similarity metric.

The performance of two different optimizers was characterized in terms of the speed and accuracy in reproducing the known bone pose. Covariance matrix adaptation evolution strategy (CMA-ES) was tested, as it is a well known gradient free optimizer used frequently in this application[1,4]. A Simplex algorithm was also tested, as it is a gradient free optimization method that requires relatively few function evaluations to converge [1,5].

RESULTS AND DISCUSSION

Upon visual comparison, the DRRs reproduced the experimental data accurately, albeit with less sharp edge information, likely due to discretization errors and artifact within the CT volume (Fig 3). A single DRR is computed within ~2 ms, and the average optimization times for CMA-ES and the Simplex algorithms were 167.9 and 10.7 seconds, respectively.
Figure 3. Comparison of DRR of bone fragment (following *in silico* translation) compared to experimentally gathered 2D X-Ray. Line profiles were sampled from the resulting images to show that DRR resulted in similar image but with higher frequency information lost
Figure 4. Mean error in translation and rotation following alignment of bone fragment to known rigid transformations. Poses 1-3 were translations in an arbitrarily selected direction of 5 mm. Poses 4 and 5 were an arbitrary rotation of up to 45 degrees.

The methods presented show promise for the real-time measurement intra-operative fragment pose. The accuracy of the fragment pose identification was sub-mm/degree for both optimization techniques (Fig. 4), but the Simplex algorithm was ~15 times faster. Even the fastest optimizations required ~10 seconds to converge to the correct solution, which is still too slow for real-time application. The DRR computation is currently performed within C++ CUDA, and the optimization within MATLAB, where ~80% of computation time is spent within MATLAB. It is expected that implementing optimization features within the C++ CUDA software and reducing the image resolution of early optimization steps will dramatically improve time performance[1].

This work was limited by the use of a non-clinical setting (single surrogate bone fragment with no soft tissue or surgical instrumentation present), and by the use of relatively small movements of the bone fragment. Future work will involve improving both temporal and spatial performance of the optimization, developing optimization strategies for multiple simultaneous bone fragments, and developing methods for translation into the OR.

COMPARING THE EFFECTIVE QUADRICEPS AND PATELLAR TENDON MOMENT ARMS IN ASYMPTOMATIC CONTROLS AND SUBJECTS WITH PATELLOFEMORAL PAIN

[1]Lucas T. Thomeer, [1]Frances T. Sheehan, PhD, [1]Jennifer N. Jackson, PhD

[1] Rehabilitation Medicine Department, National Institutes of Health, Bethesda, MD, USA
email: gavellif@cc.nih.gov

INTRODUCTION

Knowledge of a tendon's moment arm (ma) is crucial to understanding joint kinetics, as it defines the relationship between a muscle's linear force and the moment it creates. However, because the patella acts as a dynamic fulcrum, the quadriceps' moment on the tibia cannot be directly calculated. Instead, the term effective quadriceps moment arm (EQma) was coined to define this relationship [1]. The EQma has not been quantified during dynamic *in vivo* movements. In addition, there is disagreement on how pathology influences EQma. Patella alta in patients with cerebral palsy is assumed to weaken knee extension capacity by reducing the EQma [2]. Conversely, a larger EQma has been reported for subjects with patella alta, relative to controls [3]. However, patellofemoral (PF) pain was reported by some subjects in both cohorts [3]. Characterizing the relationship between the EQma and patella alta in cohorts affected by pathologies associated with patella alta will provide crucial data for surgical interventions aimed at altering PF kinematics in these cohorts. Thus, the purpose of this study was to compare the *in vivo* EQma, captured during dynamic knee extension, of asymptomatic controls to subjects with PF pain using dynamic magnetic resonance (MR) imaging. A sub-analysis compared subjects with both PF pain and patella alta to controls. A secondary goal was to correlate the EQma to the PF superior position.

METHODS

The data were collected as part of an ongoing IRB approved study. All volunteers gave informed consent. The control cohort consisted of 38 healthy knees (29F/9M, 26.7 ± 5.7 years, 62.2 ± 10.8 kg, 167.5 ± 10.4 cm). All subjects in the cohort with PF pain had a diagnosis of PF pain with a minimum six
Figure 1: Analysis of two time frames for a single control subject. **A.** PTma, relative to the TF_IHA (shown approximately), was quantified by tracking the patellar tendon insertions through integration of the CPC data. **B.** ma_q and ma_p were defined through direct image-based measures.

month history of PF pain (30F/3M, 22.3 ± 11.8 years, 57.8 ± 12.3 kg, 162.3 ± 7.4 cm).

A dynamic cine-phase contrast (CPC) MR acquisition and a multi-plane cine (MPC) MR acquisition were captured (3T, Philips Medical Systems) as each subject extended and flexed their knee through a range of motion of $10°$ to at least $40°$. To rule out any underlying pathology, high-resolution static 3D MR images were acquired and read by a radiologist.

The CPC data was integrated to quantify the PF and tibiofemoral kinematics, allowing the patellar tendon moment arm (PTma) about the tibiofemoral instantaneous helical axis (TF_IHA) to be quantified. The EQma was quantified using a visual analysis of the ratio of the patellar tendon to quadriceps force (F_p/F_q, Fig 1) and the moment balance equation for the patella relative to the PF point of contact (PC, assumed to be the center of PF line of contact in the image containing the largest patellar section):

$$EQma = PTma*(F_p/F_q) = PTma*(ma_q/ma_p)$$

ma_p: ma of the patellar tendon, relative to PC
ma_q: ma of the quadriceps tendon, relative to PC

Since the dynamic data were acquired in even temporal increments, all kinematic data were interpolated to 10° knee angle (KA) increments from 10° to 50°. All distance measures were scaled by the ratio of the average control epicondylar width to the subject's epicondylar width.

A cohort with patella alta (10F, 23.2 ± 13.2 years, 61.0 ± 16.0 kg, 162.3 ± 8.9 cm) was taken as a subset of the cohort with PF pain. All knees in the cohort with PF pain that had a superior displacement of more than one standard deviation above the control mean were included.

A two-way analysis of variance (2x4 ANOVA, SPSS 22.0) was used to assess main and interaction effects of cohort (control vs. PF pain and control vs. PF pain with patella alta) and knee angle comparisons. Pearson's correlation coefficients were found between the superior displacement of the patella and the three moment arm variables (F_p/F_q ratio, PTma, and EQma) for the control cohort and the full cohort with PF pain.

RESULTS AND DISCUSSION

The cohort with PF pain was younger (p = 0.046) and shorter (p = 0.017) than the control cohort. Age was likely not a confounding factor, as all subjects were screened for arthritis. Height was removed as a confounding factor through scaling.

Cohort (control vs. PF pain) was not a main effect for F_p/F_q, PTma, or EQma. As in other studies [3, 4], the ratio of F_p/F_q was greater than 1.0 for knee angles less than ~20° in the control cohort. For the cohort with PF pain, the ratio of F_p/F_q was greater than 1.0 for knee angles less than ~15° (Fig 2).

Cohort (control vs. PF pain with patella alta) was a main effect for F_p/F_q (significant at 40° KA), but not for PTma or EQma. This lack of difference in EQma disagrees with previous work that found an increase in EQma [1, 3]. These differences were most likely due to differing methodologies. The current study was dynamic, not static. The EQma
Figure 2: Comparisons of the cohorts (control, PF pain, PF pain with patella alta) across knee angles for F_p/F_q (top) and EQma (bottom).

was based on the PTma referenced to the TF_IHA, not the crossing point of the cruciate ligaments [3] or the tibiofemoral point of contact [1].

For two main cohorts, the F_p/F_q ratio showed a positive (r = 0.35 to 0.72, p < 0.05) and the PTma an inverse correlation (r = -0.38 to -0.55) with PF superior position. This resulted in EQma not showing a correlation to the PF superior position, except at 40° KA in the cohort with PF pain. This stands in opposition to past work that indicated the EQma is associated with patella alta [3].

CONCLUSIONS

These novel *in vivo* data acquired across a large asymptomatic control population and a population of individuals with PF pain during a dynamic extension activity requiring active quadriceps contraction fills a critical gap in our understanding of musculoskeletal dynamics. As patella alta does not result in an increased EQma, surgically altering the height of the patella in the femoral groove would not reduce the quadriceps' efficiency.

METHOD FOR THREE-DIMENSIONAL ANALYSIS OF SKELETAL MUSCLE STRAIN

[1,2] Elisabeth R. Jensen, [1] Duane A. Morrow, [3] Joel P. Felmlee, and [1] Kenton R. Kaufman

INTRODUCTION

Skeletal muscle weakness is frequently associated with stiffness changes [1,2], which may alter functional contraction and passive elongation dynamics. Cine Phase Contrast (CPC) MRI has been successfully used to quantify skeletal muscle strain distribution in a single plane [3,4]. The strain distribution was found to be non-uniform, indicating complex internal dynamics of skeletal muscle. The objective of this study was to advance CPC MRI-based analysis of muscle strain to three dimensions and to establish the output validity.

METHODS

A healthy female subject (24 y.o., 61 kg) was recruited and informed consent was obtained prior to her participation. The subject was positioned in a 1.5T MRI scanner (Signa HDX 16.0, GE Medical Systems, Waukesha, WI) and her right ankle was passively rotated between neutral and 26 degrees of plantar-flexion at 30 deg/sec for ~1300 cycles using a custom MRI-compatible apparatus. Data were collected using a commercial Fast 2D Phase Contrast sequence (50 mm/s venc, 12 time segments, 4 vps). The sequence and the apparatus were gaited to a two second cycle using a function generator. Nine adjacent sagittal image slices were acquired (5x0 mm thick, 24 cm FOV, 192x192 in-plane resolution) to cover the width of the tibialis anterior (TA). Velocity was encoded in each of the three spatial dimensions independently. Axial T2-weighted image stacks were collected with the ankle stationary at neutral and in plantarflexion (5x0 mm thick, 20 cm FOV, 320x320 in-plane resolution).

The TA muscle was manually segmented from the neutral-ankle T2-weighted images (Mimics, Materialise NV, Leuven, Belgium), then exported as a surface mesh. A 3D hexahedral mesh with 10824 elements was generated by projecting a "butterfly" volume mesh to the TA surface mesh (TrueGrid, XYZ Scientific, Livermore, CA) and was exported as an Abaqus input file (SIMULIA, Waltham, MA). Local element axis 1 was defined as parallel to the TA's long axis. Local element axis 2 was defined to be parallel to the internal aponeurosis, identified from the T2-weighted images, which varied across the TA length. The CPC-generated velocity maps (smoothed and corrected according to [5]) were used to track the 3D trajectory of each mesh node with custom software (MATLAB, The MathWorks, Natick, MA) that incorporated forward-backward integration and linear interpolation between voxels [4]. By applying these trajectories as nodal boundary conditions in Abaqus, the deformed 3D mesh of the lengthened TA was obtained.

The validity of the final deformed 3D mesh of the TA was tested in two ways: 1) The surface of the deformed mesh (exported from Abaqus) was overlaid on the T2-weighted images (plantarflexed ankle) to validate the final position. 2) The positive-to-negative transition of E13 shear strain was compared to the internal aponeurosis seen on the T2-weighted images. These lines were expected to coincide due to opposite fascicle rotation on either side of the aponeurosis (Figure 1).
Figure 1: Muscle fibers on opposing sides of an internal aponeurosis in a bi-pennate muscle (such as the TA) experience opposite shear strains with passive muscle lengthening.

RESULTS AND DISCUSSION

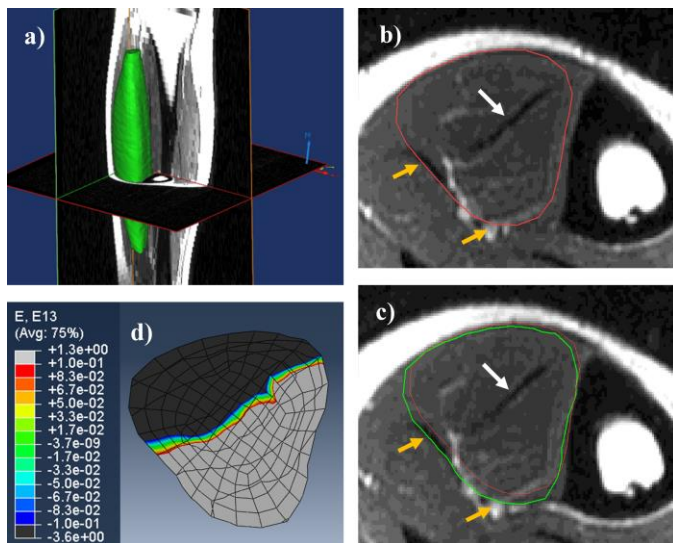
The validity of the deformed mesh was supported by the data. The three-dimensional surface boundary of the deformed mesh matched the position of the TA in the strained condition, as confirmed by the T2-weighted images (example cross-section shown in Figure 2). Specifically, the anterior, posterior, and lateral boundaries of the deformed mesh coincided with anatomical landmarks such as skin, tendon, and fat near which the original mesh was defined (Figure 2b,c). This means that the trajectories of the most superficial nodes behaved as expected, indicating that motions of the internal nodes were appropriate in both magnitude and direction. The medial boundary of the mesh did not follow the anatomical landmarks as closely due to partial volume effects: the sagittal slices which included both muscle and bone volume were noisy due to a lack of signal in cortical bone.


Figure 2: *a) Deformed mesh (green) superimposed on axial T2-weighted MRI image stack (plantarflexed ankle). b) Axial T2-weighted image (neutral ankle) with TA segmentation outlined in red. Slice corresponds to cross-section identified in (a). White arrow points to aponeurosis; yellow arrows point to identifiable anatomical landmarks of TA. c) Axial image (plantarflexed ankle) corresponding to (a) and (b) identifying segmented TA position (red) and deformed mesh outline (green). d) Corresponding cross section of deformed mesh, displaying positive-to-negative E13 shear strain transition.*

More significantly, the positive-to-negative transition of the E13 shear strain matched the image-identified internal aponeurosis throughout its length (Figure 2c,d). This supports model validity of the internal mesh elements. Mechanical analysis of bi-pennate muscle under passive elongation predicts opposite direction fascicle rotation on either side of the aponeurosis, generating opposite shear strains. The ability of the model to identify the proper transition line demonstrates strong validity.

CONCLUSIONS

Quantification of three-dimensional skeletal muscle strain may provide important insights into the internal dynamics of weak and injured muscle. Previous studies on this topic have, out of necessity, attempted to represent complex 3D dynamics in two dimensions. This study demonstrates a novel approach to quantify 3D muscle strain using CPC MRI. The current study is limited to analysis of passive elongation due to the long duration of the data collection, but future application of accelerated CPC sequences will enable analysis of active muscle contraction due to significantly reduced data collection time [6].

STIFFENING OF THE TRANSVERSE CARPAL LIGAMENT IN PIANISTS DETECTED BY ACOUSTIC RADIATION FORCE IMPULSE IMAGING

[1]Christiane Mhanna, [1]Tamara L. Marquardt, [1,2,3]Zong-Ming Li

Hand Research Laboratory, Departments of [1]Biomedical Engineering, [2]Orthopaedic Surgery, and [3]Physical Medicine and Rehabilitation, Cleveland Clinic, Cleveland, OH, USA
email: liz4@ccf.org, web: http://www.handlab.org

INTRODUCTION

The transverse carpal ligament (TCL) anchors the thenar muscles that are critical to thumb function. Contractions of the thenar muscles biomechanically stimulate the TCL and such repetitive stimulations may cause pathomechanical tissue changes such as TCL thickening and stiffening [1]. While practicing and performing, pianists forcefully and repetitively exercise their thumbs and may be at risk for TCL modifications [2]. By examining TCL stiffness *in vivo* using acoustic radiation force impulse (ARFI) ultrasound imaging, there is potential for identifying etiological factors of carpal tunnel syndrome (CTS) such as TCL pathomechanics. Thus, the purpose of this study was to investigate stiffness changes in the TCL among pianists using ARFI. We hypothesized that pianists would exhibit a stiffer TCL in comparison to non-pianist controls.

METHODS

A total of twenty healthy, right handed female volunteers participated in the study. Ten of the participants were pianists (20.4 ± 1.6 years) who practice at least ten hours per week and have at least ten years of piano experience (18.6 hours/week of practice, 12.8 years of piano experience). The remaining ten participants served as a control group (23.8 ± 3.4 years) and were non-pianists that reported fewer than five hours per day typing, texting, or performing repetitive hand movements.

Each participant sat next to a testing table with the right arm submerged in a tank of room temperature water. The hand and wrist of each subject was stabilized in a supine, anatomically neutral position within a thermoplastic splint secured with Velcro® straps (Fig. 1). ARFI images were obtained with a Siemens Acuson S2000 ultrasound system using a 9L4 linear array transducer that was stabilized using a positioning arm. The ultrasound system was equipped with Virtual Touch[TM] Tissue IQ software that permitted quantitative assessment of tissue stiffness by measuring the shear wave velocity (SWV) of tissues using ARFI technology. For each trial, a B-mode ultrasound image of the TCL and surrounding tissues was captured along with its corresponding ARFI grayscale map. Four images of the TCL were collected at the distal level of the carpal tunnel for each subject and then the experiment was repeated on the left hand.
Figure 1: Illustration of the experimental setup to obtain ARFI images of the TCL.

A customized MATLAB script calculated the SWV by manually tracing the TCL on the B-mode side and translating the selection to the ARFI image side (Fig. 2). The SWV value of each pixel within the selection was calculated and the median SWV was determined. Additionally, the thenar muscles' ulnar point (TUP), the most ulnar insertion point of the thenar muscles on the TCL, was identified. For further analysis, the TCL was divided into ulnar and radial sides, i.e. uTCL and rTCL. The uTCL was defined as the region from the TUP towards the hook of hamate, while the rTCL was defined as the

region from the TUP towards the trapezium. The median values from the four trials were averaged for each participant and then the data from the right and left hands were averaged. A one-way ANOVA was used to compare the TCL SWV of pianists and controls. Additionally, a two-way ANOVA was performed with factors of group (pianist and control) and TCL side (uTCL and rTCL). The significance level was α = 0.05.
Figure 2: A representative ultrasound image with the TCL selection outlined on both the B-mode side (A) and ARFI side (B). The hamate (H), trapezium (T), and TUP (★) are identified. The vertical line indicates the division location for uTCL and rTCL.

RESULTS AND DISCUSSION

The SWV of the TCL, uTCL, and rTCL for the control group were 5.01 ± 0.58, 4.52 ± 0.59, and 4.99 ± 0.82 m/s, respectively. The SWV of the TCL, uTCL, and rTCL for the pianist group were 5.52 ± 0.46, 4.84 ± 0.38, and 6.09 ± 0.63 m/s, respectively. One-way ANOVA revealed that the SWV of the TCL was significantly greater in pianists as compared to the control group ($p < 0.05$) (Fig. 3). Two-way ANOVA showed that the SWV was significantly affected by group ($p < 0.001$) and side ($p < 0.001$) factors. Further comparisons showed that the SWV of the rTCL was not significantly different from that of the uTCL for the control group ($p = 0.109$). For the pianist group, however, the SWV of the rTCL was significantly greater than that of the uTCL ($p < 0.001$). The ratios of rTCL to uTCL SWV were 1.10 ± 0.10 and 1.26 ± 0.14 for the controls and pianists, respectively. Comparisons across the groups showed that the controls and pianists did not significantly differ for the SWV of the uTCL ($p = 0.172$), but the SWV of the rTCL for the pianists was 18.2% greater than that for the controls ($p < 0.005$).
Figure 3: SWV of TCL, uTCL, and rTCL in pianists and controls. *$p<0.05$, **$p<0.01$, and *** $p<0.001$

ARFI imaging permitted *in vivo* examination of TCL SWV. SWV values of the control group agree well with findings of a previous study [3]. This study additionally revealed that pianists exhibit a higher TCL SWV than non-pianists. An increase in SWV is correlated with an increase in tissue stiffness [4]. While it was indicated that the TCL was generally stiffer among pianists, detailed analysis revealed that the adaptation was location dependent. The rTCL may be stiffer in pianists because that region of the TCL is physically attached to the thenar muscles and is under biomechanical stimulation when pianists play octaves and scales [5]. Previous research has shown that the thenar muscles are commonly overused in pianists and that this overuse may contribute to pain or stiffness [6]. Our study explores early signs of TCL stiffening among pianists, which could ultimately lead to CTS. Future studies are needed to determine if TCL stiffness is correlated with years of piano playing and with CTS.

VALIDATION OF AN INSTRUMNETED FIGURE SKATING BLADE TO MEASURE FORCE

[1]Deborah L. King, [2]J. Brandon Adamo, [2]Blake R. Harper, [1]Timothy Snyder, [2]Nicholas J. Whipple, [1]Stephanie R. Zybert, [2]Steven K. Charles, [2]Sarah T. Ridge

INTRODUCTION

Competitive figure skating involves an intricate combination of artistry and athleticism. To perfect the difficult jumps, spins, and throws, skaters often train 3-6 hours per day, 4-6 days per week performing over 50 jumps each day 1,2]. With this intense training, injuries are all too frequent; over 70% of elite singles skaters have reported overuse injuries [3]. Understanding the forces that act on skaters will provide information related to a better understanding of injury mechanisms in figure skating.

However, measuring impact force in skating is not trivial. Previous studies have measured on-ice forces using pressure sensitive insoles or off-ice forces on a force plate, but neither method captures all of the forces experienced on ice [2,4,5]. Recently [6], a figure skating blade (Jackson Ultima Matrix) instrumented with strain gauges was developed to measure on-ice forces (Fig. 1). Data from one landing onto a force-plate was compared between the instrumented blade and a force-plate. An r-value of 0.88 between the two force curves was reported with errors in peak force magnitude of 780N (Fz1) and 20 N (Fz2) [6]. The purpose of the current study was to validate the instrumented blade using multiple landings onto a force-plate from different heights.

METHODS

A total of 16 simulated figure skating landings were performed onto a .01 m thick rubber mat (density 1.3 x 10^3 kg/m^3) covering an AMTI (OR6, Watertown, MA) force-plate with the instrumented figure skating blade. Eight landings were performed from a height of 0.18 m and eight from a height of

0.27 m. Data were collected at 1000 Hz from both the blade and force-plate. Reflective markers were placed on the heel and toe of the boot parallel to the blade for sagittal plane recording with a SVSI StreamVision camera (Southern Vision Systems, Huntsville, AL) operating at 150 Hz.

Figure 1. Instrumented blade: Wheatstone bridge boards and strain gauges (a) - front two wrapped for data collection), signal processing board (b), compact flash card slot (c), and battery (d) wrapped for data collection. Details are in [6].

Four landings, 2 from each height, were randomly selected to perform a calibration. Blade angles were measured (MaxTraq 2D, Innovision, Columbiaville, MI) 10 frames prior to contact to a minimum of 100 frames after contact, filtered at 20 Hz and re-sampled at 1000 Hz using linear interpolation (LabView 2013, National Instruments, Austin, TX). Blade strain gauge data in volts (perpendicular to and parallel to blade) were transformed to the global (force-plate) coordinate system (vertical and horizontal), cropped from contact to 500 ms, and entered into a linear least squares regression with the corresponding force-plate data in N synchronized at contact. In total, 2000 data points were used to create the calibration matrix.

Blade angles were measured for the remaining 12 landings and force was calculated in the global coordinate system using angles and the calibration matrix. The blade and force-plate data were cropped from contact to 500 ms and low-pass filtered at 150 Hz. A zero-lag cross correlation was computed between the blade and force-plate data for each landing. Paired t-tests were used to compare peak vertical impact forces with $\alpha = 0.05$.

RESULTS AND DISCUSSION

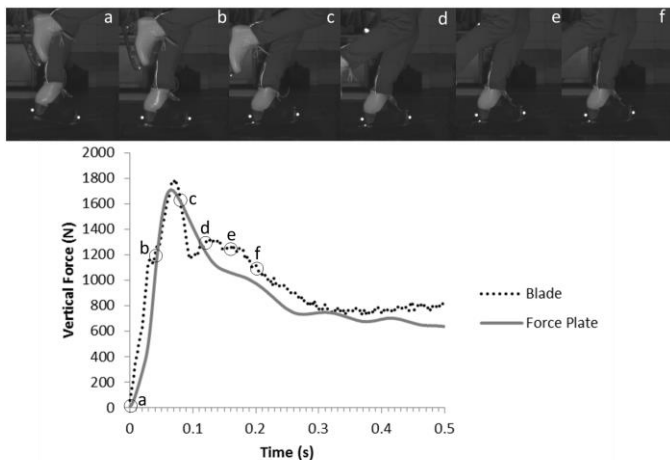
A representative force curve comparing blade data to force-plate data is shown in Fig. 2. Zero-lag cross-correlations (r-values) ranged from 0.78 to 0.97 with a median r-value of 0.90 and mode of 0.93.


Figure 2: Instrumented blade and force-plate forces for landing 10 with corresponding video frames. For this landing r = 0.93.

The difference in peak force between the blade and force-plate was not significant (p = 0.528). The difference ranged from the blade underestimating by 152 N to overestimating by 145 N with a mean difference of -17 ± 89 N (Fig. 3).

The data suggest good to excellent agreement between the forces measured from the instrumented blade to those from the force-plate. The large standard deviations in peak force differences could be due to quantization of strain from the instrumented blade designed with a resolution of 30 N compared to a 1.5 N resolution of the force-plate.
Figure 3: Average (+SD) peak force from the blade and force-plate for the 12 landings.

Non-quantified differences were observed in the shape of the two force curves. The blade often measured a small Fz1 peak (passive peak from the toe-impact seen near symbol b in Fig. 2) that was not registered on the force-plate. This could be due to the rubber mat, used to allow the skater to safely land on the force-plate, or differences in dynamics of the blade and force-plate. Further validation is recommended on an artificial ice-type surface to better mimic on-ice landings. It is also recommended that the blade be validated across different skaters to ensure that landing technique does not affect the validity of the calibration matrix and that reliability of the instrumented blade be established across days.

CONCLUSIONS

An instrumented figure skating blade self-contained underneath the boot of a skate was found to accurately measure vertical force in simulated figure skating landings performed in a laboratory setting.

INTRODUCTION

Musculoskeletal injuries are common in athletes and often result in loss of time from training and competition. Often, the injuries experienced by athletes are the result of overuse and repetitive wear on the musculoskeletal system. It has been suggested that healthy neuro-musculoskeletal systems exhibit an appropriate amount of variability interpreted as either the exploration of alternate movement strategies or a measure of adaptability within the system (Preatoni et al, 2013). Previous literature has associated limited variability, within a biological system, with unhealthy systems (Stergiou & Decker, 2011). While this theory is most commonly applied within cardiovascular or neuromuscular signals, this theory may also be applied to musculoskeletal injury. Specifically, a musculoskeletal system that exhibits limited variability would result in repeated loading and stress on the same tissues. This repeated stress to the musculoskeletal system could result in overuse injuries.

Emerging literature has suggested that nonlinear measures of variability may be more sensitive to subtle differences or changes within a movement pattern compared to traditional measures of centrality (Stergiou & Decker, 2011). A limitation of using nonlinear measures of variability is the reported need to have a continuous, deterministic time-series. This is a key limitation in certain movement patterns associated with injury including jumping and landing. However, the effect of using a continuous versus discontinuous time-series on values of nonlinear calculations such as sample entropy has not been previously evaluated.

Therefore, the purpose of this study was to determine if sample entropy (SampEn) calculated using a continuous series of jumping and landing data is statistically different from assessing a merged series of continuous landing phase data. The hypothesis was that there will be no difference in SampEn between the two sets of data.

METHODS

16 recreational athletes (Table 1) with experience in jumping and landing sports were recruited for this study. Prior to participation in the experimental protocol, each participant signed an approved informed consent form.

	Male (n=8)	Female (n=8)
Age (years)	19.0 ± 1.1	24.6 ± 5.4
Height (m)	1.81 ± 0.08	1.72 ± 0.04
Mass (kg)	66.6 ± 9.2	59.9 ± 8.7

The subjects performed three trials of 10 repeated bilateral vertical jumps for maximum height during each trial. Subjects were allowed a 30 second rest between each of the repeated jumping trials. During each of the jumping trials, subjects were instructed to land with both feet, but ensure that one foot landed on each force plate (AMTI, Watertown, MA). Three-dimensional kinematic and kinetic data were collected during each of the jumping trials using an eight camera motion capture system (Motion Analysis Corporation, Santa Rosa, CA). Lower extremity joint angles and joint resultant moments were calculated for the right limb using Visual 3D (Germantown, MD). Joint moments were calculated using standard inverse dynamic techniques and the moment was normalized to body mass multiplied by height. The variables of interest for this study were sagittal plane knee joint angles and moments as well as frontal plane knee joint angles. Two datasets were used for analysis including continuous (CONT) and discontinuous data sets. The discontinuous (DISC) dataset was characterized by removing the flight phase from

each participant's data set and splicing together the data associated with load absorption and vertical jump prior to take off to create a continuous dataset.

Sample entropy (SampEn) was used to quantify the regularity of each variable of interest for both CONT and DISC datasets (Richman & Moorman, 2000). SampEn calculations yield a value between zero and infinity which reflects the predictability of future values within a time-series based on the preceding values of that time-series. Low SampEn values (i.e. 0) represent a predictable time-series such as a sine waveform while high SampEn values (i.e. > 2-3) represent an unpredictable time-series such as white noise. SampEn values each of the variables of interest were calculated using the following algorithm:

$$SampEn(m, r, N) = \ln \frac{\sum_{i=1}^{N-m} n_i^m}{\sum_{i=1}^{N-m} n_i^{m+1}}$$

where m was the length of the compared runs (m=2), r was the similarity criterion between points in a time-series (r = 0.2 * SD), N was the number of measurements in the time-series (i.e. number of points). The SampEn values were calculated for each variable of interest for each trial for each subject. A subject mean was then calculated as the average SampEn of all trials within a given calculation method for a given subject. Subject means were used in statistical analysis of the data. A series of paired t-tests were completed to determine if any differences existed between the two datasets (CONT and DISC) with the level of significance set at alpha = 0.05.

RESULTS AND DISCUSSION
When comparing the two different datasets (CONT and DISC), no difference existed for the sagittal plane knee angle (p=0.451) or moment (P=0.798). However, the frontal plane knee angle was different between the two groups (p=0.001). In the frontal plane, the DISC data demonstrated a greater SampEn when compared to the CONT data set (Table 2).

The results of this study demonstrate that SampEn

can be used to assess movement variability during dynamic tasks such as jumping and landing as a relative measure between two movements or two groups. For sagittal plane angle and moments no difference was found between the DISC and CONT data indicating that using non-continuous data and mathematically merging it into a continuous series might be a possibility when trying to assess dynamic movements that can't easily be done in sequence.

	CONT	DISC	p-value
Sagittal Knee Angle	0.283 ± 0.071	0.298 ± 0.077	0.451
Sagittal Knee Moment	0.421 ± 0.140	0.432 ± 0.153	0.798
Frontal Knee Angle	0.690 ± 0.264	1.097 ± 0.356	0.001

The only measure that was different between the two data sets was the frontal plane joint angle. The differences in frontal plane motion could have resulted from greater variability inconsistencies in movement during the flight phase which would be present only in the CONT data, which is similar to what has previously been reported in walking and running (Kadaba et al, 1989). Therefore, future work needs to examine the differences in frontal plane linear variability to better understand the basic movement differences in order to provide information on the utility of this type of measure outside of the sagittal plane. Based on the results from this work, future studies should begin to examine the differences in both linear and non-linear variability during jumping and landing in both healthy as well as patient populations, such as those with ACL reconstruction.

USING AN ACCELEROMETER TO MONITOR RECOVERY OF GAIT BALANCE CONTROL FOLLOWING CONCUSSION

[1]Li-Shan Chou, [1,2]David Howell, and [1]Louis Osternig

[1] Department of Human Physiology, University of Oregon, Eugene, OR, USA

INTRODUCTION

An increased risk of a second concussion following the first has been reported (Guskiewicz et al., 2000; Zemper, 2003). This indicates that a sensitive examination of post-injury recovery may be a critical component in concussion management. Gait balance disturbances have been identified in individuals following concussion. Individuals with concussion exhibit greater displacement and velocity of whole body center-of-mass (COM) in the frontal plane and smaller peak COM velocity in the sagittal plane during dual-task walking than individually matched and uninjured controls (Howell et al., 2013, 2014, 2015; Parker et al., 2006).

Laboratory-based measurements require substantial equipment not often available in clinical settings where post-concussion assessments are conducted. Hence, a need exists to develop protocols utilizing inexpensive, easily implemented alternatives that provide detection comparable to camera-based systems for measuring gait stability. Accelerometry offers such a cost-effective, readily available alternative for the objective measurement of gait following concussion.

The objective of this study was to examine sagittal and frontal plane accelerations, measured with an accelerometer during dual-task walking, in a cohort of participants with concussion regularly over a 2-month post-injury period and similarly in uninjured controls. It was hypothesized that differences in sagittal and frontal plane accelerations at critical gait events would be observed between concussion and control groups.

METHODS

Seventeen subjects were identified and recruited for testing. Ten subjects (7M/3F; mean age: 19.0±5.5 years) were diagnosed with a concussion by a healthcare professional (physician/athletic trainer) and were assessed in the laboratory within 72 hours of injury and approximately one week, two weeks, one month, and two months post-injury. Seven control subjects (3M/4F; mean age: 20.0±4.5 years) were also tested according to the same timeline. Prior to data collection, all subjects and parents/guardians (if under the age of 18) provided written consent to participate in the study.

All study participants walked barefoot at a self-selected speed along a walkway while simultaneously completing an auditory Stroop test. The Stroop test consisted of the subject listening to four auditory stimuli: the recorded words "high" or "low" spoken in either a high or low pitch. Subjects were instructed to identify the pitch of the word, regardless of whether the pitch was congruent with the word. While walking, participants wore an accelerometer (APDM Opal Sensor, Portland, OR) attached with an elastic belt at L5, so that the reference coordinate system x-axis was oriented vertically downward, the y-axis was oriented to the right, and the z-axis was oriented orthogonal to the x- and y-axes toward the front. Accelerometer data were used to identify linear accelerations in the anterior-posterior and medial-lateral directions, obtained at a sampling frequency of 128Hz and saved via data-logger for offline post-processing.

The peak forward acceleration was identified at approximately 50% of the gait cycle (Figure 1A). Three distinct peak medial-lateral accelerations were identified: 1) during 25–45% of the gait cycle, 2) during 45–55% of the gait cycle, and 3) during
Figure 1: Exemplary COM acceleration profiles in the (A) forward and (B) medial-lateral directions for a gait cycle.

may affect the ability to regulate whole-body side-to-side balance control during dual-task gait, possibly due to poor COM acceleration generation and regulation. The examination of acceleration may provide a feasible way to detect dynamic balance deficits in the clinical setting using readily available technology.

55–75% of the gait cycle (Figure 1B). Absolute values were used in further analysis to normalize between right and left directions. Peak accelerations were analyzed by two-way mixed effects analyses of covariance, with average gait velocity as a covariate, in order to determine the effect of group (concussion and control), time (72 hours, 1 week, 2 weeks, 1 month, and 2 months post-injury) and the interaction between these two independent variables.

RESULTS

Results indicated no significant interactions, or main effects of group or time for mean peak forward acceleration (Figure 2A, p > .05). Peak medial-lateral accelerations 1 and 2 analyses also revealed no significant interaction effects, or main effects of group or time (Figures 2B and 2C, p > .05). Peak acceleration 3 results indicated that subjects with concussion displayed less peak frontal plane acceleration during 55%-75% of the gait cycle during dual-task walking than control participants throughout the two months of testing (main effect of group p = .04, Figure 2D).

DISSCUSSION AND CONCLUSIONS

Data from this study indicate that during dual-task walking, participants with concussion displayed less peak medial-lateral acceleration than control participants during 55%-75% gait cycle, representing the transition from double-support to single-support phases and suggest that concussion

Figure 2: Mean ± SE peak acceleration data for concussion and control groups across the two months of testing peak forward (A) and peak medial-lateral (B/C/D) directions. Including average gait velocity as a covariate, results indicated a significant difference between groups across the two months of testing for peak acceleration 3 (D).

ENERGY FLOW ANALYSIS OF HIGH AND LOW VELOCITY BASEBALL PITCHERS

Michael P. McNally, John D. Borstad, James A. Oñate, and Ajit M.W. Chaudhari

The Ohio State University, Columbus, OH, USA
email: Michael.mcnally@osumc.edu, web: http://u.osu.edu/osusportsbiomechanics/

INTRODUCTION

The throwing motion is characterized by the sequential motion of distal to proximal segments, which is assumed to be indicative of the transfer of energy through the kinetic chain [3]. This kinetic chain is a common focus both clinically and in research for improving performance, as well as for preventing or rehabilitating throwing injuries to the elbow [1]. While most studies investigating the kinetic chain tend to utilize correlational analysis, energy flow analysis enables us to estimate energy flowing into and out of segments, providing an estimate of the role muscles play in generating, dissipating, and transferring energy between segments [4]. This approach has been used to investigate differences between injured and uninjured elite tennis players during the overhead serve [2], but there has been little to no research investigating the role of energy flow in performance and injury risk during an overhead baseball throw. Therefore, it was the purpose of this study to explore differences in upper extremity energy transfer between high and low performing baseball pitchers.

METHODS

Thirty-two male high school baseball pitchers (height = 1.83 ± 0.07 m, mass = 75.6 ± 10.9 kg, hand velocity = 21.1 ± 2.0 m/s) were recorded at 300 Hz using a 10-camera passive optical motion capture system (Vicon, Oxford, UK) while throwing 15 fastballs towards a target. An upper extremity marker set consistent with the ISB recommendations was used to define shoulder joint angles, and joint torques were calculated using standard inverse dynamics equations in Visual3D (C-Motion, Inc., Germantown, MD). The last three pitches with complete data were chosen for analysis.

The 10 pitchers with the highest and lowest average peak hand velocity were separated into high and low velocity groups for comparison. Segment power (SP) was calculated as the sum of joint force power (JFP) and segment torque power (STP) at the distal and proximal ends of each segment for the trunk, upper arm, forearm, and hand of the throwing extremity throughout the pitch cycle (Equations 1-3; Winter, 1978).

$Eq.1)\ JFP = Joint\ reaction\ force \cdot linear\ joint\ velocity$

$Eq.2)\ STP = Segment\ torque \cdot joint\ angular\ velocity$

$Eq.3)\ SP_{segment} = JFP_{prox} + JFP_{dist} + STP_{prox} + STP_{dist}$

Net energy transfer was calculated as the integral of power for each segment of the arm during the arm cocking phase (stride foot contact to maximum shoulder external rotation) and arm acceleration phase (maximum shoulder external rotation to ball release), when energy is being applied to accelerate the ball.

One way ANOVA's were performed to compare net energy flow between high and low velocity groups using height and mass as covariates. A Bonferroni-adjusted alpha level of $p<0.00625$ was set *a priori* to account for multiple comparisons.

RESULTS AND DISCUSSION

Figure 1 shows energy flow through the trunk and throwing arm during the arm cocking and arm acceleration phases for high and low velocity pitchers. Pitchers with high velocity demonstrated greater net energy flow out of the trunk (-165.9 vs. -90.9 J; $p < 0.001$), and into the forearm (105.7 vs. 63.0 J; $p < 0.001$) and hand (93.3 vs. 56.2 J; $p <0.001$) during the arm cocking phase.

Greater flow of energy out of the trunk and into the arm early in the pitch cycle increases the energy of the arm, which may aid in accelerating the ball. This finding supports the importance of the trunk musculature to generate and transfer energy into the arm to improve performance. While it may seem counter-intuitive that the upper arm, forearm and hand receive more energy during the arm cocking phase than the arm acceleration phase, this result occurs because these segments actually move forward relative to the ground during the arm cocking phase, even though they are moving backward relative to the shoulder.

This analysis gives unique insights into how energy flows through the kinetic chain, and may be an alternative method to previous kinematic analyses for assessing the kinetic chain. This analysis can also be extended further down the kinetic chain to determine the role of core and lower extremity muscles in generating and transferring energy from the ground up. Energy flow may also be a useful analysis when investigating interventions aimed at core and shoulder stability, or other interventions with a purpose of improving energy transfer between segments. Due to the exploratory nature of

this study, further research is needed to corroborate these findings and determine how energy transfer relates to actual injury occurrences.

CONCLUSIONS

Performance may be improved through a greater transfer of energy out of the trunk and into the arm early in the pitch cycle. The power flow analysis used may be an effective measurement technique for better understanding the effectiveness of interventions aimed at improving the kinetic chain. Further research is needed though to understand the validity and utility of this analysis in kinetic chain tasks.

KINETICS OF YOUTH BASEBALL PITCHERS AND CATCHERS

Jessica Washington, Hillary A. Plummer and Gretchen D. Oliver

Auburn University, Auburn, AL, USA
email: goliver@auburn.edu

INTRODUCTION

Sports medicine professionals have reported elbow and shoulder injuries in youth baseball pitchers for decades [1,2], where to date these injuries have been considered an epidemic [3]. Rules and guidelines have been implemented for youth pitcher safety. Additionally in 2009 Little League added rules to prohibit pitchers from playing catcher in the same game. As it has been a coaching trend in baseball for youth pitchers to concomitantly play catcher. Furthermore, it has been reported that pitchers also playing catcher appeared to double or even triple their risk of injury [3]. With the increased injury risk of pitchers playing catcher, it was our purpose to examine the upper extremity kinetics in youth baseball pitchers and catchers.

METHODS

Baseball pitchers (n = 25; 11.5 $\pm$ 1.2 years; 153.5 $\pm$ 7.9 cm; 47.0 $\pm$ 7.3 kg) and catchers (n = 25; 11.2 $\pm$ 2.3 years; 150.6 $\pm$ 13.2 cm; 46.6 $\pm$ 10.6 kg) reported for testing prior to engaging in resistance training or any vigorous activity that day. The University's Institutional Review Board approved testing protocols.

Kinematic and kinetic data were collected using The MotionMonitor^{TM} motion capture system (Innovative Sports Training, Chicago IL) at a rate of 144Hz. Prior to testing participants had 11 electromagnetic sensors attached at the following locations: (1) the posterior/medial aspect of the torso at C7, (2) posterior/medial aspect of the pelvis at S1, (3-4) bilateral distal/posterior aspect of the upper arm, (5) the flat, broad portion of the acromion of the scapula, (6-7) bilateral distal/posterior aspect of the forearm, (8-9) bilateral distal/posterior aspect of the lower leg, and (10-11) bilateral distal/posterior aspect of the upper leg [4].

A twelfth sensor was attached to a stylus that was used for digitization of the bony landmarks described by the International Shoulder Group of the International Society of Biomechanics. Two points described the longitudinal axis of the segment, and a third point described the plane. A second axis was defined perpendicular to the plane, and the third axis was defined as perpendicular to both the first and second axis. Participants stood in anatomical position during digitization to guarantee accurate bony landmark identification.

Participants were given an unlimited time to warm-up. Following warm-up, pitchers were instructed to throw maximal effort fastballs for strikes over a regulation distance (46 feet; 14.0 meters) to a catcher, while catchers were instructed to receive a pitch from a pitcher and then throw the ball to a position player on second base (90 feet; 27.4 meters).

To calculate kinetics, inertial properties of the hand, forearm, and upper arm were calculated from previously published data [5] and scaled to each participant's body size. Biomechanical parameters investigated were bases on previous throwing comparisons. Peak values of four kinetic parameters were analyzed: elbow varus torque, shoulder internal rotation torque, shoulder horizontal adduction torque, and shoulder proximal force. The kinetic parameters were examined during three phases of the throwing motion: arm cocking, arm acceleration and arm deceleration.

RESULTS AND DISCUSSION

For statistical analysis, (2) x (3) between-subjects repeated measures analysis of variance (ANOVAs) were performed to evaluate each upper extremity kinetic variable among youth pitchers and catchers. A significance level of 0.05 was adopted and all

statistical analyses were performed with IMB SPSS 22 software. Shoulder proximal torque was the only variable that produced significant differences between pitchers and catchers ($F_{1,48}$ = 4.71; p = 0.035; partial eta squared = 0.089; power = 0.566). A follow-up t-test was then performed to determine where the difference occurred in the throwing motion and the results revealed that shoulder proximal torque was significantly different in pitchers and catchers during the deceleration phase (p = 0.027). Kinetic results are shown in Table 1.

It is known that most shoulder and elbow injuries in youth baseball are the result of the repetitive forces created during the throwing motion. During the arm-cocking phase of the throwing motion the shoulder must externally rotate and the elbow is flexed. Then to initiate the acceleration phase, the shoulder must rapidly internally rotate while the elbow extends. Shoulder internal rotation torque is produced to decelerate the external rotation and initiate internal rotation. The current study revealed no differences in shoulder internal rotation torque between pitchers and catchers. These results are similar to those found when comparing flat ground throwing to pitching from a mound [6]. However, the current study revealed greater shoulder proximal force during the deceleration phase of catchers throwing to second versus pitchers pitching from a mound. One explanation for this difference may be what has previously been reported when throwing from a mound that throwing from a mound has a mechanical advantage that may also serve as a protective mechanism versus throwing from flat ground [6].

CONCLUSIONS

To the author's knowledge this is the first study to examine a sample of youth pitchers and catchers who were similar in age, height and weight. As the trend in youth baseball is for pitchers to also train as catchers, it is important to understand the kinetics involved with the two positions. Large kinetics about the upper extremity may predispose these players to an increased incidence of shoulder and elbow injury. Additionally, further investigation should focus on the kinematic differences that may be present in youth pitchers and catchers in attempt to gain a better understanding of the kinetics about the upper extremity.

INTRODUCTION

Athletes who participate in sports that require overhand throwing motions have an increased risk of developing injuries to the medial Ulnar Collateral Ligament (mUCL). While advanced imaging is useful for diagnosing complete tears of the ligament; physical examinations are effectively used to diagnose partial tears or ligament damage. The Moving Valgus Stress Test (MVST) is used to diagnose injuries, which are not readily apparent on imaging.[1] A valgus torque is applied to the elbow of a patient with the shoulder abducted and the arm is then extended from full flexion (135°) to complete extension (at least 30°) or until pain is too severe. If the MVST reproduces the pain experienced by the patient during physical activity, the mUCL is likely damaged. The current work using cadaveric elbows, sought to quantify the dynamic movement inherent to the MVST, in order to compare dynamic and static anterior bundle band lengths and varus/valgus angles. Loaded elbows were compared using three different cases (flexion, extension and static loadings), which were then compared against an unloaded static case. The null hypothesis was that there would be no significant difference between band lengths and varus/valgus angulation in the three loaded cases.

METHODS

Seven cadaveric elbows, without histories of elbow injuries, were obtained and dissected by the chief orthopedic surgery resident. There were 5 male elbows (age 49.8±13) and 2 female elbows (age 39±24). The brachialis and triceps muscles were identified and sutured with fishing line. The mUCL was then carefully exposed and the three bands of the anterior bundle were identified. Three rows of small black spherical markers (0.8 mm diameter) were placed longitudinally along fibers of the three parallel bands (anterior, central, posterior).

Each elbow was mounted in a custom-built physiologic elbow simulator so that flexion and extension were in a horizontal plane. A follower arm was used to measure the flexion and extension angles of the free-swinging elbow using a precision encoder (US Digital HB5M). The varus/valgus angles were measured with an inclinometer (US Digital X3Q-V) attached to the forearm. Two conditions for each elbow were used: 1) no valgus load while 89 N of tension was applied to the brachialis and triceps and 2) loaded with only 4.5 N of tension applied to the brachialis and triceps but with an additional 6 N weight hanging from the wrist. This load was added to where the humeral trochlear groove meets the trochlear notch in order to provide consistent reference angles and lengths.

After calibration, cameras mounted above the elbow simulator captured the movement of the markers. The markers' locations in space were determined using a Spicatek Motion Capture Suite. The lengths of the mUCL bands were calculated from these locations. For a given angle in the loaded dynamic and static trials, differences of length and varus angle were determined by a comparison with a static unloaded trial. Two-way repeated measures ANOVAs (MiniTab, State College, PA) were used with Tukey's least significant difference for post-hoc testing if an ANOVA found significance.

RESULTS AND DISCUSSION

The statistical analysis found that the loading variable was significant, indicating that the static, dynamic flexion and dynamic extension were different ($p<0.001$). All three bands of the anterior bundle of the mUCL consistently increased in

length with a load applied to the wrist. This increase in ligament band length was determined by comparing the three loaded trials, all of which were conducted with a reference to a static unloaded trial at each angular position. The differences that existed between the loaded and unloaded trials were expected because it was reasonable to assume that any weight applied to the wrist would necessarily translate the arm in a downward direction, lengthening the three bands of the ligament.
Figure 1: A comparison of anterior band lengths for the three loaded trials using Flexion angle and Static Unloaded Band length.

The data, however, indicated that the amount of lengthening associated with the loading was not consistent among the three loaded trials. (Figure 1) The dynamic movements, both flexion and extension, both lengthen noticeably more than the static loaded trial. The increased lengthening of the ligament associated with dynamic movement was also associated with a greater change in varus angle for dynamic loaded trials than the static loaded trial. (Figure 2)
Figure 2: A comparison of changes in Varus Angle for loaded trials as a function of Flexion Angle.

While it is possible that the movement associated with the test caused the ligament to lengthen more because more fibers may be loaded at different flexion angles, the explanation for the difference may also be simpler. For instance, do to the nature of the experiment the elbow is loaded for a longer period of time during the dynamic movement. One may have to consider the viscoelastic nature of the ligament as it hangs during dynamic movement as opposed to a static loaded trial.

The quantification of the lengths of the fibrous bands of the anterior bundle furthers the understanding of the morphology of the mUCL. The data from this study combined with the work by Jackson[2] can be seen as a continuation of the work of Dugas[3]. Dugas was able to provide data about the overall anatomical structure of the anterior bundle of the mUCL.[3] Jackson was able to determine that the posterior and anterior fibrous bands of the anterior bundle were indistinguishable structurally. The difference in strain between the bands was a consequence of movement and insertion. The anterior band remained under relatively constant strain but the strain on the posterior band increased with flexion angle.[2]

The knowledge that movement and angle are contributing factors to the amount of strain on the bands of the anterior bundle may help explain the discrepancies in length between loaded dynamic and static movements especially between 75° and 120°. The anatomical structural information obtained by Dugas and Jackson combined with dynamic movement of this experiment supports the observed clinical efficacy of the MVST as shown by O'Driscoll.[1]

CONCLUSIONS
The results suggest that there is a statistically significant relationship between anterior band lengths and varus/valgus angles of the mUCL when comparing loaded dynamic flexion/extension and static trials. The relationship could be a contributing factor to the results seen by the MVST.

THE EFFECTS OF MILITARY BODY ARMOR ON KNEE MECHANICS DURING BOX DROP AND PRONE TO STANDING TASKS

[1] Megan P. Phillips, [1]Robert Shapiro, and [1]Babak Bazrgari

[1] University of Kentucky, Lexington, KY, USA
email: babak.bazrgari@uky.edu

INTRODUCTION

Modern day body armor (BA) has been successful at increasing survivability from previously lethal explosives [1], however, such success has come at the expense of a significant increase to the weight carried by dismounted warfighters. The added weight (106N) of BA has been suggested to reduce warfighter's performance and increase risk of injury. Given the important role of joint biomechanics in performance and risk of injury, the objective of the present study was to quantify BA-induced changes in knee biomechanics. Specifically, the immediate and prolonged effects of wearing body armor on several aspects of knee biomechanics during box drop and prone to standing tasks were investigated. We hypothesized that BA-induced changes in our outcome measures would be consistent with increased risk of injury (e.g., increased loading rate or joint moment) and/or impaired performance (e.g., increased time).

METHODS

A randomized cross-over study design, wherein twelve highly recreationally active (18-35 yrs.), gender balanced, individuals wore BA in one of two sessions, were used to test the effects of BA and wear duration on several measures of knee mechanics. Each session lasted ~2.5 hours and were conducted with a $1 < t \leq 7$ day window [2]. Participants completed prone to standing and box drop tests before and after 45 minutes of treadmill walking (i.e., exposure) with and without body armor.

For the box drop test, participants stood on a box (height: 37.5 cm) located next to an in-ground force platform. The participants initiated the test by stepping down onto the force platform following the investigators signal to start. They were instructed to step down on the force platform with their dominant foot (i.e., right foot for all subjects in this study) and continue walking in the forward direction off of the force platform (Fig 1). For the prone to standing test, participants started lying prone on the floor. Their feet were plantar flexed with the foot dorsum in contact with the ground. Their shoulders were in 180° of forward flexion, elbows extended with the palmer side of their hand in contact with the ground. When signaled by the investigators to begin the test, in one dynamic movement the participants brought their hands underneath their shoulders, pushed up, jumped their feet in towards their hands and stood upright (Fig 1). Each of the box drop and prone to standing tests were repeated three times for each condition while temporal, knee data (kinematic and kinetic (box drop only)) were collected.

Figure 1. 3D model of Box drop (top) and prone to standing (bottom) in Visual 3D software.
Kinematics and kinetics data were collected respectively using a motion capture system (Motion

Analysis, Santa Rosa, CA) and an in ground force platform (Bertec, Columbus, OH). Relevant outcome measures were calculated by an in-house Matlab code (Mathworks, Natick, MA) and using subject specific models, developed in Visual 3D (C-Motion Corp, Germantown, MD).

A REML GEE model (version 9.3, SAS Institute Inc., Cary, NC, USA) was used to examine the effects of armor and sex on pre-exposure measures, and the change in measures from pre-exposure to post-exposure. The pre-exposure model allowed the investigation of the immediate effect of armor and sex alone on risk of injury and performance; where the change model (post-exposure minus pre-exposure) allowed the investigation of the prolonged effect of exposure to BA on risk of injury and performance

RESULTS AND DISCUSSION

The immediate effects of body armor on both tasks were an increase of ≥ 4% (p ≤ 0.02) in temporal task durations and a decrease of ~1.66 N/kg (p = 0.03) in normalized peak ground reaction force for the box drop test (Table 1). The significant increase in box drop task duration may be related to the decrease in force, wherein the participants executed the task more cautiously due of the increased load. The decrease in the normalized peak vertical GRF while wearing BA during the pre-exposure BD test

and no significant changes in peak instantaneous loading rate or maximum knee extension moment may be an indication of participants' success in overcoming the BA-induced increase in task demand without a significant increase in risk of injury. The prolonged duration of walking with body armor (i.e., 45 minute) was not found to cause more changes in our measures than walking without body armor. Heavy loads carried by dismounted warfighters, including BA, can adversely impact force generation and sustainment, due to manpower-reducing injuries and impaired warfighter's performance in combat situations. The findings of this exploratory study can guide design of future studies aimed at understanding the underlying mechanisms responsible for the adverse effects of BA on warfighters' performance and risk of musculoskeletal injuries.

INTRODUCTION

The Bureau of Labor Statistics reported 15% of a total of 4,693 workplace fatalities and a total of 299,090 cases of non-fatal workplace injuries that were due to slips, trips and falls [1]. Slips occur as a result of failure of normal locomotion and failure of attempts at equilibrium recovery following an induced imbalance [2]. Both extrinsic factors such as the type of footwear [3] and intrinsic factors such as the knowledge or anticipation of a slip [4] have been shown to affect the outcome of a slip event.

The normal gait cycle pattern is disturbed due to the perturbation from a slip. Increased foot-floor angle and plantar flexion angle at the ankle and a greater hip flexion have been demonstrated during slips [4]. However, with perception of slippery conditions, a plantar flexed ankle to achieve a flatter foot strike has been shown previously [4]. Alternative footwear such as flip-flops have been shown to utilize a flat-foot position during heel strike while close-toed shod conditions have greater dorsiflexion [5]. The impact of these alternative footwear under slippery conditions with and without the knowledge of slippery flooring conditions haven't been fully addressed yet. The specific purpose of this paper is to analyze the impact of alternative footwear [crocs (CC), flip-flops (FF)] and an industry standard low-top slip resistant shoe (LT)] under multiple gait trials [normal dry (NG); unexpected slip (US), alert slip (AS) and expected slip (ES)] on lower extremity joint angles (hip, knee & ankle) at heel strike.

METHODS AND PROCEDURES

Eighteen healthy male participants [Age: 22.28 ± 2.2 years; Height: 177.66 ± 6.9 cm; Mass: 79.27 ± 7.6 kg] with no history of neuromuscular and vestibular abnormalities participated in this study. The study followed a repeated measures design with participants tested on three separate days wearing a counter-balanced assigned footwear, separated by a minimum of 24 hours. Kinematic and kinetic data were collected with a 12 camera Vicon motion capture system and dual force plates (AMTI & Bertec). Participants were strapped to a harness and a fall arrest track and performed multiple gait trials until normal self-selected pace walking with appropriate foot positioning onto the force plate was achieved. Participants turned away from the walkway and listened to music on head phones for 1 minute between each of these dry normal gait trials (NG). Following these trials, one particular trial was chosen to be the unexpected slip (US) and the contaminant (75% glycerol & 25% water) was applied on the second force plate, without the knowledge of the participant. With the completion of the US and cleaning the floor and footwear, participants performed a similar protocol to complete an alert slip (AS) and an expected slip (ES) with instructions of "may or may not be slippery" and "will be slippery" respectively. Sagittal plane hip, knee and ankle angles at heel strike were determined with the Vicon Nexus software. A 3 (Footwear) x 4 (Gait Trials) repeated measures ANOVA was used to analyze the joint angles at $p = 0.05$.

RESULTS

Significant interaction between footwear and gait trials existed for Ankle Angle at F (5.237, 89.034) = 2.403, p = 0.041, η_p^2 = 0.124 (Fig.1). The significant footwear x gait trials interaction was followed up by simple effect analysis. Footwear pairwise comparisons revealed significantly greater dorsiflexion angle in NG compared to US, AS and ES for CC and in NG compared to AS and ES for FF. No significant differences existed for LT across all gait trials. Gait trial pairwise comparisons revealed significantly greater dorsiflexion angle in LT compared to both CC and FF in NG, US, AS & ES trials. No significant differences existed between CC and FF for all gait trials. No significant interaction or significant difference for main effect footwear or gait trials were found in hip or knee angles at heel strike.
Fig.1: Ankle angle (degrees) at heel strike for Crocs, Flip-Flops and Low Top Slip Resistant Shoe during normal dry gait (NG), unexpected slip (US), alert slip (AS) and expected slip (ES) events. Positive degrees represent dorsiflexion and negative degrees represent plantar flexion. § denotes significant interaction; * denotes significant difference for footwear across gait trials and # denotes significant difference for gait trials across footwear.

DISCUSSION

Modifications in lower extremity joint angles appeared to be present only in the more distal ankle joint, while the proximal knee and hip joint angles showed no significant differences, suggesting the major kinematic changes in response to slips occurred at the distal end of the

lever at heel strike. The incidence of the slips across different slip trials and across types of footwear are reported elsewhere, with significantly greater incidence of slips in alternative footwear (CC & FF) compared to LT and with significantly greater magnitude of slips in US followed by AS and ES compared to NG. The LT appeared to maintain a normal dorsiflexion (close to neutral) ankle joint angle across all gait trials, while alternative footwear exhibited a plantar flexed foot position across all gait trials with significantly greater plantar flexion in slip trials. A greater plantar flexed ankle angle with alternative footwear during normal dry gait trials could be attributed to the different "touch down geometry" associated with these alternative footwear [5], while during slip trials, could be seen as an attempt to make contact with a flatter foot position, and having a greater surface area of the foot and a lesser foot floor angle, thereby preventing slips [4]. The LT had better performance in preventing slips and maintaining a normal gait pattern, and serves to be the choice of footwear for maneuvering slippery floors. Although alternative footwear serves for comfort and easy donning, it might not be the choice of footwear in slippery conditions, especially in hospitals where there is a greater use of crocs. Future research should focus on interactions of these alternative footwear and slippery conditions with an occupational workload.

EFFECTS OF PROXIMAL AND DISTAL MUSCLE FATIGUE ON REPETITIVE MOVEMENTS

Jeffrey C. Cowley, Rebecka Saunders, and Deanna H. Gates

University of Michigan, Ann Arbor, MI, USA
email: gatesd@umich.edu   Web: rehabrobotics.umich.edu/

INTRODUCTION

Upper extremity overuse injuries are a leading cause of lost work days in the United States. During repetitive tasks, muscle fatigue may contribute to the development of overuse injuries. When fatigued, people may alter their movement patterns, but adaptations to fatigue depend on which muscles are fatigued [1]. Due to the different roles of proximal and distal joints in executing movements, fatigue of proximal or distal arm muscles may affect movement differently [2-3]. Movement changes after fatigue can affect the risk of overuse injuries [4]. The purpose of this study was to determine how proximal and distal fatigue affect movement coordination and variability during an unconstrained, repetitive, work-like task. We examined subjects as they manually turned a bolt using a socket wrench. We expected that movement variability would increase after fatigue of the shoulder muscles and decrease after fatigue of the hand muscles.

METHODS

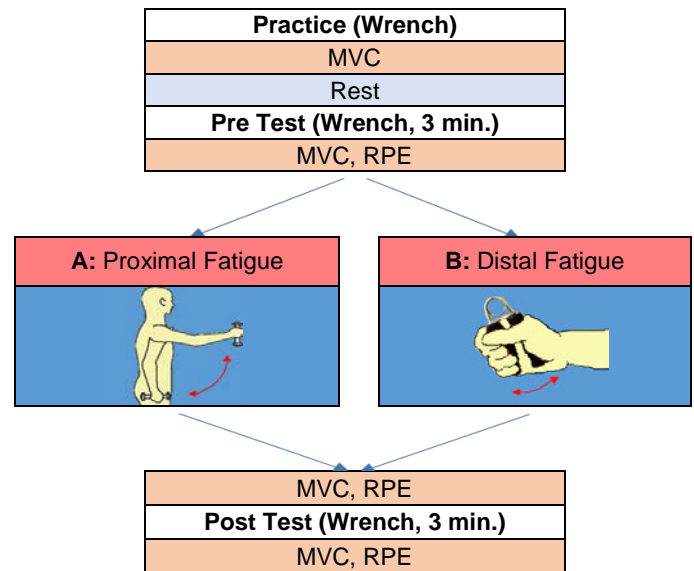
Five healthy, right handed adults (1 male) participated to date. Subjects were screened for medications or conditions which could affect arm movement. Subjects completed two experimental sessions (Fig. 1) to test the effects of proximal (A) and distal (B) muscle fatigue on a repetitive task. Subjects held a wrench in the right hand, reached up and rotated a bolt placed through a board at eye level. The task was repeated at 0.25 Hz for 3 minutes before and 3 minutes after fatigue of either proximal (shoulder flexors) or distal (finger flexors) muscles. Maximal voluntary contractions (MVC) and ratings of perceived exertion (RPE) were obtained at several points during the session to monitor fatigue (Fig. 1). The proximal fatigue protocol (A) is designed to fatigue the shoulder flexors. Subjects repeatedly raised and lowered a weight (~10 % max shoulder


Figure 1. Experimental Session. All subjects completed the same general experimental protocol. Subjects performed two trials of a repetitive wrench task, one pre-fatigue and one post-fatigue. Subjects completed two experimental sessions (A and B).

MVC) to shoulder height in the sagittal-plane with the arm straight at a frequency of 0.5 Hz. The distal fatigue protocol (B) is designed to fatigue the finger flexor muscles. Subjects repeatedly squeezed a spring-loaded grip trainer with their right hand at a frequency of 1 Hz. Subjects were instructed to match each movement phase (up/down, squeeze/release) with a metronome. Subjects performed each fatigue task for 3 minutes or until RPE ≥ 8. The movement of 47 reflective markers placed on the trunk, arms, and wrench was recorded at 120 Hz using a 16 camera motion capture system (Motion Analysis, Santa Rosa, CA). An 8-segment model was created in Visual3D (CMotion, Germantown, MA). Electromyography instantaneous mean power frequencies were calculated to quantify muscle fatigue. Movement cycles were divided into reaching and torqueing phases. The average maximum and minimum angles of the shoulder, elbow, wrist, and

trunk across all movement cycles were obtained and variability was calculated as the median absolute deviation [5]. Results are reported as mean (standard deviation).

RESULTS AND DISCUSSION

During the fatiguing tasks, MVC strength of the targeted muscle group decreased by 25% on average. Subjects completed a similar number of wrench repetitions during all pre- and post-tests.

We noted several differences in upper limb and trunk kinematics after fatigue. After proximal fatigue, subjects exhibited decreased humeral elevation, greater external rotation and forearm supination, and increased trunk movement (Table 1; Fig 2. After distal fatigue, subjects increased wrist extension and ulnar deviation (Table 1). On average these differences were quite small (< 3 deg).

Forearm pronation during the reaching phase of the movement was more variable after proximal fatigue (Pre: $1.7 \pm 0.6°$; Post: $1.9 \pm 0.4°$) and less variable after distal fatigue (Pre: $1.9 \pm 0.5°$; Post: $1.7 \pm 0.6°$). Trunk rotation variability decreased more after distal (Pre: $2.0 \pm 0.4°$; Post: $1.6 \pm 0.4°$) than proximal fatigue (Pre: $1.9 \pm 0.4°$; Post: $1.7 \pm 0.4°$). During torqueing, peak external rotation of the humerus was more variable after proximal (Pre: $3.5 \pm 0.8°$; Post: $4.5 \pm 2.1°$) but not distal fatigue (Pre: $3.1 \pm 0.9°$; Post: $3.3 \pm 1.7°$) (Fig. 2).

CONCLUSIONS

Distinct movement adaptations were observed after fatigue of proximal and distal muscles of the dominant arm during a repetitive task. Compared to pre-fatigue, subjects adopted less variable movement
Figure 2. Humeral rotation for one subject during wrench torqueing. Top: Average angle before (blue) and after (tan) shoulder fatigue. Bottom: Average angle before (blue) and after (red) hand fatigue. Shaded areas represent one standard deviation.

patterns after fatigue of the distal muscles and more variable movement patterns after fatigue of the proximal muscles. We observed significant movement redistribution after proximal fatigue, but relatively few changes in joint angles after distal fatigue. The distinct movement strategies may have reduced the effort of fatigued muscle groups, allowing fatigued muscles to recover. A reduction in variability after distal fatigue could accelerate fatigue and affect the risk of injury.

LARGER HORIZONTAL AFFORDANCES FOR PERCEIVED SAFE HANDLING ARE ASSOCIATED WITH INJURY-RISK LIFTING KINEMATICS

[1]Jon B. Doan, [2]Wayne J Albert

[1] University of Lethbridge, Lethbridge AB Canada
2 University of New Brunswick, Fredericton NB Canada
email: jon.doan@uleth.ca, Twitter: @DoanJon

INTRODUCTION

Workplaces can be dynamic environments, with variable demands on the physical and cognitive capabilities of workers. Longitudinal studies of different work types have suggested various biopsychosocial worker traits and states that may contribute to an increased injury risk [1,2], but the neuromechanical bases of these differences remains largely unknown [3-5]. The purpose of the current research was to examine affordances and associated kinematics of behaviour in an experimental occupational lifting task. It was hypothesised that participant-workers with high perceived lifting affordance (hyper-affordant) would demonstrate higher injury-risk type kinematics than those with lower perceived lifting affordance (hypo-affordant).

METHODS

One load factor from the National Institute of Occupational Safety and Health (NIOSH) 1991 lifting guideline [6] was tested, specifically horizontal distance to load at start of lift (H Factor in NIOSH 1991 model). Twenty university students (21.4 +/- 2.8 years, 13 females) volunteered to participate in the study, and provided informed consent prior to whole body placement of infrared reflective markers. Participants were positioned with feet on baseline on the floor, with all load starting positions and the load final placement position inside the calibrated volume of a camera-based motion analysis system. The test load was a rigid industrial tote (0.55m x 0.35m x 0.25m) with a fixed mass (4.5 kg) at the centre of its floor, and good bilateral handles. Participants were told they would be choosing the greatest horizontal load placement distance that they felt would be safe for completion of a lift from the floor, using a single forward step with either leg to handle and lift the load. Following this familiarization with the task, the investigator slid the load away from the participant along the tape measure on the floor. Participants told the investigator to stop at the horizontal affordance threshold (AT) they felt was safe for the lifting task as defined. Participants were given the opportunity to step, forward flex, and place their hands close to the load, without touching or lifting it, to confirm their perceived horizontal AT. Iterative increases or decreases were made to the selected distance by an investigator until the participant was completely satisfied with their AT. Following the recording of this value, each participant completed a series of 21 lifts, three at each of 60%, 70%, 80%, 90%, 100%, 110%, and 120% AT (Figure 1).

Figure 1: *Lifting trial.* After establishing their safety-based affordance threshold (AT), participants completed multiple flex-to-lift-to-place trials at relative proportions of their AT.

The lifting movement was divided into serial phases (ONSET, ADDRESS, HANDLE, LIFT), and linear and angular kinematic analysis here will focus on the ADDRESS (trunk forward flexion: reach to load on ground) and LIFT (trunk extension: return from ground with load) phases, as the most dynamic aspects of the behaviour. Participants were divided *post hoc* into two groups according to the ratio of their self-selected horizontal lifting affordance threshold (AT) to their stature (H; vertical distance between C7 marker and average ankle marker during quiet standing, as determined from pre-movement motion analysis capture). This dimensionless relationship (AT/H) has previously

been used to represent affordance as a system function of both animal and environment [7]. In this study, lifters who perceived a personal AT/H above the group mean AT/H were defined as hyper-affordant (HYPER; n = 9) while those who perceived a personal AT/H at the mean or below were defined as hypo-affordant (HYPO; n = 11). This *post hoc* grouping provided an additional serendipitous comparison – the average physical distance for the HYPER group's 80% AT was equal to the HYPO group's average 90% AT, each with a mean real distance of 0.75m. This equality allowed us to develop additional comparisons at a TRUE EQUAL distance. In the current study, we correlated height-normalised lifting affordance perceptions with TRUE EQUAL lifting kinematics, specifically a modified calculation of Burgess-Limerick and Abernethy's "postural index" [8] and a summation of time for dynamic lifting phases (ADDRESS + LIFT) to determine if affordance perceptions were associated with lifting kinematics.

RESULTS AND DISCUSSION

Perceptual and behavioural differences existed between the HYPER and HYPO sub-groups, including significantly different knee flexion angles (smaller values meaning greater knee flexion) during the ADDRESS phase (Figure 2; $F_{(1,6)} = 4.334$, $p = .039$).
Figure 2: *Magnitude of knee flexion during ADDRESS phase.* The spokes on the graph are the different lifting distances, from 60 to 120% affordance threshold, while the rings of the graphs are knee flexion anglesHYPO and HYPER affordant lifters differed significantly on knee flexion, with HYPO lifters using greater knee flexion to reach to lift the load.
Figure 3: *Association between normalized safe lifting affordance perception and lifting kinematics.* A significant association existed between height-normalized affordance perception for safe lifting and lifting behaviours, with HYPER affordant lifters using smaller postural index (more stooped lift) at higher rates (shorter duration) than HYPO affordant lifters at TRUE EQUAL distance (r=-0.47, p = .044).

CONCLUSIONS

These preliminary results suggest that kinematics for lifting are coupled with perceived lifting affordance, at least in the horizontal task context. It is possible that the examination of perceived affordances in valid occupational tasks could identify workplace contexts, worker and organizational states, and worker perceptotypes at increased risk for musculoskeletal injury. Production and manufacturing facilities may benefit from re-examination of their workspaces and manual materials handling tasks, beyond conventional guidelines, and inclusive of affordance-driven concepts of safe and acceptable work behaviours.

VALIDITY OF ACCELEROMETERS IN PREDICTING OCCUPATIONALLY RELATED LOWER EXTREMITY EXPOSURES

email: dutt.15@osu.edu

INTRODUCTION

Lower extremity musculoskeletal disorders and injuries affect a number of people in occupational settings. In many occupations, such as manual material handling jobs at distribution centers, there is exposure to prolonged standing, excessive walking on hard surfaces or uneven surfaces, stepping up or down between work surfaces, and there is vibration exposure. Quantifying these occupational exposures and their relationship to injury is necessary to determine thresholds that can be used to identify safe versus unsafe exposures levels for the lower extremities. To understand the force vectors generated at heel strike during walking, previous studies have used transient impulse forces on the tibia, also known as tibial shock [1,2].

The aim of this study was to validate the use of an accelerometer based instrumentation system that measures the transient impulse forces on the tibia, to quantify differences in material handling tasks with varying levels of lower extremity tibial shock exposure. We hypothesized that the measurement system would be able to detect variations in lower extremity tibial shock exposures across three tasks of varying exposure levels.

METHODS

Experimental Design: The study was a repeated measures design consisting of experimental conditions that simulate common types of distribution center work in which there are three different levels of tibial shock exposure as measured via the peak accelerations of the tibia.

Participants: Twenty volunteers, 11 males and 9 females between the ages of 18 and 36 years (mean = 22 years, s.d. = 5 years) participated in this study.

Mean height and weight were 1.71 m (s.d. = 0.09 m) and 69 kg (s.d. = 11 kg). None of the individuals had any lower extremity symptoms or pain 6 months prior to the time of the study. All study participants signed an Institutional Review Board (IRB)-approved consent document. All participants wore some type of athletic shoe.

Instrumentation: Single-axis accelerometers (Vernier – ACC BTA) were attached to the skin on the anterior aspect of the participants' left and right tibia and secured using a self-adhesive wrap. Sensors were attached to a data logging interface (Vernier – Lab Quest Mini) and tablet computer that were placed in a backpack carried by the participant.

Procedures and Data Analysis: Participants were instructed to complete the tasks at 3 exposure levels – Low, Medium and High Exposure. The tasks are described in Table 1 below. The sequencing of the tasks was counter-balanced across subjects and each task was repeated 30 times. The peak positive tibial accelerations were extracted for each task using MATLAB. Data were normalized for individual subjects using the mean value of the peak tibial accelerations of low exposure task and computing a ratio of each peak with the mean value. The distribution of values from each task were compared by obtaining the 50th, 75th and 90th percentile values and overall data analysis was conducted using a one-way ANOVA. Although bilateral tibial acceleration data was collected, only the leg showing the greatest tibial acceleration values was analyzed.

RESULTS AND DISCUSSION

The normalized peak tibial acceleration values for the 3 task exposure levels have been provided in Table 2. At the 50th percentile, the normalized

values of peak tibial acceleration were statistically different for the Low and Medium (p=0.0021) and the Low and High Exposure Tasks (p=<.0001). The differences between the Medium and High Exposure tasks were not statistically significant. This is because the Medium and High tasks were similar apart from the stepping off and on the platform. At 75th and 90th percentile values, the peak tibial acceleration values were statistically different for the Low and Medium (p=0.0247 and p=0.0006 respectively), the Low and High Exposure Tasks (p=<.0001) and the Medium and High Exposure Tasks (p=<.0001). These differences are illustrated in Figure 1.
Figure 1: Comparison of Normalized Peak Tibial Acceleration Values across the 3 exposure levels

Though the differences between tasks may appear small, it is important to note that in the context of daily exposure, employees at distribution centers are often working at high speeds, involved in handling heavy cases and walking on average approximately 21000 steps/day or 10 miles/day [2]. Therefore, given the cumulative exposures in material handling occupations within distribution centers, having instrumentation and associated metrics that can differentiate between task exposures could be useful in identifying lower extremity work related musculoskeletal disorder risks.

CONCLUSIONS

The data supported the hypothesis that the instrumentation and associated peak tibial accelerations metrics could differentiate between the tasks at three exposure levels and therefore can be used to develop occupational risk models.

LOW BACK PAIN STATUS AND PROLONGED STANDING ALTER CENTER OF PRESSURE PROFILES DURING CONSTRAINED STANDING

[1,2] Kaitlin M. Gallagher and [2] Jack P. Callaghan

[1] University of Arkansas, Fayetteville, AR, USA
[2] University of Waterloo, Waterloo, ON, CA
email: kmg014@uark.edu, web: http://coehp.uark.edu/12889.php

INTRODUCTION

While approximately 50% of a sample will demonstrate clinical levels of low back pain during prolonged standing[1], few pre-existing variables exist that can distinguish the two groups. The center of pressure (COP) is frequently used to assess the influence of external (vision or a task) and internal (such as pain) changes on a person's balance control. If differences are shown, assessment of the COP could provide a simple way to determine if individuals are susceptible to prolonged standing pain development and track progress in prevention strategies through interventions. Thus, the purpose of this study was to assess the influence of pain development and prolonged standing on balance characteristics during constrained standing.

METHODS

Thirty-one participants between 18 and 35 years were recruited for a prolonged standing occupational simulation. Participants were excluded if they had any previous history of low back pain that required a medical intervention or time off work longer than three days, previous lumbar/hip surgery, employment in a job with prolonged standing during past 12 months, and the inability to stand for 2 hours.

Participants performed two 2-minute constrained quiet standing tasks (with and without vision) before and after a 120-minute prolonged standing occupational simulation where participants completed assembly and sorting tasks. Upon entering the lab, participants filled out a visual analog scale (VAS) to assess their low back pain at that time. Participants then stood on two force plates (AMTI, Watertown, MA, USA) to provide separate 3D kinetics for each foot. Foot position was

standardized by creating a box with dimensions equal to the participant's foot length (with shoes). Participants were instructed to *"look straight ahead, stand as still as possible with your arms by your side and weight evenly distributed between your feet"*. Pain developer status was established using VAS scores during 120 minutes of prolonged standing

The net COP was calculated based on the methods of Winter et al.[2]. Pain developers were categorized if they exhibited a 10 mm or greater increase in their VAS scores relative to their baseline score[1,3]. The COP was filtered at 5 Hz. The mean COP position was subtracted from all data points. Mean power frequency (MPF) and the root mean square (RMS) amplitude (equitable to the standard deviation of the COP position when the mean of the signal is removed) of the COP data were calculated for each 2-minute trial. This was performed for both the medial-lateral (ML) and anterior-posterior (AP) directions.

A four-way general linear model with two between factors (Gender and Pain Group) and two within factors (eyes open/closed, pre/post prolonged standing) was run on each outcome measure. For any significant interactions, simple effects were used to determine the source of the interaction. The level of significance was set at alpha = 0.05 for all tests.

RESULTS AND DISCUSSION

Forty-two percent of participants (13/31) were characterized as pain developers during prolonged standing. There was a significant main effect of pain group for ML MPF (p=0.0454). Non-pain developers had consistently greater ML MPF than pain developers. There was also a significant

interaction between time*vision (p=0.0257, Figure 1). With vision, ML MPF was significantly higher after 120-minutes of standing than pre-standing and was comparable to the ML MPF measures found with eyes closed. Since prolonged standing uses hip abductor muscles to perform ML weight shifts during standing[4], these muscles may not adequately provide the hip-load unload strategy under normal quiet standing conditions after 120 minutes of standing exposure.
Figure 1: ML MPF compared pre- and post-prolonged standing in the eyes open and closed conditions.

Both AP and ML RMS had a significant interaction of pain group*vision (AP: p=0.0002; ML: p=0.0114; Figure 2). In general, non-pain developers demonstrated an increase in their COP RMS amplitude when they closed their eyes, while pain developers did not show this change. While there is no difference between the pain groups during normal vision, with the loss of vision pain developers still show a tighter control of the COP. This could be due to the increased gluteus medius co-contraction found previously in pain developers[3]. It may also show that although no differences exist in the two groups during normal vision, the two pain groups may be using different mechanisms to maintain their postural control. For example, the pain developers may show an over-reliance on their gluteus medius muscles to control their center pressure during normal standing.
Figure 2: ML RMS amplitude compared between pain (PD) and non-PD in the eyes open and closed conditions.

CONCLUSIONS

Both low back pain development and prolonged standing influenced the amplitude and frequency of the COP movement, respectively. Future work should investigate the lack of change in the COP amplitude with the removal of vision as a predictive test for determining if a person will have prolonged standing induced low back pain development. Second, the potential that prolonged standing could negatively influence a worker's balance over the course of the day should also be studied further.

STANDING IN ANKLE PLANTARFLEXION REDUCES LOW BACK PAIN REPORTS DURING PROLONGED STANDING

[1,2] Kaitlin M. Gallagher and [2] Jack P. Callaghan

[1] University of Arkansas, Fayetteville, AR, USA [2] University of Waterloo, Waterloo, ON, CA
email: kmg014@uark.edu, web: http://coehp.uark.edu/12889.php

INTRODUCTION
A sloped surface that allows people to work while standing in dorsi- or plantarflexion reduces reports of low back pain (LBP) development in people who report LBP during level ground standing[1]. In the study[1], people were allowed to alternate between the incline and decline surfaces. These findings raised the question of why LBP decreased: the alternating posture that would result in small cyclic flexion and extension of the lumbar spine[1,2] or because the majority of time was spent in dorsiflexion, resulting in mild flexion of the lumbar spine [1,2]. As a result, the purpose of this study was to determine if standing solely on a declining surface during an occupational simulation would decrease LBP reports. A secondary purpose was to determine changes in kinematics caused by standing on the declining surface during both acute and prolonged bouts of standing.

METHODS
Seventeen participants (nine male, eight female) aged 18-35 with no history of LBP that required medical intervention or time off work longer than three days, previous lumbar/hip surgery, employment in a job requiring prolonged standing within the last 12 months, and the inability to stand for at least two hours were recruited for this study.

A motion capture system (NDI Inc., Waterloo, ON, 32 Hz) was used to track kinematics during data collection. Rigid bodies were placed on the spine at T9, L1/L2, and sacral levels. Bilateral rigid bodies were also placed on the thighs and feet. Anatomical landmarks for each segment were tracked within the respective rigid body. A 100 mm visual analog scale anchored with "No Pain at All" and "Worst Pain Imaginable" was presented (e-VAS, University of Waterloo) to the participant on a touch screen tablet (iPad 2) to assess LBP development when they entered the lab, at the start of prolonged standing, and every 7.5 minutes during the protocol.

Standing on level ground and a declining surface (16°) were tested on two separate days. The order the participants saw the conditions were randomized. Participants were instructed to "stand as you normally would if you were required to work at a computer workstation. You can lift up each foot, change your foot position, and shift your weight back and forth. You cannot support your body weight on the table or cross your feet". During the prolonged standing task, participants worked at a computer performing a standardized typing task.

Figure 1. Level ground (left) and decline (right) standing

Once the participant was instrumented, they performed a static standing calibration trial and a maximum lumbar extension trial to determine relative angles. On the day of the sloped protocol, participants performed two 60-second foot constrained trials prior to prolonged standing to assess the acute kinematic differences between the standing positions. Participants then completed a 75-minute unconstrained standing trial while working at the computer workstation.

Participants were categorized as pain developers (PD) based on visual analogue scale scores provided during the *level ground* standing position if they surpassed a 10 mm increase in their score with respect to baseline[1]. Marker locations were imported into Visual3D (v4, C-Motion, Inc., Germantown, MD, USA) to calculate trunk, lumbar spine, hip angle, and trunk-to-thigh angle were

calculated and expressed with respect to the corresponding angle from maximum extension. The anterior-posterior distance between the location of the trunk center of gravity and joint center of the right angle was also calculated.

For the foot constrained standing trials, outcome measures were entered into a three-way general linear model with between factors of gender, pain group (PD/non-PD) and a within factor of standing condition (level/sloped). For prolonged standing, an additional within factor of time was added to the model. Significance was set at alpha = 0.05.

RESULTS AND DISCUSSION

53% of participants (9/17) were categorized as PD (four males, five females). While standing on the sloped surface, there was a 58% decrease in LBP VAS scores compared to each PD's maximum VAS on level ground (Figure 1).
Figure 2: Maximum visual analogue scale scores.

During the foot constrained standing trials, there were no main effects including pain group for the kinematics. The sloped surface induced hip flexion (p=0.035), trunk-to-thigh flexion (p=0.01), and moved the location of the trunk center of gravity posterior compared to level ground (p<0.0001) (Table 1).

During prolonged standing, there was an interaction between pain group and standing condition (p=0.022). During level ground standing, the trunk center of gravity of PDs was on average 1.7 cm more anterior to the ankle than in non-PDs. During the sloped standing condition, the location of the center of gravity moved posterior and was aligned with the ankle joint (non-PD= 0.75 +/- 1.3 cm; PD= 0.83 +/ 1.3 cm).

We hypothesized that when standing on the declining surface the main kinematic change would occur at the lumbar spine[1,2] but this was not the case. Internal measurements while standing on a declining surface corroborate this finding[3]. The sloped surface appears to prompt participants to perform a hip dominant correction, allowing for a postural change without altering the moment induced by the trunk center of gravity at the L5/S1 joint. Also, a more anterior center of gravity with respect to the ankle would result in a greater moment arm with respect to the ankle for the force of the trunk due to gravity in PDs.

CONCLUSIONS

Standing on a sloped surface altered hip and trunk kinematics and may be a reason that self-reports of LBP development are lower in prolonged standing induced PDs when they stand on this surface. These results demonstrate that altering posture that results in mild flexion of the hips and alters the trunk center of gravity location, and not necessarily cyclic movement or isolated postural changes in the lumbar spine, may be responsible for the decreased pain development.

INTRODUCTION

The most commonly accepted mechanical risk factors linked to low back injury include: (i) high force demands; (ii) frequent repetition; and (iii) awkward postures [1]. However, as noted by Gallagher and Heberger [2] these exposures have typically been examined in isolation, and are often assumed to contribute independently to risk of injury. As such, our understanding of the combined effects of different external task demands (e.g. load, speed, and lift asymmetry) on low back joint loading and injury may be limited. Therefore, the motivation for this study was to evaluate interactions between: (a) external load magnitude, (b) movement speed, and (c) symmetry of initial load placement on estimates of *in vivo* low back joint loading during an occupational lifting task.

METHODS

Thirty-four participants with an average [SD] of 9 [10] years of manual materials handling experience (mean [SD] age = 37 [10] years; height = 1.80 [0.06] m; mass = 86 [10] kg) were recruited. The inclusion criteria for participation specified that participants reported that they were free of any known musculoskeletal injury and pain at the time of testing.

Whole-body, three-dimensional kinematic data were measured at 160 Hz using a 10-camera optoelectronic motion capture system (Vicon, Centennial, CO, USA). Sets of four and five reflective markers, fixed to rigid pieces of plastic were secured to the body with Velcro® straps, and used to track the position and orientation of 15 body segments that were modeled. Two in-ground force platforms (FP6090; Bertec, Columbus, OH, USA) mounted side-by-side were used to measure reaction forces and moments between the feet and ground. The analog signals from each force platform were synchronized with the kinematic data, and sampled at a rate of 2400 Hz using Vicon software (Nexus version 1.4, Centennial, CO, USA).

Pairs of pre-gelled surface electromyography (EMG) recording electrodes (3 cm inter-electrode spacing; Medi-Trace, Kendall-LTP, Chicopee, MA, USA) were adhered to the skin, bilaterally, over the following six trunk muscle groups: (i) thoracic erector spinae (~T9), (ii) lumbar erector spinae (~L3), (iii) rectus abdominus, (iv) external abdominal obliques, (v) internal abdominal obliques, and (vi) latissimus dorsi. EMG signals were bandpass filtered (10-500 Hz) and differentially amplified (CMRR > 100 dB at 60 Hz; input impedance > 100 MΩ; TeleMyo 2400 G2 Telemetry System, Noraxon Inc., Scottsdale, AZ, U.S.A.) prior to analog-to-digital conversion at 2400 Hz. Surface EMG signals were collected synchronously with the force platform and kinematic data using Vicon software.

Each participant initially performed three lifting trials (box dimensions; 30.5 x 30.5 x 30.5 cm) that represented a low-demand condition (9.3 kg load, preferred movement speed, symmetrical positioning of load). Once these low-exposure trials were collected, the external demands of the lifting task were sequentially modified by manipulating each of the following parameters using a full-factorial design: (a) magnitude of external load – low = 9.3 kg, high = 24.7 kg; (b) movement-speed –

participants were instructed to either perform the lift in a *"controlled manner"* at their preferred speed or *"as quickly as comfortable"*; and (c) symmetry of initial load placement – the load was placed either in front of participants or at 45 degrees to the left of participants' mid-sagittal plane. Each participant completed a total of 24 lifting trials that were evenly distributed across each of the eight experimental conditions.

Reaction forces and moments derived from inverse dynamics analyses, lumbar spine kinematics, and normalized linear envelope EMG signals were incorporated into a three-dimensional, dynamic, EMG-assisted musculoskeletal model of the lumbar spine to quantify L4/L5 joint compression and shear forces [3]. All trial data were truncated to include only the ascending phase of the lifting motion based on the vertical trajectory of participants' linked-segment model centre-of-mass.

Interactions between the magnitude of the external load, movement speed, and symmetry of initial load placement on peak and cumulative estimates of L4/L5 compressive loading, as well as the normalized peak lumbar flexion angle at the time of peak loading, were evaluated with a within-subject, three-factor general linear model.

RESULTS

Significant two-way interactions between load and speed ($p = 0.0035$), as well as speed and posture ($p = 0.0004$) were revealed in peak measures of L4/L5 compressive loading. Subsequent analyses revealed significantly greater magnitudes of peak compressive loading for fast lifting trials with 9.3 kg of external load compared to the preferred speed ($p < 0.0001$; average difference = 588 N); however, there was no significant difference between the preferred and fast lifting trials performed with 24.7 kg of external load ($p = 0.5586$). Significantly greater magnitudes of peak compressive force were also observed in the high-speed trials with asymmetrical load placement ($p < 0.0001$; average difference = 580 N); however, there was no significant difference observed for the asymmetrical condition ($p = 0.5699$).

A significant three-way interaction between load, speed and posture ($p = 0.0477$) was observed in the cumulative estimate of compressive joint loading at L4/L5. Subsequent analyses of the interaction between load and speed across both symmetrical and asymmetrical load placement trials revealed a significant main effect of load ($p < 0.0001$; average difference = 724.7 Ns) and speed ($p < 0.0001$; average difference = 561.5 Ns) in trials with symmetrical load placement; however, there was a significant interaction between load and speed ($p = 0.0006$) for asymmetrical trials. Tukey's *post hoc* test revealed that both the low- and high-load conditions were significantly different ($p < 0.0001$), although a more pronounced difference (1030.6 Ns) was observed at the preferred movement speed.

A significant main effect of posture ($p < 0.0001$) was revealed in normalized measures of lumbar flexion angle at the time of peak compressive loading; however, there was no significant main effect of load ($p = 0.4297$) or speed ($p = 0.1963$) found. Tukey's *post hoc* test revealed that, on average, participants assumed more lumbar spine flexion at the time of peak compressive loading with asymmetrical load placement ($p < 0.0001$; average difference = 8.5% of full flexion).

DISCUSSION & CONCLUSIONS

Results from this investigation provide strong evidence that known mechanical low back injury risk factors should not be viewed in isolation. Rather, injury prevention efforts need to consider the complex interactions that exist between external task demands and their combined influence on internal joint loading. This non-additive response may be especially important to consider when investigating underlying mechanisms of injury.

PERCEIVED RISK OF BIOMECHANICAL FACTORS RELATED TO LOW BACK INJURY IN THE WORKPLACE

Chelsea R. Snow[1] and Diane E. Gregory[1,2]

INTRODUCTION

Nearly 80% of the population will encounter a low back problem within their lifetime despite substantial research in the area of low back pain dedicated to the understanding associated risk factors. Risk factors such as repetitive or prolonged twisting, bending, lifting, and sitting have been identified [1]; however, it is not currently known if this has been effectively translated to workers. The aim of this study was therefore to determine worker perceptions of low back injury risk factors.

METHODS

Participant Recruitment and Protocol
109 participants were recruited from four occupations: 50 office/administrative workers, 26 firefighters, 25 university students, and 8 dental workers (dentists and hygienists). Each participant was presented with a series of seven standardized images depicting different spine postures including upright and slumped sitting, lordotic and kyphotic lifting, and twisting (Figure 1) as well as one occupational-specific posture following the seven standard images (Figure 2). Participants were instructed to rate each picture on a scale from 0-10; zero representing no risk and ten representing extreme risk of injury to the low back.

Statistical Analysis
Ratings were statistically compared using a 2-way repeated measures ANOVA with occupation (4 levels: firefighter, student, dental, office) and posture (repeated measure; 7 levels) as the two factors. An alpha level of 0.05 was use determine significance.

Figure 1: Seven standardized postures (4 lifting postures, 2 sitting postures, 1 twisted posture) presented to each participant. Order was random and participants were not permitted to look back at previous postures or ratings.
Figure 2: Occupation-specific postures. A) office, B) student, C) dental, D) firefighting.

RESULTS

Collapsed across all of the standardized postures, dental workers had the highest ratings (6.2 ± 1.1)

and firefighters had the lowest ratings (4.8 ± 0.6) (Table 1).

Table 1: Average rating collapsed across the seven standardized postures. Occupations with different letters are significantly different (p<0.05).

Occupation	Average Rating	Standard Error	Significance
Fire	4.8	0.6	a
Student	5.1	0.6	a,c
Office	5.5	0.5	b,c
Dental	6.2	1.1	b

In terms of lifting postures, all four occupations rated kyphotic postures the highest (and therefore most risky), regardless of whether it included a bent or straight knee ($\sim 8/10 \pm 2$). Interestingly, office workers, firefighters and dental workers all perceived lifting with a straight leg as being significantly riskier than with a bent knee when the spine was lordotic (p<0.001), while students perceived the risk to be the same regardless of knee posture (p>0.05). In terms of sitting postures, upright sitting was rated lowest by all occupations ($\sim 2/10 \pm 2$), while slumped sitting was perceived to be approximately twice as risky as upright sitting (p<0.001). Interestingly, firefighters rated both sitting conditions significantly lower compared to the other three occupations (p = 0.003). Last, dental workers rated twisted spine postures to be as risky as kyphotic lifting postures, which was significantly higher (and therefore greater risk) than all three other occupation's ratings (p = 0.003).

The occupation-specific postures revealed interesting findings that in certain cases complemented the standardized posture findings. In particular, for the students, the slumped sitting posture in a tablet-style desk was rated similarly to the standardized slumped posture. Dental workers rated the slumped twisted posture when working with patients similar to the standardized twisting posture. Interestingly, for the office workers, the stability-ball sitting posture was perceived to have a similar risk to the low back as upright sitting. Last, firefighters rated the CPR posture similar the twisted posture and lordotic straight-knee lifting.

DISCUSSION

Lifting
The differences in posture ratings between office workers, dental workers, firefighters and students demonstrate variance among professions in terms of injury risk perception. All occupations accurately identified lordotic postures, both lifting and sitting, to be less risky than kypohotic. Interestingly, with the exception of students, lifting with bent knees was thought to be less risky than straight knees, even with identical spine postures emphasizing the "lift with your knees" training technique. The student population may not have had experience in occupations where low back injury risk training is incorporated and therefore may not be aware of this common training recommendation.

Sitting
All occupations rated upright sitting as having the lowest risk to the low back. Further, all occupations rated slumped sitting significantly more risky than upright. The more strenuous nature of firefighting may be the reason firefighters rated sitting much lower than the other occupations, which all spend a large proportion of their day sitting. Interestingly, the office workers rated the stability-ball posture to have a similar risk as upright sitting despite published work that has shown otherwise [2].

Twist
The twisted posture rating was most variable across occupations with dental workers rating it highest. Dental workers likely rated twisted postures higher as they spend much of their day in twisted sitting postures when working with patients.

CONCLUSION

The findings from this study can be used to implement new training programs and interventions that are occupation-specific.

ERGONOMIC EVALUATION OF A PROTOTYPE QUICK-RELEASE BODY ARMOR SYSTEM

[1] Brian K. Higginson and [2] Jennifer L. Wheeler

email: higginson@gonzaga.edu

INTRODUCTION

Most recent military conflicts require that body armor (and associated tactical load) be worn by soldiers during maneuvers and tactical engagements. Due to the weight and bulk of this externally carried load, self-extraction and rescuer-extraction during time-critical emergencies, such as underwater submersions and vehicle rollovers involving fire, can be difficult. In an effort to expedite extractions during time-critical emergencies, a quick-release body armor system was developed.

In addition to facilitating a quicker doffing of the system, the current system also integrates a waist belt that effectively transfers the weight of the body armor and tactical load to the wearer's waist. Most current body armor system designs require that all of the external load be carried on the shoulders, which can lead to shoulder and upper extremity pain and fatigue.

The current system incorporates a 5-point release mechanism that, once activated, allows the front armor plate to fall away via release of two sets of buckles located on the shoulder straps and cummerbunds. The design of the rear armor plate and waist belt interface requires the user to lift the rear plate out of a pocket integrated into the waist belt once the front plate has fallen away.

The purpose of the current study was to perform an ergonomic evaluation of a prototype quick-release system for military body armor and tactical loads in order to facilitate rescue efforts during time-critical emergencies.

METHODS

12 members of the local County Sheriff's SWAT team volunteered to participate in the study (Mean ± SD: 40.4±4.3 yrs, 180.3±6.8 cm, 93.5±10.3 kg). Each subject was fitted with a five-point quick-release body armor system, Kevlar helmet, and standard tactical load (simulated weight included six 30-round magazines, two fragmentation grenades, hydration system, Improved first aid kit (IFAK), and dump bag). A familiarization period was provided for each subject to practice donning and doffing the armor and load as needed. Upon completion of the familiarization session, a linear force transducer was attached to the quick-release pull lanyard, EMG electrodes were attached to muscles of the upper extremity (anterior deltoid, lateral and long head of the triceps), and an electro-goniometer was attached across the elbow joint.

Once sensor attachment was complete, the subject was asked to utilize the quick-release mechanism to remove the armor and load. This was performed using each hand in the standing and seated positions. Since the release lanyard ran along the left shoulder strap of the armor system, it was expected that outcome measures may be different when using a left vs. right handed release strategy. Each condition was unconstrained and performed three times for each condition, for a total of 12 releases per subject. All outcome measures were averaged over the three releases within a given condition.

Specific outcome measures included linear force required to initiate the quick-release mechanism, linear force required to clear the armor from the integrated waist belt, upper extremity muscle activation during the release, elbow range of motion (RoM), as well as doffing times for each of the

conditions. A 2-factor (release side x release position) Repeated Measures ANOVA was used to detect changes in outcome measures across trials (α=.05).

RESULTS AND DISCUSSION

Although muscle activation of the left anterior deltoid tended to be ~25% higher than the right, this difference was not found to be significant (p=0.270), nor was there a significant difference in muscle activation as a function of release position (p=0.764). Muscle activation of the lateral and long head of the triceps were also similar across release sides (p=0.460 and p=0.334, respectively) and release positions (p=0.175 and p=0.187, respectively). Elbow RoM was significantly greater during the left handed release strategy than the right (84.7° vs. 60.6°, respectively, p=0.005) and while in the seated position (75.7° vs. 69.4°, respectively, p=0.018).

Release force (force at the time of buckle release of shoulder strap) averaged 19.3 N. There were no differences in release force for either position (p=0.957) or release side (p=0.818). The average applied force during the doffing process was 83.1 N, with no significant differences detected between release position (p=0.296) or side (p=0.612). Maximum force applied to the release lanyard during the doffing process averaged 139.4 N, and like release force, this force was similar across positions (p=0.427) and release side (p=0.471).

Overall release time, as defined from movement initiation to rear plate clearance, took 15% longer to perform when using the right hand release strategy than the left (2.2 vs. 1.8 s, respectively, p=0.012). There was no significant change in overall release time as a function of release position. The time to maximal force production (from initial applied force on release lanyard) took significantly longer when using the right handed release strategy over the left (0.90 vs. 0.59 s, respectively, p=0.018). Similarly, the seated position resulted in longer release times than standing (0.80 vs. 0.68 s, respectively, p=0.018). Doff times were also established in which only the time from applied force on the release lanyard to rear plate clearance were considered,

effectively removing variability of time and strategy used from initiation of movement to lanyard pull. As seen with overall release time, the right handed release strategy took longer (26%) than the left (0.93 vs. 0.60s, respectively, p=0.034). Unlike overall release times, doff times were 11% greater in the seated position than the standing (0.86 vs. 0.75 s, respectively, p=0.025).

Although the increased release time using the right handed release strategy was expected (due to the requirement to reach across the body and clear the arm and release lanyard over the head and helmet, unlike the more direct approach of the left handed release strategy), it was initially unclear as to why the different release positions (standing or sitting) would result in different release times. The primary difference between the seated and standing positions was lower extremity position (~90° of hip and knee flexion), which should have no effect on upper extremity motion required to perform the release task. Upon further investigation it was found that during seated releases, the waist belt would experience vertical motion during rear armor plate clearance, preventing the plate from clearing as quickly as in the standing position. Quantification of waist belt motion, although not an initial measure of interest, revealed that the seated release position resulted in nearly twice the vertical motion as the standing position (10.8 vs. 5.6 cm, respectively, p<0.001) before rear plate clearance occurred. This finding also helps explain the increased range of motion seen at the elbow during the seated position. Vertical motion of the waist belt during doffing delayed separation of the rear plate from the belt, requiring greater elbow extension to clear the plate.

CONCLUSIONS

Although a greater elbow range of motion was required to doff the body armor system using the left hand, and muscle activation tended to be greater for this release strategy, release times were consistently lower using the left handed release. Doff times were found to be greater while in the seated position, due primarily to increased vertical motion of the integrated waist belt not seen during the standing conditions.

LOW BACK PHYSICAL DEMANDS DURING A SIMULATED DENTAL HYGIENE TASK

[1]Samuel Howarth, [1]Diane Grondin, [1]Jocelyn Cox, [2]Nicholas LaDelfa, and [2]Jim Potvin

[1] Canadian Memorial Chiropractic College, Toronto, ON, Canada

INTRODUCTION

The annual prevalence of low back pain amongst dental hygienists has been estimated to be up to 67%, and has been cited as the primary reason that dental hygienists either modified their work, or left the profession [1,2]. Previous work has suggested that the prevalence of low back pain in these professionals is likely related to the seated posture that dental hygienists adopt while performing their occupational duties [3]; however, no investigation to date has quantified the low back physical demands for dental hygienists. Thus, our primary goal was to describe the low back physical demands within a population of practicing dental hygienists during a simulated dental hygiene task (manual scaling).

METHODS

A total of 19 female registered dental hygienists were recruited for this study (Age = 30.6±5.5 years, Height = 1.66±0.09 m, Weight = 63.1±15.2 kg, Years in practice = 4.9±3.7 years). All participants were free of pain in their upper extremities as well as the upper and lower back. Technical difficulties experienced during data collection of two participants precluded their inclusion in subsequent data analyses. The protocol was approved by the Research Ethics Board at the Canadian Memorial Chiropractic College, and all participants signed an informed consent document prior to data collection.

Surface electromyographic (sEMG) recordings were obtained bilaterally, at a rate of 2048 Hz, from the lumbar and thoracic portions of the erector spinae (LES, TES) along with the cervical erector spinae, pectoralis major, anterior deltoid, posterior deltoid, upper trapezius, and lower trapezius (Bagnoli-16, Delsys Inc., Boston, MA, USA). For the purposes of this abstract, only data pertaining to the LES and TES will be discussed. Kinematics of the dental hygienist's upper arms, head, thorax, and pelvis, along with kinematics of the stool on which dental hygienists sat and worked from during our simulated task were monitored at a rate of 32 Hz with an optoelectronic motion capture system (Optotrak Certus, Northern Digital Inc., Waterloo, ON, Canada). Finally, seat pressures were recorded at a rate of 8 Hz using a pressure mat (CONFORMat, Tekscan Inc., South Boston, MA, USA) affixed to the seat pan of the stool. Seat pressure data will not be discussed further due to the scope of this abstract.

After instrumentation, participants performed a series of maximal isometric voluntary contractions (MVICs) and spine range of motion trials followed by a 30-minute manual scaling task. The scaling task required participants to manually debride nail polish that had been painted on the teeth of a dental manikin (M-1R-DA-8, Columbia Dentoform Corp., Long Island, NY, USA) to simulate plaque. All participants used the same set of instruments for the manual scaling task. Participants were given an opportunity to adjust the height of their stool, the dental chair, and the location of the overhead light prior to data collection.

All kinematic and sEMG data were initially post-processed using Visual3D (C-Motion Inc., Germantown, MD, USA). All raw sEMG data were full-wave rectified, digitally filtered with a dual pass Butterworth filter with a cutoff frequency of 2.5 Hz, and normalized to a percentage of the maximum amplitude from the MVIC trials. Relative orientations between the pelvis and thorax defined lumbar spine angular kinematics that were normalized to a percentage of each participants active range of motion in flexion/extension, lateral bend, and axial rotation. Amplitude probability distribution functions (APDFs) were derived for the

normalized sEMG and kinematic time-series data (Matlab, The Mathworks Inc., Natick, MA, USA). Dependent measurements corresponding to the 10th, 50th, and 90th percentiles were obtained from the APDFs. Since lateral bend and axial rotation kinematics could span a range between ±100%, the 10th and 90th percentile values effectively reflected peak angular deviations in both the left and right directions.

RESULTS AND DISCUSSION

Our data demonstrated that in addition to forward flexion, dental hygienists are often required to axially rotate their spine away from a neutral posture while performing a manual scaling task (Table 1). Combined flexed and rotated spine postures may present a different risk factor in dental hygienists that is not prevalent in other occupations where the seated posture has been linked to the incidence of lower back pain (e.g. occupational driving, deskwork). Furthermore, activity in both the left and right TES at the 10th percentile exceeded Jonsson's proposed maximally acceptable threshold for static work of 2% MVIC (Fig. 1) [4].
Fig 1: Muscle activity of the TES and LES at the 10th, 50th, and 90th percentiles.

Thus, it is possible that tonic low-level activity of the TES could lead to muscular fatigue and low back pain; however, it is important to note that we did not obtain measurements from the sEMG data that could be a direct indicator of muscular fatigue (e.g. shifts in median power frequency).

CONCLUSIONS

Based on our findings from the simulated manual scaling task, it is possible that the prevalence of low back pain amongst dental hygienists may be related to sustained activity of the spine extensor musculature, and adopting an axially rotated position while seated. Manual scaling is one of many occupational duties performed by dental hygienists, and future work should be conducted to evaluate low back physical demands in these individuals over an entire 8-hour workday.

EFFECTS OF FATIGUE AND ASYMMETRIC LOAD CARRIAGE ON FIREFIGHTER OBSTACLE CROSSING PERFORMANCE

INTRODUCTION

Slip, trip, and fall related injuries are among the most prevalent encountered on the fireground. These injuries commonly occur while navigating obstacles. Fatigue and load carriage are two intrinsic factors which often lead to difficulty in crossing obstacles, and thus increased risk of injury [1]. However, it is difficult to analyze firefighter fatigue in a lab setting due to an inability to replicate the fireground environment and fatigue. As such, the aim of this study was to quantify the effects of three different simulated firefighting exercise protocols and their resulting fatigue, as well as the carriage of an asymmetrical hose load, on firefighters' ability to cross obstacles.

METHODS

Twenty-four firefighters (23 male) completed three simulated firefighting activities: (1) treadmill walking in an environmental chamber (ECTM) – (14 min. at 4.5km/h, 2.5% incline, 47°C, 20% humidity); (2) simulated firefighting tasks in environmental chamber (ECFF) - 2 min. each of stair climb, hose advance, secondary search, and ceiling pull with 2 min. rest between tasks; and (3) simulated firefighting tasks performed in a live-burn building environment (BBFF) – avg. temp ~85°C. Tests were separated by a minimum of 24 hours.

Before and immediately after each exercise protocol, participants performed a set of four trials of a five-station obstacle course – one station of which involved traversing a 30-cm tall stationary obstacle. During the first two trials in each set, participants wore standard firefighting personal protective equipment of bunker gear, helmet, gloves and self-contained breathing apparatus pack (No Load condition). For the remaining two trials, each participant also carried an 11.3kg hose on the right shoulder (Load condition).

Obstacle contact errors and foot clearances were recorded and analyzed for each trial. Motion data were tracked (Qualisys, Oqus100; 200 Hz) using an arrangement of four markers on each boot, as well as on the top four corners of the obstacle. An error was recorded any time a subject contacted the obstacle. Horizontal and vertical clearances were calculated for each foot [2]. Trailing horizontal clearance (HCT) was defined as the horizontal distance from the trailing toe to the front of the obstacle at trailing foot midstance. Lead horizontal clearance (HCL) was measured from the lead heel to the back of the obstacle at lead foot midstance. The vertical clearances for each foot (VCT, VCL) were defined as the minimum of four vertical distances: between the toe and front obstacle markers, heel and front obstacle marker, toe and back obstacle marker, and the heel and back obstacle marker. Contact errors were totaled based on exercise procotol, the presence of the load, and fatigue. Clearances were analyzed via a three-way repeated measures MANOVA ((3) Protocol × (2) Load × (2) Fatigue) at a significance level of $\alpha=0.05$.

RESULTS AND DISCUSSION

Both clearances and errors appeared to be dependent on exercise protocol. Slightly fewer post-activity errors occurred following ECTM compared to ECFF and BBFF (9 vs. 12 in both cases). Significant interaction effects of protocol × fatigue were observed on HCL and VCL (Fig. 1, $p \leq 0.036$). HCL decreased from pre to post activity for ECFF and BBFF, but did not change following ECTM. This result suggests decreased step length following simulated firefighting task exercise protocols, perhaps a compensatory strategy for decreased lower limb control [3]. VCL remained consistent from pre to post activity for ECFF and BBFF, but

increased following ECTM. These results may indicate that the levels of fatigue induced by the ECFF and BBFF protocols are similar, and are both greater than those induced by the ECTM protocol. Ultimately, these results may suggest that the ECFF protocol represents a reasonable simulation of firefighting in a live-burn environment with the benefits of greater safety and climate control.

Fatigue was shown to significantly affect obstacle crossing behavior. More errors occurred post-activity versus pre-activity for the ECTM and ECFF protocols, which may suggest that fatigue resulted in increased frequency of errors. Most errors (92%) were committed by the trailing foot, so it is likely that the lack of visual feedback during trailing foot early swing phase becomes more detrimental to obstacle crossing performance when fatigued [4]. Significant main effects of fatigue were also observed on HCL and VCT, resulting in respective decreases of 1.8cm and 1.6cm (p≤0.025). The decrease in HCL may indicate reduced step length, with subjects tending to cross the obstacle later in the lead foot swing phase, perhaps allowing for increased visual feedback to compensate for a decrease in lower limb control [3-4]. The decrease in VCT agrees with the high occurrence of trailing foot errors, and supports the conclusion that a lack of visual feedback compounded with fatigue can increase risk of obstacle contact [4].

Load carriage significantly affected clearances as well, but did not heavily impact contact error totals. Approximately equal numbers of contact errors were committed with and without the hose. Significant main effects due to load carriage were observed on HCL and VCL (p≤0.043). HCL decreased an average of 3.1cm, while VCL increased 0.9cm. The increase in VCL may be a compensatory strategy employed at the expense of dynamic stability to ensure obstacle clearance when

the perceived difficulty in clearing the obstacle is greater [3]. Significant interaction effects of load × fatigue on VCT and VCL were also observed (p≤0.024). VCT remained fairly consistent from pre to post activity without the hose load, but decreased from pre to post in the presence of the hose. VCL increased from pre to post activity without the hose load, but decreased from pre to post in the presence of the hose, perhaps suggesting that it was more difficult to employ the compensatory strategy mentioned above while fatigued. These results suggest that the decreases in dynamic stability brought on by fatigue are compounded by the carriage of an asymmetrical hose load.

CONCLUSIONS
Exercise protocol, fatigue, and asymmetrical load carriage had significant effects on obstacle crossing behaviors. In general, fatigue caused contact errors to increase and clearances to decrease, with more pronounced decreases following protocols involving simulated firefighting tasks, suggesting that ECFF represents a reasonable simulation of live-burn activity. Load carriage was found to amplify the effects of fatigue, with larger decreases in clearances following exercise while carrying the hose. These findings highlight potential factors that could relate to fall risk for firefighters on the fireground.

CONTRIBUTORY FACTORS TO MUSCULAR DEMAND IN CASHIERS

[1]Jacquelyn M. Maciukiewicz, [1]Angelica E. Lang, [1]Meghan E. Vidt,
[2]Sylvain G. Grenier, and [1]Clark R. Dickerson
[1]Department of Kinesiology, University of Waterloo, Waterloo ON, Canada

INTRODUCTION

Cashiers commonly report musculoskeletal discomfort in the shoulder, neck and upper extremities [1]. In 2009, cashiers accounted for 35% of work-related injuries, with 51% of those injuries being a strain or sprain [2]. The underlying factors contributing to injuries in the cashier population include the adoption of awkward and static postures, task repetition, insufficient rest, and fluctuations in customer demands [3]. A recent emphasis for customers to use enviropackaging has caused cashiers to handle greater loads, as typical shopping bag weight has increased from ~10lbs for plastic bags to 28-38lbs for environmental bags and bins [3]. The postural demands and loads intrinsic to cashier tasks likely contribute to increased muscle effort and subsequent injury, although the role of these factors has not been explicitly evaluated in this group. The goal of this study is to evaluate the effects of packaging, workspace geometry, and work load and their interactions on muscular demand during the performance of cashier tasks.

METHODS

Twenty-five experienced cashiers (10M/15F) performed scanning and packaging tasks. A previous field study identified various key factors in a cashier environment, such as fluctuations in customer numbers and orders, types of packaging, and workstation height. Each of these factors was then evaluated in the laboratory study, in which EMG measurements were acquired to assess muscular demand. Workload intensity was evaluated at two levels which small and large orders, represented by 6 and 12 items, respectively. Three packaging types, including bins, reusable bags, and plastic bags, and three workstation heights (66cm, 78cm, 90cm) were evaluated. The low and high workstation heights corresponded with the minimum and maximum possible heights of cashier workstations. The high workstation height is the standard height in grocery stores, in which the bagging area is flush with the scanner. All combinations of intensity, package, and height parameters were evaluated in a randomized order for a total of 36 trials per participant. Cashiers were instructed to replicate their personal bagging styles and pace in the laboratory setting.

Surface EMG (Noraxon, Inc., AZ, USA) was recorded bilaterally for upper trapezius, middle trapezius, serratus anterior, anterior deltoid, middle deltoid, upper (T9) and lower (L3) erector spinae, and external oblique. EMG data was full wave rectified, normalized by MVC data, integrated, and totaled using custom a Matlab program (The MathWorks Inc., Natick, MA, USA). Total integrated EMG, which gives an assessment of overall muscular demand, was calculated by summing the individual muscle EMG signals.

Mixed effect ANOVA was used to assess the influence of gender, intensity, package type, and workstation height on total muscular demand. Post-hoc Tukey HSD was used to confirm significant differences. Analyses were performed using JMP software (v.11.2.1, SAS Institute Inc., Cary, NC, USA) with significance considered as $p \leq 0.05$.

RESULTS AND DISCUSSION

Intensity, packaging type, and workstation height (all $p<0.0001$) all influenced total integrated EMG. Higher muscular demand was observed in female participants than in male participants in all tasks ($p=0.0126$). Interactions between packaging type and workload intensity (Figure 1) ($p<0.0001$) and workstation height and workload intensity (Figure 2) ($p=0.0011$) were also influential.

In all task configurations, the 6-item tasks required less total muscular effort than the 20-item tasks (Fig.1). Packaging type had a significant effect on total integrated EMG measures, whereby plastic bags and reusable bags required similar muscular demands, which were 40% higher than the muscular demand used for trials with the bins. The smallest total muscle effort was measured when 6 item trials were packaged with the bins, while the highest muscle effort was recorded when 20 items were packaged with either reusable bags or plastic bags.

During the higher intensity trials, the greatest muscular effort was seen during the highest workstation configuration (Fig.2). There was no effect of workstation height on workload intensity for 6 item trials. Working at low and middle heights elicited 20% lower total muscular demands than tasks performed at the highest workstation height.
Figure 1: Interaction between packaging type and workload intensity for total integrated EMG. Points not connected by the same letter are significantly different (p<0.001).
Figure 2: Interaction between workstation height and workload intensity for total integrated EMG. Points not connected by the same letter are significantly different (p=0.0011).

Total integrated EMG, which is an indicator of overall muscular effort, depended on workstation configuration, packaging type, and intensity. These results demonstrate that smaller workloads, lower bagging area heights, and the use of bins reduce the total muscular demand of cashiers. However, these results are in contrast to the current standards of the cashier environment. For example, the highest workstation height is the standard height used in grocery stores. Workstation height is adjustable, but cashiers are potentially not aware of this bagging station feature, and should be instructed on how to lower the station to a more appropriate height.

Total muscular demand of cashiers is highest when processing large orders. Therefore, to reduce the muscular demand, and thereby reduce the musculoskeletal injury risk, adequate opportunities for recovery are crucial. Regular rotation through express and regular checkout lanes would reduce the muscle demands cashiers experience. Total muscle demand was assessed here, but further work is needed to characterize the role of individual and groups of muscles in the shoulder and low back during the performance of cashier work tasks.

CONCLUSIONS

Total muscular demand in cashiers can be lessened when performing work at a low intensity, with the workstation at a low height, and when packaging items in bins. The interactions identified here highlight the complex role of workspace parameters on total muscle demand, and we present steps which can be made to mitigate these demands to reduce the risk of musculoskeletal injury in this group.

EFFECT OF UNILATERAL AND BILATERAL LOAD CARRIAGE ON GAIT AND TRUNK ORIENTATION IN HEALTHY YOUNG ADULT FEMALES

[1] Kevin M. McGinnis, [1]Laura Van Der Post, [1]Jill S. Higginson
[1] University of Delaware, DE, USA
email: kevinmcg@udel.edu

INTRODUCTION

The majority of the population carries some type of bag to transport their personal items, such as a backpack, one-shoulder tote bag, or briefcase. Carrying a backpack daily has been found to cause back pain in adolescents and pain was correlated with carrying time [1]. It has also been shown that those who carry heavy loads for extended periods of time can experience blisters on the feet, knee pain, back pain, and stress fractures, among other injuries [2]. Coupled with the fact that backpack loads have been consistently increasing over the past two decades makes everyday load carriage an important issue in order to avoid chronic pain and/or injury [3]. College students often carry heavy loads over long distances and long periods of time throughout the day. However, there is little, if any, literature on how this population adapts to increased load carriage during gait. The objective of this study was to determine the alterations in the spatio-temporal parameters and trunk orientation of healthy, college-age females due to unilateral and bilateral load carriage.

METHODS

Nine healthy female college students were recruited from the local community to participate in this study. Spatio-temporal parameters (velocity, step length, stride length, stance time, and double-support percentage) were measure using a Zeno walkway pressure mat (ProtoKinetics LLC, Havertown, PA). Trunk side-to-side lean and trunk forward tilt were measured using an 8-camera motion capture system (Motion Analysis Corporation, Santa Rosa, CA). Reflective markers were place on the shoulders, iliac crests and sternum to model and track the trunk. Subjects were instructed to make two passes across the gait mat, at a self-selected pace, and 4-5 gait cycles were used

in the analysis. Four scenarios were tested: normal walking, 20% body weight added to the left shoulder, 20% body weight added to the right shoulder, and 20% body weight in a two shoulder backpack. A repeated measures ANOVA was used to determine significant differences with an alpha of 0.05.

RESULTS

Subjects walked significantly slower in the bilateral condition (1.17m/s ± 0.15) compared to control and both left and right unilateral conditions (1.26 m/s ± 0.15, 1.23m/s ± 0.15, 1.24m/s ± 0.15respectively; $p<0.05$). Subjects carrying the bilateral load had a significantly reduced stride length (1.30m ± 0.076) compared to the control condition (1.36m ± 0.079, p=0.005), but not left and right unilateral conditions (1.32m ± 0.102, 1.32m ± 0.082 respectively).
Figure 1: Step length (cm), * indicates between condition difference, t indicates between side difference.

Double support percentage increased for all conditions compared to control (26.6% ± 3.8), although only the left unilateral (28.6% ± 3.8 p=0.019), and bilateral conditions (29.4% ± 4.2 p=0.001) were significant increases. Significant

differences existed between left and right step length at all conditions (L>R) except for right unilateral load carriage. When the left and right step lengths were averaged, there were significant decreases between control (68.2cm ± 4.1) and left unilateral (65.5cm ± 4.7), right unilateral (65.8cm ± 4.8), and backpack (65.2cm ± 4.2) conditions (p<0.05; Figure 1). No differences were found for stance time.

During the control condition, subjects had an average side-to-side trunk lean of 0.90° ± 1.36 to the left. When the weight was placed on the left shoulder the subjects leaned 3.09° ± 2.00 to the right, and when the weight was placed on the right shoulder the subjects leaned 5.27° ± 2.59 to the left. In the bilateral condition, subjects leaned 0.57° ± 1.42 to the left. Differences were significant between both unilateral load carriage conditions and all other conditions (p<0.05).

During the control condition, subjects had an average trunk tilt of -3.55° ± 2.53 (negative indicates a backward tilt). The left and right unilateral conditions also had trunk tilts of -2.16° ± 2.10 and -0.93° ± 2.38 respectively. The bilateral condition had a forward tilt of 2.02° ± 4.18 and was significantly different from the control (p=0.002) and the left unilateral condition (p=0.01).

DISCUSSION

There were multiple spatio-temporal alterations made due to adding 20% body weight both unilaterally and bilaterally. Subjects walked slower and had increased double support percentage. Singh et al. found similar changes in bilateral load carriage of middle school-aged children and hypothesized that these changes could be a result of the body trying to minimize instability and/or mechanical strain of carrying the added weight [3].

Subjects also had decreased step length with any type of load carriage as well as decreased stride length between bilateral and control conditions. This also supports the compensation strategy mentioned above. Subjects were taking slower and smaller steps and increasing double support in order to support the extra weight.

Subjects also compensated for the extra weight using the orientation of the trunk. They would lean away from the application of the weight, for example: leaning left when the weight was place on the right shoulder and forward when it was centered on their back. Adding the weight causes the center of mass to move towards the application site (left, right, or back). The subjects adjust to this by leaning in the opposite direction. While this adjustment may lead to less energy expenditure during gait, it may also lead to increased pain and/or injury over time.

These changes highlight an important issue that could affect anyone who carries extra weight as part of their daily routine. It is important to determine whether alterations to normal unloaded gait put individuals at risk for pain and/or injury due to excessive load carriage, even with weights of up to 20% of a person's body weight.

THE EFFECT OF EARLY AND FREQUENT SEATED BREAKS ON LOW BACK PAIN DEVELOPMENT DURING PROLONGED STANDING WORK

Colin D. McKinnon[1], Daniel Martel[1], Jack P. Callaghan[1]
[1]Department of Kinesiology, University of Waterloo, Waterloo, ON
Email: colin.mckinnon@uwaterloo.ca

INTRODUCTION

Known pain developers (PD) will develop low back pain (LBP) during constrained, prolonged standing work tasks and tend to have muscle activation recruitment patterns that differ from non-pain developers (NPD). These pain classifications are predictable from bilateral gluteus medius co-activation profiles [1], and have been further isolated as a predisposing factor, rather than an adaptation to pain [2]. Within the first 15-45 minutes of a standing exposure, PD show a steady increase in low back pain, while NPD remain close to baseline levels of pain. While intermittent seated breaks from prolonged standing exposures create a short-term reduction in pain scores [3], these breaks do not allow complete return to pre-exposure levels and do not prevent known pain developers from reaching the PD threshold. The purpose of this study was to evaluate if early and frequent sitting breaks from prolonged standing work could effectively slow down and/or reduce LBP development in known pain developers.

METHODS

Sixteen participants (8M, 8F) performed 124 minutes of prolonged standing work with intermittent seated breaks at a 3:1 stand-to-sit ratio with increasing durations – 3 minutes:1 minute, 6:2, 12:4, 24:8, 48:16. Participants were classified as PD/NPD in a separate 2-hour prolonged standing trial. Low back perceived pain was recorded during each trial on a 100 mm visual-analog scale. Pain rating scale ranged from 'No pain' to 'Worst pain imaginable'. Participants were instrumented with surface EMG bilaterally over gluteus medius (GMED). EMG signals were low-pass digitally filtered (single pass, 2nd order Butterworth, 1.0 Hz cutoff frequency), and normalized to maximum voluntary contraction amplitudes. Cross-correlation and corresponding phase lag (τ), were calculated between the left and right GMED signals. A maximum phase lag of ±500 ms was used to extract the maximum cross-correlation for 1-miunte blocks across the session duration. Co-contraction index (Equation 1) was also calculated for left-right GMED activation in 1-minute blocks.

Equation 1:

$$CCI = \sum_{i=1}^{N} \left(\frac{EMG_{low_i}}{EMG_{low_i}} \right) \left(EMG_{low_i} + EMG_{high_i} \right)$$

where EMG_{low} and EMG_{high} are the signals with the lower and higher magnitude, respectively, at each sample

Two-way mixed GLM assessed the influence of pain group (between factor) and time (within factor) on all response measures.

RESULTS AND DISCUSSION

Significant pain group-by-time interaction effects were observed for low back pain ($p = 0.0007$). Further, pairwise comparisons between pain groups showed no differences at any time point (minimum $p = 0.06$). No pain group main effects were observed ($p = 0.133$), and low back pain reached a maximum of 7.71 ± 7.54 mm for either pain

group over the entire 124 minute session protocol (Figure 1).

No pain group-by-time interaction effects, pain group main effects, or time main effects were observed for cross-correlation ($p = 0.56$; $p = 0.59, 0.47$) or co-contraction index ($p = 0.41$; $p = 0.92$, $p = 0.23$) of the right and left GMED. Mean GMED cross-correlations collapsed across the entire session were 0.17 ± 0.37 and 0.27 ± 0.40 for PD and NPD, respectively. Similarly, mean co-contraction indices were 1066.0 ± 1217.1 %MVC and 2045.7 ± 2505.0 %MVC.
Figure 1: Low back pain showed no difference between pain groups and did not exceed 10 mm over the duration of the protocol. The dashed line shows scores from the same participants in a standing-only protocol.

Early and frequent sitting breaks were effective in reducing and delaying the onset of LBP in known pain developers during standing work. Pain measures did not exceed 0.5 mm for either pain group in the first 60 minutes of the sit-stand protocol, and did not exceed the 10 mm clinically significant change threshold [1,2,3]. GMED co-contraction has been suggested as a predisposing factor in LBP development during standing. The stand-sit protocol in this study showed no difference between pain groups for either cross-correlation or co-contraction index, and reduced both measures for PD to levels of NPD seen in previous studies of standing alone [2]. This

evidence suggests that a reduction in co-contraction may lead to an associated reduction in low back pain among known pain developers during prolonged standing work.

While the co-contraction to pain mechanism is not fully understood, experimental evidence has shown some clear trends between pain groups. Early exposures to greater than 30 minutes of long duration standing can lead to aggravation of tissues surrounding the lumbar spine which cannot be resolved with a short duration seated break [3]. With continued exposures to prolonged standing, this tissue aggravation accumulates and worsens, leading to increasing levels of low back pain [1,3]. Pain group co-contraction differences are greatest during these early exposures, specifically the first 30 minutes of a standing exposure [1]. This appears to both support co-contraction as a predisposing factor for low back pain and drive the early pain generation mechanism. The intervention implemented in this study aimed to target this time period directly, and removes the co-contraction differences between groups.

CONCLUSION

These findings indicate that a stand-sit protocol involving early and frequent seated breaks from standing work may decrease hip muscle co-contraction and the resulting onset of LBP during prolonged standing.

email: edward.nyman@utoledo.edu

INTRODUCTION

Extensive patient handling is a daily requirement in many healthcare industry professions. Eight out of ten polled healthcare workers reported having a musculoskeletal injury at one point in their career (1). Healthcare workers are particularly susceptible to lower-back injuries which ultimately cost the health care industry $20 billion per year as a result of treatment and lost work days (2). Development of evidence-based techniques to proactively address the growing number of injuries in the healthcare field is critical. The objective of this study was to examine isometric torque generation and range of motion (ROM) trends in healthcare workers as the initial component in a longitudinal study which will prospectively examine workplace injury at 6 and 12 month time intervals.

METHODS

Healthcare workers at University of Toledo Medical Center (UTMC) were recruited for voluntary participation. To be included, consenting subjects must have had no previous or current acute or chronic musculoskeletal or neurological injury, be between 18-70 years of age, 1.58-1.98 m tall, weigh less than 127 kg, and not be pregnant. A musculoskeletal range of motion and isometric strength testing protocol was based on a standard assessment protocol provided with the equipment (4.0 Rotational Spine System™, Turning Point Biotechnology, Toledo, OH, USA). The testing system (Fig. 1) allows pure transverse plane rotation independently at the hips (pelvis) and shoulders. Transverse plane (axial) range of motion can be measured, and isometric torque generation evaluated, at the shoulders (thoracic spine) under static pelvis positon (locked), as well as at the hips (lumbar spine / pelvis) with a static shoulder (thoracic spine) position. Additionally, the pelvis or shoulders can be axially rotated to any fixed point to the left or right wherein isometric torque generation measurements can be made (rather than from a neutral position only). Peak

axial rotation for the shoulders and for the hips, each measured independently to the left and right was performed under volitional control for all subjects. Peak isometric torque measurements were collected for the shoulders in both directions at 25° of right

Figure 1. Turning Point Rotational Spine System

and left rotation as well as in both directions at 0° (neutral). Additionally, peak isometric torque measurements were collected for the hips in both directions at 15° of right and left rotation as well as in both directions at 0° (neutral). ROM data were measured and recorded in degrees and isometric torque output in foot-pounds. Participant subsequent injury history data, via a single blinded approach, will later be regressed onto musculoskeletal performance measurements at 6 and 12 month intervals after testing, as part of ongoing work.

RESULTS AND DISCUSSION

A total of 146 subjects (39.3±11.6 years, 73.7±15.2 kg, 1.67±0.1 m) participated in the study. 80% (117/146) of the subjects enrolled were female.

Peak ROM at the shoulders was 82.6±15.0° to the right and 78.6±13.9° to the left (Fig. 2). Peak ROM at the hips was 42.8±10.2 ° to the right and 46.6±9.2° to the left (Fig. 2).
Peak ROM

Figure 2. Peak ROM for the pelvis and shoulders (right rotation- red, left rotation – blue)

There were no statistically significant differences in hip or shoulder ROM between left and right sides, nor between sexes when all subjects were grouped accordingly. However, when the data were further interrogated, patterns of asymmetry *within* subjects were discovered. ROM asymmetry, herein defined as greater than 10% deviation to one side from calculated within subject mean ROM, as adapted from Crenshaw (3), was present for 42% (61/146) of subjects at the shoulder level and for 55% (80/146) at the hip level. Peak isometric torque generated at the shoulders was 32.2±16.5 ft-lbs to the right and 34.6±18.0 ft-lbs to the left from neutral position (0°), 34.3±17.8 ft-lbs to the right and 32.6±16.3 ft-lbs to the left from 25° rotation to the right, and 33.9±15.7 ft-lbs to the right and 33.6±17.3 ft-lbs to the left from 25° rotation to the left (Fig. 3). Peak isometric torque generated at the hips was 33.4±16.2 ft-lbs to the right and 29.9±16.8 ft-lbs to the left from neutral position (0°), 33.0±17.8 ft-lbs to the right and 26.8±14.8 ft-lbs to the left from 15° rotation to the right, and 27.0±13.0 ft-lbs to the right and 29.5±16.4 ft-lbs to the left from 15° rotation to the left (Fig. 3).

Peak Isometric Torque Generation
Figure 3. Isometric torque generation for the pelvis and shoulders (right rotation- red, left rotation – blue)

There were no statistically significant differences in hip or shoulder peak isometric strength between left and right sides, nor between males versus females when all subjects were grouped as respective cohorts. Again, however, when the data were further interrogated, patterns of asymmetry *within* subjects were discovered. As measured from the neutral position (0°), significant peak isometric strength asymmetry, defined herein as greater than 10% bilateral difference, within subjects was present for 63% (92/146) of subjects at the shoulder level and for 69% (100/146) at the hip level.

Overall, asymmetry was both marked and contralateral for many subjects with respect to both peak ROM and peak isometric strength. Of obvious concern is the inherent increased risk of musculoskeletal injury, particularly to the lower back, in individuals who present with ROM or peak isometric strength asymmetry.

CONCLUSIONS

This work and that of previous publications support evidence of musculoskeletal ROM and strength asymmetry in healthcare workers with patient handling responsibilities. Future work will evaluate correlations between both range of motion and isometric torque generation and incidence of musculoskeletal injury occurring at the 6 and 12 month time intervals.

EXTERNAL FORCE AND DELTOID SURFACE EMG RELATIONSHIP DURING RELETIVE AND ABSOLUTE ISOMETRIC RAMP CONTRACTIONS AT THREE ANGLES

[1] David Phillips and Andrew Karduna

[1]Orthopedic Biomechanics Laboratory, Department of Human Physiology, University of Oregon, Eugene, OR
email: dphilli2@uoregon.edu, web: http://biomechanics.uoregon.edu/obl/

INTRODUCTION

The deltoid and the supraspinatus muscles are the primary abductors at the shoulder joint. There is a direct relationship between muscle EMG amplitude and muscle force. However this relationship is not linear and one variable cannot predict the other unless they are simultaneously measured. A single muscle's EMG may also not be able to predict externally measured force[1]. The EMG profile may also be affected by the rate at which force is developed. A more rapid rate of force development has a different EMG profile compared to a slower rate of force development due to different motor unit recruitment patterns [2]. Because of this, it is not known whether an absolute rate of force development would produce a more reliable EMG profile than a relative rate of force development for an individual. At different joint angles, a muscle's mechanical advantage may differ due to a changing angle of insertion, fiber length and a changing moment arm and therefore needing less activation to produce the same level of force [3].

The purpose of this study is to determine the EMG profile of the deltoid muscle during absolute and relative ramp isometric contractions at three different angles of abduction as well as the reliability of the EMG profile.

METHODS

Four subjects (2 male and 2 female) volunteered for the study. Subjects stood upright throughout the experiment. Participants were positioned so that the styloid process of the ulna was directly above the lower edge of the load cell with the elbow in full extension and the arm in the scapula plane. The arm was in the neutral, 'thumbs up' position. Three trials for the two rates of loading were conducted at each abduction angle 30°, 60° and 90°. Absolute loading

rate was 15N/s and relative loading rate was determined by the rate needed to reach 50% of subject's MVC force in 3.5 seconds. Subjects maintained the required loading rate through a real-time feedback display programmed with custom Labview (National Instruments, Austin, TX) software. The protocol was repeated after a 15 minute rest period to test for reliability.

EMG data were collected using a Myopac Jr. Electromyography unit (Run Technologies, Viejo, CA). EMG data were sample at 1000Hz and smoothed using a 300ms RMS sliding window. Deltoid EMG data were normalized to MVC at its relative angle of abduction. Force data were collected from a uniaxial load cell (Lebow Products, Troy, MI) and was sampled at 1000Hz. Force data were normalized to maximum external abduction force relative to each shoulder abduction angle.

RESULTS AND DISCUSSION

At all angles and rate of force application, force output steadily increased as deltoid EMG increased (Fig 1). At smaller shoulder abduction angles more force in generated with less deltoid EMG. This is likely due to greater supraspinatus contribution at lower abduction angles.

Differences between rate of force development and EMG level were analyzed using 2-way repeated measures ANOVA at each shoulder abduction angle. There was no significant main effect for rate of force development at any angle. The difference between absolute and relative rate of force development appears to be minimal at these submaximal and relatively slow rate of force development for both conditions. It must be noted that with the small sample, statistical power is likely insufficient to detect a difference between the rate of force development conditions. Another

consideration is that subjects that had a maximum force MVC of 105N would have had the same absolute and relative rate of force development.

A significant main effect was found for EMG level at 30° ($p < .05$), 60° ($p < .05$) and 90° ($p < .05$). This is to be expected as increasing force output with increasing EMG amplitude has been well documented.

Intraclass correlation coefficients were calculated for deltoid EMG at 10%, 20%, 30% and 40% MVC to indicate reliability (Table 1). ICC values above 0.75 are considered excellent, 0.4-0.74 good and below 0.4 are poor. ICC values demonstrated a high level reliability between the 2 sessions of measurement for 10%, 20% and 30% deltoid EMG MVC.

However, at 40% deltoid EMG, ICC values varied greatly depending on angle and rate of force development. The reason for the inconsistent reliability of external force at 40% deltoid EMG may be the point at which an additional level of motor unit is recruited resulting increased EMG amplitude. It should be noted that some subjects reached 50% force MVC before 40% deltoid EMG MVC.

Table 1: Intra class correlation coefficients for external force at different deltoid EMG levels through sub-maximal range.

Condition	Deltoid EMG Amplitude %			
	10	20	30	40
30° ABS	0.92	0.88	0.91	0.63
30° REL	0.96	0.04	0.65	0.18
60° ABS	0.98	0.78	0.75	0.75
60° REL	0.98	0.86	0.36	0.44
90° ABS	0.95	0.95	0.97	0.71
90° REL	0.75	0.66	0.96	0.84

Note: REL = relative rate and ABS = absolute rate
Figure 1: Deltoid EMG and external force relationship. 30° is blue, 60° in red and 90° in black. Absolute rate of force is represented by solid lines with relative rate of force represented by dashed lines.

CONCLUSIONS

A consistent relationship exists between deltoid EMG and external measured force. More force is generated with less deltoid EMG amplitude at lower abduction angles likely due to greater supraspinatus contributions. Currently, a relative rate of force development does not produce a different EMG profile to an absolute rate of force when performed at submaximal loading rates.

Importantly, external force is consistent with deltoid EMG amplitude within the same subject and testing session up to 30% of deltoid EMG MVC. However, the level of reliability of external force becomes inconsistent between angles at 40%

BIOMECHANICAL EFFECTS OF CRANIO-CERVICAL POSITIONS ON CERVICAL MUSCULOSKELETAL DISORDERS

[1] Sicong REN [1] [2] Wenhao LI and [1]Ming ZHANG

INTRODUCTION

Cervical musculoskeletal disorders have been becoming a global health problem which disturbs an increasing number of people [1]. Cranio-cervical position during computer use can be various due to frequent posture adjustment. Poor postures may give rise to abnormal stress on the muscles and joints leading to the development of cervical musculoskeletal disorders. Several studies based on computational models showed that optimal ergonomic design of workstation could minimize load-carrying along cervical spine [2]. A number of studies through experiment measurement suggested that there was a positive correlation between non-neutral cranio-cervical positions (e.g neck flexion, neck lateral bending, and forward head posture) and pain syndromes [3, 4]. Although considerable research has been devoted to normal movement of cervical spine, rather less attention has been paid to coupling motion of head and neck. Particularly, biomechanical characteristics of cranio-cervical protraction position are currently lacking. Therefore, the aim of this study is to determine the biomechanical effects of cranio-cervical positions on cervical musculoskeletal disorders.

METHODS

One male adult (Height: 190.3 cm; Weight: 82.2 kg; BMI: 22.6 kg/m^2; Age: 23 years old) with an experience of computer operation for 8 hours was recruited in this study. The support forces were measured using two force platforms.

Participant was asked to wear lycra pants without T-shirts or shoes, and then to do warming up of head and neck to minimize the effects of tissue creep along the cervical spine. An 8-camera, infrared motion analysis system (Vicon MX, Oxford, UK) was used to capture the three- dimensional posture of seated human. After a set of markers were attached to landmarks, participant was instructed to sit on one force platform and to step on the other one with hips and knees at 90°. The feet positioned shoulder width apart, and arms relaxed at the side of body. This study utilized repeated measure design with participant performing six sitting postures randomly. The six experimental conditions included cranio-cervical neutral position; cranio-cervical protraction; and cranio-cervical flexion. Finally all these three conditions were repeated with upright and slump sitting postures.

A generic human model with detailed neck was established using AnyBody Modelling System. The size of the model was scaled according to the participant's anthropometry. The kinematic data from motion capture was used to drive various motions. The model can calculate joint and muscle forces under each experimental condition. A preliminary model validation was performed by comparing the simulated muscle force of trapezius and muscle activity measured by electromyography.

PRELIMINARY RESULTS AND DISCUSSION

There were obvious differences in muscle recruitment among three cranio-cervical positions with upright and slump sitting postures (Figure 1 and Figure 2). For cranio-cervical protraction, trapezius-scapular muscle during slump generated 46% more force than that during upright sitting. While trapezius-clavicular muscle force was 1.5 times greater than that in upright sitting. Trapezius-scapular muscle in protraction generated 15% more force than that in flexion and neutral positon in both upright and slump sitting. Moreover,

this type of superficial muscle shared more load than other parts.
Upright Sitting

Figure 1. Cervical muscle forces in three cranio-cervical positions during upright sitting.
Slump Sitting

Figure 2. Cervical muscle forces in three cranio-cervical positions during slump sitting.

Muscle force generated by deep muscles such as multifidus and semispinalis along cervical spine, at approximately 12N, was 70% less than superficial muscles such as upper trapezius muscle. It suggested that deep muscles may bear low static loading in cervical motions.
Figure 3. Comparison results between simulated trapezius-scapular muscle forces and EMG envelope.

In order to examine the validity of the simulation, a comparison of trapezius muscles between the simulation results and EMG envelope was performed (Figure 3). From the EMG, trapezius muscles became more active in slump than in upright sitting. This finding can be seen in the simulation, indicating that three cranio-cervical positions with slump sitting required more muscle forces than that with upright sitting.

CONCLUSIONS

Our model simulated three cranio-cervical positions under two major sitting conditions which are commonly adopted during high-tech devices use. These results showed the static behavior of cervical spine as different types of load act on the muscles. It was concluded that extensor muscles including trapezius and multifidus muscles played an important part in maintaining cranio-cervical positions, especially for protraction position. Moreover, superficial muscles were found to be more responsive to positional changes of head and neck than deep muscles. This work may provide insight into understanding the mechanism of cervical musculoskeletal disorders caused by cranio-cervical positions.

THE EFFECT OF SUBMAXIMAL HAND FORCE EXERTION ON SHOULDER MUSCLE ACTIVATION

[1] Meghan E. Vidt, [1] Kimberly A. Meszaros and [1] Clark R. Dickerson

[1] University of Waterloo, Waterloo, ON, Canada
email: mvidt@uwaterloo.ca, web: http://ahs.uwaterloo.ca/kin/research/diesel/

INTRODUCTION

Upper extremity injuries are common sequelae of fatigue and over exertion in the workplace [1]. Hand location and muscular activity influence the muscular effort required to perform upper limb tasks. The intrinsic complexity of the shoulder and upper limb preclude experimental measurements on all possible hand locations in the upper limb workspace. Quantitative description of the effect of hand location, load magnitude, and direction would facilitate the assessment of the individual and total muscle activity required to perform upper limb tasks, which are commonly performed with submaximal loads [2]. The overall goal was to characterize individual and total muscle responses to submaximal workloads at hand locations in the upper limb workspace and develop predictive equations describing the spatial- and load-dependencies of muscle activity.

METHODS

Twenty right-hand dominant males (mean age 21.6±2.7 years) participated. Muscle activation was recorded at 1500 Hz from 14 muscles (anterior, middle, and posterior deltoid, biceps brachii, triceps brachii, supraspinatus, infraspinatus, clavicular and sternal insertions of pectoralis major, latissimus dorsi, serratus anterior, upper, middle and lower trapezius) using surface EMG (Telemyo 2400R T2, Noraxon, Scottsdale, AZ). Maximal voluntary contractions were performed for each muscle to normalize recorded muscle activity.

Participants performed submaximal exertions at five different hand locations within the upper limb workspace. The umbilicus served as the origin, with +X-axis to the right, +Y-axis anterior, and +Z-axis superior. All hand locations were defined in a single plane 30cm anterior to the umbilicus. The five hand locations included: 1) neutral (X=20cm, Z=20cm); 2) upper right (X=40cm, Z=60cm); 3) lower right (X=40cm, Z=-20cm); 4) upper left (X=-20cm, Z=60cm); 5) lower left (X=-20cm, Z=20cm). Five trials were collected at each location for all combinations of 4 hand force exertion levels (20N, 30N, 50N, 60N) in 6 directions (upward, downward, left, right, forward, backward), for a total of 120 trials. Each trial was 7sec, allowing the participant to ramp up to the desired force level; 1min of rest was given between trials to reduce the effect of fatigue. Hand forces were measured using a 6-degree of freedom transducer (MSA-6, AMTI, Watertown, MA) fixed on a robotic arm (Motoman HP50N, Motoman Inc., West Carrollton, OH).

EMG was processed by removing DC bias, then high pass filtered with a 4th order Butterworth filter with a 30Hz frequency to remove heart rate contamination. Signals were linear enveloped, full wave rectified, and low pass filtered with a 4th order low pass Butterworth filter with a 4Hz cutoff frequency. EMG signal for each muscle was normalized by its corresponding MVC. To represent each static hand force, average EMG was calculated over a 1sec window. Signal during time 5-6sec of the trial was selected to avoid any ramping to the desired force level. Total muscle activity, which is an assessment of overall muscular effort, was calculated by summing individual muscle activities.

Six one-way repeated measures ANOVAs were used to evaluate differences between total muscle activation across different force magnitudes for each exertion direction. Bonferroni corrections were applied and post-hoc Tukey HSD tests were used to confirm significance at $p \leq 0.0083$. Multiple linear regression using a forward stepwise method (p=0.1 to enter; p=0.05 to leave) was used to develop prediction equations for each muscle for each hand exertion direction; equations included a term for

force magnitude and linear, quadratic, and cubic terms for each X and Z location. All analyses were performed using JMP software (v.11.2.1; SAS Institute Inc., Cary, NC).

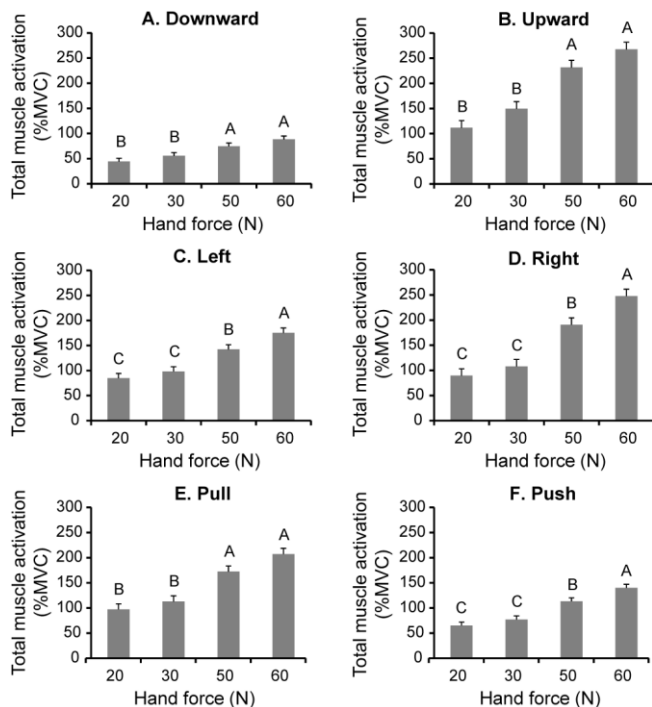
RESULTS AND DISCUSSION


Figure 1: Least squares mean ± SEM for total muscle activity for A) downward, B) upward, C) left, D) right, E) pull, and F) push exertions at different hand force loads. Different letters within each subplot denote significant differences.

Total muscle activity was smallest for the 20N load and greatest for the 60N load for all exertion directions (Fig.1). The results indicate that force magnitude has a nearly linear effect on total muscle effort. The greatest total effort was seen for upward exertions, which oppose gravity, and the smallest total effort was observed for downward exertions, which correspond with the direction of gravity.

Predictive equations developed for each individual muscle and total muscle activity demonstrated a dependence on force magnitude and linear, quadratic, and interaction terms for X and Z hand positions in the Y=30cm plane (Fig.2). Individual and total muscle activity was not dependent on cubic terms of spatial hand location for exertions in any direction. Previous work has identified a spatial

dependency of muscular demand for three-dimensional hand locations within the upper limb workspace for 40N [3,4] and maximal [5] exertions and the current work corroborates this spatial dependency. Notably, total muscle activation increased linearly with increased hand force magnitudes for all exertion directions, indicating that hand force is directly related to total muscle effort. These results can be leveraged by healthcare workers and ergonomists to evaluate the muscle effort required for tasks across the upper limb workspace requiring various force magnitudes.
Figure 2: Spheres depicting spatial dependency of total muscle activity for downward (top row) and upward (bottom row) exertions of 20N and 60N magnitudes.

CONCLUSIONS

Muscular demand is influenced by spatial location, load, and direction of exertion. The spatial and load dependency relationships reported here provide a valuable tool to predict approximate muscular demands in the upper limb without the need for lengthy experimentation.

INTRODUCTION

Multifocal lens glasses (MfLs), commonly worn by middle-aged and older adults, are known to reduce contrast sensitivity and depth perception [1], alter gait biomechanics [2] and increase fall risk [3]. Existing research on the biomechanics of MfL wearers has focused on single step navigation under a constant set of environmental conditions [2, 3]. Because MfLs affect functional vision, environmental conditions that make steps easier to see (e.g., through better step edge contrast or lighting) may provide benefits in this population. Furthermore, the use of handrails may provide alternative sensory information and reduce the need for vision when navigating stairs, which may also benefit MfL wearers.

This study aims to quantify the effects of certain ergonomic factors and the use of hand rails on the biomechanics of multiple stair negotiation in MfL wearers. This study focused specifically experienced older adult MfL wearers (70-80 years), representing a population at high risk of falling in the community. In addition, this study considered multiple stairs, in contrast to previous single-stair study designs, since multiple stairs require accurate foot placement and may be more challenging for MfL wearers.

METHODS

Five older adults (4 male, 1 female; age 72.8± 2.7 years, height 1.76± 0.68 m, mass 84.2 ± 18.8 kg) who are experienced bifocal (n=3) or progressive lens glasses wearers (n=2) were tested. Subjects did not have self-reported balance, gait or vision abnormalities, and each subject was screened for abnormal otolith and vestibular-ocular reflex (VOR) functioning. Subjects provided informed consent, and the study was approved by the University of Pittsburgh Institutional Review Board.

Subjects completed a gait assessment while wearing their current MfLs and a pair of single lens glasses that matched the upper portion of their prescription. Motion capture was used to track the following markers bilaterally at 120 Hz: anterior and posterior head markers, anterior and posterior superior iliac spine, second metatarsal head, anterior most point on the first toe, posterior and inferior-most point of the heel.

Subjects ascended a set of three stairs (19.0 cm tall and 28.0 cm deep), while their spectacles (MfL or single lens glasses), lighting (high or dim), step contrast (high or low) and use of handrails were systematically modified. Step contrast levels were achieved using an angle bar attached to the corner of the steps matching the color of the surrounding stair (low contrast) or contrasting with the stair (high contrast) (Fig. 1). Subjects completed three trials for each handrail x contrast x lighting condition for one lens before switching to the other lens condition; within a single trial, all steps were either high or low contrast. Lens order and the order of each condition were randomized.

Figure 1. Staircase shown in high contrast (bottom stair) and low contrast (top stair) configurations.

Leading and lagging toe clearance values were calculated by taking the minimum perpendicular distance between the toe markers and the step edge as the foot crossed over a stair. Step position was calculated as the distance between the stair edge and the heel marker at heel contact. Heel contact on the stairs was calculated at the local maxima of vectors calculated from the positions of the sacral marker

(midpoint of posterior iliac spine markers), consistent with methods from Zeni et al. [4]. Head angle was calculated using Euler angles relative to the global reference frame. The local coordinate system was established using vectors calculated from the midpoint of the back head markers to the midpoint of the front head markers (y-axis) and from the midpoint of the left head markers to the midpoint of the right head marker (z-axis was perpendicular to the plane formed by this vector and the y-axis). Head angles during the static trial (when subjects looked straight ahead) were offset from the dynamic trials to account for subtle differences in marker placement. The minimum, mean and maximum sagittal plane head angle (head pitch) were reported during the entire step preceding foot contact during the second stair. Repeated-measures ANOVA methods were applied to determine how these biomechanical variables were affected by lens type, environmental conditions (lighting and contrast), the use of handrails, and all first order interactions. Just the results from the second stair (when the subject was walking in steady state) are presented. The alpha value was set to 0.05.

RESULTS & DISCUSSION

The use of MfLs compared with single lens increased minimum leading toe clearance on the second stair from 5.4 ± 2.6 cm to 6.2 ± 2.7 cm (p=0.025). As failure to clear the stair edge would result in a trip or fall, an increased leading toe clearance while wearing MfLs could be an attempt to increase the subjects' factor of safety during stair ascent. Increased leading toe clearance has also been observed in single stair or curb ascent while wearing MfLs [3]. The finding that increased leading toe clearance occurs on the second stair suggests that MfLs might affect individuals in the same way whether they are navigating one or multiple stairs.

Subjects increased head pitch minimum, mean and maximum angles when they were not using the hand rail (Figure 2). The observed effect suggests that railings reduce the need for visual information since the subjects did not look down as much when using handrails. The use of handrails may provide subjects alternative sensory information that is used to locate their position relative to the stairs, which may reduce the need for increasing head angle.
Figure 2. Effect of handrail use on minimum, mean, and maximum head angles during stair ascent.

Subjects also placed their foot more posterior when stepping on step with a low contrast edge (8.4 ± 3.7 cm) than a high contrast edge (7.7± 3.7 cm). This shift in step placement suggest that a safer foot placement is used when good contrast is provided. Providing good contrast on each stair edge may reduce the risk of "missed edge of step accidents," which are prevalent among MfL-wearers [5].

No other main or interaction effects were statistically significant, nor were interaction effects observed between the multifocal lens glasses and environmental effects or use of hand rails. Preliminarily, it appears that certain environmental factors may compensate for the negative effects of MfLs, but that these effects act independently and not interactively. These results may need to be viewed with caution, however, as a larger subject pool will provide the necessary power to identify more subtle interaction effects (this study aims to increase the number of subjects to 20).

THREE DIMENSIONAL FINITE ELEMENT MODEL OF THE BRAIN RESPONSES TO THE TOP IMPACTS OF A CONSTRUCTION HELMET

[*]John Z. Wu, Christopher S. Pan, and Bryan M. Wimer
National Institute for Occupational Safety and Health, Morgantown, WV, USA.
*Email: jwu@cdc.gov

INTRODUCTION

Traumatic brain injuries (TBI) are among the most common severely disabling injuries in the U.S. Approximately 1.7 million cases occurred in civilians annually during 2002-2006 [1]. Construction helmets are considered as essential personal protective equipment to reduce TBI risks at work sites. Despite wide applications of the finite element (FE) modeling in the study of the injury mechanisms of TBI [2] and in the design of sport [3] or military helmets [4], there is limited analytical study of the construction helmet [5]. In the current study, we proposed a practical FE modeling approach that would be suitable for engineers to optimize construction helmet design.

METHODS

The FE meshes of the head-brain-neck complex were developed by using a commercially available data base (Materialise, Leuven, Belgium). The FE models were constructed using FE software ABAQUS (version 6.9). The surface scans of the skin, skull, and brain were applied to generate the FE meshes. The head-brain-neck complex consisted of scalp, skin tissues, skull, cervical vertebra (C1, C2, and C3), discs, brain, brain stem, cerebrospinal fluid (CFS), and spinal cord (Fig. 1). The brain tissues included the cerebrum and cerebellum; the brain stem contained the midbrain, pond, and medulla oblongata. The spinal cord included the surrounding pia mater. The CFS was considered to cover over the entire external surface of the brain, brain stem, and the spinal cord. The discs contained both annulus fibrosus and nucleus pulposus. The CFS was constructed using membrane elements, whereas all other components were constructed using 3D continuous elements. The helmet model consisted of a shell and a suspension system. The shell geometry was obtained by the scanning of a representative, commercially available construction helmet (Model: V-Gard, MSA Safety Inc., Pittsburgh, PA, US). The geometry of the suspension system was constructed using a graphic software Inventor (Autodesk, San Rafael, CA, US). The materials of the scalp, skull bone, cervical discs, and vertebral bone were considered as linearly elastic, whereas the skin, brain, brain stem,
Figure 1. FE model of the head-helmet complex. The head model contains brain, brain stem, spinal cord, CSF, skin, skull, vertebra, and discs.

and spinal cord were considered as hyperelastic and viscoelastic.

The simulations were performed using an implicit dynamic procedure. Initially, a cylindrical object (2 kg) was at a height of 3.27 m above the helmet top. For $t > 0$, the object was released and fell due to the gravity; it reached a speed of 8 m/s just before impacting with the helmet (Fig. 2). The falling object made the contact with the helmet shell at the center. The FE model was applied to analyze the effects of the neck and body mass on the brain responses during the impact by applying three neck boundary conditions: (1)-"Free" (no constraints were applied at the neck, i.e., the effect of the neck and body mass became negligible), (2)-"Mass" (a point mass of 10 kg was attached to the neck bone), and (3)-"Fix" (the neck was constrained).

RESULTS

The head FE model has been calibrated using the experimental data in literature. The predicted brain pressures at four locations agree well with the experimental measurements (results not shown). The peak contact force between the helmet and scalp was found to be 6119.9, 7328.7, and 7345.8 N, and the corresponding head acceleration peaked at 1350.9, 1244.9, and 1188.1 m/s^2, respectively, for the "Free", "Mass", and "Fix" neck boundaries, respectively. The maximal and the minimal brain pressures during the impact were found at the parietal and posterior fossa regions, respectively, and around 3.65 ms, when the accelerations reached

the maximums. The time histories of the brain pressures at the parietal and posterior fossa locations are shown in Fig. 3.

DISCUSSION AND CONCLUSIONS

In a majority of the head-brain models that are used for frontal impacts in automobile crashes, the neck is not included. It is believed that the effects of the neck on the brain responses are negligible [2]. However, the head-helmet stiffness in the top impact, which is primarily considered in the design of the construction helmet, is substantially greater than that in the frontal impact. Therefore, the effect of the neck and body mass during impact could be a non-negligible factor in the helmet design. Our analysis indicated that the exclusion of the effects of the neck and body mass can cause overestimations of HIC (Head Impact Criteria) and the peak head acceleration by 33% and 12%, respectively, whereas an underestimation of the peak impact force by 17%. Excluding the effects of the neck and body mass would not only cause an overestimation of the peak brain pressures at the parietal and posterior fossa locations by 6-12%, but also vary the patterns of the time-histories of the brain pressures (Fig. 3).

For biomedical engineering applications, it is difficult to precisely account the effects of the neck and body mass on the dynamic responses of the head-brain in FE analysis, because FE model usually does not include the entire human body. In the current study, we have established reasonable upper and lower bounds of the precise solutions for this particular problem. The stiffness of the neck for a real person should be higher than that for the model with the concentrated mass at the boundary (i.e., "Mass"), whereas lower than that for the model with a fixed boundary (i.e., "Fix"). Our analysis indicated that the first peaks of the acceleration and impact force of the head obtained by using these two models differ by less than 1% (Fig. 3, tests "Mass" and "Fix"). Therefore, a good estimation for the precise solution is obtained by an average of the solutions obtained using these two models.

EFFECTS OF WORKING ENVIRONMENT FACTORS ON UPPER EXTREMITY MECHANICAL PROPERTIES DURING POWERED HAND TOOL USE

[1]Xu Xu, and [2]Jia-Hua Lin

INTRODUCTION

Powered hand tools are widely used for fastening screws and nuts during assembly operations. Compared with manual tools, whose output torque is directly adjusted by the operator, powered hand tools are driven by power sources such as high pressure air or electricity. If the build-up torque exceeds the operator capacity, displacement of the tool occurs and results in upper extremity movement and eccentric muscle exertion of the operator, which is related to muscle damage and muscle soreness. Working environment factors, such as working height, working distance, and joint hardness, have been found to significantly affect hand displacement during powered hand tool use. In the current study, the mechanical properties of the upper extremity were identified under various working environment factors. The goals of the study were to understand whether those working environment factors affect the mechanical properties of the upper extremity during actual tool use.

METHODS

Thirty male participants with no chronic or existing musculoskeletal disorders participated in the study (mean age = 38.4, S.D. 13.3). The experimental protocol was approved by the local institutional review board, and informed written consent was obtained from each participant. The tool operation configuration of a pistol grip tool on a vertical surface was examined. The pistol grip tool had an automatic shutoff mechanism. Two joint (J) simulators (soft and hard) were used to represent typical assembly tasks. The joint hardness was defined as the angle of joint rotation from joint contact to tool shutoff. The working heights (V) were 30 cm below, 30 cm above, and at shoulder height; the horizontal distances (H) were 25, 50, and 75% of the maximum forward reaching distance. A task platform consisting of two joint simulators was designed to provide the tool operation configuration (Figure 1). A potentiometer (174-0321T, Space Age Control, Palmdale, CA, USA) was used to record the rotational displacement of the handle. A torque transducer (TQ503-63, Omega Engineering, Stamford, CT, USA) was placed between the joint and the tool to measure the torque generated by the tool (Figure 1). All signals were collected at 1000 Hz by an A/D converter.
Figure 1: Experiment setup

The torque generated by the tool ($\mathbf{T}$) and the rotational displacement ($\boldsymbol{\theta}$) of the tool during the build-up period were first extracted for each trial. The rotational velocity ($\dot{\boldsymbol{\theta}}$) and rotation acceleration ($\ddot{\boldsymbol{\theta}}$) during the build-up period were then calculated using first order and second order finite differences of $\boldsymbol{\theta}$. For a second order linear system, the dynamic equation can be written as:

$$\mathbf{T} = K\boldsymbol{\theta} + C\dot{\boldsymbol{\theta}} + J\ddot{\boldsymbol{\theta}}, \qquad (1)$$

where K and C are torsional stiffness and torsional damping coefficient for the upper extremity, and J is the effective moment of inertia of the upper extremity combined with the tool. $\mathbf{T}$, $\boldsymbol{\theta}$, $\dot{\boldsymbol{\theta}}$, and $\ddot{\boldsymbol{\theta}}$ are all column vectors with same number of rows,

which is the number of samples during the build-up time period. The value of K, C, and J were then estimated by the least squares method (Konczak et al., 1999)

RESULTS AND DISCUSSION

For the pistol grip tool on a vertical surface, the mean stiffness, damping coefficient, and effective mass of the upper extremity were 5.55×10^3 N/m, 80.0 Ns/m, and 2.22 kg, respectively. Joint type was a significant factor for all mechanical properties (Figure 2). The mean stiffness increased 12% and 131% for inexperienced and experienced operators, respectively. For the hard joint, the mean stiffness, damping coefficient, and effective mass were 4.07×103 N/m, 103.3 Ns/m, and 1.27 kg, respectively, while for the soft joint, those values were 7.03×103 N/m, 56.7 Ns/m, and 3.16 kg, respectively.

The hard joint was associated with less stiffness and effective mass, as well as a greater damping coefficient. Such effects could be a result of the nonlinearity of human movement dynamics. The current study modeled the upper extremity as a linear system and the mechanical properties represent the mean values across a fastening sequence. However, because of reflex delay and electromechanical delay between the stimulus and muscle force generation, the stiffness of the upper extremity at the very initial phase during powered hand tool use can be assumed to be zero (Ay, 2011). Although the length of this initial period needs to be further studied, it is clear that the shorter the total fastening time, the more the mechanical properties in a linear model would be affected by the initial phase.

CONCLUSIONS

Mechanical properties of the upper extremity can be used to describe the displacement of powered hand tools. The results suggest that joint type has significant influences on mechanical properties in the tested operating configuration. The results of this study suggest that joint type needs to be considered during the design of a powered hand-tool workstation.

LOWER EXTREMITY JOINT STRATEGY VARIES WITH STEP WHEN TRANSITIONING ONTO DIFFERENT STAIR RISERS WITH AND WITHOUT ANKLE LOAD

[1,2]Toyin Ajisafe & [1]Jianhua Wu

[1]Texas A&M University, Corpus Christi, TX, USA. Email: toyin.ajisafe@tamucc.edu
[2]Georgia State University, Atlanta, GA, USA.

INTRODUCTION

Muscle power bursts indicate joint strategy during locomotion [1]. Previous research has outlined important power bursts around toe-off (late stance to early swing) that are associated with surface accomodation and avoidance: A3 (ankle plantarflexor power generation burst) upwardly accelerates the lower extremity and body prior to toe-off; K3 (knee extensor power absorption burst) decelerates the rapidly flexing knee after midstance; H3 (hip flexor power generation burst) is associated with pulling off the lower limb into swing; K5 (knee flexor power generation burst) occurs during swing and was previously thought to only emerge during surface avoidance [1]. Transitions between level and stair walking have been linked to increased mishaps [2], and external ankle load has been suggested as a potentially effective neurofaciltatory tool; however, despite their potential to reveal joint strategy, no studies have investigated the relativity of the foregoing power bursts when transitioning onto stairs of different heights with and without external ankle load. This knowledge may help further guide task-specific gait rehabilitation and inform fall prevention programs.

METHODS

Participants: Twenty young adults (21.68 ± 2.49 years; 169.70 ± 9.56 cm; 63.91 ± 9.62 kg) participated in this study: seven males (21.71 ± 1.25 years; 177.43 ± 7.53 cm; 69.92 ± 8.34 kg) and 10 females (21.75 ± 3.45 years; 163.82 ± 6.36 cm; 60.5 ± 7.59 kg).

Experimental design: Participants (fitted with 15 retroreflective markers) walked barefoot overground and negotiated an intervening three-step staircase (Fig. 1). There were three stair heights: low stairs (LS) (17 cm riser), medium stairs (MS) (24 cm riser), and high stairs (HS) (31 cm riser), and two external ankle load conditions: no load (NL) and bilateral ankle load (AL) (1.92 ± 0.29 kg). Lower extremity power bursts around toe-off, i.e., A3, K3, H3 and K5 were calculated.

Data collection:
Eight conditions (3 stair height x 2 step x 2 ankle load) were tested. The order of conditions was randomized using a block design. Five trials were collected for each condition. Kinematic data was captured using a 7-camera 3-D Vicon motion capture system (100 Hz) and a Sony 120x digital zoom reference video camera. Two adjoining AMTI force plates (Fig. 1) registered ground reaction forces. A trial was deemed valid, if the lead and trail feet fully contacted the force plates in succession and transitioned onto the stairs successfully.

Data analysis: The interval between initial contact on the second force platform (FP2) and contralateral initial contact on the first stair was delineated as the first floor-to-stair transition step (TS1) (Fig. 1). The interval between initial contact on the first stair and contralateral initial contact on the second stair was delineated as the second floor-to-stair transition step (TS2) (Fig. 1). It is noteworthy that TS2 has been considered both a transition and a steady-state step [3, 4]. Ensemble mean and standard deviation (SD) values were calculated for A3, K3, H3, and K5 bursts across five trials for each condition.

Statistical analysis: A series of 3 stair height x 2 step x 2 ankle load ANOVA with repeated measures was calculated to determine the effects of the factors on the outlined power bursts. Post-hoc pairwise comparisons with Bonferroni adjustments were conducted when appropriate. Statistical significance was set at $p < .05$.
Figure 1: Floor-to-stair transition steps. TS1: interval between initial contact on second force plate (FP2) to initial contact on stair 1; TS2: interval between initial contact on stair 1 to initial contact on stair 2.

RESULTS AND DISCUSSION

There were three-way interactions of stair height, step and ankle load on A3, H3 and K5 ($F_{2,32}$ = 197.12, p < .001; $F_{2,32}$ = 34.35, p < 0.001; $F_{2,32}$ = 10.81, p < .001), respectively. H3 and K5 power bursts were both observed at TS1 and TS2 in the current study suggesting a deliberate strategy to both accommodate and avoid the stair edge. While there was greater reliance on A3 power generation at TS1 in the medium stairs, the low and high stairs were characterized by greater reliance on H3 burst. Conversely, while there was greater reliance on H3 power generation at TS2 in the medium stairs, the low and high stairs were characterized by greater reliance on A3 power generation. Also, the medium stairs was associated with the most diminutive K3 power bursts, suggesting a level of exteroceptive familiarity such that there was not as much need to decelerate the rapidly flexing knee prior to toe off. Relatedly, the presence of ankle load seemed to have increased the need to decelerate the rapidly flexing knee only when ascending the medium stairs.

CONCLUSIONS

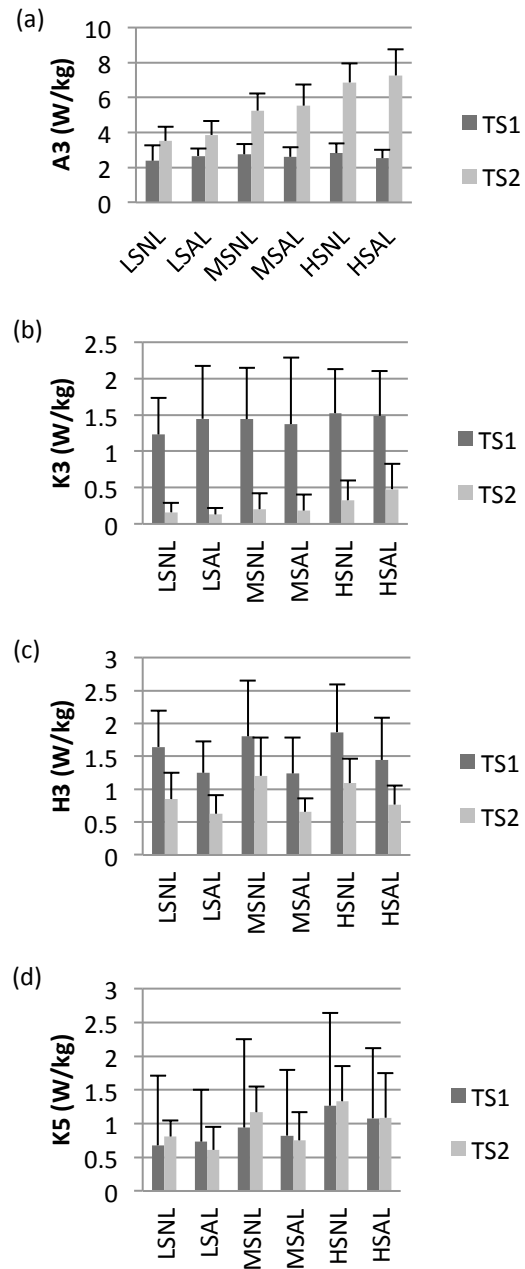
Although stair ascent is considered a surface accommodation task, K5 bursts can emerge to help avoid the stair edge. Surface accommodation seemed less of a priority at TS2 when ascending less familiar riser heights, i.e., low and high stairs.


Figure 2: Mean lower extremity power bursts around toe-off: (a) A3, (b) K3, (c) H3, (d) K5; LSNL (low stair without ankle load); LSAL (low stair with ankle load); MSNL (medium stair without ankle load); MSAL (medium stair with ankle load); HSNL (high stair without ankle load); HSAL (high stair with ankle load)

AVERAGE MINIMUM TOE CLEARANCE MAY NOT CONTRIBUTE TO INCREASED FALL RISK IN PATIENTS WITH CHRONIC OBSTRUCTIVE PULMONARY DISEASE

INTRODUCTION

Despite decades of multidisciplinary research, one out of every three older adults will fall each year [1]. In 2013, this amounted to over 2.5 million non-fatal fall injuries with 734,000 of these patients being hospitalized [2]. There is a need to find measures that can analyze fall risk to identify potential fallers and one potential measure is minimum toe clearance (MTC). MTC occurs during swing phase when the toe is at maximum velocity and the distance between the toe and the ground is at a minimum. The chances of having a trip related fall are highest at the MTC [3]. Fallers have a significantly lower toe clearance compared to non-fallers [4]. One disease that leads to a higher susceptibility to falls is chronic obstructive pulmonary disease (COPD) [5], currently the third leading cause of death in the United States and prevalent in older age groups [6]. Patients with COPD have weaker and more fatigable muscles [7], as well as, impairments in balance [8], which could lead to their higher fall risk.

The purpose of this study is to investigate MTC in patients with COPD to potentially identify a reason why patients with COPD are at a higher risk of falling. We hypothesized that patients with COPD would have lower MTC compared to healthy controls for both a rested and a post-activity tests. MTC could be decreased in patients with COPD compared to healthy controls due to patients with COPD having distal leg muscles that are both weaker and have increased fatigability [7]. We also hypothesized that there would be a reduction in the MTC for the COPD group when going from rested to post-activity tests and no change in the control group. As leg muscles get tired from activity it should become harder for patients with COPD to lift the foot as high, but controls should be able to compensate and maintain normal MTC.

METHODS

Sixteen patients with COPD (9 male, 63.8±8.8yrs, 88.3±24.6kg, 171.1±11.6cm) and 21 healthy control subjects (10 male, 66.1±7.0yrs, 80.61±18.3kg, 166.0±16.5cm) were recruited for this study. There were two walking tests that were performed, rested and post-activity. All the patients with COPD and controls performed the rested test. All patients with COPD and four controls performed the post-activity test.

Test 1 – Rested: Subjects walked across a 10 meter walkway at their self-selected pace. Marker trajectories were collected using data from three-dimensional motion capture (Motion Analysis Corp., Santa Rosa, CA; 60 Hz). One minute of rest was taken for all subjects between trials to prevent muscle tiredness or breathlessness. A total of five trials were collected.

Test 2 – Post-activity: Subjects walked at their self-selected speed on a treadmill at a 10% incline until the self-reported onset of muscle tiredness or breathlessness. Controls walked for 15 minutes. Once either symptom was elicited or 15 minutes was reached, the subject was immediately removed from the treadmill and the subject completed five walking trials without any rest between trials.

Minimum Toe Clearance: A virtual toe marker was built in Cortex (Motion Analysis Corp., Santa Rosa, CA) based on the heel, toe, and lateral metatarsal markers placed on the foot. Using custom Matlab code, MTC was calculated from the swing leg as the minimum distance from the toe to the ground during mid-swing. For each walking trial the MTC was calculated for the right leg and averaged across all steps for the trial. For each subject all five trials were averaged to get an average MTC for each of the two

tests. Group means for COPD vs controls rest and post-activity tests were compared using independent t-tests. Group means from the COPD and control groups rest vs post-activity tests were compared using dependent t-tests.

RESULTS AND DISCUSSION

There were no significant differences in COPD rest vs control rest (p = 0.57), COPD post-activity vs control post-activity (p = 0.84), control rested vs control post-activity (p = 0.41), and COPD rested vs COPD post-activity (p = 0.17). There was an increase, not significant, in the MTC of the patients with COPD when compared to the control group in the rest tests, which is opposite to what was hypothesized (Figure 1). The patients with COPD could be raising their foot higher to exaggerate lifting their foot to not have the foot catch the ground.
Figure 1. Mean minimum toe clearance for each condition for controls (light blue) and COPD patients (black) in the rested (solid) condition and the no rest (pattern) condition.

When performing the post-activity test, the patients with COPD had lower MTC values, not significant, compared to controls (Figure 1). Therefore patients with COPD had higher MTC values at rest, but lower MTC values during the post-activity test. The decrease in the MTC of the patients with COPD in the post-activity test as compared to the rested test, although not significant, partially supports the second hypothesis. The decrease could be due to tired muscles in the legs causing the toe to be slightly closer to the ground during swing phase. Patients with COPD not only have weaker dorsiflexors and quadriceps compared to age-matched healthy controls, but they also have increased fatigability [7]. Weakness and fatigability in these muscles would cause the foot to be lower during swing phase. A larger difference was expected especially if the

COPD subjects were truly walking with an altered gait due to tired muscles. If the patients with COPD were putting in more effort to raise their foot higher to avoid contact of the toe with the ground during swing phase, then it would be expected that their ability to raise their leg higher would be diminished when they were tired from activity.

Although MTC has been used in previous literature [3,4], the lack of significant differences seen between the average MTC in patients with COPD and controls could be an indication that other measures should be utilized to determine what causes the patients with COPD to have higher fall risk. One potential measure is MTC variability. The variability of MTC was greater in elderly compared to young men and may increase the risk of tripping in the elderly [9].

CONCLUSIONS

There were no significant differences between controls and the patients with COPD for the rest and post-activity tests. There was an increase in the MTC in the patients with COPD as compared to the controls during the rested tests, although this did not reach statistical significance. The MTC of the patients with COPD decreased in the post-activity test as compared to the rested tests however this also did not reach statistical significance. The decrease could have been due to the muscles being tired from activity and a larger study may have more power to detect a statistically significant difference. Other measures (i.e., MTC variability) may provide larger and significant differences between patients with COPD and controls.

ACKNOWEDGEMENTS

Factors Influencing Frontal Plane Kinematics and Kinetics Before and After Total Knee Arthroplasty

INTRODUCTION

Knee osteoarthritis (OA) is associated with increased varus knee alignment, altered gait kinematics and kinetics, quadriceps weakness, and high muscle co-contraction indices (CCI), all of which negatively affect joint integrity [1-4]. Total knee arthroplasty (TKA) generally improves function and relieves pain associated with severe knee OA. However, even after TKA, more patients have difficulty with daily activities than age-matched controls (52% versus 22%) [5]. Studies have investigated changes in strength, muscle activity, knee alignment and gait before and after TKA, but they primarily studied sagittal plane kinematics or made comparisons to controls [4,6]. To assess potential contributing factors of suboptimal TKA outcomes, it is important to understand how kinematics and kinetics may be affected by CCI, strength, and knee alignment before and after TKA.

The purposes of this study were to investigate: 1) how frontal plane knee kinematics and kinetics during gait are related to CCI, knee flexion and extension strength, and standing knee alignment both before and 6 months after TKA, and 2) if preoperative variables can be used to predict postoperative kinematics or kinetics.

METHODS

19 subjects (21 knees: 4 M / 17 F, age 57.6 ± 7 y, height 1.67 ± 0.9 m, weight 93.8 ± 16 kg, BMI 34.2 ± 5.4 kg/m^2) awaiting TKA provided IRB approved consent to participate in this study. Movement analysis was performed during gait at a self-selected speed approximately 1 month before and 6 months after surgery. Knee flexion and extension strength were estimated by maximum voluntary isometric contraction measured on a Biodex System 3 Dynamometer [Biodex Medical Systems; Shirley, NY]. A modified Point Cluster Technique was used with ten motion capture cameras [MX-F40: Vicon, Oxford UK] at 150 Hz to calculate kinematics [7]. Standing knee varus alignment was extracted from static calibration trials, as similar methods have shown good correlation with radiographic alignment [8]. Ground reaction forces were sampled at 1500 Hz from Bertec 4060-10 force plates [Bertec Corp; Columbus, OH], and lower extremity joint loading was estimated with inverse dynamics. Weight acceptance (WA) was defined as the time period from heel strike to peak knee flexion angle. Peak and mean knee adduction angles and moments (pKAA, mKAA, pKAM, & mKAM) were found over WA for the involved limb.

EMG was collected at 1500 Hz for rectus femoris (RF), vastus lateralis (VL), vastus medialis (VM), semimembranosus (SM), biceps femoris (BF), lateral gastrocnemius (LG) and medial gastrocnemius (MG). EMG was filtered with a zero lag, 4th order, 10 Hz low-pass Butterworth filter and full wave rectified. EMG was normalized to the maximum EMG measured during submaximal reference exercises, as this technique is suggested for use in pathological populations [9]. Trials with poor EMG were removed from further analysis. Average CCI for the involved limb over WA were calculated for total, medial and lateral quadriceps-hamstring (QH, MQH, and LQH), and total, medial and lateral quadriceps-gastrocnemii (QG, MQG, and LQG) co-contractions (Eq. 1) [3].

$$avgCCI = \frac{1}{n}\sum_{i=1}^{n}\left(\frac{lower\ EMG_i}{higher\ EMG_i} \times (lower\ EMG_i + higher\ EMG_i)\right)$$

Equation 1. Average CCI over n samples during WA.

Statistical analysis was completed using Minitab 17 Statistical Software [Minitab Inc., State College, PA]. Depending on the distributions of the variables, paired t-tests or Wilcoxon Rank-Sum tests were used

to test for differences between the paired preoperative and postoperative variables. Similarly, Pearson's correlation or Spearman's rank-order coefficients were calculated to estimate the association between selected pairs of independent variables.

RESULTS AND DISCUSSION

Before TKA, increased standing varus alignment was associated with increased preoperative pKAA and mKAA (Table 1). CCI and strength were not related to frontal plane knee kinematics or kinetics.

Six months after TKA, increased LQH, QH and standing varus alignment were associated with increased mKAA (Table 1). Increased LQH and standing varus alignment were also associated with increased pKAA. When standing alignment was used as a covariate, LQH remained significantly related to both mKAA and pKAA (p 0.025), but QH was no longer significantly related to mKAA (p=0.178). Other CCI and strength were not related to frontal plane knee kinematics or kinetics.

Preoperative variables were not found to predict postoperative kinematics or kinetics. Preoperative standing varus alignment was not significantly related to postoperative pKAA or mKAA (p 0.453). All frontal plane knee kinematics and kinetics, QH, LQH, and standing alignment significantly decreased after surgery (p 0.004). Other CCI and strength were not significantly different before and after TKA.

CONCLUSIONS

While studies may disagree on whether knee varus alignment and muscle co-contractions are related, our results suggest that both factors may be related to frontal plane knee kinematics after TKA [3,6]. We did not find a relationship between preoperative standing alignment and pKAM, which contrasts previous work that found varus alignment and pKAM are related in subjects with knee OA [10]; this relationship should be further investigated in a TKA population. Regarding the second purpose of this study, significant preoperative variables were not associated to postoperative kinematics. Interestingly, standing alignment was the only variable associated with knee angles both before and after TKA, while 2 CCI parameters emerged after surgery. Since a surgeon corrects preoperative deformity during TKA, our results may suggest an interplay between postoperative limb alignment, CCI, and kinematics that warrants further investigation and could suggest an ability to leverage intraoperative measurement to predict postoperative functional outcomes of TKA.

THE EFFECTS OF VARUS AND VALGUS MIDFOOT ORTHOTIC POSTING ON ANKLE AND MIDTARSAL JOINT ANGLES DURING WALKING: A MULTI-SEGMENT FOOT ANALYSIS

[1]Joaquin A. Barrios and [1]Hilary F. Feskanin

[1]University of Dayton, Dayton, OH, USA
email: jbarrios1@udayton.edu

INTRODUCTION

The use of varus and valgus posting in foot orthotic devices has received considerable attention in the biomechanical literature as a conservative means to treat a variety of lower limb disorders. Based on previous research on foot orthoses, nearly all testing has been conducted on devices under the rearfoot. While rearfoot eversion is a key component of the overall foot pronation mechanics, there has been almost no direct research on the kinematic effects of posting aimed at the midfoot (Ferber & Benson, 2011). This paucity of research is largely due to historical limitations in kinematic foot modeling, and can be partly addressed with the growing use of multi-segment foot models. Therefore, the purpose of this study was to assess three-dimensional ankle and midtarsal joint kinematics during shod walking with either varus or valgus posting to the midfoot region using a multi-segment foot model. We hypothesized that varus posting would decrease eversion mechanics at the rearfoot and midfoot compared to the stock orthoses, and valgus posting would increase eversion mechanics.

METHODS

Twenty healthy female subjects were recruited for the study (Table 1). Potential subjects were excluded if they reported any history of spinal or lower extremity pathology in the previous year. Standing Arch Height Index was recorded. To prepare for data collection, subjects were fitted with an established reflective marker set to the right lower extremity and pelvis, which was supplemented with a modified version of a recently established three-segment foot model (Bruening et al., 2012). New Balance Minimus running shoes were used. The shoes has been custom modified with marker cut-outs in the upper, as well as a midline zipper in the upper from the distal tip of the shoe up through the tongue (see figure). Finally, commercially available foot orthoses (Vasyli Medical, San Rafael, CA, USA) were used. The base orthotic device served as the control condition, and 6 degree varus and valgus posts were added to the same stock device for the posted conditions. Due to the novel zipper modification, a markered foot could be removed without disturbing the marker configuration.
Data collection commenced with a static calibration and functional hip motion trial. Walking trials were then collected along a 23 m walkway at a self-selected speed, using average sacral marker velocity along the line of progression while the subject traversed the volume. All trials were controlled at the established speed within 5%. The control condition was collected first, followed by the two posted condition in random order.

Video data were captured using an 8-camera VICON (Oxford Metrics, Oxford, UK) Nexus system (100 Hz), and kinetic data using a Bertec (Columbus, OH, USA) force platform (1000 Hz). Five usable trials were labeled and trimmed to stance in Nexus, exported in C3D format, and post-processed in Visual 3D (C-Motion, Bethesda, MD, USA). Cardan joint angles (X (Sagittal) – Y (Frontal) – Z (Transverse)) were calculated. Custom Labview software code (National Instruments, Austin, TX, USA) was used to extract the target variables of interest from the array data. The target variable list was comprised of the 3D ankle and midtarsal angles at initial contact, peak deflections, and the corresponding excursions, expressed in degrees. SPSS (v20.0, IBM, New

York, USA) was used to perform repeated measures analyses of variance using an alpha level set to 0.05, with planned comparisons between the posted conditions to the control condition.

RESULTS AND DISCUSSION

Table 1: Mean (SD) subject descriptive data (N = 20)

Age (y)	Height (m)	Weight (kg)	BMI (kg/m²)	Standing Arch Height Index
22.0 (1.7)	1.7 (0.1)	62.9 (8.9)	23.2 (3.4)	0.33 (0.03)

In general, the purpose of this foot orthotic study was to evaluate the effects of 6-degree varus and valgus midfoot posts on 3D midtarsal and ankle joint angles during walking in healthy females. A three-segment foot model and a shoe customized with a longitudinal zipper were used to facilitate a novel assessment of midtarsal joint mechanics in different orthotic conditions. The female subjects in this study were young, healthy, and presented with normal arch height structure in standing (Table 1).

At the rearfoot, neither the varus nor valgus midfoot post elicited changes in any plane (Table 2). This is a novel finding suggesting that midfoot-targeted orthotic devices have localized effects to the midfoot region, and that more proximal rearfoot kinematics are not secondarily affected by such devices. Future testing for the influence of changes to midfoot mechanics on kinetic parameters is warranted, as is evaluating for effects at more proximal body regions such as at the knee and hip.

At the midfoot, changes by condition were observed in all three planes of motion. All subjects landed with midtarsal plantarflexion, inversion, and slight abduction. Valgus posting elicited increases in midtarsal dorsiflexion total motion, peak eversion and total eversion motion, and peak abduction. These increases are anecdotally in line with greater midfoot pronation in response to lateral posting.

The varus posting to the midfoot did not affect the midtarsal joint in the sagittal plane. However, we unexpectedly observed a small increase in midtarsal eversion. However, at approximately half a degree of motion, this finding may be within the error of the measurement. Decreased abduction excursion was also observed, which supports the notion that less pronation is occurring at the midfoot region, for which abduction is considered a component motion.

CONCLUSIONS

In summary, the multi-segment foot kinematic data support the notion that midfoot posting strategies affect the midtarsal joint but not the rearfoot, and that varus or valgus posting largely introduce changes that reduce or increase pronatory mechanics in the midfoot region, respectively.

MUSCULAR AND METABOLIC CHANGES IDENTIFIED DURING PROLONGED LOAD CARRIAGE ON VARIABLE GRADES

Jessica Batty, Meghan O'Donovan, Carolyn K. Bensel, and Leif Hasselquist

Natick Soldier Research, Development and Engineering Center, Natick MA
E-mail: jessica.m.batty.civ@mail.mil

INTRODUCTION

The negative consequences of prolonged load carriage on soldiers' physical status continue to be a major concern for military services worldwide. However, there is little research into the effects on soldiers of prolonged load carriage and the research that has been done has focused primarily on changes in energy cost as a function of load weight and time marching on a level grade [1]. In one study [2], muscle function was recorded before and after a 2-h march at either a 0% or a -8% grade with a 25-kg backpack load. The two grades resulted in similar decrements in muscle force production. The current research was designed to mimic the physical demands of a more realistic load carriage scenario by varying grade during a prolonged march and including a load typical of the weight soldiers carry. Oxygen consumption ($\dot{V}O_2$) was also recorded during the march. The purpose was to determine the muscular and metabolic effects of a load carriage paradigm with 1 h (H1) of uphill walking followed by 1 h (H2) of downhill or of variable graded walking, for a total march distance of 9.6 km.

METHODS

Eleven soldiers (Age, 23$\pm$3 yrs; Ht, 179.3$\pm$8.0 cm; Wt, 86.2$\pm$12.5 kg; $\dot{V}O_{2peak}$, 49.2$\pm$4.4 ml·kg^{-1}·min^{-1}) conducted 2-h treadmill marches at 1.34 m·s^{-1} under 4 combinations of load and grade (I: 6-kg load, H1 at 4% grade, H2 at -8% grade; II: 6-kg load, H1 at 4% grade, H2 at variable grade; III: 40-kg load, H1 at 4% grade, H2 at -8% grade; IV: 40-kg load, H1 at 4% grade, H2 at variable grade). The variable grade conditions consisted of 10-min of walking at each of three grades (-8%, 0%, and 4%, in order), followed by another 10 min at each of the grades. $\dot{V}O_2$ data (ml·kg^{-1}·min^{-1} adjusted for body weight) were averaged over 2-min collection samples taken at 10- min intervals during the march (COSMED, Chicago, IL). The average $\dot{V}O_2$ values for H2 were obtained and used in subsequent analyses. Isokinetic lumbar muscle flexion and extension data were collected immediately before and after the march for 5 maximal muscle contractions at 20°·s^{-1} and 21 maximal muscle contractions at 60°·s^{-1} (Biodex, Shirley, NY). A mean was obtained over each set of trials and a difference was calculated as the pre- minus the post-march measure. Separate repeated measures analyses of variance (ANOVAs) were done to assess muscle strength differences and average $\dot{V}O_2$ values for each of the 4 march conditions. In those instances in which an ANOVA yielded a significant main effect ($p < .05$), post hoc analyses were performed with a Bonferroni correction applied.

RESULTS AND DISCUSSION

Lumbar pre- minus post-march muscle strength scores revealed: a) Significant differences in isokinetic lumbar extension at 20°·s^{-1} between the 6- and the 40-kg loads, reflecting larger decreases in power ($p < .005$) and total work ($p < .005$) and a smaller decrease in peak torque ($p < .01$) for the heavier load condition; b) A significant difference in isokinetic lumbar extension at 20°·s^{-1} between constant downhill and variable grades, reflecting a larger increase in time to peak torque ($p < .05$) for the constant grade condition; c) For 60°·s^{-1} isokinetic lumbar extension, significantly larger decrements in power ($p < .05$) and total work ($p < .05$) with the heavier load at the variable grade (IV) compared with the constant grade (III), and essentially no differences between constant and variable grades with the lighter load (I and II, respectively; Fig. 1).

$\dot{V}O_2$ responses for H2 of the march demonstrated: a) No significant interaction between the load and the grade variables ($p > .05$); b) A significant difference between the 6- and the 40-kg loads, reflecting higher metabolic cost ($p < .001$) for the heavier load condition; c) A significant difference between constant downhill and variable grades, reflecting higher energy cost for the variable grade ($p < .001$; Fig. 2).

Study results indicate that neuromuscular impairment, displayed as reduced strength of lumbar muscles, can be identified upon completion of a 2-h loaded march. Muscle strength is affected by load weight carried and grades traversed during the march. However, results for slow ($20°\cdot s^{-1}$) and fast ($60°\cdot s^{-1}$) isokinetic test velocities of lumbar extension, likely requiring different patterns of slow- and fast-twitch muscle fiber recruitment, differed somewhat from each other. The $20°\cdot s^{-1}$ data indicated strength decrements for the 40-kg compared with the 6-kg load and for the variable compared with the constant downhill grade, but the interaction between load and grade was not significant ($p > .05$). The $\dot{V}O_2$ data results for the second hour of the march were similar insofar as oxygen cost was higher for the heavier load and for the variable terrain, and there was not a significant interaction between load and grade ($p > .05$). In contrast, the $60°\cdot s^{-1}$ test velocity did reveal a significant interaction ($p < .05$). For the lighter load, there was little change in muscle strength as a function of grade condition. However, strength decrements were substantial for the heavier load carried on the variable compared with the downhill grade. Considering the lumbar muscle strength and the metabolic results, it can be posited that the fast isokinetic test velocity revealed generalized, whole-body muscle fatigue induced by carrying a heavy load on a variable grade, which required uphill and level as well as downhill walking, whereas the slow test velocity reflected a more localized fatigue of the lumbar muscles.

CONCLUSIONS

Reduction in lumbar muscle strength over a prolonged march appears to be linked to the load carried and the variability of the grade of the march.

Variable grade traversals may contribute more substantially to soldiers' loss of mission effectiveness than a downhill traversal.

EFFECT OF PLANTAR FASCIA STIFFNESS ON FOOT ENERGY ABSORPTION DURING OVERGROUND WALKING

[1] Erica A. Bell, [2]Kota Z. Takahashi, [1]Patrick M. Rider, [2]Gregory S. Sawicki, and [1]Zachary J. Domire

INTRODUCTION

The foot plays a vital role in locomotion, providing support and standing balance as well as aiding in shock absorption and propulsion. The foot-to-ground interaction during locomotion allows for the modulation of the force generating capacity of the ankle plantar flexor muscle-tendon unit and recent studies have shown the foot's ability to shift ankle muscle operating conditions during ground contact to influence locomotion [1, 2]. The ankle joint has been implicated for its importance in providing energy to propel the body forward. However, the functions of the foot structures in locomotion are less clear. Intrinsic foot structures play a role in foot movement that can affect gait and local changes in these structures can have significant effects on movement and balance. While the ankle provides positive (propulsive) energy, the metatarsal-phalangeal (MTP) joint causes negative (dampening) energy to be done by the foot [3], where mechanical energy is absorbed during forward propulsion (Figure 1).
Figure 1: Diagram of the foot and ankle during late stance, where rotation of the MTP joint acts to dampen (i.e., perform negative work) the ankle push-off work.

We anticipate that a stiffer foot will decrease the mobility of the MTP joint and deformation ability of the foot, thereby decreasing the magnitude of energy absorption. The plantar fascia is a key structure in regulating MTP joint mobility during locomotion and may regulate the magnitude of foot energy absorption. **Therefore, the overall goal of this study is to investigate the effects of plantar fascia stiffness on foot mechanics.**

METHODS

Four healthy subjects (two males and two females, ages 24.0 ± 2.2 yrs, height 1.75 ± 0.07m, and body mass 75.0 ± 19.2 kg) with no previous foot surgery, current plantar fasciitis, osteoarthritis, or musculoskeletal injuries that would compromise walking ability participated in gait analysis and ultrasound scans. All subjects gave informed consent for this protocol approved by the Institutional Review Board at East Carolina University. An eight camera 3D motion capture system (Qualisys, Gothenburg, Sweden) and an embedded force plate (AMTI, Watertown, MA) were used to collect kinetic and kinematic data during overground walking. Subjects walked at four speeds (1.2 m/s, 1.3 m/s, 1.5 m/s, and 1.7 m/s), where 1.5 m/s is considered a normal walking speed. An Aixplorer ultrasound system (SuperSonic Imagine, Aix-en-Provence, France) was used to perform ultrasound elastography scans of the plantar fascia while subjects were lying prone, with feet hanging just off of an examination table. Elastography is a cutting edge medical imaging technology that can be used to non-invasively examine tissue material properties in vivo.

Walking data was processed and analyzed using Visual3D software (C-Motion Inc., Germantown, MD). Elastography measurements were taken by selecting a 1mm diameter circular region of interest located centrally in the tissue, and calculating the mean shear modulus of this region. Regression analysis was used to determine relationship between peak negative power and plantar fascia stiffness across the four walking speeds.

RESULTS AND DISCUSSION

The regression analysis of average peak negative power as a function of plantar fascia stiffness is shown in Figure 2. Foot energy absorption, as measured by peak negative power, increased with walking speed, and was more dramatic at higher speeds (Figure 3). Plantar Fascia stiffness had a strong, positive relationship with foot energy absorption at all walking speeds. There is a moderate relationship of body mass and plantar fascia stiffness (Figure 4).
Figure 2: Linear regression analysis of plantar fascia stiffness and average peak negative power across all walking speeds.

We did not make an actual measure of deformation of the MTP joint. However, given that power absorption increased with stiffer feet, it is likely that the deformation stayed the same, as foot stiffness varied across individuals.
Figure 3: Distal foot power curves across all speeds for a representative subject.
Figure 4: Relationship between body mass and plantar fascia stiffness.

CONCLUSIONS

The results are contrary to our hypothesis. It seems as though increased stiffness of the foot results in greater energy absorption by the foot. This might increase the energy costs of locomotion. However, it could potentially be advantageous in terms of performance. Further research is needed to clarify this relationship.

PLANTAR REGIONAL PEAK PRESSURE AND MINIMAL SHEAR STRESS PROFILES IN DIABETIC AND NON-DIABETIC PATIENTS

[1] Visar Berki and [1] Brian L. Davis

[1] The University of Akron, Akron, OH, USA
Email: vb20@zips.uakron.edu, Web: http://www.uakron.edu/engineering/BME/

INTRODUCTION

The measurement of plantar pressure and shear stress profiles is increasingly being applied to the problem of skin tissue breakdown and ulceration in diabetic patients. The complex nature of plantar pressure and shear stress profiles during gait presents a multitude of possibilities for their assessment. Our current objectives were to determine (i) the instantaneous regional peak pressures in diabetic and non-diabetic patients, (ii) the instantaneous regional points of minimal shear stress, and (iii) the relationship, if any, between the two data sets. If there was a significant relationship between peak pressures and low shear, this would lend support to the idea that tissue is "squeezed" radially outwards from points of peak pressure, with zones of almost no shear stress at the center of these regions. Our goal was to investigate these relationships for diabetic patients with peripheral neuropathy and non-diabetic control patients.

METHODS

Pressure and shear stress data were collected on 29 human subjects: 16 control patients (9M, 7F; Age: 47.6±5.8 years; Weight: 824 N) and 13 neuropathic, diabetic patients (8M, 5F, Age: 61.6±14 years, Weight: 944 N). Each subject walked barefoot across a custom built shear and pressure collection system that is aligned in the center of a 3 m. x 0.6 m. platform. The center of the walking platform contains a 40 x 58 x 0.17 cm^3 surface stress sensitive film (S3F) [1] that the subject was required to step on with the second of three steps. Four separate steps were recorded for each subject at a sampling rate of 50 Hz. Every step data set consisted of multiple 2-D arrays for pressure, medial-lateral shear, and anterior-posterior shear stress data, representing each sampled timeframe.

Each array contains pressure and shear stress data for every 1.6 mm x 1.6mm area of contact between the plantar and ground surfaces.

For every time frame, regional pressure peaks that correspond to the highest pressure in any 4.8mm by 4.8mm region of pressure values were recorded, along with their respective location coordinates. Simultaneously, shear stress coordinates were recorded, on the condition that the values corresponded to shear stress magnitudes of less than 25 Pa in all four directions (medial, lateral, anterior, and posterior). The distances between all minimal shear stress and regional peak pressure points were calculated, for all time frames.

Two sets of relationships between regional peak pressure and regional minimal shear stress points were then generated. The first set investigated each regional pressure peak, and calculated whether that peak occurred near any point that was considered as a minimal shear stress. The second relationship set investigated each regional minimal shear stress, and calculated whether that value occurred near any regional peak pressure point. Two points were considered to be nearby if they occurred within the same 4.8mm by 4.8mm neighborhood of coordinates. The final results indicated (i) the total number of regional peak pressure points, and how many of those points were near a minimal shear, and (ii) the total number of minimal shear points, and how many of those points occurred near a regional peak pressure point.

RESULTS AND DISCUSSION

For every time frame that contained pressure and shear stress data from any given patient, we observed that there were multiple instantaneous pressure peaks occurring on the plantar contact

surface. There were also numerous points of minimal shear during the same time frames. The total number of points occurring throughout the entire stance phase (multiple time frames) was summed and compared between diabetic and non-diabetic patients (Table 1). The results show that on average, diabetic patients have a higher number of regional peak pressure points (718 vs. 460) and also a higher number of minimal shear stress points (140 vs. 92) on the plantar surface. It is also evident that there were far more points of peak pressure as compared to points of minimal shear over the course of the entire stance phase. These findings are consistent with the concept that neuropathic diabetic patients have arches that flatten more than control subjects. As an arch flattens, there are concomitantly increased sites where local pressures increase. Of note is the fact that for diabetic and control subjects there was little difference in (i) the ratio of regional peak pressure points occurring near minimal shear points, and (ii) the ratio of minimal shear points occurring near regional peak pressures.

CONCLUSIONS

The current study has revealed that diabetic patients with peripheral neuropathy experience more instantaneous pressure peaks as the plantar skin surface makes contact with the ground. We believe that this is in fact an indication of a collapse in the supporting arch structure of the foot, as is often the case in diabetic patients with foot pathologies. The increased number of peak pressure points means that there is likely a greater surface area that makes contact with the ground, which also explains the increased number of minimal shear stress points. In this scenario, both peak pressures and minimal shear stresses would be more widely distributed.

Previous studies have tried to predict shear stresses based on vertical loading parameters, given the absence of commercial plantar shear force platforms [2]. We examined our results for a possible relationship between regional peak pressure points and points of minimal shear. We conclude that we can safely predict minimal shear points with more than 84% certainty by observing the locations of peak pressures. But we cannot necessarily predict peak pressure points by observing minimal shear locations, as the occurrence rate is less than 19%.

INTRODUCTION

Humans and animals alike possess capacity for path integration. This capacity allows them to navigate the world around them by perceiving how their body is moving relative to the environment [1]. Path integration can underwrite basic adaptive behaviors such as foraging for food and the capacity to return to one's home location.

Path integration is based upon the use of sensory information to perceive the angles turned and distances traversed by the body as it moves through the world [1]. Perception of the distances traveled during navigation is known to depend upon sources of visual and non-visual information. Non-visual information has been shown to principally rely upon information derived from the movements of the limbs during locomotion (i.e. kinesthetic perception)[2]. In the absence of visible landmarks, vision and kinesthetic perception have been shown to have an approximately equal impact on human path integration [3].

Investigations of kinesthetic distance perception have shown that perception of distance traveled while blindfolded depends upon the way in which the legs are coordinated [2]. In this research, manipulating the gait patterns employed by participants across the outbound and return phases of a simple homing task was found to result in systematic biases in task performance. The two principal gait patterns employed in this research were a walk and a gallop-walk. The gallop-walk involves stepping forward with the right foot, bringing the feet together to parallel, and then repeating this process. While performing a simple homing task, participants who used a gallop-walk as the outbound gait in the homing task, followed by walking in the return phase of the homing task, produced a systematic underestimation bias. Alternatively, either walking or running outbound followed by walking in the return phase produced no bias [1].

We hypothesized that visual information specifying distance traveled, unlike kinesthetic information for distance traveled, would not depend upon the gait patterns used by participants to complete the task.

METHODS

Eleven subjects, who are healthy individuals between the ages of 19 and 36, were recruited. Participants performed variants of a simple distance matching task consisting of a study phase and a test phase. In the study phase participants either walked or gallop-walked a set distance, and were instructed to get a sense of the distance they had traversed. In the test phase participants were asked to reproduce the studied distance from the study phase by walking a matching distance.
Figure 1. Complete (left) and partial (right) blindfolds used in experiment.

The potential contribution of kinesthetic and visual information in the distance matching task was investigated by manipulating the distances traversed in the study phase (6.5, 13, or 19.5m), the gait pattern employed in the study phase (walk, gallop-walk), and the availability of visual information in both study and test phases (complete blindfold, partial blindfold). The complete blindfold occluded all vision. The partial blindfold, similar to a visor, allowed the subjects to see only the immediate ground surface in front of them (about 2m). The partial blindfold prevented the subjects from getting any distance cues from visual landmarks. Experimental trials consisted of randomly presented combinations of the 3 independent variables (2

vision x 3 study phase distances x 2 study phase gait patterns).

On each experimental trial subjects put the blindfold on. They were instructed which gait pattern to employ in the study phase, which was either a walk or a gallop-walk. Participants then walked or gallop-walked a straight-line path until instructed to stop by the experimenter. While leaving the same blindfold on, subjects were then given instructions to walk a matching distance to that traversed in the study phase by continuing to walk in the same direction until they perceived a matching distance had been traversed.

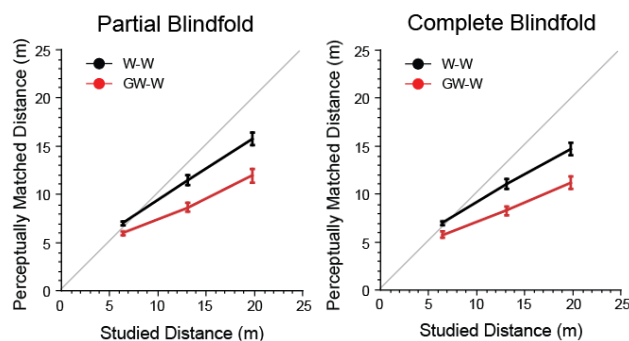
RESULTS and DISCUSSION


Figure 2. Distances of walked reports in the test phase as a function of distance traversed in the study phase, study phase gait, and the availability of visual information.

A systematic bias in reports was observed as a function of manipulating the study phase gait ($F(1,10) = 26.91$, $p < 0.001$). Although a main effect of vision was observed in the distance-matching task ($F(1,10) = 15.00$, $p < 0.01$), the presence or absence of vision did not diminish the systematic bias resulting from the manipulation of study phase gait patterns (Fs<1). These results are not consistent with our original hypothesis that the availability of visual information across the study and test phases would attenuate the bias resulting from manipulating study phase gait patterns.

CONCLUSIONS

In attempting to interpret these finding, we noted particular characteristics of the results we obtained. We observed that the magnitude of bias resulting from manipulation of the study phase gait was significantly greater than what has previously been observed in the investigation of kinesthetic homing

tasks [2]. Additionally, a general bias towards underestimation of all distances was observed in our data that again is not observed in previous studies. Given these differences, a possible interpretation of our results is that participants in our experiment did not perceive distance in the same way as in previous homing task research. One possibility is that their reports may be biased by other variables such as effort. Effort is known to affect distance perception in some task contexts but not others [4]. Specifically, this research shows that effort affects attempts to reproduce the distance traveled along a recently traveled route (i.e. a distance matching task), but does not affect the ability to return to a fixed location in the environment (i.e. a homing task). In light of recently observed differences in the cost of transport for walking and gallop-walking [5], our results are consistent with the participants matching the following relation [6]:

$$\text{Study}\left(\frac{\text{Metabolic Effort}}{\text{Specified Distance}}\right) = \text{Test}\left(\frac{\text{Metabolic Effort}}{\text{Specified Distance}}\right)$$

We are planning to run a second experiment identical in design to our first experiment with the exception that participants will be asked to perform a homing task rather than a distance matching task.

INTRODUCTION

Exercise is important for cardiovascular health and overall well-being. Running is a popular mode of exercise that is associated with repetitive loading of the lower limb joints. Repetitive mechanical loading of the knee may accelerate cartilage degenerative changes, particularly when administered in large doses [1] or when administered to cartilage previously exposed to injury [2]. Knowledge of interventions to minimize exposure to knee joint contact forces during running may be advantageous in the management of people at risk for knee joint osteoarthritis, such as individuals with a history of knee joint injury. Reducing step length leads directly to reduced patellofemoral joint (PFJ) force per step and per kilometer [3]. However, the influence of step length during running on tibiofemoral joint (TFJ) kinetics are less well known. The purpose of this study was to test if the reductions in PFJ force per step and per kilometer are also observed at the TFJ.

METHODS

Twenty subjects who ran at least twice per week for no less than 16 km/week volunteered to participate in this study (10 males, 10 females, 22.6 years). All participants were asymptomatic in their lower extremities during the last 2 months and had no history of lower extremity surgery.

Following acclimation to the treadmill, participants ran at their preferred pace (2.84 m/s) and step length. Step length then was then manipulated by increasing and decreasing step rate by 10% using audio cues provided by a metronome while running at the same velocity. After 2 minutes of practice in each condition, lower extremity kinematics (240 Hz, Qualysis AB, Gothenburg, Sweden) and ground reaction forces (2400 Hz, Bertec Corp, Columbus, OH) were recorded. Foot strike pattern was held consistent between step length conditions.

Knee joint contact forces were estimated using a biomechanical model with inputs of hip, knee, and ankle angles, net joint moments, and joint reaction forces calculated using an inverse dynamics approach [4]. Muscle cross sectional area, line of action, and moment arms as a function of joint position at each joint were derived from the literature to estimate quadriceps, hamstrings, and gastrocnemius muscle forces during the stance phase of 5 steps. PFJ force was determined using quadriceps force after adjusting for cocontraction of the knee flexors. TFJ force was estimated as the sum of knee joint reaction forces and muscle force components applied through an 8.8° posterior tibial slope [5]. Medial TFJ contact forces were estimated as the force necessary to balance the frontal plane knee joint moment and total knee compression forces around contact points at 25% and 75% of subject-specific knee joint width [6].

Variables of interested included total PFJ, TFJ, and medial TFJ impulse per step and total PFJ, TFJ, and medial TFJ impulse per km. Impulse per kilometer was derived as the product of impulse per step and steps required to run a km in each condition. Separate repeated measures ANOVAs were used to test for differences in these variables between each step length condition ($\alpha = .05$)

RESULTS

A 10% shorter step length reduced TFJ impulse per step by 12.5% (p<.001), medial compartment TFJ impulse by 13.1% (p<.001), and PFJ impulse by 19.0% (p<.001). A 10% greater step length increased TFJ impulse per step by 17.3% (p<.001), medial compartment TFJ by 17.1% (p<.001), and PFJ impulse by 25.8% (p<.001).

A 10% shorter step length did not reduce TFJ impulse per km (p=.246) or medial compartment TFJ impulse per km (p=.187). However, a shortened step length reduced PFJ impulse per km by 10.3% (p=.014) despite the increased number of steps per km (Fig. 1). Conversely, a longer step length increased TFJ impulse per km by 6.9% (p=.003), TFJ medial compartment impulse per km by 6.7% (p=.003), and PFJ impulse per km by 14.8% (p<.001) despite the decreased number of steps per km. Post hoc analysis of muscle forces revealed greater gastrocnemius impulse but lower quadriceps impulse per kilometer with each decrease in step length (Figure 2).
Figure 1: Total tibiofemoral joint (TFJ), patellofemoral joint (PFJ), and medial compartment tibiofemoral joint (Med TFJ) impulse per kilometer. Error bars represent the 95% confidence interval. BW=body weights
* *p*< .05 compared to preferred step length
Figure 2: Total hamstrings, quadriceps, and gastrocnemius muscle impulse per km during step length conditions.

DISCUSSION

The purpose of this study was to examine simultaneous effects of step length changes on PFJ and TFJ kinetics during running. We observed a significant increase in both PFJ and TFJ impulse per step and per km with an increase in step length. Increasing step length resulted in 30 additional body weights per km in the TFJ and 31 additional body weights per km in the PFJ. Interventions to decrease step length among runners who demonstrate a particularly long step length may facilitate some knee joint injury prevention and treatment efforts.

Decreasing step length from the preferred condition reduced PFJ and TFJ impulse per step and PFJ impulse per km. However, TFJ impulse per km was not reduced with a shortened step length. This was due to increased gastrocnemius impulse per km. Gastrocnemius force increases TFJ impulse but has little effect at the PFJ due to a relatively small moment arm to the knee joint. PFJ impulse is a function of quadriceps impulse, which was reduced per km while running with a shorter stride. Running with a foot strike closer to the center of mass tends to decrease the braking ground reaction force and negative work of the quadriceps [7].

CONCLUSIONS

We observed increased PFJ and TFJ impulse per km with increased step length. A shorter step length reduced PFJ impulse per km. For people who chose running as a mode of exercise, modifications to reduce step length may be beneficial, particularly among individuals at increased risk for knee joint injuries exacerbated by or associated with repetitive cyclical loading. Future studies will investigate cumulative PFJ and TFJ loads while running with varied step lengths among runners at risk for premature PFJ and TFJ osteoarthritis such as individuals with a history of ACL reconstruction.

TIBIAL CHARACTERISTICS OF HABITUAL MID/FOREFOOT AND REARFOOT STRIKERS

[1] Elizabeth R. Boyer, [1] Alyssa Gantz, and [1] Tim R. Derrick

[1] Iowa State University, Ames, IA, USA

email: ehageman@iastate.edu, web: http:// http://www.kin.hs.iastate.edu/

INTRODUCTION

The purpose of this study was to quantify differences in the distal tibia bone geometry and properties between habitual rearfoot strikers (hRF) and habitual midfoot/forefoot strikers (hFF).

METHODS

Male and female runners who consistently ran 10+ mi/wk were recruited, age 18-35. All were free of injury in the prior 3 months, had not switched foot strike styles within the past 2 years, were not previous or current tobacco users, and did not have a history of amenorrhea.

A 2-mm thickness CT scan (Toshiba Prime 40) was obtained for each participant's right leg 1/3 of the way from the ankle to the knee using the following settings (120 kV, 50 mAs 100 mA with 0.5 sec/rotation). Based on the relationship between the Hounsfield scale and apparent bone density, the elastic modulus of all elements were determined from the CT image. Dependent variables included: cross-sectional area (CSA), inner diameter for the AP (AP_i) and ML (ML_i) directions (see Fig 1), outer diameter for the AP (AP_o) and ML (ML_o) directions, peak elastic modulus (E), average E across the entire cross section, area moment of inertia about the AP (I_{AP}) and ML (I_{ML}) axes, and section modulus (Z). Z was calculated for both AP (Z_{AP}) and ML (Z_{AP}) axes as moment of inertia divided by its respective width.

Data were analyzed with a MANOVA. Significance was assessed at $\alpha < 0.05$. Because of the small sample size, we also calculated effect sizes.

RESULTS AND DISCUSSION

Subject characteristics are shown in Table 1 for 5 hRF and 7 hFF who have completed their CT scans. Bone data are shown in Table 2.

The two groups did not differ based on age, height, mass, BMI, or running mileage (all $p \geq 0.49$).

None of the univariate analyses were significantly different between groups because of the small sample size (all $p \geq 0.563$). However, based on the effect sizes, there was a medium to large E.S. for both AP and ML inner diameters being smaller in hFF. If outer diameter is held constant, a smaller inner diameter would increase I, so this is beneficial for hFF. There was a small/medium E.S. for peak E being larger in hFF, indicating they have stiffer bones in at least one area of their tibia, but this trend was not observed for average E. There were several small effect sizes for I and Z about both axes, being slightly larger for hRF. Since bending predominates the loading in the tibia during running (Meardon & Derrick, 2014), hRF may have slightly more resistance to these stresses. Perhaps the larger ground reaction force loading rates associated with rearfoot striking partially explain the larger I and Z, since we found bone stresses are actually higher in shod mid/forefoot striking than rearfoot striking (data presented in another abstract).

CONCLUSIONS

Since the majority of bone properties were similar or only marginally different between groups (excluding inner diameters), the loading differences hRF and hFF experience solely due to how they run does not seem to distinguish their bone geometry and properties from one another. Other variables, such as gender, mass, other physical activity that participants currently or previously engage in, diet, or genetics may play a larger role in the large variability seen within and between groups. Perhaps

if we included only runners who ran 40+ miles/wk and running was their predominant form of exercise, more distinct bone differences would have been observed.

Figure 1: Example tibia cross-section with AP and ML inner (i) and outer (o) diameter definitions.

IDENTIFICATION OF COMPENSATORY MOVEMENT PATTERNS IN PATIENTS WITH AMPUTATION USING SEPARATION OF ANGULAR MOMENTUM

[1] Brecca M. Gaffney, [2] Cory L. Christiansen, [1] Bradley S. Davidson

[1] University of Denver, Denver, CO, USA
[2] University of Colorado Denver, Aurora, CO, USA
email: brecca.gaffney@gmail.com

INTRODUCTION

Rehabilitation practice following amputation uses gait training to improve ambulation and reduce adverse effects of overloading the musculoskeletal system [1]. These patients exhibit compensatory movement patterns, which are difficult to treat, and are prone to misidentification through observation. Quantitative biomechanics provides a combination of variables that identify movement compensations (e.g. kinematics, inverse dynamics) [2], which lacks the standardization needed for clinical translation.

Assessing individual angular momentum components of each segment within the context of total angular momentum is a potential method for describing clinical movement compensations. The principal of angular momentum separation indicates two components of total momentum [3]:
1. Transfer Momentum: angular momentum of the segment with respect to the point of reference.
2. Rotational Momentum: angular momentum of the segment with respect to its center of mass (COM).

Referencing transfer momentum to the foot mimics inverted pendulum dynamics, which accurately represent the stance period during gait [4]. Within this framework, these components indicate the ability to achieve forward progression and coordination of segmental rotations.

The objective of this investigation was to assess compensatory movements in patients with amputation using angular momentum separation. We hypothesized that patients with amputation would have similar performance (transfer momentum), but with different segmental strategies (rotational momentum) in all three planes compared to controls.

METHODS

Seven male participants with dysvascular transtibial amputation (age: 54.5 ± 3.8 years, BMI: 27.9 ± 1.0 kg/m^2) and seven healthy male control participants (age: 63.7 ± 6.7 years, BMI: 26.1 ± 2.6 kg/m^2) performed three gait trials at 1.0 m/s. Motions were recorded from 64 skin markers (100 Hz) and used to create a 15-segment model (Figure 1). Inertial properties of the amputated limb were modified [5].

$$\mathbf{h}_{foot} = \mathbf{h}_{i/foot} + \mathbf{h}_i$$

$$\mathbf{h}_{i/foot} = (\mathbf{r}_i - \mathbf{r}_{foot}) \times m_i(\mathbf{v}_i - \mathbf{v}_{foot})$$

$$\mathbf{h}_i = \mathbf{I}_i \times \boldsymbol{\omega}_i$$
Figure 1. Total angular momentum ($\mathbf{h}_{foot}$), transfer momentum ($\mathbf{h}_{i/foot}$), and rotational momentum ($\mathbf{h}_i$) with respect to the amputated foot COM (right foot for controls) was calculated for each segment (i). All vectors are expressed in path coordinates ($\mathbf{e}_{frontal}$, $\mathbf{e}_{sagittal}$, and $\mathbf{e}_{transverse}$) defined by the velocity vector of the body COM.

Segment momenta were scaled by participant mass, body height, and walking speed for visualization. Peak (minimum and maximum) transfer momentum during stance period and rotational momentum during entire gait cycle were compared between groups using an ANCOVA (covariates: mass and height) and level of significance set as $\alpha=0.05$.

RESULTS AND DISCISSION

The transfer momentum had similar waveforms across segments and progressively larger magnitudes associated with superior segments

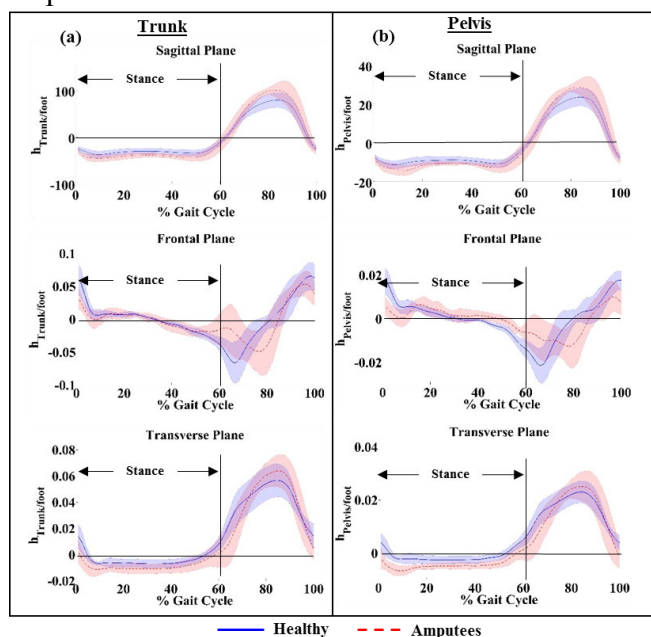
(Figure 1), which corresponds well with the inverted pendulum model of forward progression during gait. Sagittal plane transfer momentum was not different, which corresponds to the similar rate of forward progression (functional performance) between groups (Figure 1a). In the frontal and transverse planes, maximum peak momentum of the pelvis was smaller in patients with amputation compared to controls (P=0.02, P=0.01, respectively) (Figure 2b), and occurred during weight acceptance (0-12% of gait cycle). Smaller momentum during weight acceptance may be a protective strategy adopted at the hip to increase stabilization by reducing segmental speed with respect to the involved limb.


Figure 2. Transfer component of angular momentum of the (a) trunk and (b) pelvis in the sagittal, frontal, and transverse planes (analyzed for *stance* period only).

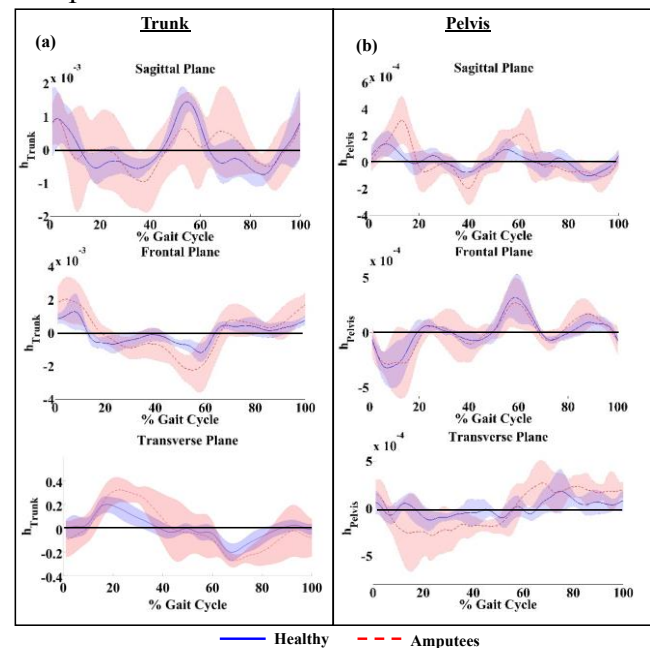
The rotational momentum waveforms were dissimilar across segments (Figure 3). In the sagittal plane, peak momentum of the pelvis was larger in patients with amputation in comparison to controls (P=0.01), and occurred during weight acceptance and contralateral heel strike (Figure 3b). Higher momentum of the trunk during weight acceptance is consistent with Trendelenburg gait and increased momentum at contralateral limb heel strike may be a result of impactful loading (exaggerated braking) caused by the lack of the ankle plantarflexor muscle function on the amputated limb. In the transverse plane, peak momentum of the trunk was larger inpatients with amputation in comparison to controls (P=0.02) (Figure 3a), which is likely a result of decreased rotational stabilization at the hip and pelvis.


Figure 3. Rotational component of angular momentum of the (a) trunk and (b) pelvis in the sagittal, frontal, and transverse planes.

CONCLUSION

This investigation demonstrates the segmental contributions of transfer and rotational components of total angular momentum taken with respect to the stance foot in patients with amputation and healthy controls during gait. These results indicate that the loss of the ankle plantarflexor muscle function resulted in altered trunk and pelvis momentum in all three planes. Compensatory movement patterns observed at the pelvis and the trunk likely indicate coordination between the hips and low back during gait, which is consistent with previous findings [6]. The compensatory strategies used by patients with amputation may have long-term adverse effects caused by asymmetric and abrupt loading patterns.

A SIMULATED INVERTED PENDULUM
APPLIED TO HEMIPLEGIC CEREBRAL PALSY GAIT

INTRODUCTION

Children with hemiplegic cerebral palsy exhibit diminished motor control, range-of-motion, and strength, not only of the affected lower extremity, but also of the ipsilateral upper body (Winters Type I, II, III, and IV). An inverted pendulum (IP) model of gait can be used to understand the role of gravity in propulsion [1,2], within a framework of biomechanical studies, including joint power patterns [3]. Forward dynamic simulations of an IP [4], applied to normal gait during single support, previously demonstrated predictive value for gait velocities and horizontal ground reaction forces (GRF), but not for vertical GRF. McGrath et al. [5] suggested that a simplified head-arms-trunk (HAT) segment may be stabilized by hip musculature near mid-stance in healthy subjects, but this may not fully represent normal or pathological gait. We hypothesized that our previous findings would extend to patients with hemiplegic cerebral palsy.

METHODS

After informed consent approved by the human subjects committee, seven pediatric patients with hemiplegic cerebral palsy (mean age, height, mass: 11.6 yr, 1.4 m, 36.1 kg), were enrolled in the study. They presented as Winters Type I, II, and IV (n = 3, 1, 3, respectively). Kinematic data were collected at 120 Hz (Vicon 612 system). A thirteen-segment, full-body model was implemented in Visual3D, and the instantaneous center-of-mass (COM) was calculated. Horizontal and vertical GRF (F_h, F_v) were collected at 1560 Hz using three AMTI force plates. Subtracting average center-of-pressure (COP) coordinates from those of the instantaneous COM at mid-stance provided the length of a rigid IP for the affected side, used in forward dynamic simulations [4]. Bonferroni-adjusted dependent t-tests assessed differences across key points in forward velocity (V_{min}, V_{final}), timing (tV_{min}, tV_{final}), and force profiles (F_{h-min}, F_{h-max}, F_{v-max1}, F_{v-min}, F_{v-max2}) [4].

RESULTS AND DISCUSSION

The rigid IP accurately simulated all key points, apart from F_{v-max1} ($P \leq 0.002476$), which coincided with a mean sagittal hip power burst (Fig 1, Col A). Patient 03 (Type II) exhibits nearly zero hip power, with conflicting knee and ankle power patterns (Fig 1, Col B). Patient 07 (Type IV) exhibits an early onset forward F_h (Fig 1, Col C), with a slightly decreased F_v, a large hip extensor power generation burst, and nearly zero knee and ankle power; these are similar to five other patients.

CONCLUSIONS

We conclude that a rigid IP suggests these patients relied, in part, on gravity for propulsion during single support. A companion study suggests a telescoping IP may also reveal the use of joint powers.

INTRODUCTION

Children with hemiplegic cerebral palsy exhibit diminished motor control, range-of-motion, and strength, not only of the affected lower extremity, but also of the ipsilateral upper body (Winters Type I, II, III, and IV) [1]. Patients in this study exhibited mild to severe hemiplegic gait (Figure 1).

Winters Type I   **Winters Type II**   **Winters Type IV**
Figure 1. Hemiplegic Types. Winters Type I: left foot drop in swing, mild left internal foot progression angle. Winters Type II: equinus induced right knee recurvatum, with increased hip extension. Winters Type IV: right upper and lower extremity deviations in sagittal, coronal, and transverse planes.

An inverted pendulum (IP) model of human gait can be used to understand the interplay between gravity and joint powers in propulsion. Dynamic walking models have shown that human-like gait can be achieved on downward slopes through gravity alone [2,3]; yet, additional sources of propulsion are needed for level gait [4,5]. Such an analytical finding was supported by inverse dynamics of a telescoping IP directly applied to normal gait [6]. Here, pendulum radial kinematics (telescoping) improved the prediction of both horizontal and vertical ground reaction forces (GRF). Without telescoping, GRF predictions deviated significantly from actual values, during sagittal power bursts at the hip, knee, and ankle joints. We hypothesized that these findings would extend to patients with hemiplegic cerebral palsy, despite a range of mobility disabilities and prior treatment.

METHODS

After informed consent approved by the local human subjects committee, seven pediatric patients (mean age, height, mass: 11.6 yr, 1.4 m, 36.1 kg), diagnosed with hemiplegic cerebral palsy, were enrolled in the study. They presented as Winters Type I, II, and IV (n = 3, 1, 3, respectively). Five patients had prior heelcord lengthenings, one had concurrent hip adductor and iliopsoas lengthenings, one had gastrocnemius BOTOX injections, one had no prior treatment. Kinematic data were collected at 120 Hz using a ten camera Vicon 612 system. A thirteen-segment, full-body model was implemented in Visual3D (C-Motion Inc.), and the instantaneous full-body center-of-mass (COM) was calculated. Horizontal and vertical GRF (Fh, Fv) were collected at 1560 Hz using three AMTI force plates. Subtracting average center-of-pressure (COP) coordinates from those of the instantaneous COM provided an IP with optional telescoping action [6]. Affected-side inverse dynamics in Visual3D provided lower extremity joint powers. Five repeated measures ANOVAs with Tukey HSD *post hoc* tests detected differences ($P \leq 0.05$) among actual and predicted minima and maxima in Fh and Fv, with and without telescoping. Root mean square (RMS) errors quantified differences between actual and predicted Fh and Fv.

RESULTS AND DISCUSSION

Telescoping across all patients (mean 2.1 cm) improved the fidelity of Fh and Fv in single support, compared to non-telescoping (Table 1; Figure 2 a, b with RMS values). Mean joint power curves (Figure 2 c) demonstrated an increased and extended hip power generation burst, coincident

with knee power absorption and generation, and ankle power absorption. Movement strategies varied across patients, as in these examples: Patient 03 (Winters Type II) presented with hip, knee, and ankle power absorption during early single support, coincident with a 2.9 cm compression of the telescoping IP. Patient 07 (Winters Type IV) presented with a large hip power generation burst throughout single support, coincident with the onset of a 3.9 cm extension of the telescoping IP and simultaneous forward *Fh*. Without telescoping, *Fh* and *Fv* deviated substantially from actual values for both of these patients.

CONCLUSIONS

Despite their varied mobility disabilities, a telescoping IP improved the fidelity of *Fh* and *Fv* during single support, as compared to the non-telescoping action. The mean magnitude for telescoping was 2.1 cm across all patients, with examples of compression (Patient 03, Winters Type II, 2.9 cm) and extension (Patient 07, Winters Type

IV, 3.9 cm) highlighting the effects of Winters Type in hemiplegic cerebral palsy gait. As found previously in normal and diplegic cerebral palsy gait [5,6,7], a telescoping IP reveals, at least in part, the use of joint powers in propulsion.

For each kinetic variable (% bodyweight), maxima and minima in underline{actual data} were compared with inverse dynamics data predicted after Buczek et al. [6] at the same relative time (i.e., percent of single support). ACT = actual data, TEL1 = inverse dynamics with telescoping, TEL0 = inverse dynamics without telescoping. Data are means and (standard deviations) with n = 7. (*) indicates significant at $P \le 0.05$.
Figure 2. Illustrated Statistical Results for GRF and Joint Powers. For all panels, one walking trial for each of seven hemiplegic cerebral palsy patients were averaged across single support. Panels (a) and (b) include actual (solid), predicted with telescoping (dashed, average length change 2.1 cm), and predicted without telescoping (stippled) horizontal and vertical ground reaction forces; RMS errors are % bodyweight. Panel (c) includes mean sagittal joint powers at the hip, knee, and ankle. Power bursts H1, K2, A2 are after Winter DA (Biomechanics and Motor Control of Human Gait, 2nd Ed., 1991).

THE EFFECT OF HIP ABDUCTOR FATIGUE ON FRONTAL PLANE KINEMATICS DURING WALKING AND RUNNING

INTRODUCTION

Female runners are reported to be twice as likely to sustain lower extremity overuse injuries compared to their male counterparts. Moreover, females with certain overuse injuries demonstrate excessive hip frontal plane motion during the stance phase of running (1). Reduced hip abduction strength has also been observed in the aforementioned population, and it has been suggested that excessive hip motion may be the result. However, the potential relationship between strength and kinematics examined during walking remains unclear. For example, patients with knee osteoarthritis have been reported to display weaker hip abduction strength but similar frontal plane hip and pelvis kinematics when compared to controls (2). Thus, it may be possible that the muscular demand of the task may influence the relationship between strength and kinematics. The greater vertical ground reaction forces (GRF) during running should place a higher demand on the hip musculature to stabilize the hip/pelvis during motion. During walking, however, the GRF may not be great enough to exceed the force generating capacity of the musculature even in the presence of reduced strength. Therefore, the purpose of this study was to determine the effects of reduced hip abductor strength on the frontal plane kinematics of the hip and pelvis during walking and running. A fatigue protocol was used to simulate a reduction in hip abduction strength. It was hypothesized that following the hip abductor fatigue protocol, hip adduction and pelvic drop would increase in the running condition but not during walking.

METHODS

Participants included 29 healthy female runners (age: 28±6 yrs; height: 1.66±0.06 m; mass: 61.35±11.35 kg). Lower extremity kinematic data were collected while participants walked (1.1 m/s) and ran (2.7 m/s) on a treadmill before (prefatigue) and after (postfatigue) a hip abductor fatigue protocol. Retroreflective markers were placed bilaterally on bony landmarks of the pelvis and lower extremity and 3D co-ordinate data were collected at 200 Hz (Motion Analysis Corp, Santa Rosa, CA). Joint/segment angles were calculated in Visual 3D (C-Motion Inc, Germantown, MD). Isometric hip abductor strength measurements were conducted with the participants in a side-lying position using a dynamometer (Biodex III, Shirley, NY). Strength measurements were recorded prefatigue and postfatigue. The fatigue protocol was conducted with the participants in a side-lying position performing lateral leg raises to a target bar set at 20° of hip abduction. Each participant was instructed to raise, hold, and lower the leg at a pace of 40 beats per minute (1 beat for each phase) until failure of the set (unable to reach the bar on 2 consecutive occasions). Participants performed 3 sets with a 30 second rest period in between sets, after which isometric strength was assessed. Fatigue was defined as a minimum 20% reduction in hip abduction torque. Variables of interest included peak hip adduction and pelvic drop during stance. A two-way repeated measures ANOVA was conducted comparing peak angles in both prefatigue and postfatigue (fatigue) conditions during walking and running (task). The primary hypothesis was assessed by analyzing the interaction effect (task*fatigue).

RESULTS

Peak isometric hip-abduction strength (52.1±12.1 Nm/kg) was reduced 33% (35.8±11.1 Nm/kg) at the end of the fatigue protocol. Peak hip adduction angle yielded significant main effects for both task

effect (p < .05) and fatigue effect (p < .05). However, a significant interaction was not found between task and fatigue. Peak contralateral pelvic drop angle yielded no significant effects. The descriptive data are reported in Table 1. Average time to fatigue was 435.8 (164.7) seconds.

Table 1: Mean (SD) kinematic values before and after fatigue during walking and running.

	Prefatigue	Postfatigue
Pelvic Drop (°)		
Walking	5.7 (1.7)	5.6 (1.8)
Running	5.8 (2.7)	5.8 (2.5)
Hip Adduction (°)		
Walking	11.1 (3.0)	9.6 (3.0)
Running	17.9 (4.4)	15.4 (4.1)

DISCUSSION

In contrast to the hypothesis, this study found no significant interaction effect (task*fatigue) for either hip adduction or pelvic drop. We had expected to see an increase in hip adduction following fatigue during running but not during walking. However, the analysis of the main effects revealed that hip kinematics were altered following fatigue in both the walking and running tasks. Surprisingly, fatigue resulted in a reduction in hip adduction during both tasks. It is difficult to offer an explanation for this finding. However, Dierks et al. (3) postulated that ipsilateral pelvic tilt or ipsilateral trunk lean could be used as strategies to control hip adduction in the presence of hip abductor muscle fatigue. Indeed, Smith et al. (4) reported that when comparing groups with either weak or strong hip abductors during a hopping task, the weak group displayed significantly greater ipsilateral trunk lean and ipsilateral pelvic tilt. Our findings show that ipsilateral pelvic tilt was not used as a compensatory strategy in the present investigation. However, ipsilateral trunk lean was not measured in this study and may have been adopted as a compensatory strategy to offload the hip abductor musculature.

Although differences were noted in peak hip adduction following fatigue, subjects may also have landed with less adduction. Evidence for this can be seen in figure 1 in which the angle-time plot is provided for the entire stance. This suggests that the participants may have attempted to land with the hip in a less adducted position to reduce the load placed on the hip abductor muscles after impact. Further analysis of the gait cycle prior to initial contact may lend insight into anticipatory strategies.
Figure 1: Hip adduction ensemble curve during running

CONCLUSIONS

A reduction in hip abductor muscle strength following a fatigue protocol resulted in no changes in pelvic drop. However, hip adduction during both walking and running was reduced following the fatigue protocol.

DOES THE ADDITION OF PERTURBATION TRAINING IMPROVE GAIT ASYMMETRIES IN ATHLETES AFTER ACLR WITH DIFFERENT MECHANISMS OF INJURY?

Jacob J. Capin, Mathew Failla, Elizabeth Wellsandt, Lynn Snyder-Mackler
University of Delaware, Newark, DE, USA
email: capin@udel.edu

INTRODUCTION

Upwards of 250,000 anterior cruciate ligament (ACL) injuries occur annually in the United States [1], with the majority of these injuries occurring through a noncontact mechanism of injury (MOI) [2]. Although many athletes undergo ACL reconstruction (ACLR) to restore normal function and biomechanics, gait asymmetries commonly persist. Even among those who achieve symmetrical strength, gait asymmetries may persist up to 2 years after ACLR [3], which may predispose athletes to an increased risk of ACL re-injury [4]. Despite persisting asymmetries, most physicians utilize temporal guidelines for return to sport decisions rather than objective, functional criteria [5]. Moreover, faulty mechanics are associated with a noncontact MOI; thus athletes who sustain noncontact ACL injuries may demonstrate greater asymmetries as compared to those with contact injuries, and potentially be at even greater risk for re-injury or the development of negative sequelae such as post-traumatic osteoarthritis. It is unclear, however, if athletes after ACLR with different initial mechanisms of injury will benefit from different post-operative training programs.

The purpose of this study is to compare the effects of a type of specialized neuromuscular training rehabilitation program, perturbation training, on gait biomechanics of athletes after ACLR who sustained either a contact or noncontact MOI. We hypothesize that athletes with noncontact injuries who receive perturbation training will demonstrate the greatest improvements in correcting gait asymmetries from pre- to post-training.

METHODS

This study is a secondary analysis of prospectively collected data. Forty-seven level I and II athletes [6] (78.7% male, 22.9 ± 8.40 years) with a unilateral ACLR (22.3 ± 7.69 weeks) were included in this study. Patients were randomly assigned to a strengthening control group or strengthening plus perturbation training group (PERT), and classified as having a contact (N=19) or noncontact (N=28) MOI via self-report data verified by a licensed physical therapist.

Gait kinematic and kinetic data were collected at baseline (time 1) and after training (time 2) using an embedded force plate and 8-camera Vicon 3-D motion capture system with retro-reflective markers to track the pelvis and lower extremities. Gait variables were analyzed at peak knee flexion (PKF) during stance phase, including: hip flexion angle (HFA) and moment (HFM), hip adduction angle (HAA) and moment (HAM), knee flexion angle (KFA) and moment (KFM), and knee adduction angle (KAA) and moment (KAM). A 2x2x2 ANOVA was used to compare each gait variable with respect to time, MOI, and group. Alpha level was set to ≤0.05.

RESULTS AND DISCUSSION

Significant interactions or main effects (see table 1) were not found for any of the 8 gait variables analyzed at PKF. Our hypothesis that the non-contact group receiving perturbation training would show the greatest improvement in gait asymmetries was not supported. The findings suggest that there is no difference in biomechanical benefits to post-operative perturbation training between treatment groups with respect to MOI and time.

Baseline differences between the strength and PERT groups within the noncontact cohort exceeded MCID values [7] for KFA and KFM and approached MCID values [7] for HFA and HFM. These findings indicate that within the noncontact

cohort, the strength group may have been initially more asymmetric and thus had greater room for improvement, which could have influenced our lack of significant findings. Rigorous inclusion criteria, pre-enrollment physical therapy, similarity between training programs (i.e. all subjects received strengthening, agilities, hops, and jumps), and small sample sizes of these preliminary data may also contribute to our non-significant findings. Finally, it is possible that gait may be too simple an activity in these higher-level athletes to detect asymmetries that may exist during more demanding, sport-like activities and may have improved with a post-operative perturbation training program.

Inter-limb asymmetries did exist among frontal and sagittal plane hip and knee gait biomechanical data regardless of MOI or treatment at both time intervals. KFAs and KFMs at PKF exceeded the MCIDs of 3° and 0.04 N*m/Kg*m [7], respectively, across all 4 groups at time 2. Further research is necessary to identify appropriate training methods to ameliorate inter-limb asymmetries among athletes after ACLR.

CONCLUSIONS

Gait asymmetries exist across various cohorts within the ACLR population during the time-frame at which most athletes begin return to sport activities, but do not differ between patients with noncontact versus contact MOI. Moreover, these asymmetries still persist in a relatively simple task (i.e. walking) despite neuromuscular training in addition to traditional rehabilitation. Even greater asymmetries likely exist across these groups in higher-level activities. Clearly, there is continued need to study training programs to address these deficits that predispose athletes to increased risk for further knee pathology and osteoarthritis.

INTRODUCTION

Adolescent idiopathic scoliosis (AIS) is a prevalent orthopedic problem in children between 10 and 16 years of age [1]. If left untreated, scoliosis can lead to asymmetry of the trunk, which may lead to more serious cardiorespiratory and other orthopaedic problems [2]. Gait asymmetry of ground reaction force (GRF) in AIS has been frequently investigated; however, previous studies have reported conflicting results, with some studies reporting a significant relationship between gait asymmetry in GRF and the severity of the spinal deformity, and some studies reporting no significant relationship [3,4].

The goal of this current study is to provide greater insight into gait asymmetry in AIS patients. This study specifically investigated whether the asymmetry of the GRF magnitude and timing in AIS patients would be associated with spinal deformity and pelvic tilt.

Spinal deformity is the primary orthopaedic characteristic in AIS and the degree of asymmetry ostensibly affects the degree of gait asymmetry. GRF reflect the whole-body motion and are sensitive to individual body segment kinematics. Previous studies have shown that pelvic tilt is correlated with leg-length inequality, and leg length inequality can affect GRF phase times [5,6]. We therefore hypothesized that (i) between-leg asymmetry of GRF magnitude variables would increase with spinal deformity, and (ii) asymmetry of GRF time variables would increase with pelvic tilt (PT).

METHODS

Nine adolescents (3 male and 6 female; ages = 15±1.24 years) with AIS participated and all participants provided written consent. The study was approved by Chungju Konkuk University Hospital.

Frontal plane spinal radiographs were taken. The degree of spinal deformity was quantified using two measures:
- The maximum Cobb angle (MCA; [7]), calculated as the largest angle in the frontal plane among the absolute values of all existing Cobb's angles greater than 10°.
- A new exploratory measure, the adjusted Cobb angle (ACA), calculated as the sum of Cobb's angles in the frontal plane considering the direction of the angle, with the ACA being positive if the angle is going counter-clockwise with respect to the perpendicular line of the vertebrae at the bottom of the curve, and negative when the angle is going clockwise.

PT was also quantified and was calculated as the angle between the line connecting the right and left iliac crest and the horizontal line in the frontal plane.

In the gait data collections, participants were instructed to walk naturally, at a self-selected, comfortable speed along a 20-m walkway. GRF were measured from two force platforms embedded in the middle of the walkway. Starting position was adjusted so that subjects stepped consecutively on the platforms with the right and left feet without deliberately targeting the platforms.

To assess the gait asymmetry between legs, the Asymmetry Index (AI) was calculated using the following formula:

$$AI = \frac{R - L}{0.5 * (R + L)}$$

Where R and L represent the values of a specific GRF component from the right foot and the left foot, respectively [8]. AI was calculated for selected peak and average magnitudes of the vertical and anterior-posterior GRF, as well as the timing of peaks and the braking/propelling phases of stance. Correlations between AIs and the spinal deformity measures were calculated by linear regression ($\alpha = 0.05$).

RESULTS AND DISCUSSION

The average walking speed of the subjects (1.22 ± 0.17 m/s) was similar to previously reported walking speeds for this age group [9].

There were significant correlations between the AI of average vertical GRF over the stance phase (Fz_{AVG}) with MCA and ACA, but not with PT (Table 1). The GRF timing results such as AI of the average stance phase contact time (T_{stance}), indicated that there was an association between the asymmetry of T_{stance} and PT, while there was no significant association of T_{stance} with ACA or MCA (Table 1).

Our study used a new index, the adjusted Cobb's angle, which considers multiple directions of scoliosis curvatures in addition to maximum Cobb's angle. Both the maximum and adjusted Cobb's angles showed significant correlation coefficients with the asymmetry of GRF magnitude.

CONCLUSIONS

In general, our study shows that the gait asymmetry of both magnitudes and time variables of GRF are associated with the severity of the spinal deformities and pelvic tilt: the spinal deformity is generally associated with the between-leg asymmetry in GRF magnitudes, while the pelvic tilt is associated with the asymmetry of the time variables.

A PRINCIPAL COMPONENT ANALYSIS-BASED CORRECTION METHOD FOR ANATOMICAL FRAME VARIATION IN GAIT ANALYSES

Allison Clouthier and Kevin Deluzio

Mechanical and Materials Engineering, Queen's University, Kingston, ON, Canada
email: allison.clouthier@queensu.ca, web: http://hmrc.engineering.queensu.ca/HMRL/

INTRODUCTION

Multicentre studies are rare in the area of three dimensional gait analysis due to the challenges associated with combining gait waveform data from different laboratories. One of the largest contributors to the differences that occur between laboratories is inconsistencies in marker placement [1] resulting in discrepancies in anatomical coordinate systems. Principal component analysis (PCA) is a statistical technique that can be applied to waveform data to identify and quantify group differences [2]. Therefore, we propose a PCA-based method that can be applied to identify and correct for the effect of anatomical frame variation on gait kinematic and kinetic data.

METHODS

The proposed correction technique begins with the application of principal component analysis (PCA). For a matrix containing waveform data, X, PCA extracts features or loading vectors, U, that are associated with variation and assigns scores, z, for each loading vector to each subject such that $X = zU$. It is then possible to identify differences between datasets by comparing mean z-scores. This correction method essentially ensures that the data from both sets have similar scores for all principal components. This is accomplished by adding the difference in mean z-scores between the two datasets multiplied by the loading vector to the waveform for each subject from one dataset for all principal components where the two datasets differ significantly:

$$x_{corr} = x + \sum_{i \in S} (\bar{z}_{Ai} - \bar{z}_{Bi}) u_i$$

where x is the waveform for one subject, $\bar{z}_{Ai}$ and $\bar{z}_{Bi}$ are the mean scores for the ith principal component for datasets A and B, and u_i is the loading vector

for the ith principal component. The summation is carried out over the principal components that differ significantly between the two datasets (S).

The correction technique was demonstrated on the knee kinematics of 24 healthy subjects walking overground at the Human Mobility Research Laboratory in Kingston, ON. The knee joint angles were perturbed by rotating the thigh coordinate system about its long axis by -5, 5, and 10° (Figure 1) thus creating three additional sets of angles for each subject. The resulting differences in joint angles were then corrected using the PCA-based method. A correction was applied for a principal component if a significant difference (p<0.05) was identified using Student's t-test. No knowledge regarding the source of the induced error was used in the correction process.
Figure 1: The rotated thigh coordinate systems used to create the perturbed data sets.

RESULTS AND DISCUSSION

The perturbed knee adduction angles are shown in Figure 2A and the resulting waveforms following the correction of the rotated coordinate system angles are shown in Figure 2B.

In this example, corrections were only applied for principal components found to differ significantly from the 0º case. However, this criteria could be modified depending on the level of agreement desired. In theory, if the data was corrected for every PC, the resulting means from the two datasets should be equivalent, while the variation in each dataset is preserved.

These data with joint angle errors induced by a misaligned thigh coordinate system was used to demonstrate the correction method because the source of error (crosstalk) is exactly known and well understood [3] and it is therefore possible to ensure the correction that is applied is appropriate. In verification of this, the applied correction was found to be very similar to the analytically calculated error induced [4]. In addition, since the four datasets were obtained from the same subjects, it is clear that the joint angles should be the same. However, this technique can also be applied to data collected on different subjects in different laboratories, providing the population demographics are similar. Because variation is maintained using this method, differences between laboratories will be corrected while any effect of pathology, surgical intervention, etc. should be unaffected, providing it is the same at both centres. Therefore, application of this technique may enable synthesis of inter-laboratory 3D gait data and therefore multicentre studies in this field.

CONCLUSIONS

The ability of the proposed PCA-based method to identify and correct for differences in data caused by variation of the anatomical reference frame was demonstrated on a dataset where differences were induced by a known perturbation.

INTRODUCTION

The severity and progression of medial knee osteoarthritis (OA) has been linked to increased loading in the medial compartment of the knee. Because this load is difficult to measure *in vivo*, the knee adduction moment is often used as a surrogate measure. Despite this, the strength of the relationship between these two measures has been questioned and it has been found that a combination of adduction moment and flexion moment is a better predictor of medial knee loading [1]. Other factors may also affect joint loading however. Increased varus alignment has been found to be a risk factor for OA [2] and the gastrocnemii provide a large contribution to the knee contact force [3]. Additionally, previous studies relating medial loads to gait parameters have generally included limited numbers of participants from a total knee replacement population. Therefore, the goal of this study was to determine the contribution of static alignment and external moments to the prediction of medial knee contact loads for healthy and OA populations.

METHODS

18 participants with knee OA diagnosed by an orthopedic surgeon and 18 healthy controls walked at a self selected speed at the Human Mobility Research Laboratory in Kingston, ON while marker trajectories and ground reaction forces were recorded. A standing full length radiograph was taken for each participant. A generic musculoskeletal model [4] was scaled for each participant based the radiograph and anatomical markers. Inverse kinematics, inverse dynamics, residual reduction, and muscle analysis were completed in OpenSim 3.2. Static optimization was performed to estimate muscle forces and resulting tibiofemoral contact loads were calculated [4]. Static alignment was defined by the hip-knee-ankle (HKA) angle which was measured on each radiograph. Varus and valgus alignment were defined by negative and positive values of the HKA angle, respectively.

A stepwise multiple linear regression analysis was carried out to determine the ability of external measures to predict the medial compartment force. Inputs to the regression model included the HKA angle ($^{\circ}$), knee adduction moment (Nm/kg), knee flexion moment (Nm/kg), and ankle plantar flexion moment (Nm/kg). The first and second peak medial contact forces (BW) and the impulse (integral of force with respect to % gait cycle) were predicted. The timing of the first and second peak was based on the first and second peak in the knee adduction moment (Figure 1) and parameters used to predict contact force were all taken at these instants. Similarly, the impulses of the moments were used as inputs when predicting the contact force impulse.

RESULTS AND DISCUSSION

The resulting coefficients for the multiple linear regression models are shown in Table 1. A coefficient of 0 (represented by a "-" in the table) indicates that the input did not significantly improve the contact force prediction and is not included in the model.

A large portion of the variation in medial knee contact force was explained by the model, with better predictions for the peak forces than the impulse. The adduction moment was an important predictor of medial knee contact force for all measures and both groups. For the second peak, the

ankle plantar flexion moment aided in predictions. This is likely due to the large contribution of the gastronemii to the contact force at this point in the gait cycle. The knee flexion moment has previously been shown to be important in predicting medial loading, but was only significant for the first peak in the control group in this study. This may be a result of the increased variability and decreased magnitude of the knee flexion moment at peak 1 in the OA group.
Figure 1: Knee adduction moment and medial contact load for a representative subject. The timing for peaks 1 and 2 was based on the adduction moment and generally corresponded with peaks in the contact force.

An important finding here is that the models for the control and OA groups are not equivalent. The regression coefficients were different for the two groups and the HKA angle was an important predictor for the OA group, but not the control group. It was expected that increased varus alignment would be correlated with larger medial loads; however, this likely was not significant for the control group due to the small range of HKA angles (-4.5 to 3.2°) compared with the OA group (-19 to 4.5°).

One limitation of this study is that the contact loads were calculated through static optimization using some of the same external moments that were used as inputs to the regression model. However, contact forces and R^2 values were similar to those obtained using in vivo measurements of joint loading [1].

CONCLUSIONS

The multiple linear regression model was able to explain a large percentage (>70% for peaks 1 and 2) of the variation in medial knee contact forces for participants with knee OA and healthy controls using static alignment and external moments. However, the models used for these two groups differed. Therefore, it may be important to use population specific models when creating surrogate measures for medial knee loading.

INTRODUCTION

Quantifying human movement is essential for understanding normal function, which allows the ability to distinguish and characterize movement abnormalities. Recently, researchers have successfully investigated dynamic muscle function with the aid of imaging techniques such as magnetic resonance imaging and ultrasound imaging (USI). These image-based methods can complement existing methods for quantifying human movement based on indirectly estimated joint loads and muscle electrical activity [1], and might provide a more direct assessment of physiological muscle function. Imaging can separately assess different deep-seated muscle groups directly, overcoming the limitations presented by cross talk with traditional electromyography (EMG) [1,2] Concurrently assessing muscle function and joint mechanics using USI, EMG and 3D motion analysis during a dynamic task such as gait possesses the potential for further understanding the pathophysiology of poorly understood joint diseases. The goal of this study was to investigate the reproducibility of dynamic ultrasound measurements and relate them to conventional biomechanical measures during gait in healthy volunteers.

METHODS

Eighteen healthy participants (23±2 years; 1.7±0.1 m; 65.9±9.4 kg) completed 3 gait trials at a self-selected pace (1.06±0.17 m/s). Lower extremity joint moment, EMG values and *rectus femoris* (RF) muscle function were assessed concurrently during the stance phase of gait from the dominant leg. USI measures were collected in a longitudinal view while the ultrasound (Ultrasonix Sonix) cart traveled alongside study participants over a custom-built track system. Intra-class correlation coefficients assessed inter-trial reliability of ultrasound measures, whereas pearson Product-Moment Correlations investigated relationships between hip and knee joint moments and EMG with USI muscle function measures. Standard Error of Measurement (SEM) and Minimum Detectable Difference at 95% (MDC_{95}) were calculated. Statistical significance was assessed at $p<0.05$.

RESULTS AND DISCUSSION

Table 1 provides descriptive statistics, ICC, SEM, and MDC_{95} for the muscle function variables of interest. USI measures of peak and average muscle thickness during loading and full stance showed excellent reliability, with low SEM and Minimum Detectable Difference. *Figure 1* represents the relationship between peak muscle thickness and *rectus femoris* muscle activation during the load absorption phase.
Figure 1: Relationship between *rectus femoris* muscle activation and muscle thickness (R^2=.568) measured via ultrasound during the load absorption phase. It denotes that decreased thickness (stronger contraction) relates with greater muscle activation.

During stance, significant relationships existed between hip and knee joint moments and USI measures of dynamic muscle function (p<0.05). *Table 2* depicts the relationships between muscle function and hip and knee joint moments. Higher peak hip abduction, extensor and external rotation moment were associated with larger *rectus femoris* muscle thickness. A significant negative relationship was found between *rectus femoris* muscle activation and muscle thickness (-.714<*r*<-541, p<0.05), except with average muscle thickness during terminal stance.

CONCLUSIONS

Our results demonstrate that peak and average muscle thickness can be confidently quantified using imaging techniques during gait. Our results further determine that *rectus femoris* muscle

thickness changes are strongly related to hip and knee joint moments, and the eccentric contraction of the RF is associated with increased activation of the same muscle as well as other muscles of the lower extremity. Our findings are the first to our knowledge investigating the relationship between movement biomechanics and dynamic ultrasound-based measures of muscle function. Future studies should consider applying similar methods to patients with pathological conditions.

DIFFERENCES IN STANCE PHASE KINEMATIC AND MUSCLE ACTIVITY AFTER EIGHT WEEKS OF INSOLE USE

Brendan Cotter and Janessa D.M. Drake

Department of Kinesiology and Health Science, York University, Toronto, ON
cotterbd@yorku.ca

INTRODUCTION

Between 60-85% of individuals experience low back pain (LBP) at least once in their lives (1). One method currently used to alleviate and prevent LBP, is the use of insoles designed to affect change in the kinematic and/or kinetic chain by reducing pronation during stance phase (1). While changes in shank and foot motion supporting the kinematic change have been observed during walking, these changes appear to have little effect on the knee, hip, or pelvis (2). In addition to correcting posture, insoles may act to protect the chain by increasing the strength and reaction time of muscles involved in spine stabilization, such as gluteus medius (3). While previous research implies that inserts may reduce LBP through a reduction of shock absorption and/or foot realignment, most orthoses-related LBP research is solely questionnaire based, and there is little known behind the mechanism that makes them a successful treatment for LBP. The purpose of this study is to examine and quantify whether a neuromuscular training insole can alter surface EMG, and joint kinematics, during the stance phase of walking following eight weeks of use.

METHODS

Eight males and eight females were given a neuromuscular training insole and were observed walking prior to the insertion and eight weeks after insertion. The insoles are designed for arch support that changes in height and stiffness. The adjustable aspect allows users to follow a progression, moving from the softest/shortest, to the hardest/tallest insert over the eight week period. Participants were equipped for passive reflective markers for motion capture. Electrodes were placed on a variety of torso and lower limb muscles, in order to capture surface EMG. Participants angular range of motion, mean, maximum and minimum angle were observed pre-post intervention, in addition to their average muscle activation.

RESULTS AND DISCUSSION

While the insoles did not appear to have a large effect on surface EMG or lower limb and lumbar spine kinematics, they did appear to have an effect on thoracic spine movement. Thoracic spine mean, maximum and minimum flexion angle (±sem) was initially observed as 7.23° (2.55), 10.81° (2.56) and 3.64° (2.59), respectively (Fig. 1). Following the intervention a mean of 1.20° (2.37), a maximum of 4.38° (2.53), and a minimum of -1.79° (2.31), was observed. In addition to the thoracic spine, lumbar spine and trunk flexion also appeared to be reduced, although these differences did not appear to be significant. Additional differences were found in other segments when the data was subdivided into male and female populations, as well as left and right limb stance phase.

No differences were found to support a reduction in spinal flexion as a result of the kinematic chain. While a reduction in thoracic flexion was found post intervention, there was no indication this was a result of differences found in lower limb kinematics. There was no trend of the knee or hip displaying less internal rotation, or the pelvis displaying less anterior tilt, post intervention.

While the intervention did result in slight changes in surface EMG, considering the magnitude of the change and the observed kinematics, they did not

appear to alter the biomechanics of walking. Due to the change in thoracic spine sagittal plane motion, it is possible that there were initial changes in EMG that were no longer present following the eight week intervention. Future research should also examine the immediate effects of these insoles on kinematics and surface EMG, to further our understanding on how insoles could possibly reduce low back pain.

CONCLUSIONS

Following the intervention participants displayed less thoracic spine flexion during stance phase. This change in kinematics could help to relieve some off the stress placed on the spine during walking. There was no evidence to support that this reduction in thoracic spine flexion was a result of changes in pelvis, hip, or knee kinematics. Similarly, the insoles appeared to have little effect on muscle activation following eight weeks of use. Considering the reduction in spinal flexion without any major side effect being detected, these insoles may be beneficial for individuals suffering from LBP.

APPROXIMATE ENTROPY OF TRUNK AND FOOT ACCELERATIONS DURING WALKING

[1] Jordan J.W. Craig, [1] Adam Bruetsch, and [1] Jessie M. Huisinga

[1] Human Performance Laboratory, The University of Kansas Medical Center, Kansas City, KS, USA
email: jcraig2@kumc.edu

INTRODUCTION

Gait instability is indicative of fall risk, and is commonly characterized by irregular frontal plane motion of the center of mass [1]. Frontal plane instability is reflected in variable step width, as foot placement is constantly adjusted to keep the head and trunk stable and upright [2]. Unfortunately, step width and medial-lateral trunk motion are not easily measured outside of a research or gait laboratory setting. Wireless accelerometry measurement methods have been gaining popularity for their ability to gather information about human gait outside of the laboratory setting [1]. These portable sensors provide a means of measuring relevant parameters to quantify instability in the motion of the trunk and feet, without the need for motion capture or force plate systems. However, these methods don't allow for direct measurement of step width which is related to fall risk and lateral postural control [1].

Approximate entropy (ApEn) quantifies the repeatability of a time series and has previously been utilized to quantify variability during gait [3]. ApEn is of particular interest in this study for analyzing how foot placement is constantly altered in order to stabilize trunk motion during walking.

The aim of this study was to examine whether accelerations at the trunk are more tightly controlled, and thus more repeatable, than accelerations at the feet. We hypothesized that accelerations at the trunk would be more repetitive and less variable than accelerations at the feet.

METHODS

Twenty healthy adult subjects participated in this study (mean 43.5 years, range 27 – 58 years). Participants walked on a treadmill at a self-selected pace for 3 minutes while wearing tri-axial accelerometers (Opal, APDM, Portland, OR) on their right ankle and sternum. Accelerations of the trunk and foot were recorded at 128 Hz for the duration of the trial. Previous literature has shown that accelerations are attenuated inferiorly to superiorly within the trunk segment [4]; thus, we chose to place the trunk accelerometer over the sternum rather than the lumbar spine in order to measure what is theoretically the more stable position on the trunk. ApEn and root mean square (RMS) values were calculated for the acceleration time series from the foot and trunk sensors in frontal and sagittal planes which resulted in four ApEn and RMS values for each subject – trunk sagittal, trunk frontal, foot sagittal, and foot frontal. A custom MATLAB code was used to calculate ApEn [5] and RMS values. To calculate ApEn, we chose a vector length of m = 3, and calculated time delay (τ) for each individual subjects' data sets. Optimizing τ for each individual time series helped ensure accurate ApEn calculations for each time series. A 2x2 ANOVA was performed on the ApEn and RMS values and Pearson's correlations were used to assess the relationship between sensor locations within the same plane.

RESULTS AND DISCUSSION

ApEn values showed a main effect of location (F = 322.996, $p < 0.01$), and a main effect of plane (F = 66.218, $p < 0.01$). Similarly, RMS values showed a main effect of location (F = 38.295, $p < 0.01$), and a main effect of plane (F = 195.902, $p < 0.01$). Post-hoc paired t-tests between locations revealed that ApEn values were significantly lower for the accelerations at the foot compared to the trunk ($p < 0.01$) in both the frontal and sagittal planes, and that RMS values were significantly higher for the accelerations at the foot compared to the trunk ($p < 0.01$) in both the frontal and sagittal planes (Table

1). There was a significant positive correlation between foot and trunk acceleration ApEn values within the sagittal plane only (r = 0.565, *p* = 0.009) (Figure 1).

Table 1: Mean (standard deviation) for ApEn and RMS values, significance for paired t-tests.

	Foot	**Trunk**	***P* - value**
ApEn Frontal	1.327 (0.109)	1.700 (0.121)	< 0.01
RMS Frontal	5.213 (2.053)	1.915 (1.159)	< 0.01
ApEn Sagittal	1.096 (0.137)	1.647 (0.140)	< 0.01
RMS Sagittal	6.930 (2.864)	1.977 (1.266)	< 0.01
Figure 1: Correlation between ApEn of acceleration time series of foot and trunk in sagittal plane (* denotes p < 0.01).

Our results show that ApEn of foot acceleration was less than that of the trunk, indicating that accelerations at the foot are less variable, or more repeatable, than accelerations at the trunk. This is seemingly in contrast to previous findings which showed inferior to superior decreases in variability [4], the acceleration of the foot was not considered in the previous study [4], and it is important to keep in mind that the magnitudes of acceleration at the feet are much larger than that of the trunk. Thus, the overall finding is that greater movement repetition, as identified by ApEn, is higher at the feet. Also, RMS showed higher variability at the feet compared to the trunk which would indicate overall greater amounts of variability at the feet. Finally, as indicated by a lack of significant correlation in the frontal plane, some subjects may be able to stabilize their trunk independent of foot placement and thus have more repeatable foot accelerations, while other subjects may rely more heavily on foot placement to stabilize their trunk and thus have less repeatable foot accelerations. Taken together, these results indicate that the body may aim to reduce overall motion at the trunk, rather than specifically reducing the variability of the oscillatory movement pattern during gait.

CONCLUSIONS

The results of this study illustrate the utility of objectively measuring motion of the body during gait, specifically with the use of small portable accelerometer available for use outside of a research laboratory. Since common gait parameters relating to stability (ie. step width) are not easily measured outside of a research laboratory, it is important to explore the application of these portable tools for objective gait measurements. The findings of this study highlight significant patterns in steady-state gait, with a methodology that could be performed nearly anywhere.

BAREFOOT VERSUS SHOD: EFFECTS OF BACKPACK LOADS ON WALKING MECHANICS

Kevin D. Dames and Jeremy D. Smith

Biomechanics Laboratory, University of Northern Colorado, Greeley, CO

Email: kevin.dames@unco.edu; website: www.unco.edu/biomechanics

INTRODUCTION

Minimally supportive shoes intended to mimic the barefoot condition are a popular form of footwear. With a lack of cushion under the foot, changes in walking gait are evident. Differences such as greater peak loading rate, reduced lower limb joint ranges of motion, and shorter steps have been observed in barefoot walking [1, 2]. Backpack loads also promote altered kinetic, kinematic, and spatiotemporal walking patterns [3, 4]. Increased ground reaction forces (GRFs) experienced while loaded [5] may exaggerate adaptations made to reduce discomfort of barefoot walking. The purpose of this study was to investigate the effects of loading and footwear on walking patterns in young, healthy individuals.

METHODS

Twelve participants (7 female, 5 male; 22.64±2.77 yrs., 1.73±0.11 m, 70.9±12.67 kg) walked overground at 1.5 m·s^{-1} under four conditions: Barefoot Unloaded (BU), Shod Unloaded (SU), Barefoot Loaded (BL), and Shod Loaded (SL). A backpack load (15% of body mass) was worn during loaded conditions, but not included in total body mass when normalizing data. Motion (100Hz) and ground reaction force data (2000Hz) were combined through inverse dynamics to estimate joint reaction forces and moments, which were then used to estimate joint powers. Spatiotemporal and peak GRF data were also included as dependent variables. GRFs and joint powers were normalized to body weight and mass, respectively. Trial peaks were averaged and used in statistical analyses. Differences between conditions were assessed via a series of 2x2 ANOVAs with repeated measures. Alpha was set at .05 for all tests.

RESULTS

Loading increased the first and second vertical GRF (VGRF) peaks (Figure 1). Minimum VGRF between peaks was greater while barefoot and loaded, respectively. Greater braking and propulsive GRFs were observed while shod and while loaded (Figure 1). Ankle power absorption increased
Figure 1. Mean vertical and AP GRF according to condition. * indicates significant footwear effect. † indicates significant load effect.

immediately after ground contact (0-10 % of the gait cycle) while walking shod, but was not altered for the remainder of the gait cycle or by load. At the knee, greater power absorption occurred during early stance (~0-10 % of stride) and just prior to toe-off (~50-60% of stride), whereas power generation increased after the initial loading response (~20% of stride) while walking with a

backpack load. Only load lead to increased power absorption at the hip during stance (40-50% of stride), whereas both loading and walking barefoot increased power generation at the hip prior to toe off (50-60% of stride) (Figure 2). Walking shod resulted in increased stride lengths, stance times, swing times, and double support times. However, loading only increased stance and double support times (Table 1).

DISCUSSION AND CONCLUSIONS
The data presented here highlight that young, healthy adults increase peak knee and hip powers during stance at a fixed walking speed while loaded. Spatiotemporal data agree with the literature for the barefoot [1, 2] and loading conditions [3]. Loading exaggerates the shorter strides observed while barefoot. Barefoot walking elicited decreased peak braking/propulsive GRFs compared to shod walking, which disagrees with previous work [1]. A proportional increase in GRFs with incremental load magnitudes has been shown [5]. The 15% increase in mass while loaded in the present study resulted in 12.5%, 13.7%, 10.1% and 14.17% increases in initial VGRF, second VGRF, braking and propulsive peaks while shod. However, these increased to a lesser extent while barefoot: 11.9%, 11.8%, 9.3%, and 11.99%. Thus, walking barefoot promotes a strategy to reduce peak GRFs while loaded.

During early stance, walking barefoot promoted a reduction in braking GRF and ankle power absorption. The latter is attributed to a less dorsiflexed ankle at foot strike and smaller dorsiflexor moment [1]. No footwear effects were noted in knee power, but hip power generation was increased at toe off while barefoot. This strategy represents a pull-off from the hip rather than increased push-off with the ankle to initiate swing.

Overweight/obese individuals walking barefoot may also exhibit similar responses to those observed here. However, if sensitivity to plantar pressures promotes the altered barefoot walking mechanics, the decreased sensitivity of plantar surface mechanoreceptors in obese individuals [6] may attenuate the observed responses seen here with added load. Comparison between normal weight and overweight individuals is necessary to determine if the changes observed here by adding 15% of body mass while barefoot are also evident between groups whose body masses are 15% different.

An attempt to minimize discomfort while barefoot is evidenced by reduced braking and propulsive GRFs and an increased VGRF at mid-stance. These GRF changes resulted in a greater reliance on the hip for power generation during stance and less reliance on the ankle for power absorption immediately after impact with the ground. This data suggests that the hip was exposed to higher loads during barefoot walking and while carrying a backpack load, which may have implications on joint health over the long term.

AVERAGING TRIALS VERSUS AVERAGING TRIAL PEAKS: IMPACT ON STATISTICAL TESTS

Kevin D. Dames, Jeremy D. Smith & Gary D. Heise
Biomechanics Laboratory, University of Northern Colorado, Greeley, CO
Email: kevin.dames@unco.edu; website: www.unco.edu/biomechanics

INTRODUCTION

Gait data is commonly displayed in figures as an average of many trials and/or averaged across participants. Smoothing the data in this way reduces the impact of inter-trial variability inherent in the data [1]. However, discrete data points, such as peaks, are used in statistical tests to define differences (i.e. an increase or decrease) between groups. The magnitudes of differences in means, sample sizes, and standard deviations are meaningful components of these statistical models [2]. However, it is often unclear how authors identify a dependent variable from multiple trials. Thus, the purpose of this study was to determine whether identifying dependent variables from an average trial profile versus identifying dependent variables from an individual trial and then averaging influences statistical outcomes.

METHODS

Twelve participants (7 female, 5 male; 23±3 yrs., 1.73±0.11 m, 70.9±12.7 kg) walked overground at 1.5 m·s^{-1} under four conditions: Barefoot Unloaded (BU), Shod Unloaded (SU), Barefoot Loaded (BL), and Shod Loaded (SL). A backpack load (15% of body mass) was worn during loaded conditions, but not included in total body mass when normalizing data. Motion (100 Hz) and ground reaction force data (2000 Hz) were combined through inverse dynamics to estimate joint reaction forces and moments, which were then used to estimate joint powers. Peaks were defined according to the conventions described by Winter [3]. Ground reaction forces (GRFs) and joint powers were normalized to body weight and mass, respectively. Dependent variables were identified from each individual trial and then averaged across the three trials and by first averaging the three trials to create an average profile and then identifying the peaks from this average profile. The mean difference and a percent change in the means between the two methods were determined. Differences between conditions were assessed via a series of 2x2 ANOVAs with repeated measures (α=0.05). These

statistical tests were repeated for each method of identifying dependent variables.

RESULTS

Figure 1 presents vertical and anteroposterior (AP) GRFs for a subject. Note the time shift in the mean curve versus the trial curves. Figure 2 displays ankle powers of another subject who also shows this time shift. The average percent change in means and the magnitude of the difference between using the two methods are shown in Table 1. Table 2 presents statistical contrasts (i.e., *p*-values) for the dependent variables according to the method used.
Figure 1. Vertical and AP GRFs for three trials (black dashed lines) and their mean (red solid lines).
Figure 2. Ankle power curves for three trials (black dashed lines) and their mean (red solid line). The arrows indicate when the minimum occurs – 32% of stride for two trials; 35% for the other trial. The mean curve minimum occurred at 33% of stride.

Bolded values indicate variables for which the two methods did not result in the same decision about whether to accept or reject the null hypothesis. Abbreviations are the same as in Table 1.

DISCUSSION AND CONCLUSIONS

For some dependent variables, the two methods resulted in <1% difference in means (see Table 1). Additionally, most decisions from the ANOVA did not change despite p-values differing (see Table 2). However, two dependent variables that were significant when chosen from the average profile peaks were not significant when peaks were chosen from the individual trials (see Table 2). To further test these two methods using non-experimental data, we simulated data by creating various sine waves of differing amplitude and phase relationships in MATLAB. In addition, we investigated the effects of the time interval between data points on the mean value obtained for a peak. Two observations were made: (1) introducing a phase shift in the sine waves resulted in misrepresentation of the peak amplitude when selected from the average curve, but no error was made when the individual trial peaks were averaged; (2) decreasing sampling frequency (i.e., increasing the time interval between points) caused error in both methods. The first observation supports the notion that an average data profile can mask true trial peaks due to the phase shift that occurs when trials are combined. This shift occurs even with normalization, as presented in the power and GRF data here. The second observation underlines the importance of Nyquist's theorem for choosing adequate sampling rates. Overall, the results of our analysis suggest that for statistical analysis, discrete dependent variables should be chosen from the individual trials rather than from an average data profile.

THE EFFECT OF STEP HEIGHT PERTURBATION ON HUMAN GAIT

[1,2]Osman Darici, [2]Hakan Temeltas and [1]Arthur D. Kuo

[1]The University of Michigan, MI, USA
[2]Istanbul Technical University, Istanbul, TURKEY
email: odarici@umich.edu

INTRODUCTION

A minor step height disturbance can potentially disrupt human walking, especially for an inattentive person. Prior awareness such as from vision can help to plan and adjust for a disturbance, but the compensation technique and mechanical consequences of a bump are largely unknown. A simple inquiry confined only to two dimensions may thus yield insight. We therefore sought to explain basic strategies for a single small bump encountered during steady walking, limited to the sagittal plane.

The expectations for a bump are as follows. A small, single-step change in ground height—the bump—may have relatively minor effect on stability, but it will generally slow at least one walking step. If average walking speed is to be recovered, the body must be accelerated accordingly. If the bump is anticipated, there is opportunity to speed up ahead of time, and perform other pre- and post-bump compensations for the step onto and off of the bump. An unanticipated bump can potentially be more disruptive, because it allows compensations to take place only after the fact, perhaps requiring more effort. In the present study, we used a simple model to make these expectations more explicit, and predict some of the mechanical effects of a bump. We also conducted an experiment to examine how humans actually compensate.

METHODS

The experimental paradigm entailed steady treadmill walking interrupted by occasional single bumps. These were applied (Fig. 1) as foam boards, 3 cm thick (height change) placed before the subject episodically. Bumps were either anticipated with vision (termed Visible), or unanticipated due to visual obstruction of the bump (termed Not-Visible). Compensations were evaluated through measured changes in gait parameters such as step length and period, and with estimates of work performed on the body center of mass (COM).

As a simple model, we considered a point mass for the pelvis with rigid, pendulum-like legs taking fixed step lengths. This is similar to the "rimless wheel" [1], except walking on level ground powered by either an impulsive push-off from one leg prior to the opposite leg's heel strike collision, or a torque applied to the stance hip to accelerate during stance. This model predicts that an unanticipated bump will cause the heel strike to occur unexpectedly early, shortening that step's period and length. The bump will also cause a reduced and early collision, with the trailing leg push-off occurring relatively late. To regain lost speed, the model should immediately accelerate by applying stance hip extension torque. This will be followed by an amplified collision stepping back down, again to be compensated for with stance-phase acceleration.

There are several advantages to the anticipated case. It is particularly economical to speed up before the bump, and apply a pre-emptive push-off prior to the collision. This then requires less speed-up after the bump, although some extra hip extension would still be expected for the stance phase on bump and perhaps the subsequent step after the collision.

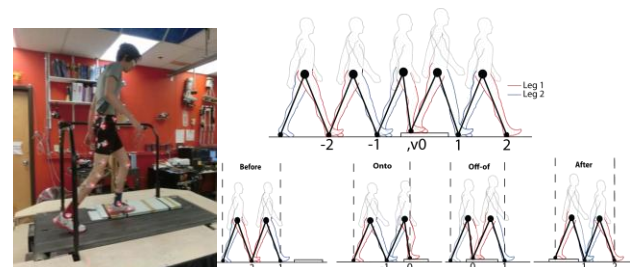
We measured the effect of bumps on the gait of 8 healthy adults. In the Visible cases, subjects could see the perturbation coming, and hear the foam slid-


Figure 1: The experiment (left) and model (right) for bump and surrounding steps.

ing on the treadmill before it was released. In Not-Visible tests they wore basketball dribbling glasses (obstructing lower part of vision) and headphones to impede hearing. The steps were termed Before, On-to, Off-of, and After bump; Onto refers to the step ending with a heel strike on bump. The heel strikes were numbered sequentially, with 0 denoting the heel strike onto the bump. We quantified step parameters and COM work rates.

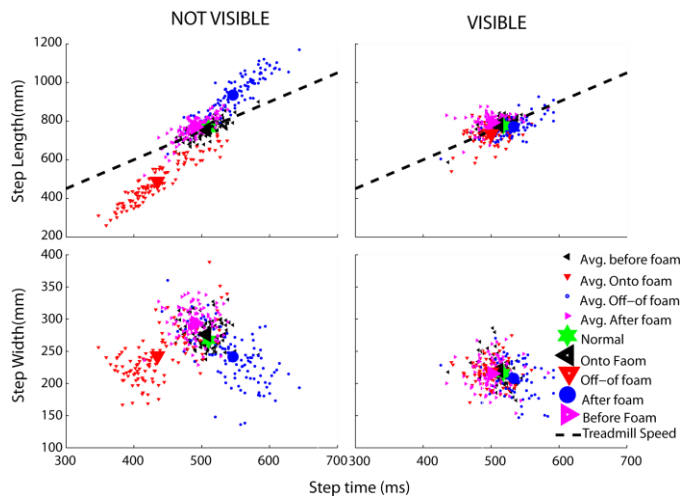
RESULTS AND DISCUSSION


Figure 2: Step lengths and widths of steps onto, and off of bump, vs. step periods (time). Dashed line shows treadmill speed. Not-visible (left column) and Visible (right column) conditions are shown.

Step lengths and periods largely followed model predictions (Figure 2). With the Not-Visible bump, the steps onto bump were significantly shorter in length and period ($P < 0.05$), because of the unexpectedly early heel strike. The off-of bump steps were also longer in length and period due to the slower stance phase and later heel strike. Visible bumps resulted in much smaller effects, with step length differences of no more than 5%, suggesting a considerable effect when the bump is anticipated.

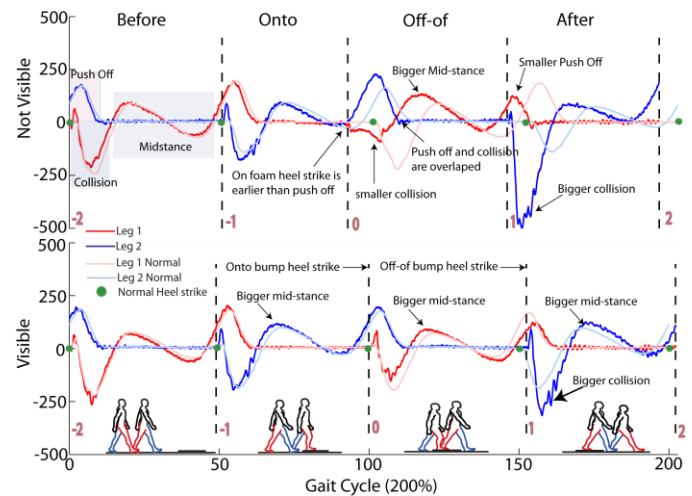
Work performed on the COM also largely agreed with predictions (Figure 3). These are summarized in three phases: positive Push-off work, negative Collision work with the other leg, Middle-stance work, the latter occurring in the stance phase between Collision and next Push-off (Figure 3, before bump step). With Not-Visible bumps, the onto


Figure 3: COM work rate vs. time for steps surrounding bump. The step ending with heel strike 0 onto bump is labeled "Onto", with leg 1 landing on the bump.

bump heel strike (Figure 3, vertical bar 0) started early relative to Push-off, unlike normal walking [2], and with less Collision work. The middle-stance work was greater than normal in the ensuing stance phase, consistent with active speed-up originating from the hip. The Collision off the bump onto level ground was also greater, due to the downward fall of the COM. With Visible bump, the onto push-off was earlier to anticipate the early Collision. The middle-stance work was only slightly greater than normal, indicating a smaller speed-up. The same was true for the Middle-stance work in post-bump step, suggesting continued speed-up after the amplified Collision due to the stepping off the bump.

Anticipation of a minor bump in the road allows for better and smaller gait adjustments than the unanticipated case. Basic effects of a bump in the road, and the proper compensations, may be explained by a very simple dynamic walking model.

DEVELOPMENT OF AN ELASTIC FORCE-FIELD TO INFLUENCE MEDIOLATERAL FOOT PLACEMENT DURING WALKING

[1]Jordan Broadway, [1]Elizabeth T. Nyberg, and [2,1]Jesse C. Dean

[1] Medical University of South Carolina, Charleston, SC, USA
[2] Ralph H. Johnson Veterans Affairs Medical Center, Charleston, SC, USA
email: deaje@musc.edu

INTRODUCTION

Active control of mediolateral foot placement is an important contributor to bipedal walking stability. Results from human walking experiments (1) and model simulations (2) indicate that appropriate foot placement is a relatively simple, economical strategy for stabilizing gait. Recently, we found direct evidence that uninjured humans actively modulate their mediolateral foot placement based on the mechanical state of their center of mass (3).

However, this gait stabilization strategy may be disrupted in clinical populations. For example, stroke survivors often walk with their paretic leg placed quite far laterally (4), likely due in part to a reduced ability to accurately control their foot placement (5). This disruption of the mechanically-appropriate control over foot placement may contribute to the increased fall risk among this population.

While the importance of mediolateral foot placement during human walking is generally accepted, it has thus far been difficult to investigate this topic through direct experimental manipulation. Instead, previous work has typically observed gait behavior in various contexts, and used trends in foot placement location to provide insight into the underlying mechanical principles.

Based on the current limitation in our ability to experimentally manipulate foot placement during human walking, we have developed a simple elastic force-field. The purpose of these initial experiments was to determine whether our force-field is able to influence mediolateral (ML) foot placement without altering the anteroposterior (AP) gait progression required for normal walking.

METHODS

We built an elastic force-field designed to exert controllable ML forces on the swing leg while walking on a treadmill. The force-field (Fig. 1) consists of two nylon-coated steel wires running parallel to the treadmill belts, in series with extension springs. The wires are secured to load cells on rolling trolleys, which can be quickly re-positioned using linear actuators. The wires pass through vertically-oriented slots on leg cuffs strapped laterally to the participants' legs, a setup with minimal friction during AP leg motion.
Figure 1. Force-field (A) and leg cuff (B).

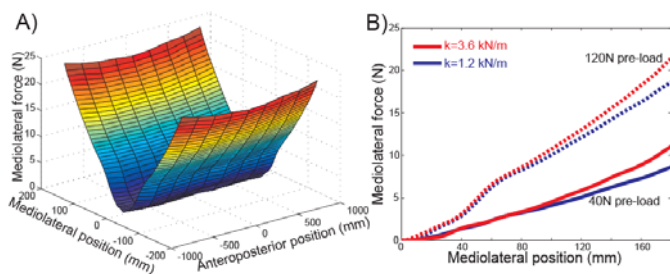
We quantified the AP and ML forces exerted by the wires on the leg cuffs, using a calibration frame to position the cuff around a grid above the treadmill. Net AP forces were always small (<1.4N), while net ML forces clearly varied with ML position (Fig. 2A), forming a "channel". The depth of this channel (indicative of how strongly deviations from the central ML position are resisted) was slightly influenced by the series spring stiffness, and more strongly by the initial spring pre-load (Fig. 2B).


Figure 2. ML forces varied with ML position (A), as modulated by spring pre-load and stiffness (B).

We tested whether the force-field (pre-load=120N; stiffness=3.6 kN/m) had the desired effect of influencing ML foot placement without altering AP progression. Six control participants (3M/3F; age= 23.2±0.4 yrs; height=1.77±0.11 m; mass=72±14 kg; mean±s.d.) performed seven 3-minute trials while walking on a treadmill at 1.25 m/s. In the first and last trials, participants walked normally. In the other randomized-order trials, participants walked with the force-field set to one of five positions (encouraging step widths of 0, 10, 20, 30, or 40 cm).

We calculated average step width and length based on LED markers placed on the left and right heels. We used repeated-measures one-way ANOVAs to determine whether walking in the force-field influenced either of these spatiotemporal metrics.

RESULTS AND DISCUSSION

Walking in the force-field significantly (p<0.0001) influenced step width (Fig. 3A). As expected, participants walked with wider steps when the force-field channels were far apart and narrower steps when the force-field channels were closer together. In contrast, the force-field had no apparent effects on step length (p=0.60; Fig. 3B). These initial results indicate that our simple elastic force-field can influence ML foot placement during walking without interfering with AP progression.
Figure 3. Walking in the force-field influenced step width (A) but not step length (B).

While the force-field influenced step width, participants did not simply adopt the step width encouraged by the force-field. Instead, step width appeared to be a compromise between the normal step width and the prescribed force-field width (Fig. 4). Based on these initial results, participants may have been more reluctant to walk with the narrower-than-normal step widths encouraged by the force-field, although this requires further investigation.
Figure 4. Actual step widths fell between normal values and those encouraged by the force-field.

CONCLUSIONS

We have developed a force-field which can be used to alter ML foot placement without affecting AP progression. Our device will allow us to conduct controlled experimental investigations of how ML foot placement contributes to bipedal gait stability among both controls and clinical populations.

DYNAMIC RELIABILITY AND VALIDITY OF PRESSURE-MEASURING INSOLES

[1] Jessica DeBerardinis, [1] Mohamed B. Trabia, Ph.D., [2] David Samson, and [2] Janet S. Dufek, Ph.D.

[1] Department of Mechanical Engineering, University of Nevada Las Vegas, Las Vegas, NV, USA
[2] Department of Kinesiology and Nutrition Sciences, University of Nevada Las Vegas, Las Vegas, NV, USA
email: deberj1@unlv.nevada.edu

INTRODUCTION

Several commercial insole systems are available for measuring plantar pressure during dynamic activities. Researchers have typically tested the reliability and/or validity of these systems by using static weights or by selecting specific anatomical sites such as, the heel pad region or the metatarsal heads of the foot [1, 2]. We argue that the dynamic validity of these systems should be evaluated by the inclusion of all active sensors in the system during walking. The purpose of the study was to examine the reliability and validity of pressure measuring insoles across the entire plantar surface of the foot during walking.

METHODS

Thirty volunteers (15M, 15F, 26.3±5.9 yrs., 73.1± 21.2 kg) granted institutionally approved written consent to participate. After demographic data was obtained, participants were fitted with insoles that closely matched their foot size. The insoles (Medilogic; Schönefeld, Germany; 60 Hz) were placed inside their socks, next to the skin. The subjects were then asked to perform the following: sit and lift their feet off the floor (~2-4 cm) for five seconds, stand stationary for 15 seconds, sit again and lift their feet off the floor for five seconds, and finally, stand and walk approximately five meters at a self-selected pace over two consecutive force platforms (Kistler, Winterthur, Sweden; 1000 Hz), placing only one foot on each platform. Each subject repeated this task until three successful trials were obtained, which was defined as having full contact by each foot with each force platform.

The force and pressure data were filtered using a low pass Butterworth filter with a cutoff frequency of 1/8 of the sampling frequency. The pressure data were transformed into force data by multiplying the pressure measured by each sensor by the area of the sensor (1.125 cm^2). Then, DC bias for the insole data was removed by subtracting the average of the first no load (feet in air) measurements from all subsequent force values.

Insole force data were next calibrated by dividing the average force measured while fully loaded (subject standing) by the recorded weight of the subject. This calibration factor was then applied to the insole force measurements. The insoles only measure pressure in the sagittal plane. Thus, to provide comparison, we excluded the measured force component that was normal to the sagittal plane:

$$F_N = \sqrt{F_y^2 + F_z^2} \; Eq(1)$$

where, F_y and F_z are the anterior-posterior and vertical components of the ground reaction force, respectively.

Dependent variables (DVs) included bilateral assessment of the first ($F1$) and second ($F2$) vertical ground reaction force maxima and the local minimum (FM) between these two maxima for the F_N curve. Support time (ST) was also identified. The time of occurrences of the force platform and insole variables were matched. The insole force values at the times of occurrence of the three force variable were used to represent force measured by the insoles. The effect of limb on the force insole variables was also considered. It was observed that the force-time curves of the force platforms and insoles qualitatively matched in only 25% and 32% for the left and right feet respectively (Figure 1). Data were statistically evaluated using a two-way (instrument x limb), repeated measures ANOVA (SPSS, version 22; α=0.05).
Figure 1. An exemplar qualitatively strong (top) and weak match (bottom) between the insoles and the force platforms.

RESULTS AND DISCUSSION

Descriptive data are given in Table 1 while ANOVA summary is shown in Table 2. The results showed that there was no significant interaction or limb main effects. However, there was a significant main effect for instruments, suggesting that the force platforms and the insoles were not measuring the same force values during walking, which was additionally supported by the observed qualitative differences in the force curves.

Table 1. Main effect (Instrument, Limb) mean and standard deviation values for all *DVs*. Each instrument includes both left and right limb while the limbs (left and right) include both instruments.

	Force Platform	Insole	Left	Right
F1 (BWs)	1.06±0.09	0.69±0.23	0.87±0.02	0.83±0.02
FM (BWs)	0.86±0.10	0.74±0.16	0.83±0.02	0.76±0.02
F2 (BWs)	1.09±0.12	0.65±0.15	0.89±0.02	0.85±0.02
ST (s)	0.81±0.12	0.86±0.13	0.84±0.02	0.83±0.02

CONCLUSIONS

The objective of this research was to dynamically assess the reliability and validity of pressure-sensing insoles. Reliability was supported, by lack of between-limb-differences. The small effect size for limb (average $\delta^2 = 0.046$), suggested bilateral internal consistency between matched insole pairs. Differences were observed in the force values

measured across the entire plantar foot surface between force platforms and pressure-sensing insoles, with the insoles underestimating the forces, suggesting lack of validity between forces measured with force platforms versus these insoles. Qualitative differences in the shape of the time-force curves were also observed. A possible explanation may be the dampening characteristics of the insoles; being incapable of relaxing to normal at a fast enough rate. Therefore, one should be cautious when using these insoles to represent plantar forces during gait. Further research may explore help better understand the insoles characteristics.

FEMORAL NECK LOADS IN YOUNG AND OLDER ADULTS DURING STAIR ASCENT AND DESCENT

[1]Chen Deng, [1]Jason C. Gillette, [1]Timothy R. Derrick
[1]Iowa State University, Ames, IA, USA
email: chend@iastate.edu ; web: http:// www.kin.hs.iastate.edu/

INTRODUCTION

Hip pain is a daily occurrence in 14.3% of adults 60 years and older [1] and is a risk factor for falls and hip fractures in older adults [2]. The femoral neck is of particular concern with hip fractures since 50% of femoral fractures occur at this site [3]. The loading environment of the femoral neck can be analyzed to estimate how bone loads are changed by age and physical activities, which may provide further understanding of hip pain and cumulative damage to the femoral neck for older adults. In this study, femoral neck stresses were estimated during stair ascent and descent for both healthy young and older adults. Greater femoral neck stresses were expected for older adults due to bone loss in this area. This may help explain the increased hip pain and fall risk among older adults.

METHODS

seventeen older adults (7 males, age: 60 ± 6 yr, body mass: 75 ± 14 kg, height: 1.73 ± 0.05 m; 10 females, age: 57 ± 5 yr, body mass: 67 ± 8 kg, height: 1.67 ± 0.05 m) and twenty young adults (10 males, age: 23 ± 3 yr, body mass: 80 ± 14 kg, height: 1.76 ± 0.07 m; 10 females, age: 23 ± 3 yr, body mass: 62 ± 10 kg, height: 1.70 ± 0.07 m) with no lower limb injuries volunteered to participate. All subjects performed 5 successful trials of stair ascent and 5 successful trials of stair descent with a 3-stair staircase. Motion capture data (160 Hz, Vicon MX, Vicon, Centennial, CO, USA) and force data (160 Hz, AMTI, Watertown, MA) were collected during each trial.

Raw force data and motion capture data were input into Matlab programs and low-pass filtered at 6 Hz. Inverse dynamics with rigid body assumptions was used to calculate 3-D joint moments and reaction forces at the hip, knee and ankle joints of the right leg. A musculoskeletal model was used to obtain maximal dynamic muscle forces, muscle moment arms and orientations for 44 lower limb muscles at each time point. Static optimization was used to select a set of muscle forces that minimized the sum of the squared muscle stresses and balanced the sagittal plane hip, knee and ankle moments, frontal plane hip moment, and the transverse plane hip and ankle moments with the external moments for each frame of data. Muscle forces, joint reaction forces and joint moments were used to estimate the 3-D moments and forces at the midpoint of the femoral neck. These loads were applied to an individualized elliptical model of the bone structure to estimate the stresses on the periphery of the anterior, posterior, inferior, and superior portion of the femoral neck. The outer and inner diameters were estimated by the age and gender specific quadratic prediction equations [4] and the ratio of maximal to minimal diameters [5].

MANOVA was used to compare maximum femoral neck stresses between young and older adults for stair ascent and descent. Experiment-wise alpha was set as 0.05. The univariate ANOVAs used alpha = 0.05 if MANOVA was significant. Statistical analyses were performed using IBM SPSS Statistics 22.

RESULTS AND DISCUSSION

MANOVA indicated a significant main effect on maximum femoral neck stresses for young vs. older adults during stair ascent (p = 0.011) and descent (p = 0.011).

Figure 1 shows that femoral neck stresses were predominantly compressive on the anterior, posterior and inferior aspects and mostly tensile on the superior aspect. There were generally two peaks (P1 and P2) on the stress curves.

As shown in Table 1, young adults had a higher maximum tensile stress at the superior femoral neck site for P1 (p = 0.01). Older adults had higher

compressive stress at the posterior femoral neck site for P2 (p = 0.007). No significant differences were found during stair ascent for the other maximum stresses at the anterior (P1: p = 0.572; P2: p = 0.791), posterior (P1: p = 0.371), superior (P2: p = 0.171), and inferior (P1: p = 0.478; P2: p = 0.577) sites. There were no differences during stair descent for maximum stress at the anterior (P1: p = 0.784; P2: p = 0.912), posterior (P1: p = 0.073; P2: p = 0.131), superior (P1: p = 0.209; P2: p = 0.541), and inferior (P1: p = 0.113; P2: p = 0.511) site.

Most femoral neck stresses were statistically similar when comparing young and older adults during stair ascent and descent. One comparison where older adults had significantly higher maximum femoral neck stresses was at the posterior site during stair ascent. The increased compressive stresses at the posterior femoral neck may be of interest in terms of potential effects on cumulative bone structure damage and hip joint pain for older adults.

CONCLUSIONS

With one exception, comparisons did not support the research expectation that older adults would have higher femoral neck stresses in stair ascent and descent, which are activities associated with hip joint pain and fall risk. Greater compressive stresses in the posterior femoral neck during stair ascent are of potential concern. Femoral neck models for older adults that incorporate individualized bone mineral densities, accumulated micro-damage merit further investigation.

Gender Differences in the Association Between
Acute Articular Cartilage Metabolism and Ambulatory Kinetics

INTRODUCTION

Females have an increased prevalence of knee articular cartilage (AC) degradation [1]. Serum cartilage oligomeric matrix protein (COMP) has emerged as a reliable biomarker that reflects AC turnover. In able-bodied individuals, serum COMP concentration increases in response to physical activity, and this increase is thought to represent AC metabolism due to exercise-induced load [2]. Baseline serum COMP concentration and the acute COMP increase due to physical activity differ between males and females [3, 4]. It is unclear, however, if certain ambulatory mechanical variables are associated with acute serum COMP concentration increase, and if this correlation varies between genders. Identifying which mechanical variables are most closely associated with acute serum COMP concentration increase, due to physical activity for each gender, may provide further insight regarding possible mechanisms leading to AC degradation differences. The purpose of this study was to evaluate gender differences in the associations between serum COMP change and ambulatory kinetics.

METHODS

Eighteen able-bodied subjects (Table 1) completed three data collection sessions (slow, medium, fast) in a counterbalanced order, separated by 24 hours. For the slow session, subjects walked at a preferred speed. For the medium and fast sessions, subjects ambulated at speeds of 50% and 100% greater than the preferred walking speed. For each session, subjects ambulated 4000 steps. Ten high-speed video cameras (240 Hz) and an instrumented treadmill (1200 Hz) captured synchronized video and ground reaction force data for five stance phases at 1000, 2000, 3000, and 4000 steps. Several discrete mechanical variables that have been linked to knee

load during ambulation were averaged across these 20 stance phases. Also, 3-ml blood samples were collected immediately pre- and post-ambulation for each session. COMP was determined using an enzyme-linked immunosorbent assay. A stepwise multiple linear regression analysis, for each gender, was used to evaluate the associations between serum COMP change (post-walk concentration minus pre-walk concentration) and the discrete mechanical variables, which included peak vertical ground reaction force (vGRF), vGRF load rate (LR), and peak net internal hip flexion (HF), hip extension (HE), hip abduction (HAB), knee flexion (KF), knee extension (KE), knee abduction (KAB), plantarflexion (PF) and ankle inversion (AI) moments. Further, an independent t-test was used to compare change in serum COMP concentration, due to ambulation, between genders ($\alpha = 0.05$).

Table 1. Subject demographics (mean ± SD)

	N	Age (yrs)	Mass (kg)	Height (m)
Male	9	24 ± 1	75.7 ± 6.7	1.76 ± 0.07
Female	9	22 ± 2	61.0 ± 5.6	1.64 ± 0.05

RESULTS AND DISCUSSION

For male subjects, the multiple regression analysis produced a model that explained 78% of the total variance in serum COMP change (adjusted R^2 = 0.72). This model included the following significant predictor variables: LR (p = 0.01), PF (p < 0.01), vGRF (p < 0.01), HAB (p = 0.03), and HE (p = 0.05). The relationship between these predictor variables and serum COMP change, due to ambulation, was defined by the following prediction equation:

$$\Delta COMP = 5.6 + 1.9\,(LR) + 40.6\,(PF) + 48.6\,(vGRF) + 24.5\,(HAB) - 29.0\,(HE)$$

For female subjects, the resulting model explained 24.5% of the total variance in serum COMP change

(adjusted $R^2 = 0.23$). This model included only KE as a significant predictor ($p = 0.01$) and defined by the following prediction equation:

$$\Delta COMP = -8.16 + 12.4 \, (KE)$$

Additionally, when pooled between all speeds, average serum COMP concentration change, due to ambulation, was significantly greater for males (30.3 ± 20.2 ng·ml^{-1}), relative to females (12.5 ± 19.1 ng·ml^{-1}; $p = 0.002$).

Our findings indicate that an increased KE is associated with greater increase in serum COMP change for females (Figure 1). For males, increased LR, PF, HAB, and vGRF, and decreased HE is associated with a greater increase in serum COMP change due to ambulation.
Figure 1. Regression plot and line depicting the relationship between serum COMP change and KE for females.

These findings corroborate other data that indicate compressive knee load is related to ground reaction force characteristics and lower-extremity joint moments, and that these forces and moments may contribute to AC breakdown [5]. It is difficult to explain the regression model differences between genders. One possible explanation may be the difference in ambulation speed. On average, ambulation speed for female subjects was 23% less than male subject's speed. The difference in speed could be one reason why males generally had higher peak kinetic variables (Table 2) and greater serum COMP concentration change. Further studies need to be conducted to address this issue.

CONCLUSIONS

Acute articular cartilage metabolism, due to physical activity, can be partially explained by ambulatory kinetics. For males, increased serum COMP change correlated with the joint moments of the ankle and hip and ground reaction force characteristics, while the internal knee extension moment partially explains acute serum COMP change in females.

These data could provide useful information for researchers and clinicians who measure either ambulatory mechanics or serum COMP in efforts to learn more about the effects of physical activity on articular cartilage. Further examination of these significant predictor variables, for each gender, is warranted within populations who suffer from joint pathologies involving AC degradation.

INTRODUCTION

Entropy provides a measurement of how much information is present in a system [1]. The amount of information relates to the predictability of a time series: how periodic or random it is [2]. Approximate entropy (ApEn) and sample entropy (SampEn) are two commonly used entropy measures in biomechanics. Both measures use a vector length m, which compares each vector to all other vectors of the same length throughout a time series to see if they fall within a tolerance r; however, SampEn removes the bias of self-matches for each vector and is generally preferred to ApEn [1]. The last parameter of SampEn and ApEn is the length of data N, which has been shown to have a larger affect on ApEn in short biological data sets [2]. Typically, biomechanical data sets are very short (e.g., <200 data points) and it has been found that SampEn is more reliable than ApEn for shorter data sets [2]. Further, SampEn has relative consistency for short data sets because the entropy value does not 'flip' based on the data length. Therefore, the primary aim of this study was to investigate the relative consistency and independence to N of both ApEn and SampEn when larger biomechanical data sets are available. It was hypothesized that SampEn will maintain relative consistency across multiple data lengths whereas, ApEn will demonstrate issues with relative consistency as data length changes.

Furthermore, there have been quite a few studies that have found differences in kinematic [3, 4], kinetic [4], and other biomechanical measures [4] between overground and treadmill walking. However, the set speed of the treadmill may have a much larger effect on nonlinear measures (such as entropy) when compared to a variable speed while walking overground. The secondary purpose of this experiment was to determine the effect on entropy of walking overground versus on a treadmill. It was hypothesized that overground walking will have a larger entropy value (less periodic) than treadmill walking (more periodic) for both ApEn and SampEn.

METHODS

Fourteen volunteers (age: 25±4.2 years, height: 170.8±11.9 cm, weight: 69.4±16.9 kg) participated in this research. No one reported lower extremity injuries or pathology that would affect normal gait.

Each participant was required to make two separate visits. They were instrumented with footswitches (Trigno™ 4-channel FSR Sensor, Delsys Inc., Natick, MA) during both visits to record heel strikes while walking. The first visit consisted of the participant walking on an overground (eighth-mile) track for one hour. The second visit was completed on a treadmill, walking at a self-selected speed, for one hour. The data from both trials was processed using MATLAB code that detected heel strikes and output step times: a temporal measure of the time from heel strike to the following heel strike of the opposite foot.

SampEn(m,r,N) and ApEn(m,r,N) were calculated on the two trials of step time data. The following parameter ranges were used for a total of 80 parameter combinations:
- Vector length to be compared – m: 2 and 3.
- Similarity tolerance – r: 0.15, 0.2, 0.25, and 0.3 times the standard deviation of the entire data set.
- Data length – N: 500, 1000, 1500, 2000, 2500, 3000, 3500, 4000, 4500, and 5000.

For ApEn and SampEn, a value of 0 indicates a perfectly repeatable time series. For perfect white noise, ApEn will result in a value of 2 and SampEn has no upper limit. Independent t-tests were used to determine the effect of mode (overground vs

treadmill) for ApEn or SampEn. Dependent t-tests were used to determine the effect of parameter choice on ApEn and SampEn.

RESULTS AND DISCUSSION

Supporting our first hypothesis, SampEn maintained relative consistency across all data lengths and for all combinations of parameters. However, ApEn demonstrated issues with relative consistency. As can be seen in Figure 1, when r=0.20, ApEn for the treadmill condition is less than that of the overground condition at a N of 500 but as the data length increases, the ApEn values 'flip' and the treadmill entropy value becomes greater than the overground value at N=2500. SampEn also demonstrated independence of data length. The entropy value using ApEn grew much faster than SampEn (Figure 1). Furthermore, due to the elimination of the self-matching in the SampEn calculation, for every parameter combination SampEn was significantly greater than ApEn (Figure 1). The differences in SampEn values using different tolerances (r) are illustrated in Figure 2. The condition with greater entropy value switched between treadmill and overground for tolerance values r = 0.2 and 0.25 for all data lengths.
Figure 1. ApEn vs. SampEn in both overground (OG) and treadmill (TM) walking using a tolerance of r = 0.2 and vector length m = 2.

Treadmill entropy values for SampEn were always greater than the overground entropy values, although this was never significant. This was opposite of the hypothesis and may be caused by the need to adapt normal walking speed fluctuations to maintain position on the treadmill belt. On the other hand, using ApEn, the treadmill had larger entropy only after 2500 steps and smaller entropy for overground trials, demonstrating a lack of relative consistency.
Figure 2. Effect of data length and tolerance on SampEn using vector length m = 2.

CONCLUSIONS

SampEn should be used over ApEn for all biological data lengths, as it is consistent and independent across all data lengths. Further emphasis is put on the selection of the tolerance r for both SampEn and ApEn and data length N for ApEn. Using an improper parameter combination may result in reporting findings that are an artifact of parameter selection. Entropy should be calculated at a large range of different parameter selections and analyzed fully before a final set of parameters is selected to ensure relative consistency.

The effect of leg retraction on stability during running

Nihav Dhawale and Madhusudan Venkadesan

Department of Mechanical Engineering and Material Sciences, Yale University, USA

Email: nihav.dhawale@yale.edu, Web: http://mvlab.yale.edu

1 Introduction

Simple models of running with spring-like and massless legs (SLIP models) show improved stability when the swing leg is retracted at higher speeds [1], and experimental data show increased rate of retraction of the swing-leg when running on terrains with steps [2]. Recent work [3] with robots and detailed models of that robot suggest that there is a trade-off between energetics and stability, and not the simple relationship between stability and swing-leg retraction that was predicted by spring-legged inverted pendulum (SLIP) models of running. However, the mechanical basis for how swing-leg retraction affects stability versus energetics remains unknown. Here, we analyze an alternative model for running [4], which includes many realistic features including dissipative collisions, active-push-off, swing-leg retraction, and yet remains mathematically tractable and generalizable across running animals. We find that instabilities associated with loss of balance in the sagittal plane (*tumbling*) are the major source of instability on uneven terrains. Importantly, truly open-loop running is most stable when retraction rate is zero. In contrast, an optimal leg retraction speed exists if the runner estimates the slope of the terrain at touchdown in planning a leg retraction strategy. On uneven terrains, this once-per-step sensory strategy shows far superior performance than any open-loop runner by stabilizing the orientation of the runner.

2 Methods

Following [4], we approximate the runner as an impulsive bouncing disc in the sagittal plane. Drag-free projectile flight phases are punctuated by stance when an impulse redirects the disc's momentum. Stance is modeled as an impulse-rigid response where the total impulse (force integrated over time) during stance is prescribed by an appropriate collision law. The collision consists of two sub-phases, a passive collision that is modeled by two coefficients of restitution (normal ε_n and tangential ε_t) applied at the point of contact, and an active impulse (two force-impulses and one torque-impulse), applied in a constant direction with respect to the lab frame. Sensors detect contact and determine when to apply an impulse against the ground, but no other knowledge of the terrain or ball's state is used. In that sense, this model is open-loop. The constant impulse is chosen such that the bouncing mass will execute a perfectly periodic trajectory on flat ground. Where the tangential collision is inelastic, we include a torque-impulse term that would maintain a constant orientation on flat ground.

The normal coefficient of restitution, ε_n, models elastic energy storage, and the tangential coefficient of restitution models swing leg retraction. We assume that the foot does not slip on the ground, and therefore the tangential coefficient of restitution should always equal to 0. However, retracting the leg at a constant rate, reduces the tangential collision. Consider a runner of leg length r_{ball} (equal to the disc's radius) that moves on a flat ground with a forward speed v_x, and a leg retraction rate of ω_{ret}. When ω_{ret} is exactly equal to v_x/r_{ball}, there is no longer any tangential collision, equivalent to $\varepsilon_t = 1$, because the foot is moving forward at zero speed at the instant of contact. Following this logic, ε_t for a runner whose speed in the direction tangential to the terrain is v_t is given by,

$$\varepsilon_t = \frac{\omega_{ret} r_{ball}}{v_t} \qquad (1)$$

Therefore maintaining a constant ε_t requires knowledge of the tangential speed with respect to the terrain,

i.e. both the forward speed, and the slope of the terrain at the oncoming point of touchdown. A constant leg retraction rate will cause ε_t to vary with changes in the terrain's slope and with speed fluctuations. Using a constant ω_{ret} is therefore an open-loop strategy, while a constant ε_t is a once-per-step sensing and anticipatory strategy.

Simulations used $\varepsilon_n = 0.6$ ($\sim 40\%$ elastic energy storage for human running), speed = 3m/s, ensemble size = 10^5, orientation bounds = $\pm\pi/6$ from vertical, based on angle between legs at typical step length.

3 Results and Discussion

The optimal open-loop runner, with a constant leg retraction speed, is one with no leg retraction at all (figure 1). However, the number of steps to failure depends only weakly on the leg retraction strategy used, varying from 6–10 steps (median of 100,000 runners) at the extremes of leg retraction rates. By comparison, the closed-loop strategy that incorporates the oncoming slope of the terrain in selecting a leg retraction rate, performs nearly an order of magnitude better. The optimal closed loop strategy consists of retracting the leg at the exactly the speed that would minimize the tangential collision, and runs for 36 steps. However, not retracting the leg fast enough, or too fast, are both detrimental for the closed-loop runner, and at the extremes, the performance is as bad as the open-loop runner.

In open-loop operation, almost all ($> 99\%$) of failures are due to violations of orientation bounds (headhits). The optimal closed-loop runner fails only due to a violation of speed bounds, and with increasing suboptimality of the retraction strategy, the proportion of headhits (stumbling forward or backward) increase.

Because we only consider impulses, and not detailed time history of forces, the results of our simulation are more generally applicable than models which assume specific mechanisms for force transmission. However, unlike SLIP models, our model can address realistic ground collisions, energy consumption, and rough terrains with slope variations. Therefore, we propose this model as a generalized template to understand the mechanics of running, and perhaps as a design guide for robotic runners.
Figure 1. Median number of steps for the open and closed-loop ε_t strategies on uneven terrain.

4 Conclusions

Leg retraction benefits the runner who uses sensory feedback once per step to plan a strategy. Any retraction at all is detrimental for the purely open-loop runner, but only marginally so. Therefore, under imperfect sensory feedback, our results suggest the use of a retraction policy that does not entirely eliminate tangential collisions, and relies on sensory information on the slope of the terrain to plan an optimal retraction rate.

INTRODUCTION

Walking is a fundamental task most people rely on throughout their daily routine. Patients suffering from many different injuries or pathologies strive to maintain their walking ability, developing compensatory strategies to maintain a successful gait [1]. There is clinical evidence that normal gait kinematics can be retained even while the kinetic patterns are significantly different than normal [2]. While there is great interest in how patients compensate for particular injuries, much of the focus is specifically placed on the healing process in order to refine rehabilitation methods and track recovery. For example, certain populations have shown better adoption of successful compensation strategies than others during functional tasks after anterior cruciate ligament repair [3]. These results suggest a need to more fully understand the compensation strategies developed by the neuromuscular control system (NCS) throughout recovery from injury.

The underlying goal of this study was to examine the progression of changes to compensation strategies during recovery from injury. Recovery from ankle injury was simulated using a custom ankle-foot orthosis (AFO) with adjustable bidirectional resistance to ankle motion. The ankle was chosen due to its importance to gait propulsion [4], and the AFO provided a controlled experimental environment for simulating abnormal gait with known conditions [cf. 5]. Our hypothesis was that some of the compensations employed during the full perturbation would *not* change at a comparable rate with the reductions in stiffness; rather they would exhibit relative discontinuities at certain points during reduction in perturbation, or switch between coexisting strategies.

METHODS

Ten able-bodied male subjects (25.5 ± 5.1 yr, 77.4 ± 11.4 kg, 1.77 ± 0.05 m) participated after giving informed consent. A custom AFO was fabricated for the left lower limb, outfitted with a linear pneumatic cylinder (DSNU-5/8"-5"-P; Festo, Hauppauge, NY) to restrict ankle motion by pressurization. Force produced by the cylinder was measured with a bi-axial load cell (LC202-100; Omega, Stamford, CT). The protocol encompassed two consecutive days. On the first day, subjects were fitted with the AFO and walked *without* the cylinder on a Bertec Instrumented Treadmill (Columbus, OH) to identify a comfortable walking speed and allow acclimation to the AFO. On the second day, to record motion using a three-dimensional motion-capture system (460 Datastation; Vicon, Oxford, UK), reflective markers were attached to the pelvis, lower limbs, and AFO.

The following walking assessments were then performed on the treadmill: **NC**- seven minutes wearing the AFO with zero resistance (no cylinder); **p100**- 15 minutes with the cylinder attached and pressurized to 100 psig; **p60**- seven minutes at 60 psig; **p20**- seven minutes at 20 psig; **NC2**- condition NC repeated for 15 minutes. In order to study *steady-state* compensations, marker locations, ground reaction forces, and cylinder force (for **p100-p20**) were recorded for the final 30 seconds of each assessment. Sagittal-plane joint angles, net muscle moments, and cylinder torque were computed using custom MATLAB code (R2012a; Mathworks, Natick, MA). To facilitate averaging, pertinent gait events were aligned using piecewise linear length normalization [6].

Each subject's average behaviors in conditions **p100** through **NC2** were compared against their normative data in **NC** *throughout* the gait cycle using the regions of deviation method [7]. Briefly, the deviation from **NC** of each subject's average behavior in each condition was computed as the distance it lay outside one standard deviation of that subject's **NC** average for each point in the cycle.

These deviations were statistically compared against zero (i.e., no deviation) with a one-sample *t* test at every time point in the gait cycle ($\alpha = 0.05$) [8]. All points proving significantly different were then considered *regions of deviation* from the NC condition for the group.

RESULTS AND DISCUSSION

Compensations to the increased ankle stiffness occurred throughout the gait cycle, affecting both gait event timing and joint kinematics/kinetics. Perhaps the most interesting compensations were in response to impaired plantarflexion during loading response: 0-15% of the gait cycle (Fig 1). During p100, subjects responded with a slight reduction in dorsiflexor moment. However, this compensation alone was not sufficient to return to normal ankle kinematics, leading subjects to develop a secondary compensation of increased hip and knee flexion (Fig 2). This combination of distinct strategies helped subjects maintain a symmetric gait in the presence of reduced ankle plantarflexion.
Fig 1: Group averages of left ankle angle during NC (black) and p100 (red).

During recovery from the perturbation (p60-NC2), the reduced plantarflexion gradually diminished, becoming statistically insignificant by NC2. However, the distinct kinetic and kinematic compensation strategies found in p100 returned to normal at *different* rates. The biological ankle moment returned to normal gradually, but the kinematic compensations at the hip and knee disappeared by p60. This result suggests that after a certain point in recovery, subjects were able to overcome the ankle perturbation in loading response by solely adapting their ankle kinetics; they no longer required the additional kinematic hip and knee compensations to maintain a successful gait.

The observed recovery compensations during loading response support the existence of discontinuous changes to neuromuscular adaptations during continuous recovery from an injury, as well as coexisting compensation strategies. This information can inform clinicians to the need for different rehabilitation strategies throughout a patient's recovery, depending on the compensations present at the time. It should be noted that the overall scope of this work was much broader, and could not be conveyed here. Several other adaptations were present throughout the gait cycle, with similar findings of discontinuous or coexisting adaptations during recovery. One major shortcoming of this work was the inability to record truly *continuous* recovery data through more intermediate ankle stiffness conditions. Thus, discussion of *discontinuous* adaptations above must be taken in context, relative to the stiffness changes.
Fig 2: Group averages of left hip and knee angles during NC (black) and p100 (red) for 0-30% of the gait cycle.

CONCLUSIONS

The results from this study show the possibility of coexisting neuromuscular compensations due to injury, which return to normal at different rates. This nonlinear behavior could have major potential implications for the design of rehabilitation protocols, and should be studied in more depth.

Changes in Walking Kinematics Following Bilateral Isolated Lower Extremity Joint Fatigue

[1] Sarah Hovey, Seth Higgins, Kimberly Dahl, Natasha Francksen, Jonathan Foster and D. Clark Dickin

[1] Biomechanics Laboratory, Ball State University, Muncie, IN, USA
email: biomech@bsu.edu, web: www.bsu.edu/biomechanics

INTRODUCTION

In the human body, muscular fatigue is characterized by a reduction in the force generating capacity of a muscle [1]. Alterations of movement patterns often occur following muscular fatigue as compensation for the impairment in the muscle's ability to produce and control force. Fatigue-related changes in normal gait patterns result in a shift in muscle activation from fatigued to less fatigued muscles in order for the body to continue performing the task [2]. Often times these changes occur at the expense of proper biomechanics, which may lead to elevated risk of musculoskeletal injury in the lower extremity [1, 2]. During locomotion, and other whole body tasks, general fatigue of the lower extremity is typically the result. While the whole lower extremity may be fatiguing the resistance to fatigue is variable across the joints [3]. The ankle has been identified as less fatigable than the knee, however reduced function in any joint may compromise joint mechanics at all lower extremity joints [1]. It was therefore the purpose of this study to determine the impact of bilateral fatigue at individual joints of the lower extremity on joint kinematics during walking.

METHODS

Eleven male participants (21.4 ± 3.1 years) walked on a treadmill at 1.39 m/s for 2-minutes: prior to fatigue, immediately following fatigue, and 10-minutes post fatigue. Fatigue of the flexor and extensor muscles of the ankle and knee was induced on separate days using 3-bouts of isokinetic fatiguing contractions at 60°/s until a 50% reduction in peak force occurred. Joint kinematics were captured using a 14-camera Vicon motion capture system (VICON Inc., Denver, CO, USA) collecting at 120 Hz and an AMTI force plate instrumented treadmill (AMTI Inc., Watertown, MA, USA) collecting at 2400 Hz with a modified Plug-In Gait marker set that included marker clusters on the thigh and shank of each leg.

Dominant leg ankle, knee and hip kinematics were calculated at initial impact and at maximal joint excursion during mid-stance using Visual 3D software (Version 5.0, C-Motion, Germantown, MD, USA) and data were analyzed using a repeated measures analysis of variance in SPSS. Alpha level was set at $p \leq .05$.

RESULTS AND DISCUSSION

Significant main effects were revealed for time, but not between for the joint fatigued or time x joint interaction. At initial ground contact, the hip was more extended at 10 minutes post fatigue compared to both pre-fatigue and 2 minutes post fatigue ($F_{(1,30)}=4.22$, $p=.013$). While the ankle angle demonstrated greater dorsi-flexion at pre-fatigue than in all three post fatigue conditions ($F_{(3,30)}=22.7$, $p<.001$) (Table 1). At the knee ($F_{(3, 47.83)}=4.56$, $p=.030$) and ankle joints ($F_{(3,30)}=16.04$, $p<.001$) greater maximum flexion and dorsi-flexion angles were seen for both the pre-fatigue and at the end of the 2-minute post fatigue walk than for immediate post and 10-minute post fatigue (Table 1).

Inducing bilateral fatigue at isolated joints in the lower body altered joint motion at all three major joints. The results suggest that while bilateral lower extremity fatigue, at either the ankle or knee, alters walking kinematics the individual joints did not exhibit a differential effect in walking kinematics. At the ankle joint, a reduction in initial contact dorsi-flexion angle was seen following fatigue that did not recover across the 10-minute post-fatigue recovery period. Similar patterns emerged at the hip at initial impact in that fatigue impaired hip flexion immediately post fatigue and although hip flexion angle returned to pre-fatigue levels at the end of the immediate post fatigue walking trial it was again reduced at the 10 minute post fatigue walk. At the

knee and ankle joint fatigue caused an immediate reduction in knee maximum knee flexion and ankle dorsi-flexion that returned at the end of the 2-minute walk period but then was again impaired at the 10-minute post fatigue time. This pattern suggests that lower extremity kinematics may return to normal levels after continuous walking following muscular fatigue but can return during rest. Given a period of rest the individual experiences a general restriction in joint motion that closely resembles the levels experienced immediately after the period of fatigue. Importantly, allowing the individual time to activate and move following fatigue appears to have a restorative effect on joint motion. Overall, the findings suggest a more rigid limb following the fatiguing contractions, potentially reducing the ability to attenuate the forces from landing and increasing the risk of musculoskeletal injury. Although normal joint function seems to return relatively quickly once the individual is permitted to walk and movement joints.

CONCLUSIONS

The study findings confirmed the negative impact of muscular fatigue on joint performance during locomotion and extended them to walking.

Interestingly changes in joint kinematics were not significantly different between isolated bilateral ankle and knee fatigue. These findings suggest that although each individual joint may fatigue differently the impact of its fatigue is relatively similar in terms of joint kinematics. This study demonstrated both the importance and impact of the knee and ankle joints to overall lower extremity functioning.

COMPLEXITY OF GAIT POST STROKE

[1,2] Eric L. Dugan, [3] Stephanie A. Combs-Miller, Jeff Eggleston, Cara M. Masterson, and [2] Cassidy M. Berlin

[1] Seattle University, Seattle, WA, USA

INTRODUCTION

Determining how individuals will respond to therapeutic interventions focused on improving gait function after stroke is challenging. Some individuals demonstrate improvements in walking speed via the recovery of pre-stroke gait patterns, while others may increase speed through the strengthening of compensatory movement patterns [1]. Traditional measures of gait function derived from spatio-temporal parameters, such as gait speed, do not delineate between recovery of pre-stroke patterns or compensation, and thus, do not provide information about a patient's ability to adapt their gait to different tasks and environmental constraints. There is a critical need to develop methods that differentiate among capacities for adapting movement patterns in individuals with stroke.

One approach to understanding the health and adaptability of biological systems is through the measurement of complexity. Since complexity represents the adaptability of the biological system in question, the assessment of complexity of movement parameters is particularly attractive when attempting to better understand the recovery processes after events such as stroke.

Therefore, the primary purpose of this study was to determine whether the complexity of gait in persons with hemiparesis due to stroke is different to that of individuals without disability during a gait task. Based on the previous work documenting the decrease in complexity [2, 3] of biological signals with age and disease, our hypothesis was that the complexity would be significantly lower in the group with stroke compared to the group without disability.

METHODS

Participants with chronic stroke and participants without disability were enrolled in this case-control study. Participants with stroke had to meet the following inclusion criteria: 1) minimum of 6 months post stroke, 2) able to walk for at least 10 meters on level surfaces without physical assistance or use of an assistive device and/or lower extremity orthosis, 3) continue to experience residual deficits from the stroke that affects walking ability. Participants without disability were included if they were able to walk without physical assistance or use of an assistive device or orthosis during all home and community activities. Exclusionary criteria for the participants without disability included: 1) known neurological condition or any neurological deficits such as prior stroke, 2) current musculoskeletal condition outside typical age-related changes, and 3) complications from health conditions that influence walking.

All participants completed a 2-minute walk at their preferred pace around a level, tiled indoor walking track. During the walking tasks, three dimensional accelerometer data from wireless inertial measurement units (IMUs) (InterSense Inertia Cube BT) worn on each lower extremity segment [foot, shank, thigh] and pelvis were collected (60 Hz) using MotionMonitor software (Innovative Sports Training, Inc.).

These data were used to determine the complexity of the gait patterns using the multivariate, multiscale entropy (MMSE) algorithm developed by Ahmed and colleagues[4]. The calculation of MMSE results in a measure of complexity across multiple time scales and provides a means for comparing the movement complexity across groups

and/or conditions. The complexity index was calculated from the MMSE results and represents the area under the MMSE curve and provides a way of comparing the physiological complexity of gait across multiple time scales.

Two-tailed, independent t-tests with a significance level of $p < .05$ were used to test the hypothesis that the complexity index for each limb segment would be lower in the participants with stroke compared to that of the healthy participants.

RESULTS AND DISCUSSION

A total of 22 participants were enrolled in this case-control study (11 with chronic stroke and 11 participants without disability). Participants with chronic stroke had significantly ($p < 0.05$) lower complexity at every lower limb segment and the pelvis compared to healthy controls during overground walking, see Table 1.

The results of this study support the hypothesis that in individuals with stroke would exhibit lower levels of gait complexity compared to that of healthy participants and are consistent with previous studies of the temporal variability of upper extremity movement in individuals with stroke [5].

Greater complexity is thought to signify the overall health of a system and its underlying physiological capacity to adapt to everyday stresses. Healthy biological systems exhibit complex behaviors while age and disease reduce this complexity [2, 3]. The results of this study support this paradigm.

CONCLUSIONS

The reduced complexity of gait after stroke represents a decrease in the adaptability in the neuromotor system. This information may discern between those patients who are more likely to respond to therapeutic interventions and those who will not. Ultimately this information could allow therapists to tailor interventions in such a way to optimize function.

ENERGY SUBSTRATE USE DURING WALKING AS A FUNCTION OF STEP RATE

Farzad Ehtemam, Ryan M. Sapp, James M. Hagberg, and Ross H. Miller

University of Maryland, College Park, MD, USA
email: rosshm@umd.edu, web: http://sph.umd.edu

INTRODUCTION

Humans can walk at a given speed using a range of mechanically feasible step rates. When the choice of step rate is unconstrained, we tend to choose a moderate rate near the center of this range. The mechanisms behind this subconscious choice are unknown, but a popular hypothesis [1] supported by data [2] is that the preferentially chosen step rate minimizes the rate of metabolic energy expenditure.

An implicit assumption of this "minimum energy" hypothesis is that the nervous system monitors and regulates muscle energy metabolism. Repeated activation of muscles during movement requires energy consumption (e.g. the ATP used in powering the crossbridge cycle), which must be matched by energy production through substrate metabolism. Energy consumption as an optimality criterion in human gait has been widely studied, but the energy production side of this relationship has received minimal attention [3].

In this study, we examined energy production (substrate oxidation of fat and carbohydrates) when walking at a range of step rates. Since this was a preliminary/exploratory investigation, no specific hypotheses were formed, but due to the traditionally observed U-shaped relationship between step rate and energy rate in walking, we expected the oxidation rate of the substrate producing the majority of energy to also be U-shaped.

METHODS

Ten healthy young adult subjects participated in accordance with institutional guidelines. Subjects fasted for at least three hours, and were asked to refrain from alcohol for 24 hours before their test and to not exercise on the day of the test. Subjects walked on a level motorized treadmill at 1.25 m/s.

The subject's preferred step rate (PSR) was first determined by counting the number of steps taken in a minute. Subjects then walked for five minutes at each of seven different step rates: PSR and ±5, 10, and 15% of PSR (randomized order with breaks between trials). Step rate was primed using a metronome, and subjects were instructed to match the timing of their heel-strikes with the beat.

Breath-by-breath rates of oxygen consumption and carbon dioxide production were measured using a metabolic cart (Oxycon Pro, CareFusion, San Diego, CA) and averaged over the final 2 min of each step rate. Mass-specific rates of gross energy expenditure, carbohydrate oxidation, and fat oxidation were calculated assuming protein produced 12.5% of the energy consumed [4,5].

RESULTS AND DISCUSSION

Repeated-measures ANOVA showed no significant effect of step rate on carbohydrate oxidation (p=0.374, Fig 1b) and significant effects on metabolic rate and fat oxidation (p<0.05, Figs 1a, 1c). The gross metabolic rate was significantly greater at ±15% PSR than at PSR (Fig. 1a). Both the gross metabolic rate and the fat oxidation rate were well fit as functions of step rate by 2nd-order polynomials ($R^2 = 0.89$ and 0.95, with significant quadratic terms (p<0.001). The carbohydrate oxidation was invariant with respect to step rate (Fig. 1b) and was not well fit by the 2nd-order polynomial ($R^2 = 0.26$).

In summary, we saw that the U-shaped relationship between metabolic rate and step rate was explained by fat oxidation, which was also U-shaped, unlike carbohydrate oxidation. Protein oxidation was also U-shaped with respect to step rate, but this relationship was assumed, not measured. Thus, when subjects walked at non-preferred step rates,
Figure 1. Means and standard deviations for (a) gross metabolic rate, (b) rate of carbohydrate oxidation and (c) rate of fat oxidation, when walking at different step rates. Dashed lines are 2nd-order polynomial fits. * = significantly greater than the value at the preferred step rate.

energy expenditure increased, and fat was used as the fuel to provide this additional energy.

One possible explanation for these results is that humans have evolved to prefer gaits that minimizes fat utilization, sparing consumption of an energy source that has historically been difficult to obtain. For example, prior to animal domestication, obtaining fat required hunting, while carbohydrates could be obtained more consistently and safely through foraging. Obtaining fat elsewhere would require availability of forageable oil-rich foods (e.g. nuts).

A conceptually related notion, the "thrifty gene" hypothesis, has been suggested as an explanation for the high prevalence of diet-related conditions such as obesity, type 2 diabetes, and metabolic syndrome [6]. Measurement of protein use, which was not done here, could further examine the theory that the preferred step rate spares substrates primarily obtained through hunting and meat consumption.

Another possible explanation is that adjustments to the step rate of walking rely on fat in order to spare carbohydrates for use in more intense physical activities such as running. Carbohydrates are less energy-dense than fats, but can supply their energy more quickly, and are thus relied upon as fuel more and more as the intensity of physical activity increases [7]. During low-intensity activities such as walking, humans may prefer to modulate our energy expenditure using primarily fat, saving carbohydrates for situations where energy is needed quickly (e.g. fleeing from danger).

CONCLUSIONS

This study suggests minimization of fat oxidation drives the shape of the energy-step rate relation in human walking. This result provides an energy-production perspective on decision-making in the gait mechanics of humans. Evolutionary studies of movement might also find this substrate minimization important in the context of ecological constraints that shaped our gait prior to agricultural revolutions. Further studies are needed to investigate the effects of abundance of nutrients in modern societies on this minimization process.

GROUND REACTION FORCE COMPARISION OF PREDICTION-BASED AND DIRECT FORCE MEASUREMENT SYSTEMS

[1] Portia Flowers and [1] Trent M. Guess

[1] University of Missouri, Columbia, MO, USA
email: flowerspp@health.missouri.edu, web: www.mizzoumotioncenter.com

INTRODUCTION

Accuracy in ground reaction force measurements is critical to gait analysis interpretation. The current gold standard in ground reaction force (GRF) data collection is the use of force plates. While accurate, force plates are expensive and restrictive. However, markerless, plateless motion capture systems may provide a less expensive and easier method for kinetic data collection and analysis, allowing for less preparation time and restricted movement. Previous studies have described the use of plateless motion capture techniques to obtain GRF [1, 2]. The purpose of this study was to compare GRF obtained via force plate and plateless systems.

METHODS

After providing written informed consent approved by the institution's human subjects review board, all subjects performed 5 trials of a vertical jumping task. Data was collected via two force plates (AMTI Optima) synced with Vicon Nexus 2.0 software and with an 18-camera markerless motion captures system (Organic Motion BioStage). Force plate GRF were collected for each leg independently at 1000Hz. Resultant force magnitudes were determined from the vertical and shear forces and reported. Using a visual hull reconstruction method of tracking segment motion [3], markerless kinematic data were sampled at 120Hz and processed via third party software (Dynamic Athletics DARI, Vault software). In addition to joint angles, DARI also predicted GRF magnitudes for each leg from the markerless kinematics. GRF magnitudes during the landing phase of vertical jump were time normalized. Average GRF throughout the jump cycle and peak GRF during landing for each limb was used in this analysis. Landing phase was determined as the

instant after foot contact with the ground until end of motion. Trials were collected simultaneously, with subjects performing a single elbow flexion motion before each task to sync the two systems.

Coefficients of multiple correlations (CMC) and root mean square (RMS) error were used to determine relationship and accuracy of GRF waveforms for the entire jump cycle. Between-system agreement was assessed by calculating the mean difference within 95% confidence intervals (CI) to determine consistency of peak forces across all trials, and two-way, mixed effects, average, Intraclass Correlation Coefficient (ICC) with 95% CI to determine absolute agreement of peak force between methods. Intra-session reliability of both methods were assessed via Cronbach's alpha to determine consistency of peak forces across all trials, and ICC to determine absolute agreement of peak force between the first and last trials.

RESULTS AND DISCUSSION

Ten healthy adults (5F/5M, age = 26.1 ± 3.7 yrs, height = 1.71 ± 0.1 m, weight = 69.1 ± 12.3 kg) were recruited for this study. Between-system averaged CMC values revealed good agreement throughout the jump cycle (Table 1). However, ICCs revealed moderate agreement in peak GRF between the two methods under the left (ICC(3,k)=0.493) and right sides (ICC(3,k)=0.423) (Table 2). Large average RMS error revealed an absolute discrepancy between the two methods, further evidenced by a consistent trend toward less DARI predicted peak GRF on both limbs (left limb mean difference=400.2N, right limb mean difference=337.4N) (Table 2, Figure 1).

For intra-session reliability, Cronbach's alpha revealed excellent agreement for all measures

across 5 trials in both the direct (0.875-0.872) and predicted (0.950-0.968) force measurements (Table 3). Agreement of peak force between the first and last trials were moderate for direct (ICC(3,1)=0.471-0.501) and predicted (ICC(3,1)=0.622-0.871) force measurements.

Table 1: Mean CMC and RMS error comparing between-system waveforms of GRF magnitudes for each limb.

Limb	CMC	RMS error
Left	0.86	106.5 N
Right	0.86	110.1 N

Table 2: Mean peak GRF during vertical jump landing.

	Left limb	Right limb
ATMI GRF (N)	1160.7±295.9	1134.7±447.9
DARI GRF (N)	760.5±205.9	797.3±187.4
Mean Diff (95% CI) (N)	400.2 (264.1, 536.4)	337.4 (64.2, 610.7)
ICC(3,k) (95% CI)	0.493 (-0.19, 0.87)	0.423 (-0.42, 0.83)

Table 3: Intra-session reliability measures

		ATMI	DARI
Cornbach's Alpha	Left	0.875	0.950
	Right	0.872	0.968
ICC (3,1)	Left	0.471 (-0.12, 0.84)	0.622 (0.08, 0.89)
	Right	0.501 (-0.12, 0.85)	0.871 (0.57, 0.97)

With an overall error of nearly one body weight (based on the study sample average), this discrepancy may be a reflection of the sampling rate of the markerless motion capture system. With a maximum sampling rate of only 120Hz, it is possible that the markerless system is unable to accurately track dynamic movement such as jump landing, resulting in a consistent underestimation of peak GRF. However, with excellent within-system agreement, relative measurements may be appropriate for the plateless system.
Figure 1: Representative mean GRF in forceplate (ATMI) and plateless (DARI) systems for one subject.

CONCLUSIONS

The potential for using DARI predicted GRF measurements via markerless motion capture is promising, as average force magnitudes were consistent across trials, which was comparable to the gold standard of force plate methods. However, a consistent underestimation of GRF, possibly due to undersampling and inaccurate motion tracking, makes DARI predicted GRF data reliably inaccurate, particularly for high frequency dynamic events. Additionally, DARI predicted GRF is limited by its ability to only provide force magnitudes without direction. Without knowing the components of GRF, it is difficult to identify and diagnose pathologic movement, making clinical use impractical at this time. Future studies should seek to develop equations to account for the difference in force between the two methods.

KINEMATIC COMPARISION OF MARKER-BASED AND MARKERLESS MOTION CAPTURE SYSTEMS

INTRODUCTION

Accuracy in motion analysis systems is critical to gait analysis interpretation. The current standard in kinematic motion capture is a marker-based system, using passive or active markers placed on specific anatomical locations to track human movement. However, marker-based methods are highly dependent on marker placement accuracy and require long preparation times. Markerless motion capture systems may provide an easier method for motion analysis, allowing for less preparation time and restricted movement. Previous studies have described the use of markerless motion capture systems [1-3]. The purpose of this study was to compare hip, knee, and ankle joint kinematics outcomes between marker-based and markerless systems.

METHODS

After providing written informed consent approved by the institution's human subjects review board, all subjects performed 5 trials of a Right-Left-Right side cutting maneuver (Figure 1). Markerless motion was collected using 18 cameras (Organic Motion BioStage). Subjects wore a fitted blue short sleeved shirt, fitted black long pants and orange ankle socks to ensure segment identification in the markerless motion capture system. Holes were cut out of the clothing to accommodate placement of 14 retroreflective markers placed on the clavicle, strernum, and C7 & T10 vertebrae, and bilaterally on the acromioclavicular joint, upper arm, lateral humeral epicondyle, forearm, ulnar and radial styloid processes, 2nd metacarpal joint, anterior & posterior superior iliac spines, thigh, lateral femoral condyle, shank, lateral malleolus, heel, and 2nd metatarsal joint. Thigh and shank marker clusters were added for the functional joint calibrations.

Markers were placed by a single tester with good reliability (Intracorrelation Coefficient=0.754).

Marker-based motion was collected using a Vicon MX-T40S 8-camera motion capture system (Vicon, Oxford, UK). Marker-based kinematic data were sampled at 100Hz, processed using Vicon Nexus 2.1 software, and filtered at 6Hz using a 4th order Butterworth filter. Vicon's Plug-In Gait skeletal model with functional joint calibration was used to determine joint angles. The Symmetrical Center of Rotation Estimation (SCoRE) [4] was used to estimate the hip joint center and Symmetrical Axis of Rotation Analysis (SARA) [5] was used to estimate the knee joint axis. Using a visual hull reconstruction method of tracking segment motion [3], markerless kinematic data were sampled at 120Hz and processed via third party software (Dynamic Athletics DARI, Vault software). Trials were collected simultaneously (Fig. 1), with subjects performing a single elbow flexion motion before each task to sync the two systems. Hip and knee angles in the sagittal, frontal, and transverse planes, and ankle angles in the sagittal plane were calculated for the planting limb (left). Using peak elbow flexion as the point of synchronization, data obtained from the markerless system were time synchronized to the marker system.

Coefficients of multiple correlations (CMC) and root mean square (RMS) error were used to determine relationship and accuracy of joint angle waveforms from 1st right heel strike to 2nd right toe-off.

RESULTS AND DISCUSSION

Eight healthy adults (3F/5M, age = 26.6 ± 4.0 yrs, height = 1.72 ± 0.09 m, weight = 71.8 ± 12.3 kg) were recruited for this study. Between-system

averaged CMC values were largest in the sagittal plane, with strongest relationships at the hip and knee (Table 1). Between-system relationships were weakest in the frontal and transverse planes, particularly at the knee. It is possible that such weak correspondence may be due in part to limited range of motion in those planes. RMS errors were smallest in the frontal plane, which reflects a smaller range of motion in that plane. Despite the strongest relationship between systems at the hip in the sagittal plane, average RMS error was also the largest, indicating an absolute discrepancy between the two systems. Once normalized to joint range of motion, RMS errors were largest at the hip in the non-sagittal planes, indicating a possible difficulty in identifying hip joint kinematics. In addition, while joint centers and axes were defined in the marker-based system using a functionally relevant determination, joint centers and axes as defined by the markerless system are unclear. Therefore, a possible disagreement in such definitions may have contributed to the weak between-system relationships, particularly in the non-sagittal planes of movement.

CONCLUSIONS

The potential for using markerless motion capture methods may be limited by the joint of interest as well as the plane of motion. Analysis of joint motion in the sagittal plane may have the best potential for application. However, the viability of a markerless system such as Organic Motion is ultimately dependent on a full understanding of joint center and axes definitions in the markerless system, which is critical to joint angle determination, particularly in non-sagittal planes. Future studies should include day to day repeatability to assess the use of markerless systems in longitudinal testing.

FOOT AND ANKLE KINEMATICS DURING DESCENT FROM VARYING STEP HEIGHTS

[1] Emily Gerstle, [1]Kristian O'Connor, [1]Kevin Keenan, and [1]Stephen Cobb

[1] The University of Wisconsin-Milwaukee, Milwaukee, WI, USA
email: egerstle@uwm.edu

INTRODUCTION

Ankle injuries account for approximately two million emergency room visits in the US annually. An estimated 26% of those injuries occur due to a fall from steps [1]. A study utilizing random population surveys found the total incidence of ankle injuries to be up to five times greater than the emergency room visit estimates [2].

Previous research has modeled the foot as a single rigid segment and focused on hip, knee and ankle movement during multiple step descent [3-5]. However, a study by Yu, 1997 reported the stepping mechanics of descending a single step differed from multiple step descent. Furthermore, recent studies have shown there is significant motion within the distal articulations of the foot during gait [6, 7].

The purpose of this study was to identify foot and ankle kinematics of uninjured individuals during descent from varying step heights.

It was hypothesized that landing strategy would transition from the rearfoot to the forefoot as step heights increased. These changes were anticipated to be accomplished through significant kinematic differences in the rear-, mid-, and forefoot both at initial contact and during weight acceptance. Regarding initial contact in the sagittal plane, the rearfoot, midfoot and medial forefoot were predicted to become more plantarflexed while the lateral forefoot would become more dorsiflexed. In the frontal plane a more inverted position was expected at both the rear and midfoot. We further hypothesized that the rearfoot and medial forefoot ranges of motion during the weight acceptance phase of the step down would be increased when initial contact was made with the forefoot versus the rearfoot. Finally, we proposed that the midfoot and lateral forefoot range of motion would be decreased during weight acceptance to facilitate foot stability when initial contact was made with the forefoot.

METHODS

Participants:
15 participants (8 female, 7 male; age = 25.6 ± 5.4 years; height = 173 ± 9.7 cm; mass = 70.8 ± 13.4 kg) were recruited for the study. All subjects had weight bearing ankle dorsiflexion ROM $\geq 25°$, did not wear bifocals, and had no history of lower extremity surgery or recent injury.

Gait analysis:
A 10 camera motion analysis system was used to capture 3D positions of clusters of retroreflective markers placed on the foot and leg to define five functional articulations [Rearfoot complex (RC), Lateral midfoot (LMF), Medial midfoot (MMF), Medial forefoot (MFF), and Lateral forefoot (LFF)].

At a self-selected pace, participants walked along a level 5 m walkway, stepped down a height of 5, 10, 15, 20 or 25 cm and continued walking. After completing practice trials to establish a consistent self-selected pace 10 trials were recorded for each step height.

The calibrated anatomical systems technique was used to reconstruct 3D segment positions and orientations. Joint angles between adjacent segments were calculated using the joint coordinate system technique.

Data analysis:
Univariate RM ANOVAs were performed with five within subject factors (step height) to investigate sagittal plane RC, MMF, LMF, MFF, and LFF initial contact angles and ranges of motion during weight acceptance. Frontal plane RC, MMF, and LMF initial contact angles and ranges of motion

during weight acceptance were also calculated. Pairwise comparisons with Bonferroni adjustments were performed to investigate significant RM ANOVA results. Significance level for all tests was set at $\alpha = 0.05$.

RESULTS AND DISCUSSION

Initial contact angles
In the sagittal plane the LMF was significantly more plantarflexed at the 25-cm step compared to the 5-cm (p=0.003) and 10-cm (p=0.026) steps.

In the frontal plane, the RC at the 25-cm step was significantly more inverted than the 20-cm height (p=0.023). While at the 20-cm step the LMF was significantly less everted then at the 10-cm height (p=0.022).

Range of motion
The sagittal plane RC ROM differed significantly between the 5-cm and the 20 and 25-cm heights as well as between the 10-cm and 25-cm steps. During weight acceptance, the RC plantarflexed at the 5 and 10-cm steps but dorsiflexed at the 20-cm and 25-cm steps. The LMF went through significantly greater dorsiflexion ROM at the 25-cm step compared to the 5-cm step (p=0.008). Finally, the LFF went through significantly more dorsiflexion at the 25-cm step compared to the 5-cm (p=0.013) and 15-cm (p=0.038) steps.

The frontal plane RM ANOVA for the RC was also significant (p=0.049), however the pairwise comparisons did not show any significant differences between any of the step heights.

CONCLUSIONS

The kinematics during negotiation of a single step are influenced by step height. At higher step heights, the more inverted RC and less everted LMF initial contact positions may act to stabilize the foot during the forefoot landing. The increased RC dorsiflexion ROM during weight acceptance as height increased, was consistent with the transition from a heel to forefoot landing strategy. The increased LMF and LFF dorsiflexion ROM during weight acceptance may have been due to the ground reaction force location associated with a forefoot landing strategy. The change in landing strategy preference may be clinically relevant due to the fact that the plantarflexed position of the ankle joint during the forefoot landing strategy results in decreased bony joint stability thus placing greater dependency upon ligaments and muscles (dynamic stabilizers) of the ankle and foot. This may be especially important in groups that may have compromised strength and/or ligamentous stability such as older adults or patients with chronic ankle instability.

Foot Placement Optimization During Lateral Maneuvers

INTRODUCTION

The ability to safely maneuver through one's environment is crucial for community ambulation. However, for many impaired populations, changing direction during gait challenges both balance and endurance. The purpose of this study was to examine how changing foot placement during a simple "lane-change" walking maneuver affects performance, stability, and energetic cost. We hypothesized that as foot placement of the leading limb (the limb used to initiate the maneuver) increased from narrow (during a cross-over step) to wide (during a lateral side-step), both lateral stability and total lower limb joint work performed during the maneuver would increase. Thus, we expect a trade-off exists between stability and joint work when choosing between foot placement positions in lateral maneuvers.

METHODS

Ten healthy subjects performed overground walking maneuvers. During each maneuver trial, subjects initially walked straight for 5 meters (m) within a 0.36 m wide lane. At the end of this path, subjects were instructed to place their right foot on the ground and maneuver as quickly as possible to a parallel walking lane beginning 0.38 m left of the near border of the initial walking lane. Four conditions were tested in which the mediolateral position of the right foot placement at the maneuver location was varied. The four conditions were:

Step In – Right foot placement 0.25 m left of the center of the initial walking lane, resulting in a "cross-over" step maneuver.

Middle – Right foot placement centered laterally in the initial walking lane, resulting in a "side-step" step maneuver.

Step Out – Right foot placement 0.25 m right of the center of the initial walking lane, resulting in a "side-step" step maneuver.

Unrestricted – Lateral right foot placement was freely chosen by the subject.

All trials were performed at subjects' preferred overground walking speed. Speed was monitored via infra-red sensors to ensure consistency across conditions. Subjects practiced each condition before data were collected from five trials. Motion capture cameras recorded lower limb kinematics and force plates measured ground reaction forces.

Maneuver performance was quantified by maneuver time and peak lateral velocity. To examine lateral stability, we calculated the minimum lateral margin of stability (MoS) [1] during the gait cycles of the trailing limb (from left limb heel strike before the maneuver began to the following left limb heel strike, which was the first step within the new walking lane) and leading limb (from right limb heel strike at one of the four maneuver condition locations to the following right heel strike). A smaller MoS will increase susceptibility to external perturbations, suggesting a decrease in lateral stability. To examine mechanical energy cost, we calculated total work (sum of absolute values of positive and negative work) performed in both the frontal and sagittal planes of the hip, knee, and ankle joints of the Trailing Limb and Leading Limb. We then calculated total work performed by the lower limb by summing across all joints.

RESULTS AND DISCUSSION

As expected, step width at heel strike of the leading limb increased significantly (ANOVA; $p < 0.0001$) as foot placement became more lateral from the **Step In** to the **Step Out** conditions. **Unrestricted** step

width was not significantly different from the **Middle** condition (post hoc; p > 0.05).

Maneuver Performance
There were no significant differences between conditions for total maneuver time or peak lateral velocity during the maneuver (ANOVA; p = 0.9210 and p = 0.0510 respectively).

Lateral Stability
During the trailing limb gait cycle, there were significant differences between conditions in MoS (ANOVA, p < 0.0001) (Figure 1). For the **Step In** condition, MoS was significantly smaller than all other conditions (p < 0.05) and was negative, indicating that the extrapolated center of mass position crossed outside of the base of support during this step. There were no differences between conditions in MoS during the leading limb gait cycle (ANOVA, p = 0.2047).
Figure 1: Minimum Lateral Margin of Stability in the trailing limb across conditions. * indicates signficantly different from **Middle** condition.

Mechanical Energy
Total lower limb joint work in both the sagittal (ANOVA, p = 0.0370) and frontal (ANOVA, p = 0.0289) plane was significantly different between conditions for the leading limb, with the greatest total work done during the **Step Out** condition and least work done during the **Step In** condition (Figure 2). For the trailing limb, there were no significant differences between conditions in either sagittal

(ANOVA, p = 0.4464) or frontal (ANOVA, p = 0.8239) plane total joint work.
Figure 2: Total Sagittal Plane Work for the Leading Limb. * indicates significantly different from **Step In** condition.

CONCLUSIONS

During a simple "lane-change" maneuver, lateral foot placement of the leading limb affects both lateral stability and energetic cost. As steps become wider, both passive lateral stability and total lower limb joint work increase. Given free choice of foot placement, subjects choose a position similar to the **Middle** condition. While it would require less mechanical energy to perform a **Step In** (cross-over) maneuver and be more passively stable to use a wide **Step Out** (side-step) maneuver, subjects choose a **Middle** step position, suggesting they optimize for both stability and energetic cost. Quantifying these trade-offs in a control population informs future interpretations of data from patient populations.

THE RELATIONSHIP BETWEEN VARIABILITY AND ASYMMETRY DURING GAIT

Robert W. Gregory

Southern Connecticut State University, New Haven, CT, USA
E-mail: gregoryr3@southernct.edu, Web: http://www.southernct.edu/

INTRODUCTION

The mechanics of running have been studied extensively for the past 30 years. However, the etiology of running injuries continues to elude both researchers and clinicians; 27%-70% of distance runners can expect to be injured during any 1-year period [1]. Two factors that have recently been implicated in the development of running-related overuse injuries are movement variability and asymmetry.

Variability has been linked to the health of biological systems in a variety of contexts. This observation led to the formulation of the variability and overuse injury hypothesis: the likelihood of overuse injury is greatest at small magnitudes of variability and the potential for injury decreases as the variability increases [2]. Very high variability can also result in injury and there must be a window of 'higher variability' in which non-injured athletes function [3]. In addition, asymmetry has also been linked to overuse injuries in runners. Asymmetry in gait is often described as a difference in a kinematic or kinetic parameter between the right and left sides. While some level of asymmetry is normal in uninjured runners [4], recent research suggests that injured runners have less asymmetry than non-injured runners [5].

To date, there has been no examination of the link between movement variability and asymmetry during gait. Intuitively, it seems reasonable to hypothesize that increased levels of asymmetry will result in higher variability. Consequently, asymmetry may contribute significantly to the role of functional variability in preventing overuse injuries in runners. Therefore, the purpose of this study was to determine if there is a relationship between variability and asymmetry in recreational distance runners during walking and running.

METHODS

Thirteen healthy recreational runners (5 M, 8 F; age: 31.3 ± 11.0 yr, height: 1.69 ± 0.09 m, mass: 68.7 ± 18.6 kg) participated in this study. All participants ran at least 20 miles per week and were injury-free at the time of the study. All participants provided informed consent according to the procedures established by the Institutional Review Board at Southern Connecticut State University.

The same type of running shoe (Nike Air Pegasus 30+; Beaverton, OR) was worn by all participants. Participants walked (4 km/hr) and ran (10 km/hr and 12.5 km/hr) on an instrumented treadmill (Zebris FDM-T; Isny im Allgäu, Germany). The three conditions were presented in random order. For each condition, the participants walked or ran for six minutes. Kinematic and kinetic data were collected during the last minute of each trial at a sampling rate of 300 Hz and filtered using a 4th order, low-pass Butterworth filter with a cutoff frequency of 25 Hz.

For each participant, a minimum of 30 strides were analyzed. The following kinematic variables were measured: step length, step time, stance phase %, and swing phase %. The following kinetic variable was measured: peak vertical ground reaction force. Descriptive statistics (mean and standard deviation) were calculated for all variables. Variability was assessed using the coefficient of variation and asymmetry was evaluated as the difference in a kinematic or kinetic parameter between the right and left sides. A repeated-measures MANOVA was used to estimate the differences in variability and asymmetry for all variables across the three gait conditions; the Pearson product moment coefficient of correlation was used to estimate the relationship between variability and asymmetry for all variables for each of the three gait conditions.

RESULTS AND DISCUSSION

The results for the kinematic and kinetic variables measured in this study are shown in Table 1. The values presented are those for the right (dominant) side. There were significant increases in step length ($F_{2,24} = 112.6$, $p<0.0001$), swing phase % ($F_{2,24} = 197.1$, $p<0.0001$), and peak vertical ground reaction force ($F_{2,24} = 33.0$, $p<0.0001$) with increasing gait velocity. There were significant decreases in step time ($F_{2,24} = 64.8$, $p<0.0001$) and stance phase % ($F_{2,24} = 197.1$, $p<0.0001$) with increasing gait velocity.

Movement variability was larger during running as compared to walking for step time ($F_{2,24} = 4.62$, $p<0.05$) and stance phase duration ($F_{2,24} = 14.2$, $p<0.0001$), but smaller for swing phase duration ($F_{2,24} = 18.0$, $p<0.0001$) (see Table 1). The variability of step length and peak vertical ground reaction force did not change across gait conditions.

The levels of asymmetry for the kinematic and kinetic variables measured in this study were similar to those found in previous studies [4, 5]. Asymmetry did not vary across gait conditions for all measured parameters. While there were several exceptions, the relationship between variability and asymmetry during gait was not significant for the measured parameters (see Table 1).

CONCLUSIONS

High levels of asymmetry are typically thought to be associated with injury or gait inefficiency; symmetrical lower extremity movement patterns during running are often a goal. However, some level of asymmetry is normal in uninjured runners [4, 5]. In addition, there is a window of 'higher variability' in which non-injured athletes function [3]. Intuitively, it seems reasonable to hypothesize that increased levels of asymmetry will result in higher variability. However, there is not a strong relationship between variability and asymmetry during gait. Therefore, it is unlikely that natural levels of asymmetry contribute significantly to the role of functional variability in preventing overuse injuries in runners.

PARTIAL LEAST SQUARES FOR DISCRIMINANT ANALYSIS OF KINEMATIC AND KINETIC DATA

[1] Elizabeth A Hassan and [1] Kevin J Deluzio

[1] Dept. of Mechanical Engineering, Queen's University, Kingston, ON, Canada
email: elizabeth.hassan@queensu.ca

INTRODUCTION

Studies of human movement often demand simultaneous analysis of multiple quantities, such as joint angles and moments from several joints. Multiple comparisons can be challenging to interpret using multi-way ANOVAs or ANCOVAs. Linear discriminant analysis, in combination with Principal Component Analysis has been proposed as an improvement that allows for information from multiple complete waveforms to be analyzed [1]. This abstract proposes that additional discriminant performance enhancements can be achieved by combining Partial Least Squares with discriminant analysis.

Partial Least Squares (PLS) is a generalized form of PCA. PLS has been applied extensively to analysis of multivariate chemometric data [2] but has not yet been widely applied in biomechanical analysis. The only known applications of PLS to gait data are short examples in [3,4].

The primary difference between PLS and PCA is that PCA extracts components that explain the maximum amount of *variance* in the data (X) but PLS extract latent variables that explain the maximum amount of *covariance* between the data (X) and the grouping variable (Y). If the between group variance is larger than the within group variance, the techniques are equivalent, but if they are equal or the within group variance is large PLS is superior for group discrimination [5]. This advantage is particularly useful in cases with large subject-subject variability and when group differences are subtle, which are often the case in biomechanical analysis.

METHODS

To evaluate the performance of PLS-DA for gait compared with PCA-LDA, it was tested on an already published data set. The data set includes knee kinematic and kinetic data from 63 asymptomatic control subjects and 50 subjects with severe osteoarthritis; the details of the data collection are summarized in Deluzio and Astephen [1]. These techniques were compared using the misclassification rate, along with misclassification rates using the peak and PC scores of the knee adduction moment.

This data was preprocessed with PCA using MATLAB code written by our lab group. A 90% trace criterion was used to evaluate the correct number of components to extract. The remaining PC scores composed the data (X) matrix, with control and osteoarthritis being coded as 0-1 respectively as Y.

The PLS analysis was conducted using MATLAB code written by the author, based on the algorithm outlined in Abdi [6]. Discriminant analysis and cross-validation was conducted with built in MATLAB functions. The number of columns in X was reduced to a more parsimonious set of 5 variables using the criteria described in Andersen and Bro [7]. Model validity was checked using a randomization test in which the Y indices were randomized, according to the procedure described in Szymanska et al [8].

RESULTS AND DISCUSSION

The PLS procedure described above yielded 2 Latent Vectors, (LVs) extracted from 5 input variables (X columns). Using the scores of these two LVs, it was possible to separate the groups with

a linear discriminant function, as shown in Figure 1. The misclassification rate was 7% using a leave one out procedure, which is equivalent to that achieved by Deluzio and Astephen [1], 8%, but both techniques were much better than peak knee adduction moment alone, or a single set of principal component scores, as shown in Figure 2. The variable selection procedure resulted in similar variables being identified as most important to the prediction as shown in Table 1.

With PLS analysis, the selection of number of inputs to include and number of variables to extract can be somewhat subjective. In this analysis, we evaluated the discriminant performance over a range of possible inclusion criteria and found that for this data set, the performance is similar over the range of 3 to 13 input variables, ranging from 5.3 to 10% misclassification, and chose 5 variables as being close to the approach in the original paper [1]. Extracting a third LV did not improve the prediction; therefore the analysis used two LVs for parsimony.

CONCLUSIONS

The results of the PLS and LDA analysis suggests that PLS as a processing step prior to LDA can at least equal that of PCA-LDA, but with the advantage of automatic variable selection. In cases of highly collinear data, this selection process is likely more stable than stepwise procedures, and the extracted PLS latent variables are orthogonal, which is the ideal case for LDA performance. Additionally, there are opportunities for enhanced interpretation, which will be discussed in future work.

Table 1: Comparison of variable importance extracted from PCA-LDA and PLS-LDA

PCA-LDA [1]	PLS-LDA (Current Analysis)
Flexion Moment PC2	Flexion Moment PC2
Flexion Angle PC2	Flexion Angle PC2
Flexion Moment PC1	Adduction Moment PC1
Adduction Moment PC1	Adduction Moment PC2
	Flexion Angle PC1
Figure 1: Each point corresponds to one observation's scores of that observation on the two extracted latent variables. Blue dots are normal subjects, red are severe OA. The linear discriminant function is shown as a black dashed line. Misclassification rate 7%.
Figure 2: Misclassification rate based on leave one out procedure for peak, PC1 and Pc2 scores of the knee adduction moment, the rate quoted by Deluzio and Astephen for PCA-LDA and PLS-LDA with variable selection.

FOOT DISSIPATION DURING ANKLE PUSH-OFF: HUMAN WALKING INSIGHTS FROM A MULTIARTICULAR EMG-DRIVEN MUSCULOSKELETAL MODEL

Eric C. Honert, Karl E. Zelik

Vanderbilt University, Nashville, TN, USA
eric.c.honert@vanderbilt.edu, karl.zelik@vanderbilt.edu

INTRODUCTION

Humans perform a burst of push-off work with their trailing limb during the step-to-step transition in walking. This push-off helps redirect the body's center-of-mass, reducing collisional energy losses after heelstrike and enabling economical gait [1]. However, the foot performs negative work during this phase of gait [2], which counteracts a fraction of the positive push-off work of the ankle. These conflicting ankle and foot behaviors are difficult to reconcile with previous findings on energy-saving mechanisms used during gait, and dynamic walking principles emphasizing the importance of center-of-mass push-off [1].

This study sought to investigate one plausible explanation for the conflicting ankle and foot behaviors during push-off. We hypothesized that our current understanding of ankle and foot function is obscured by methodological limitations in commonly-used biomechanical estimates. A key assumption in inverse dynamics and other segment-based kinetics estimates [2] is that joint moments and powers originate from monoarticular sources (e.g., muscle-tendon units). These estimates do not account for multiarticular muscles, such as the flexor digitorum and hallucis longus (FDHL) muscles, which articulate across the ankle and toe joints.

The purpose of this study was two-fold. First, we sought to develop a data-driven musculoskeletal model of the ankle and foot that allowed us to approximate muscle-specific contributions to gait. Second, we aimed to estimate the magnitude of work and power errors that may be inherent in conventional biomechanical estimates which neglect multiarticular muscles, and determine if these errors might impact our current interpretation of ankle and foot function during push-off in walking.

METHODS

Three healthy male subjects (24±5 years, 88±14 kg, height: 1.8±0.1 m) participated in this gait analysis study. All subjects gave informed consent to the protocol. Subjects walked at 1.25 m/s on a split-belt instrumented treadmill (Bertec). Six degree-of-freedom kinematics and kinetics of the shank and foot were derived from a ten camera motion tracking system (Vicon) in conjunction with post-processing via C-Motion Visual3D. Prior to walking, four surface EMG sensors (Delsys) were placed on muscles that contribute to ankle plantarflexion: soleus, medial gastrocnemius, lateral gastrocnemius, and the FDHL (measured together due to limitations in surface EMG). Marker and force data was filtered at 10 Hz and 25 Hz, respectively. EMG data was demeaned, high-pass filtered at 150 Hz, rectified, and low-pass filtered at 10 Hz. All filters used were 3rd order, zero-lag Butterworth filters.

We developed a sagittal plane musculoskeletal model in order to estimate the individual ankle and foot muscle contributions to push-off during walking. To do so, we used a simple EMG to force mapping algorithm and integrated it with conventional gait analysis measurements, using techniques and simplifying assumptions similar to previously published musculoskeletal models [3, 4].

To estimate the potential errors in conventional ankle and foot power calculations due to neglecting multiarticular muscles, we assumed the FDHL muscle-tendon units performed no mechanical work. In other words, we assumed the multiarticular FDHL acted isometrically during push-off, effectively like a cable across the ankle and toe joints. Using our model we then computed how much the FDHL contributed to the conventional ankle and foot power calculations (i.e., the inaccuracy error inherent in

these measures if the multiarticular muscle were acting isometrically). Subtracting these multiarticular power contributions from the conventional ankle and foot estimates yielded updated estimates for ankle and foot power, which may better reflect the underlying physiology.

RESULTS and DISCUSSION

We found that our EMG-driven musculoskeletal model was able to reproduce inverse dynamics based sagittal plane ankle power with high fidelity ($R^2 = 0.98 \pm 0.01$, Fig. 1A).
Figure 1: Ankle power at 1.25 m/s for one subject. (A) EMG-Driven Model power reproduced the sagittal plane inverse dynamics estimate. (B) Muscle group contributions to plantarflexion power based on EMG-Driven model. The FDHL are the multiarticular muscle tendon units acting about both the ankle and toe joints.

Next, we estimated the errors that might results from neglecting the multiarticular ankle-toe (FDHL) muscles in inverse dynamics. We found that inverse dynamics may over-estimate sagittal ankle push-off work by about 1.9 ± 0.9 J (Fig. 1B: area under FDHL muscle tendon unit power curve), or about 6% of ankle push-off work, at 1.25 m/s.

We also discovered that the foot may not dissipate as much energy as previously estimated (Fig. 2). On average, we found that there is -9.3 vs. -10.5 J (updated vs. conventional estimate) of negative foot work during push-off, and 2.2 vs. 1.5 J of positive foot work during push-off at 1.25 m/s.
Figure 2: Updated Estimate of foot power was calculated by subtracting the multiarticular muscle tendon unit power (FDHL assuming isometric contractions) from the Conventional foot power estimate based on a deformable foot model [2].

The musculoskeletal model presented provides an estimate of muscle-specific power contributions to ankle plantarflexion push-off during walking, which can then be used to account for multiarticular muscle function. Preliminary findings suggest that the positive ankle work may be over-estimated, and positive foot power under-estimated, by about 1.9 J. Rather than purely dissipating energy during push-off, these findings suggest that the foot may also undergo a cycle of viscoelastic energy storage (~9 J) followed by energy return (~2 J), which may have implications for prosthetic foot design. However, the foot still appears to absorb more energy during push-off than it returns as positive work in terminal stance. This simple musculoskeletal modeling approach provides an updated estimate of muscle-specific contributions to gait, and could potentially be applied to other joints to improve our fundamental understanding of biological movement.

ACCURACY OF RUNNING DATA FROM THE GARMIN FORERUNNER

Iain Hunter, James Tracy, Shaquille Walker, and Jordan Eatough

Brigham Young University, Provo, UT, USA
email: iain_hunter@byu.edu, web: http://biomechanics.byu.edu

INTRODUCTION

Measurements of running mechanics are prevalent in a variety of studies [1]. Recent advances in running watches have provided increased possibilities for obtaining data related to the mechanics of running. The Garmin Forerunner 620 (GF) with heart rate monitor (HRM) displays and stores stride rate (SR), vertical oscillation (VO), ground contact time (GT), heart rate, distance, pace, and elevation. As with any new technology, these data will only be useful if they are correct.

Typically, the measurements listed above are recorded in a lab setting on a treadmill. If the Garmin watch provides accurate data, these measurements will be available for running outside of a lab where speed is not constrained, surfaces are not fixed, and a more natural environment can be used for data collections.

This study performed a comparison between the GF and a Vicon Nexus motion analysis system in measuring stride rate, ground contact time, and vertical oscillation.

METHODS

A Garmin Forerunner 620 with a heart rate/accelerometer strap was attached to each of 8 experienced runners. They ran at five speeds including: 3.35, 3.84, 4.47, 5.36, and 6.70 m/s (8:00, 7:00, 6:00, 5:00, and 4:00 per mile paces). The running was completed on a force instrumented treadmill (AMTI, Watertown, MA).

While running, measurements were taken using motion capture software (Vicon Nexus 2.1, Oxford, UK) running at 250 Hz. The Vicon Plug-in Gait model provided positions of the feet and center of mass which were used for calculating the same

parameters that the GF exported (stride rate, ground contact time, and vertical oscillation).

After a three minute warm-up, subjects ran at each speed in the order listed above for 30s. During the final 20s of each stage, measurements were simultaneously recorded from both the watch and Vicon system. Ground time was measured through the motion analysis software by observing the ground reaction forces and positions of the feet. Vertical oscillation was taken from the low to high points of the center of mass within each step using the outputs from the Plug-in Gait model. Stride rate was measured from foot-strike events. The GF reported these same measurements using the accelerometers in the watch and chest strap. The methods of calculation used in the GF are understandably not documented; therefore, it is not possible to explain here how GT and VO are calculated.

Three univariate ANOVA were completed (one for each dependent variable) with condition and speed as fixed factors.

RESULTS AND DISCUSSION

The Garmin Forerunner 620 matched the motion capture system very well on stride rate. However, it overestimated ground contact time and vertical oscillation by 15% and 20% respectively (Figure 1 and Table 1). This is encouraging for those interested in using the GF for research purposes outside of a lab setting as improvements come in future software and hardware releases of the GF.

There were no significant interactions for condition by speed. This tells us that the differences between the GF and the motion analysis system are not different between different speeds. So, if a method can be determined for adjusting the output at one

speed, the same adjustment should be possible across all speeds. Since this is the first device to perform these measurements, the GF may be improved over time to become more accurate.
Figure 1. Average stride rate, ground time, and vertical oscillation between conditions.

The expected trends of stride rate, ground time, and vertical oscillation with increases in running speed were observed with the GF. So, even if the values of each measurement from the GF are not exactly correct, they were increasing or decreasing with speed in the same pattern as the motion capture data showed.

This study did not collect enough measurements for an investigation into the variability of the GF data. However, it is possible that since the variability of certain running characteristics increase with fatigue,

the watch may be useful for analyzing how variable these measures are as a run progresses. Over a 20-s measurement, a good understanding of the variability of the steps could not be completed. Future studies could investigate how well the watch estimates variability of the outputted measurements over extended running for studies [2]. That would serve as a method for using the watch outside of a lab setting for extended running.

It is possible that with additional information from the GPS signal, providing a more accurate pace estimation, may improve that ground contact time and vertical oscillation estimations. Since this study was performed in an indoor laboratory, an outdoor setting might lead to more accurate data.

CONCLUSIONS

The Garmin Forerunner 620 with HRM is accurate at measuring stride rate, but overestimates ground contact time and vertical oscillation. The overestimations are often by a consistent percentage, but not in every case. As a research tool, the potential is there for accurate data in the future, but some improvements are still needed.

INTRODUCTION

Patients with unilateral transtibial amputation often exhibit asymmetries in their gait pattern, even after receiving gait training during their rehabilitation [1-2]. Asymmetries have been associated with increased risk of back pain, as well as knee pain and osteoarthritis of the intact limb and osteoporosis in the affected limb [2-4].

Previous work involving individuals with amputation has shown that stance time asymmetry feedback using a force treadmill is effective at improving symmetries during a single session of walking [5]. While gait retraining using real-time feedback from a force treadmill may be effective, these treadmills are cost prohibitive for most clinics. A low-cost, mobile system would be more suitable for clinical- as well as home-use.

Accelerometers which communicate via Bluetooth are becoming readily available and have the potential to be used in the community. However, the accuracy of the information from these devices compared with that from an instrumented treadmill is unknown. Therefore, as a first step, the purpose of this study was to determine whether accurate unilateral stance times could be obtained from acceleration data using an instrumented treadmill as the standard.

METHODS

Five healthy individuals (age: 24.8±4.3yrs; height: 1.75±0.1m; mass: 73.0±15.3kg) walked normally for 1 minute at four speeds (1, 1.2, 1.4, and 1.6 m/s) on an instrumented treadmill (AMTI Inc., Watertown, MA) wearing standard lab shoes (Nike Air Pegasus). One marker placed on the lateral aspect of the right forefoot was used to determine right from left ground reaction forces. Force (1,000Hz) and marker (100Hz) data were collected using the same system (Vicon Motion Systems Ltd., Oxford, UK).

Force data were filtered using a 45Hz low pass, zero-phase shift Butterworth filter. A dual linear fit algorithm was used to determine force-based foot strike and toe off events. The dual linear fit algorithm iteratively fits a straight line to data just before and after potential event samples. The sample at which these two lines have the lowest residuals becomes the event index.

A tri-axial accelerometer (IMeasureU, Auckland, NZ) collecting at 1,000Hz to an onboard SD card was placed on the medial distal tibia (Fig. 1). A custom algorithm was developed to identify patterns in the x-component of the acceleration data corresponding to heel strike and toe off (Fig. 2). The x-axis of the accelerometer is approximately aligned with the anterior-posterior axis of the shank.

Figure 1: Accelerometer placed on the distal tibia.

Before walking, subjects tapped their heel on the front belt of the treadmill. This provided a clear spike in both the acceleration and force data for time synchronization. Stance times computed from the force data were compared to corresponding stance times computed from the acceleration data.
Figure 2: Synchronized vertical ground reaction force (orange), which used the dual linear fit (DLF) model to determine heel strike and toe off events, and x-component acceleration (blue) for 10 seconds of walking for a subject.

RESULTS AND DISCUSSION

1029 stance times were compared over a total of 20 1-minute walking trials (5 subjects x 4 speeds; Fig 3). 969 of the 1029 (94.2%) matched force- and accelerometer-based stance times were less than 3% different from each other. The mean stance time difference was 6±9.5ms while the mean absolute stance time difference was 11±7.9ms. The two measurement techniques were also highly correlated, having a 99% confidence interval for the criterion-referenced reliability interclass correlation of [0.956, 0.996].
Figure 3: Scatter plot of all compared stance times. Subjects are color-coded while speed is indicated by symbol. Lines indicating an exact match as well as ±3% difference from force-based stance time calculation are also shown.

The acceleration-based stance time algorithm was not able to determine stance times for only 5 of 1034 possible steps (all for Subject 4). Subject positioning on the treadmill resulted in force-based stance time data not being available for 3 steps.

It is important to note that this investigation was done with a convenient sample of healthy individuals on an instrumented treadmill. It is not known if this algorithm would be robust enough for the ambulation of individuals with amputation. Further, instrumented treadmills inherently produce noisy data. Force data were filtered and a dual linear fit model was used to determine stance times as accurately as possible, but even these times could include some level of error.

Determining accurate stance times using an accelerometer is the first step in developing a clinically viable mobile system that provides feedback to improve stance time symmetry. This type of feedback system will have clinical- and home-use applications to a broad range of individuals, including those with amputations and total joint replacements.

CONCLUSIONS

Stance times calculated using an accelerometer attached at the ankle are highly correlated with stances times calculated using force data from an instrumented treadmill.

QUANTITATIVE ASSESSMENT OF MOVEMENT SMOOTHNESS DURING EMOTIONAL GAIT

Gu Eon Kang[1,*] and Melissa Gross[1]

[1]University of Michigan, Ann Arbor, MI, USA
*Email: guekang@umich.edu

INTRODUCTION

Emotion changes movement pattern. Movement smoothness is one such thing that is likely to be altered by feeling emotions. The effect of emotion on movement smoothness has been assessed in gestural movements [1], and more energetic gestures (angry and happy) were correlated with greater jerk than less energetic gestures (sad), as might be expected since jerk was not normalized. Recently, jerk analysis (normalized for movement duration and amplitude) has been applied to the whole body center-of-mass (COM) and movement smoothness has been quantified during sit-to-walk performed with emotions [2]. The study reported jerkier sit-to-walk for sadness than for anger or joy. Emotional gait is associated with alterations in kinematics [3] but movement smoothness has not yet been quantified. The purpose of this study was to examine the effect of emotion induced by autobiographical recall on movement smoothness during gait. We quantified movement smoothness during emotional gait using jerk analysis.

METHODS

Eighteen healthy adults (11 women; 20 ± 2 years; 167 ± 7 cm) participated after giving informed consent. Gait data were collected from 41 markers using an 8-camera motion capture system (60 Hz), and were low-pass filtered (6 Hz).

For each gait trial, we asked participants to recall autobiographical episodes for inducing four target emotions: joy (high arousal, positive), anger (high arousal, negative), sadness (low arousal, negative), and neutral emotion. After recalling each emotion, participants walked across the laboratory (10 m). Participants performed three trials with each emotion in a block. After each trial, they rated the intensity of the four target emotions that they felt in the preceding trial using a 5-point Likert scale (0, 1, 2, 3 and 4). Angry, sad and joyful trials were trials with score ≥ 2 for anger, sadness and joy, respectively. Neutral trials were trials with neutral emotion with score ≥ 2, and anger, sadness and joy with score < 2.

We used Visual3D software to compute gait parameters, linear jerk for the whole body COM, head, and wrist in antero-posterior (AP), medio-lateral (ML) and vertical (VT) directions, and angular jerk for the hip, knee and ankle in the sagittal plane during one gait cycle. For normalizing jerk, the sum of the squares of jerk was multiplied by the fifth power of gait duration, and was divided by two and the second power of linear or angular displacement covered during the gait duration. Finally, linear jerk score (NJS) and angular jerk score (AJS) were considered as the square root of the normalized jerk [4]. A higher jerk score indicated a more jerky movement.

A mixed model with random effects of participants and fixed effects of emotion and gender was used to evaluate effects on outcomes. Bonferroni correction was applied for post-hoc pairwise comparison between emotions and genders ($p < .05$).

RESULTS AND DISCUSSION

Gait parameters differed among the target emotions (all $p < .001$). Pairwise comparison indicated that gait parameters differed between neutral emotion and the high arousal emotions (joy and anger), and between sadness and the high arousal emotions (all $p < .05$) (Table 1). Between sadness and neutral emotion, only cadence was different ($p < .05$) (Table 1). Cadence was greater for women (59.9 strides/min) than for men (55.4 strides/min) ($p < .01$).

Both NJS and AJS differed among the target emotions (all $p < .01$). Head AP-NJS was greater for sadness than neutral emotion ($p < .05$) (Table 1). COM and head AP-NJS and VT-NJS, wrist VT-NJS, were greater for sadness than anger and joy (all $p < .05$) (Table 1). Lower limb AJS was also greater for sadness than anger ($p < .05$). Head ML-NJS was greater for women (1505) than for men (1209) ($p < .05$).

CONCLUSIONS

Emotion induced by autobiographical recall was associated with changes in movement smoothness during gait. Our findings demonstrated that linear movement of the whole body COM and head in AP and VT directions, and linear movement of the wrist in the VT direction was jerkier for sadness than for anger and for joy. Angular movement of the lower limb in the sagittal plane was jerkier for sadness than for anger. To our knowledge, this is the first to quantify movement smoothness during emotional gait. In line with a recent study [2], this study confirmed the importance of assessing movement smoothness in embodiment of emotion.

OBESITY IS ASSOCIATED WITH INCREASED JOINT TORQUES AND RELATIVE EFFORT DURING GAIT: PRELIMINARY FINDINGS

INTRODUCTION

Obesity has been linked to altered gait kinematics and kinetics. For example, individuals who are obese walk with less hip and knee flexion and more ankle plantar flexion during stance [1]. They also exhibit higher hip and knee extensor torques [2], and higher ankle plantar flexor torque [1, 2]. Increased joint loading with obesity may increase the risk of musculoskeletal pathology.

Altered lower extremity strength may explain the differences in gait kinematics and kinetics between obese and healthy-weight individuals [2]. To better understand the importance of lower extremity strength during gait, earlier work investigated relative effort, or joint torques expressed as a percentage of maximum available joint torque [3]. Higher relative effort among obese individuals may help explain their altered gait.

To better understand the obesity-related changes in joint load during gait, and to assess the importance of muscle strength, the purpose of this study was to investigate whether and to what extent lower extremity joint torques and relative effort during gait differ with obesity.

METHODS

Participants included seven healthy-weight (HW, age: 22.3 ± 3.4 years, BMI: 22 ± 2 kg/m^2) and seven obese (OB, age: 23.6 ± 3.8 years, BMI: 31.7 ± 3.8 kg/m^2) females. Participants with any self-reported history of neurological, cardiac, or musculoskeletal disorders were excluded from the study.

Gait trials were performed at a self-selected speed on a 10-meter walkway. Ground reaction forces were sampled at 1000 Hz from a force platform (Bertec Corporation, Columbus, OH) embedded in the middle of the walkway, and kinematics were sampled at 100 Hz using a six-camera motion analysis system (MX-T10, Vicon Motion Systems Inc., L.A, CA).

Strength measures included isometric and isokinetic (concentric and eccentric) maximum voluntary contractions (MVCs) of the right lower extremity. Torques were sampled at 200 Hz using a Biodex System 3 dynamometer (Biodex Medical Systems, Inc., Shirley, NY), in plantar flexion (PF), dorsiflexion (DF), knee extension (KE), knee flexion (KF), hip extension (HE), and hip flexion (HF).

A sagittal plane, rigid-link model was created, and inverse dynamics analysis was used to estimate resultant joint torques at the ankle, knee, and hip during the stance phase of gait. Relative effort was determined using the method reported by Anderson and Madigan (2014) [3]. At the instants of peak torques, relative effort was calculated as:

$$Relative\ Effort = \frac{T}{A + P} \times 100$$

where T is the peak resultant joint torque, and A and P are the respective active and passive components of available strength determined using a model relating joint torque, angle, and angular velocity [4, 5]. Peak absolute torques and relative effort were compared between groups using unpaired t tests. Statistical analyses was performed using JMP Pro 10 (SAS Institute, Inc., Cary, NC).

RESULTS AND DISCUSSION

Joint torques (Figure 1) and relative effort (Table 1) during gait differed with obesity. Peak torques were higher for the OB group in HF (30%; $p=0.011$), KE (101%; $p=0.006$), and PF (53%; $p<0.001$). Relative effort during gait was 70% higher in KE ($p=0.033$; Table 1). The mean gait speed was 1.33 m/s, and did not differ between groups ($p=0.071$).
Figure 1: Ensemble averaged sagittal plane torques during stance for OB (dashed) and HW (solid) participants. Positive values are flexor/dorsiflexor torques and negative values are extensor/plantar flexor torques.

The higher HF torque among obese participants during gait has not been reported previously, though the higher knee extensor torque in this group is consistent with earlier evidence [2], as is the higher plantar flexor torque [1, 2]. In general, the current findings suggest that obese individuals walk with higher joint loads.

The higher KE relative effort among obese participants, despite them having higher KE absolute strength [6], suggests that obese individuals are more likely to be limited by knee extensor strength during gait. Furthermore, high muscle forces to produce large KE torques may increase knee loading beyond the increase due to higher weight. The large (>1) value for PF relative effort in both healthy-weight and obese groups suggests that both groups walk near the limits of their available PF strength during gait.

This large PF relative effort, though, may have been influenced by participants not generating true maximum strength during strength measurements or to underestimation of maximum available torque using the torque model.

Table 1: Peak Torque (Nm) and Relative Effort (mean ± SD)

	Peak Torque during gait (Nm)		Relative Effort	
	HW	OB	HW	OB
HE	49.3±19.1	61.1±19.2	0.51±0.31	0.55±0.24
HF	53.4±9.5	69.8±10.9*	0.61±0.17	0.59±0.09
KE	27.1±14.8	54.6±15.9*	0.5±0.26	0.85±0.28*
KF	18.3±5.7	24.2±15.7	0.4±0.16	0.53±0.33
PF	92.9±14.2	142.3±18.5*	1.29±0.36	1.93±0.74
DF	13.5±6.3	14.1±5.3	0.45±0.17	0.4±0.18

* indicates a significant difference between HW and OB groups ($p<0.05$)

CONCLUSIONS

Obese individuals exhibited higher joint torque at HF, KE, and PF which suggests elevated joint loads in this group. Furthermore, higher KE relative effort among obese individuals may indicate greater likelihood of gait limitations due to KE strength, as well as excessive knee loading that can adversely affect the knee joint.

KNEE JOINT MOMENTS DURING SINGLE-LEG FORWARD HOPPING

Rebecca L. Krupenevich and Ross H. Miller

University of Maryland, College Park, MD
Email: rlkrup@umd.edu

INTRODUCTION

Hopping is not often performed by healthy adults, but is common in amputees when not wearing their prosthetic leg, and in individuals who have their leg in a cast. Many physicians advise against hopping for ambulation in lower-extremity amputees, but recognize that in some situations it is unavoidable, for example, when maneuvering around the home before being fitted for a prosthesis [1], or simply when wearing the prosthesis is not convenient.

The prevalence of knee osteoarthritis (OA) in the intact limb of lower-extremity amputees is nearly twice that of non-amputees [2]. Increased loading of the intact limb is thought to be a contributing factor to the higher rate of OA in amputees compared to non-amputees [2]. However, to our knowledge there have been no studies investigating knee joint loading during single-leg forward hopping, in any population. Therefore, assessing the loads on the knee joint during single-leg forward hopping would enable us to make recommendations on whether frequent single-leg hopping is safe and healthy for the knees.

The purpose of this study was to compare the knee joint mechanics, specifically frontal and sagittal plane joint moments, of healthy adults during walking, running, and single-leg forward hopping. We hypothesized that knee joint moments would be greater in hopping than in walking or running.

METHODS

Six healthy adults (2 males, 4 females) participated after giving written informed consent. Participants completed three different locomotion conditions: running for three minutes at 3.0 m/s and walking for five minutes at 1.0 m/s around a 50-m indoor track, and three trials of hopping forward on one leg across a 12-m platform at 2.0 m/s. The target speeds were chosen because they were close to self-selected speeds in pilot testing.

Kinematic data were captured using a 12-camera Vicon motion capture system, and force data were captured using eight Kistler force plates embedded in the platform. Knee joint moments were calculated by inverse dynamics using Visual3D. A one-way repeated measures ANOVA ($p < 0.05$) tested for the effect of locomotion condition on the external knee adduction moment's (KAM) peak, impulse, and loading rate (LR), and the peak knee flexor moment (KFM). These variables were selected due to their prior association with OA [3-5]. Post-hoc testing was performed using Tukey's LSD.

RESULTS AND DISCUSSION

Average performed speeds for each condition were: hopping (1.93±0.11 m/s), running (2.87±0.05 m/s), and walking (0.99±0.08 m/s). Average stride lengths were: hopping (0.88±0.25 m), running (1.80±0.30 m), and walking (1.01±0.30 m). The mean values of joint moment time series for all locomotion conditions are presented in Figure 1.

The ANOVA revealed a main effect for locomotion condition on all outcome variables, with several significant post-hoc differences, all with $p < 0.01$:

For KAM impulse
- Between hopping and running (0.92±0.31 vs. 0.54±0.18 %BW*Ht*s)

For peak KAM
- Between hopping and running (4.44±2.06 vs. 2.48±0.89 %BW*Ht)
- Between hopping and walking (4.44±2.06 vs. 2.57±0.39 %BW*Ht)

For peak KFM
- Between hopping and running (20.02±3.99 vs. 17.2±2.96 %BW*Ht)
Figure 1: Mean joint moments for the sagittal (top) and frontal (bottom) planes during the stance phase. Positive values are external flexor or adduction moments.

- Between hopping and walking (20.0±3.99 vs. 3.98±1.26 %BW*Ht)
- Between running and walking (17.2±2.96 vs. 3.98±1.26 %BW*Ht)

For KAM LR
- Between hopping and walking (0.52±0.14 vs. 0.25±0.04 BW*Ht/s)
- Between running and walking (0.40±0.05 vs. 0.25±0.04 BW*Ht/s)

Hopping therefore increased the assessed features of the knee joint moments (peaks of KFM and KAM, impulse of KAM, and KAM LR) compared to walking and/or running. Peak KFM, peak KAM, and KAM impulse have been previously associated with the longitudinal initiation and/or progression of knee OA [3,4], and KAM LR has been associated

cross-sectionally with poorer tibiofemoral cartilage health scores [5]. These differences in moments would presumably be manifested internally as increased or otherwise abnormal mechanical loading of the articulating tibiofemoral surfaces. In particular, the rapid horizontal starting and stopping motion of hopping likely places high shear forces on the knee, especially if the compressive loading presumably reflected by these joint moments is also high.

The relatively high risk of OA in intact limb of amputees is thought to result from increased loading due to overreliance on this limb in performing activities of daily living. Therefore, hopping as a form of ambulation may contribute to the development of knee osteoarthritis by placing loads on the cartilage that it is not accustomed to sustaining, and warrants further investigation in the amputee population.

CONCLUSIONS

Single-leg hopping is often performed by lower-extremity amputees when ambulating without a prosthesis. However, hopping places large loads on the knee joint, and increased knee joint loading may be a contributing factor in the development or progression of knee OA. Therefore, it may be advisable to limit single-leg hopping as a form of locomotion in amputees.

MECHANICAL WORK PERFORMED BY THE LEGS OF CHILDREN WITH HEMIPLEGIC CEREBRAL PALSY

James E. Gehringer and Max J. Kurz

Munroe Meyer Institute, University of Nebraska Medical Center, Omaha, NE, USA
Email: mkurz@unmc.edu, web: http://www.unmc.edu/mmi/

INTRODUCTION

Cerebral palsy (CP) results from a brain insult that occurs before or slightly after birth. Children with CP who have a hemiplegic presentation have an insult that affects one hemisphere of the brain, which results in more noticeable impairments on one side of the body. Prior experimental work has shown that the impaired leg of these children generates uncharacteristic external mechanical work for redirecting and lifting the center of mass during gait [1,2]. It has been suggested that the atypical external mechanical work may be the reason that these children often have a greater metabolic cost for walking than their typically developing peers. Although these insights are enlightening, we still have limited understanding on the mechanical work performed by the individual joints of the impaired and unimpaired legs during the double and single support phases. Fulfilling this knowledge gap may provide further insight on which joints are producing a greater positive work for a higher metabolic cost. Furthermore, these new insights may help in the design of physical therapy paradigms that are directed at improving the gait efficiency of these children. The purpose of this investigation was to evaluate the mechanical work performed by the individual joints of the impaired and unimpaired legs of children with CP who have a hemiplegic presentation.

METHODS

15 children with CP who had a spastic hemiplegic presentation (Age = 10.1 ± 2 yrs.) and a Gross Motor Function Classification Score (GMFCS) level of II participated in this investigation. All of the children routinely wore prescribed ankle-foot-orthosis (AFO) for community ambulation, but did not require an assistive mobility device (*i.e.*, forearm crutches, wheeled walker). For the experiment, the children walked barefoot at a self-selected pace along a 16-meter walkway as the three-dimensional bilateral lower extremity joint kinematics were captured with an 8-camera motion capture system (120 Hz). Concurrently, a series of four force platforms were used to measure the ground reaction forces for the individual legs (1200 Hz). Inverse dynamics were used to calculate the respective joint moments during the stride, and the joint powers were calculated from the product of the joint moments and joint angular velocities. The positive and negative mechanical work performed by the ankle, knee and hip joints was calculated by integrating the respective power curves. The calculated mechanical work was normalized by the child's body mass.

The net mechanical work performed by the impaired and unimpaired legs was evaluated separately during the double and single support phases. This involved summing the positive and negative work during the respective phase. During double support, the mechanical work was evaluated when the leg was in either the lead or trailing positions. The lead position indicated that the leg was in a position ahead of the center of mass during double support, while the trail position indicated that the leg was in a position behind the center of mass during the double support. Separate repeated measures ANOVAs (Leg X Joint) were used to evaluate the mechanical work performed during the single support phase, and double support phase when the leg was in the lead or trail positions.

RESULTS & DISCUSSION

During double support, we did not find a Leg main effect for the mechanical work performed by the impaired and unimpaired legs while they were in the lead position. This indicated that the negative work performed by the respective legs was similar ($P= 0.70$; Unimpaired = -0.03 ± 0.01 J/Kg; Impaired= -0.04 ± 0.01 J/kg). As the lead leg, the ankle and knee of both the legs produced negative mechanical work,

while the hip generated positive work. However, we did not find a significant Leg x Joint interaction (P=0.12), indicating that the mechanical work performed by the joints of the respective legs were similar in the lead position.

There was a significant Leg main effect for when the legs were in the trail position during double support (P=0.004; Unimpaired = 0.24 $\pm$ 0.03 J/kg; Impaired = 0.10 $\pm$ 0.01 J/kg), indicating that the unimpaired leg produced more positive work than the impaired leg. We also found a significant Leg x Joint interaction (P<0.001). Our follow-up post-hoc analyses indicated that the ankle (P=0.002) and hip (P=0.0002) joints of the unimpaired leg produced more positive work than the impaired leg. In addition, the knee joint of the unimpaired leg also generated more negative work than the impaired leg (Figure 1, P= 0.0002).

We did not find a significant Leg main effect during the single support phase (P=0.645), which indicated that the positive work produced by the unimpaired and impaired legs was similar (Unimpaired = 0.12 $\pm$ 0.04 J/kg; Impaired = 0.10 $\pm$ 0.03 J/kg). During single support, the ankle and hip of both legs produced positive work, while the knee generated negative work. Despite these observations, we did not find a significant Leg X Joint interaction (P=0.093), indicating that the work produced by the joints of the respective legs was similar during single support.

Our results show that the primary differences in the mechanical work performed by the impaired and unimpaired legs occurred during double support when the respective legs were in the trailing position. The unimpaired leg produced 58% more positive work than the impaired leg while acting as the trailing leg during double support. Evaluating the amount of positive work performed by the respective joints indicates that the difference in the amount of positive work performed was primarily due to the ankle joint, and secondarily due to the knee and hip. We suspect that the larger amount of positive work performed by the unimpaired leg likely represents a compensation strategy that was used to offset the diminished positive work performed by the impaired leg during the preceding double support phase. Potentially, this compensation strategy may play a large role in the higher metabolic cost seen in children with CP who have a hemiplegic

presentation. We suggest that gait training strategies that focus on improving the work performed by the muscles of the impaired leg while in the trailing position of double support may improve the gait efficiency of these children. Possibly this may be accomplished with similar biofeedback devices that have been successfully used to improve the double support propulsive forces generated by the legs of the elderly [3].
Figure 1: Mechanical work performed for each leg as the trail leg during double support. Blue = Impaired Leg, Orange = Unimpaired Leg. Asterisk signifies P $\leq$ 0.05.

Many of the participating children wore AFOs on their impaired leg during their daily ambulatory activities. We selected to not have the children wear their AFOs during our experiment to eliminate the potential differences in the AFO construction on the mechanical work performed by the joints. It is possible that the mechanical work profiles seen in this investigation may be quite different and beneficial if the children wore their AFOs. However, we are somewhat cautionary with these speculations because many of the AFO designs used by the children included a plantarflexion stop that may further hinder the positive mechanical work produced by the impaired ankle while in the trailing leg position. This may require the contralateral leg to produce even more positive work during the double support phase. These speculations remain to be challenged by future investigations on the mechanical work produced by children with CP.

THE EFFECT OF SHOE HEEL ELEVATION ANGLE ON STRIKE PATTERN

INTRODUCTION

Running is a very popular physical activity that has many cardiovascular and muscular health benefits, but running can also be a source of musculoskeletal injuries such as stress fractures that are mainly caused by repetitive high vertical impact [1].

A possible contributor to running related stress injuries is the foot strike pattern. Previous barefoot running studies have consistently shown that rear foot strike patterns induced greater vertical impact peaks and vertical ground reaction force loading rates (LR) to the skeletal system when compared to a more midfoot or forefoot strike pattern. However, the efficacy of altering shoe structure to change foot strike patterns, vertical impact peaks, and LR during shod running is not as clear [2].

Previous studies have found that heel height and heel drop seems to be a critical factor in altering running behavior; however, these studies examined heel height and heel drop independently of each other, while ignored heel elevation angle. The heel elevation angle (HEA) is important because the heel height and heel drop do not take into consideration the shoe size, which will affect the overall angle of the shoe [3,4].

To the best our knowledge, the HEA has never been studied regarding its influence on the running behaviors. The goal of this study was to investigate the influence of HEA on strike index (SI), foot strike angle (FSA), anatomical foot angle (AFA), and loading rate (LR). See Methods for details of these measures.

METHODS

Nine female volunteers between 18 to 28 years of age (shoe size = 235 mm) participated in the study. All subjects were healthy habitually shod rearfoot strikers without any history of neuromuscular disorders, who ran at least twice a week for a total weekly distance of at least 16 km.

Four pairs of customized shoes, provided by a shoe manufacturer, were used for this study. All shoe characteristics were identical except the shoe HEA. All shoes had the same metatarsus height (7.5 mm) but different heel heights. The heel height differences were carefully manufactured to make 4 different HEA's (0°, 1°, 2°, and 3°). HEA was defined as the angle between the ground and line from heel to metatarsus in the insole [5].

Eight retro-reflective markers were placed on the shoe as depicted in the Fig. 1. Kinematic data were recorded using 10 Vicon cameras (Vicon motion systems, Oxford, UK). Ground reaction force and center of pressure data were collected using 10 force plates positioned in series (Kistler Instrument Corp., NY). Running speed was monitored using customized photoelectric sensors.

The subjects were asked to run around a 60-m track at a controlled speed of 2.6 m/s (± 5%) for 15 minutes in each shoe. Data was collected throughout the whole 15 minutes, and the first 10 minutes were used as an adaptation period, while the last 5 minutes were used for data analysis.

The SI was calculated as the location of the center of pressure at initial contact in the percentage of the total foot length [6]. The FSA was defined as the

angle formed by the line of markers A and B between at quiet resting and at initial contact during running as shown in Figure 1 [7]. Anatomical foot angle (AFA) was calculated by subtracting the HEA from FSA. The LR was calculated the slope of the line from 20% to 80% of stance time to impact peak of the vertical GRF.

A one-way repeated measures ANOVA was used to examine the effect of HEA on these dependent measures. Statistical significance was set at $p < 0.05$.
$$AFA(\theta) = FSA(\alpha)-HEA(\beta)$$

Figure 1: Reflective marker placement and schematic illustration of FSA (α) and HEA (β) measurement. AFA (θ) was represented by subtracting HEA (β) from FSA (α).

RESULTS AND DISCUSSION

There was a main effect for HEA on SI (Figure 2). At the two higher HEAs (2° and 3°), the COP at initial ground contact was significantly closer to the heel compared to the 0° HEA condition. In addition, three out of nine participants changed their foot strike pattern from rearfoot strike at 3° and 4° HEA to midfoot strike at 0° HEA. These results suggest that changes in HEA of shoes can alter running strike pattern.
Figure 2: Strike index for four different heel elevation angles.

Similarly, FSA increased as HEA increased (Figure 3). The FSA were significantly greater for the 3°

HEA as compared to the 1° HEA ($p < 0.01$) and 2° HEA ($p = 0.02$) HEA. FSA was correlated with SI, R = 0.89-0.98 ($p < 0.01$) according to HEA. Regression coefficients among HEA were not different ($p = 0.3$). This result is consistent with a previous finding which demonstrated that the FSA was significantly correlated with SI (R = 0.92 ($p < 0.01$)) from forefoot, midfoot and heelfoot strike pattern [7]. However, AFA were not significantly different among the shoes ($p = 0.3$). Moreover, no differences in the impact peak and LR were found (not shown in figure). These results indicate that altering strike pattern was not caused by adaptations of foot strike patterns, rather the differences were due to the structure of the shoes.
Figure 3: Foot strike angle and Anatomical foot angle for four different heel elevation angles.

CONCLUSIONS

The main finding of the study was the correlation of HEA with SI. It seems that lower HEA shoe have induced more anterior strike pattern; however, this change in the strike pattern was not associated with the AFA, impact peak and LR during stance.

THE RELATIONSHIP BETWEEN CLINICAL MEASURES AND STAIR CLIMBING BIOMECHANICS IN PATIENTS WITH TOTAL KNEE ARTHROPLASTY

Jacqueline Lewis, Gregory Freisinger, Laura Schmitt, Robert Siston and Ajit Chaudhari
The Ohio State University, Columbus, OH, USA
email: lewis.1127@osu.edu

INTRODUCTION

Total knee arthroplasty (TKA) is a generally successful surgical procedure to treat end-stage knee osteoarthritis; however, suboptimal outcomes, including difficulty stair climbing, do occur [1]. Clinicians use the stair climbing test (SCT) to track functional status, where a patient ascends and descends a flight of stairs as fast as possible and a faster time suggests better function and increased mobility capabilities. Decreased (faster) SCT time is associated with increased knee extension strength in TKA populations [2].

Although SCT time gives an estimate of a TKA patient's function, the relationship to stair climbing biomechanics and underlying knee function is not well defined. It is possible that patients introduce negative adaptations to their gait in order to climb stairs faster, rather than restoring biomechanical function to match those of healthy populations. These adaptations could include increased loading or altered movement patterns at the knee, hip or low back, which may be detrimental in the long term. We hypothesized that faster SCT times and increased knee extension strength of the involved limb would be associated with increased peak knee and hip flexion moments (pKFM, pHFM), of the involved limb, and decreased trunk lean.

METHODS

Twenty-two patients (7 male/15 female, age: 59.9±6.9 y, mass: 94.8±17.1 kg, ht: 1.7±0.1 m) with predominantly medial compartment osteoarthritis were recruited by three orthopedic surgeons at The Ohio State University Wexner Medical Center and provided IRB-approved informed consent. All participants underwent a primary TKA, using a posterior stabilized prosthesis. (Zimmer NexGen LPS Flex, Warsaw IN). Biomechanical and clinical assessments were completed approximately 6 months following surgery.

During the biomechanical assessment, each patient performed stair ascent and descent trials on a custom made 3-step staircase (tread depth: 25.5 cm, tread rise: 20 cm). The first two steps of the staircase were attached to force plates (Bertec 4060-10, Bertec Corp; Columbus, OH) embedded in the floor to capture stair climbing ground reaction forces at 1500 Hz. Marker data were collected at 150 Hz by 10 cameras [Vicon MX-F40; Oxford, UK]. A modified point-cluster marker set was used to calculate kinematics [3]. Inverse dynamics were calculated using custom Bodybuilder (Vicon; Oxford, UK) and MATLAB scripts. Marker and force data were filtered with fourth order low-pass Butterworth filters at a cutoff frequency of 6 Hz. All moments were expressed as externally applied to the joint of interest and were normalized by body weight times height. Peak forward trunk lean during stance phase was calculated using the markers placed on 10th thoracic and 7th cervical vertebrae, by determining the peak angle relative to global vertical axis in the sagittal plane.

Each patient completed the SCT on a 12 step, carpeted staircase (tread depth: 28 cm, tread rise: 16.5 cm). Patients were instructed to ascend, turn around and immediately descend the staircase as fast as possible, in a safe manner. The use of one handrail was allowed if necessary. Isometric knee extension strength was measured with a Biodex System 3 dynamometer [Biodex Medical Systems; Shirley, NY] with the involved limb held at 60 degrees of knee flexion. The resulting maximal knee extension torque was normalized by each participant's mass (Nm/kg).

Spearman rank order correlation coefficients were used to test the association between the

biomechanical and clinical measures. An alpha of 0.05 was used to denote significance.

RESULTS AND DISCUSSION

pKFM during ascent and pHFM during descent were significantly associated with knee extension strength; however, SCT time was not associated with any biomechanical measures (Table 1). Increased trunk lean was associated with increased pHFM, but not pKFM (Table 2).

Table 1: Spearman correlations between clinical and biomechanical variables.

		SCT		Ext Strength	
Ascent	**pKFM**	r=-0.24	p=0.28	**r=0.42**	**p=0.05***
	pHFM	r=0.34	p=0.12	r=-0.37	p=0.09
	Trunk Lean	r=0.26	p=0.24	r=-0.25	p=0.26
Descent	**pKFM**	r=-0.14	p=0.53	r=0.38	p=0.09
	pHFM	r=0.41	p=0.06	**r=-0.53**	**p=0.01***
	Trunk Lean	r=0.37	p=0.09	r=-0.35	p=0.11

Table 2: Spearman correlations between trunk lean and flexion moments at the hip and knee.

	Ascent		Descent	
	pKFM	**pHFM**	**pKFM**	**pHFM**
Trunk Lean	r=-0.212 p=0.344	**r=0.643 p=0.001***	r=-0.116 p=0.608	**r=0.503 p=0.017***

The purpose of this study was to evaluate the relationships between clinical and biomechanical measures during stair climbing in a population after TKA. Knee extension strength was associated with pKFM during ascent and pHFM during descent, which suggests that the demand on the knee joint is greater during ascent, while demand on the hip joint may be greater during descent. Although increased knee extension strength is associated with faster SCT times [2], biomechanical measures were not significantly associated with SCT time. There was a trend between pHFM and SCT time, where pHFM

increased with increasing speed. A forward trunk lean is often used by TKA patients and is thought to minimize demand on the quadriceps [4]. However, increased trunk lean was not associated with decreased pKFM in this study, suggesting that increased trunk lean may not reduce load at the knee joint. Increased trunk lean was associated with increased pHFM, indicating that trunk lean may increase load on the hip joint. This could put the hip at risk for joint degeneration or injury.

There were several limitations associated with this study. The biomechanics were measured on a 3 step staircase and not during the SCT. Also, this was a cross-sectional study and we did not control trunk angle or test patients at multiple trunk angles.

CONCLUSIONS

The findings of this study suggest that patients with faster SCT time did not have larger pKFMs compared to patients with slower SCT times. SCT time was not associated to any of the investigated biomechanical variables, so further study is needed to fully understand how demand on the hip and knee joints change with faster SCT speed in a TKA population. More trunk lean was associated with increased pHFM, so clinicians must be wary that improving a patient's SCT time does not have a detrimental effect on other joints. Focus on decreasing trunk lean during stair climbing may be beneficial to TKA patients. Further study testing individual subjects at different trunk lean angles is necessary to fully understand this relationship.

Effects of Prolonged Walking at Preferred Speed in Individuals with Multiple Sclerosis

INTRODUCTION

Alterations to spatiotemporal gait parameters such as increased stride width and dual support time, and decreased stride length, stride time, and gait speed, are characteristic of preferred walking speed (PWS) gait in Multiple Sclerosis (MS) [1] and are generally considered to be reflective of gait instability. Maintaining gait stability in dynamic, cluttered environments is essential for accomplishing tasks of daily living.

Individuals with MS often report elevated levels of symptomatic fatigue, a combination of reversible motor and cognitive impairment, which appears to be unrelated to disease status or patient disability [2] and can be exacerbated by prolonged activity. Furthermore, symptomatic fatigue has been associated with postural instability [3]. However, it is currently unclear how symptomatic fatigue influences gait stability in individuals with MS.

The purpose of the present study was to assess the impact of an induced physical fatigue through a prolonged walking bout on PWS gait parameters in individuals with and without MS. We hypothesized that individuals with MS would display a more stable gait pattern, demonstrated by increased dual support and decreased swing times in response to induced fatigue.

METHODS

Eight participants with mild to moderate MS (7 female, age =43.5 years, height = 1.67 m, mass = 74.2 kg, PDDS < 3) and eight age, gender, height, and weight matched controls (7 female, age = 42.1, height = 1.69 m, mass =73.5 kg) participated. Controls (CON) were required to be free of neurological impairment.

PWS was determined on a treadmill by self-selection of walking speed as belt speed was systematically increased and decreased. The protocol consisted of three minutes of PWS followed by 24 minutes of imposed speed walking (range $0.6 - 1.4 \text{ms}^{-1}$), and finally three minutes of PWS. Overall fatigue was assessed at baseline and, pre- and post-walking using the Visual Analog Fatigue Scale (VAS-F) [4] with scale anchors of "no fatigue" and "exhaustion".

Stride length, width, duration, cadence as well as stance, swing, and dual support percentage were computed across gait cycles for each PWS trial. Variability was assessed with the coefficient of variation (CoV). Dependent variables were compared using a mixed-model, repeated measures ANOVA with time as the repeated factor and disease status as the grouping factor ($\alpha = 0.05$). Trends towards significance ($\alpha < 0.1$) are discussed due to the relatively small sample sizes.

RESULTS AND DISCUSSION

Fatigue

Comparison of baseline, pre-walking, and post-walking VAS-F scores revealed significant main effects of group and time. Post-hoc comparisons revealed significantly higher levels of fatigue in the MS group ($\sim 17\%$, $p < 0.029$). Both groups reported increased fatigue post-walking compared to baseline ($\sim15\%$, $p < 0.001$) and pre-walking ($\sim8\%$, $p < 0.02$). Fatigue rates of change between baseline/pre-walking and pre-walking/post-walking were not significantly different between groups.

Gait Parameters

No significant difference in PWS was found between the MS ($1.03 \pm 0.39 \text{ ms}^{-1}$) and CON groups ($1.21 \pm 0.21 \text{ ms}^{-1}$). Alterations to spatiotemporal gait parameters were observed in both groups following the walking bout. In particular, stride time (trend, $p < 0.06$), stride length ($p < 0.02$), stance % (trend, $p < 0.07$), and dual support % ($p < 0.04$) increased while cadence ($p < 0.02$) and swing % (trend, $p < 0.07$) decreased following prolonged walking. A trend for greater dual support % ($p <$

0.09) was observed for the MS group relative to controls.

Gait Variability

Gait parameter variability was not impacted by prolonged walking in either group. However, trends for group differences were observed. The MS group displayed increased CoV for stride width ($p < 0.06$), stance time percentage ($p < 0.07$), swing time percentage ($p < 0.09$), dual support percentage ($p < 0.08$), and cadence ($p < 0.09$).

CONCLUSION

In contrast to previous work [1], gait parameters of the MS group were not found to be significantly different than healthy individuals. This may reflect relatively low levels of disease-related impairment (PDDS < 3). One exception was a trend for increased dual support percentage in the MS group, a finding consistent with earlier reports [1]. Greater dual support percentage represents a reduction in the amount of time spent in single support where the COM is more likely to be located outside of the stability boundaries. Additionally, fatigue-related alterations to gait parameters were seen in both groups following prolonged walking. In general, these changes reflected tendencies of both groups to favor more stable gait identified by increased stance and dual support percentages and shorter swing percentages post-walking.

Finally, the increased variability in stride width observed in the MS group could be a signature of a less controlled gait pattern and associated with the increased rate of falls in this population. An important question is how changes in coordination and coordination variability of the lower extremities, trunk and arms are linked to this increased stride width variability.

Fatigue levels, as measured by the VAS-F, were overall greater in the MS group, consistent with previous findings [3]. Fatigue increased similarly in our MS cohort compared to controls in response to prolonged walking, which may explain the similar response to the walking protocol in both groups.

HEEL ROCKER MECHANICS IN GAIT ARE DIFFERENT BETWEEN LIMBS AND COMPARED TO CONTROLS FOLLOWING ACL RECONSTRUCTION

INTRODUCTION

Normalization of gait is a primary goal of early rehabilitation following anterior cruciate ligament reconstruction (ACLr), which is expected to be achieved 8-12 weeks post-ACLr [1]. However, between limb asymmetries in knee extensor moment can persist 6-24 months post ACLr [2], suggesting that strategies used to restore gait during early rehabilitation are not effective at restoring loading mechanics. Their long-term persistence is of concern as they have been attributed to the progression of knee osteoarthritis in this population [3].

Reduced peak knee flexion angle, range of motion, extensor moment, and power absorption in the surgical limb compared to the nonsurgical limb have been identified during loading response (LR) of gait (first 20% of stance phase) [2]. During this phase, the knee flexes to accept body weight in LR just after heel strike using a heel rocker mechanism to decelerate and progress the body over the stance limb [4]. The heel rocker is characterized by forward shank progression after initial contact, resulting in knee flexion, eccentric quadriceps contraction and peak knee extensor moment [4]. Decreased knee extensor moment and knee flexion range of motion in the surgical limb during loading response suggests that individuals are altering ground reaction forces (GRF) and heel rocker mechanics to reduce knee extensor loading.

The purpose of this study was to compare heel rocker mechanics during gait between limbs in individuals following ACLr and to healthy controls.

METHODS

Seven individuals (4 females, 25.1 ± 11.4 years) status post-ACLr (84.7 ± 15.0 days post-op) and six healthy controls (4 females, 22.8 ± 5.0 years)

performed 3 walking trials across a 10 meter walk way at a self-selected speed.

Three-dimensional kinematics (250 Hz) were collected using a 11-camera motion capture system (Qualisys, Inc. Sweden). Ground reaction forces (GRF; 1500 Hz) were quantified using AMTI force platforms (Newton, MA, USA). Laser timing gates (Brower, UT, USA) were used to determine gait velocity. Three dimensional joint kinematics, ground reactions forces and anthropometrics were used to calculate net joint moment using standard inverse dynamics equations. Kinetic data were normalized to body mass. Sagittal plane shank angle and angular velocity were calculated. Shank angle was measured relative to the horizontal, such that a positive angle refers to when the proximal portion of the shank is more posterior than the distal portion. Similarly, a negative angular velocity indicates that the proximal portion of the shank is progressing anteriorly relative to the distal end.
Figure 1: Shank conventions. Positive shank angle (red) and negative shank angular velocity (yellow).

Knee range of motion (initial contact to peak knee flexion), peak knee extensor moment, peak vertical and posterior GRFs, average shank angle (initial contact to 50% stance), and peak negative shank angular velocity were identified during LR. Data were averaged between limbs to represent healthy control mechanics.

Paired sample t-tests were used to compare differences between the surgical and nonsurgical limbs in individuals following ACLr. Gait velocity and differences between the control data and the surgical and nonsurgical limbs of ACLr were

compared using independent samples t-tests. Significance p≤0.05. Effect sizes were calculated.

RESULTS AND DISCUSSION

On average, individuals following ACLr had a 56% decrease in knee extensor moment and an 8° difference in knee range of motion in the surgical compared to the nonsurgical knee. The between limb differences in these participants 3 months post ACLr are larger but consistent with previous studies reporting decreased sagittal plane knee loading in individuals 6-24 months following ACLr. While peak vGRF were not significantly different between limbs, a 25% decrease in pGRF was observed in the surgical limb compared to the nonsurgical, suggesting that LR strategies may work to reduce braking forces more than vertical forces to limit extensor moments in the surgical knee.

Between limb differences were noted in shank kinematics indicating that individuals following ACLr also modulate components of the heel rocker mechanism during LR to reduce knee flexion and the demand on the knee extensors. On average, throughout LR individuals maintained a shank position that was angled more posteriorly in the surgical knee compared to the nonsurgical knee. A greater posterior angle will shorten the lever arm for the already reduced braking forces (pGRF), further decreasing knee extensor moments. In addition to a more posteriorly rotated shank throughout LR, individuals following ACLr also demonstrated decreased peak shank angular velocity in the surgical compared to nonsurgical limb. Rapid knee flexion during LR is facilitated by rotation of the shank over the foot. Decreased angular velocity of the shank likely further reduces the demands for eccentric quadriceps action contributing to between limb differences in knee extensor moments.

When comparing ACLr to healthy controls, no differences were found in gait velocity (p=0.416; ES=0.45). Similar to between limb comparisons in ACLr, significant differences were observed between ACLr surgical limbs and controls for all variables except peak vertical ground reaction force (p=0.06). The only difference noted between ACLr nonsurgical limb and controls was observed in knee range of motion. Larger knee flexion range of motion was observed in ACLr nonsurgical limbs than controls suggesting that individuals following ACLr may be altering mechanics of the nonsurgical limb to normalize gait.

CONCLUSIONS

Despite the observable normalization of gait at 3 months post ACLr, subtle alterations in LR variables related to loading (GRFs) and heel rocker mechanics result in lower knee extensor moments in the surgical knee. These preliminary data suggest that individuals alter braking forces and shank position and velocity to reduce sagittal plane loading of the knee. It is likely that these kinematic and kinetic variables are related to an overall strategy aimed at shifting the demands away from the knee extensors in the surgical limb. Furthermore, it is not known if these strategies are driven by underlying joint impairments or learned motor adaptations. Future work with larger samples sizes investigating these relationships will inform interventions aimed at improving these mechanics.

A PLANAR DUAL-SLIP MODEL OF INCLINE AND DECLINE WALKING

INTRODUCTION

The planar Dual Spring-Loaded Inverted Pendulum (Dual-SLIP) or bipedal spring-mass model [1] is known to reproduce the vertical oscillations of the center of mass (CoM), the double-peak ground reaction force (GRF) pattern, and the finite duration of double support in human walking on level ground. This conservative model consists of a point mass and two massless spring legs of equal stiffness and produces stable, symmetric gaits across a range of speeds. To extend the model to incline and decline walking, however, mechanisms to allow for asymmetric steps and for injecting/absorbing energy are required since the potential energy necessarily changes with each step. A recent extension of the planar Dual-SLIP model to 3D [2] introduces such mechanisms by allowing touchdown and liftoff to occur at leg lengths less than the free length, (thereby exhibiting ground impact and toe-off characteristics) and by allowing the free lengths of the legs to vary linearly between gait events. This paper investigates how these same mechanisms can be introduced in the planar Dual-SLIP model to reproduce the sagittal plane motion and GRF characteristics of human incline/decline walking.

MODEL DESCRIPTION

Figure 1 depicts the planar Dual-SLIP model, which has leg stiffness k, instantaneous stance and swing leg lengths l_A and l_B, and swing leg angle with the vertical θ, walking up an inclined surface indicated by a small step. Figure 2 depicts the internal leg "actuation" scheme for this model, which alters when in the gait the energy is stored and released compared to a passive spring. Beginning the cycle at midstance (MS) of single support of the trailing leg A (SS_A), defined as the instant of zero vertical CoM velocity, the free length of leg A, $\ell_A(t)$, initially ℓ_{MS}, changes linearly with a slope of β_A until liftoff (LO). At LO, the length of leg A (L_{LO}) is less than its free length ℓ_{LO} at that instant, so the GRF immediately before LO is non-zero, similar to the effect of toe-off. Likewise at touchdown (TD), the length of the leading leg B (L_{TD}) is less than its free length ℓ_{TD} at that instant, so the GRF is non-zero immediately after TD, similar to the effect of ground impact if the leg had mass. From TD to MS, the free length of leg B, $\ell_B(t)$, changes linearly with a slope of β_B, returning to ℓ_{MS} at MS to ensure periodicity. With this scheme, energy can be injected/absorbed for walking on inclines/declines.

Fig. 1: Planar Dual-SLIP model of incline walking.
Fig. 2: Illustration of the actuation variables for the leading leg B (red) and trailing leg A (blue). Solid/dashed lines are free/actual leg lengths.

Gaits are generated via a nonlinear optimization to identify the parameters $\{L_{TD}, L_{LO}, \ell_{TD}, \beta_A, \beta_B, \theta_{TD}\}$ that produce a 2-step periodic walking gait at 1 *m/s* for an 80 *kg* mass with a leg spring stiffness of 20 *kN/m* and a nominal leg length of 1 *m*. (ℓ_{LO} is omitted from the list because it can be computed from the other parameters.) Constraints require each leg's length to remain less than its free length and the vertical GRFs at *MS* to be at least 60% of body weight. Cost functions serve to minimize the GRFs immediately before touchdown and immediately after liftoff and to achieve human-like double support ratios of about 0.2. A multiple-shooting strategy is used to solve the optimization problem by dividing it into three phases: single support of the trailing leg, double support, and single support of the leading leg.

RESULTS AND DISCUSSION

Figures 3 and 4 show the motion of the Dual-SLIP model and the vertical GRFs in ascent and descent. In ascending an incline, the leading leg (red in Fig. 3 left) touches down with a reduced leg length, representing the increased knee flexion found in humans at *TD* on inclines [3]. Also, the vertical GRF peak after *MS* (blue in Fig. 3 right) is increased compared to the peak before MS, as is the case in human incline walking [4]. In descending a decline, the trailing leg (blue in Fig. 4 left) has a reduced leg length at *TD* of the leading leg, representing the increased knee flexion humans exhibit in late stance on declines [5]. Likewise, the vertical GRF peak before *MS* (red in Fig. 4 right) is greater than that after *MS*, similar to what is found in human decline walking [6]. Comparing the values of β_A and β_B for incline and decline walking highlights the greater significance of eccentric muscle activity in the weight acceptance phase [7] of decline walking.

CONCLUSIONS

This paper demonstrates that modifying the traditional planar Dual-SLIP model of human walking to allow changes in the free length of the leg spring during a stride and touchdown/liftoff at leg lengths less than the instantaneous free length enables accurate matching of the key characteristics of human walking on inclines and declines.

INDIVIDUAL LIMB TRANSITION WORK DURING WALKING
IN SERVICE MEMBERS WITH TRANSFEMORAL AMPUTATION

INTRODUCTION

The transition between limbs during healthy gait is characterized by [1,2]: trailing limb positive work generation, and leading limb negative work absorption. Past studies examining asymmetric gait have shown that when one affected limb generates less positive trailing work due to ankle weakness, the contralateral (intact) limb will absorb greater negative leading work [3,4]

Greater negative leading intact limb work is suggested to be compensation for affected limb weakness and has been positively correlated to greater metabolic energy consumption in persons with transtibial amputation [3]. The majority of negative work from the leading limb is absorbed at the knee and through soft-tissue [5].

To date, little is known about transition work in persons with unilateral transfemoral amputation (TFA), although prosthetic ankle weakness is present and metabolic consumption during walking is higher than controls. The objective of this analysis was to examine individual limb transition power and work in persons with TFA. We hypothesized that persons with TFA will produce significantly less positive trailing prosthetic limb work and significantly greater negative leading intact limb work compared to controls. Additionally, joint-level transition power was examined to provide more insight into leading limb transition work [5].

METHODS

A retrospective analysis, approved by the Walter Reed National Military Medical Center Institutional Review Board, was performed for 12 male persons with TFA (30.3±5.4 years, 1.81±0.06 m, 97.2±13.4 kg) and 12 speed-matched male controls (31.0±7.6 years, 1.82±0.05 m, 90.9±10.6 kg). All persons with TFA were evaluated ≥6 months post-injury and wore the microprocessor-controlled C-leg (Otto Bock, Duderstadt, Germany).

Data were collected at the Walter Reed Army Medical Center and Walter Reed National Military Medical Center Biomechanics Laboratories. Individuals walked at a self-selected velocity along a 15 meter walkway. Kinematics were tracked (120 Hz) via retro-reflective markers using a 23-camera motion capture system (Vicon, Oxford, UK) and ground reaction forces were collected (1200 Hz) from 6 force platforms (AMTI, Watertown, MA, USA) embedded in the walkway. Data was processed in Visual3D (C-Motion, Germantown, MD, USA).

Individual limb transition work was calculated using the individual limbs method [2]. First, instantaneous external mechanical power was calculated for each limb by taking the dot product of center of mass velocity and each limb's ground reaction force. Second, trailing prosthetic and leading intact limb external mechanical work were calculated by integrating instantaneous external mechanical power for each respective limb during transition (intact limb foot-strike to prosthetic limb foot-off). Joint-level transition power was calculated using inverse dynamics.

Two independent t-tests ($p<0.05$) were used to compare transition work between the: (1) trailing prosthetic and trailing control limbs, and (2) leading intact and leading control limbs, using SPSS version 21.0 (IBM, Armonk, NY, USA).

RESULTS AND DISCUSSION

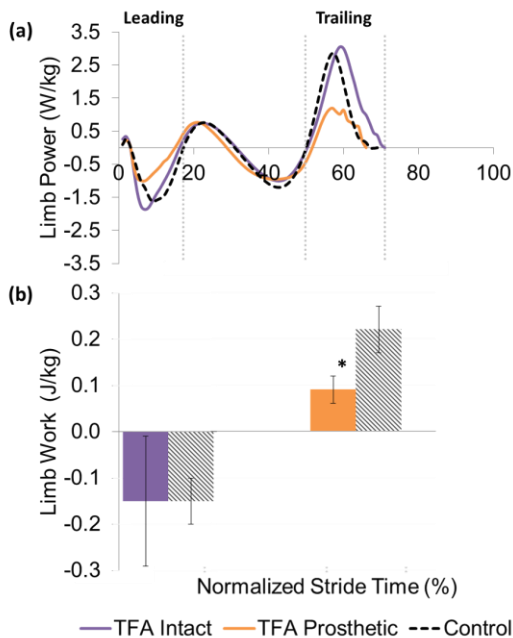
Persons with TFA and controls walked at 1.30±0.01 m/s and 1.33±0.01 m/s, respectively. Mean limb power and work produced by persons with TFA and controls are shown in Figure 1.


Figure 1: Mean limb (a) power over 1 stride and (b) work calculated during the transition from intact limb foot-strike to prosthetic limb foot-off. Error bars display ±1 standard deviation. *Indicates significant difference from control.

As expected, the lack of propulsion and ankle plantar-flexion provided by passive prosthetic ankles [1] attributed to significantly less (p<0.001) positive trailing prosthetic work generation by persons with TFA compared to controls. However, unlike other patient populations that exhibit unilateral ankle weakness [3,4], persons with TFA did not absorb greater negative leading intact work compared to controls (p=0.979).

Mean knee joint power produced by persons with TFA and controls is compared in Figure 2. Interestingly, the standard deviations in leading intact limb work and leading intact knee power, the joint that absorbs a majority of leading work [5], were relatively large compared to controls. These variations may indicate differences in walking strategies regarding compensation for prosthetic

limb weakness in persons with TFA. Further analyses should be performed to determine factors contributing to these variations.
Figure 2: Mean knee power over 1 stride for the (a) TFA intact and (b) control limbs. Grey shading displays ±1 standard deviation.

AUDIO AND VISUAL BIOFEEDBACK AS METHODS OF GAIT RETRAINING TO REDUCE TIBIAL ACCELERATION UPON FOOT STRIKE

Alexander M. Morgan, Christopher F. Geiser, Philip J. Malloy, Kristof Kipp

Marquette University, Milwaukee, WI
Email: alexander.morgan@marquette.edu

INTRODUCTION

About 15% of all injuries that occur in runners are stress fractures [3]. Nearly half of these stress fractures occur at the tibia. Larger tibial peak positive accelerations (PPA's) at foot strike during running have been associated with a higher risk for stress fracture [2, 4]. Visual and audio biofeedback have both effectively reduced these PPA's in real-time [1, 2, 4, 5]. However, the comparative effectiveness of these two has not been established. While visual biofeedback can be used clinically in the laboratory as a means of decreasing PPA's, this is neither portable nor realistic. Audio biofeedback, however, can be used in a realistic setting through the use of portable technology. As such, audio biofeedback could provide constant feedback during running on a more consistent basis and in a setting that is common to each individual.

PURPOSE

To compare the effectiveness of audio versus visual biofeedback on tibial PPA's during running.

METHODS

Twenty-one healthy, recreational runners (11 female and 10 male) between the ages of 18 and 25 were recruited to run for this study. Subjects were required to be currently running at least 10 miles per week and identify as a heel-striker. A tri-axial accelerometer was placed on the distal, anteromedial aspect of the right tibia. Lower extremity kinematic data were collected via a 14 infra-red camera system. A treadmill was placed within the capture volume of the cameras. Biofeedback was provided via a custom LabVIEW program. The program provided visual biofeedback by displaying continuous accelerometer data on a

TV screen in real-time. Furthermore, the program provided audio biofeedback via a continuous, real-time sound. The sound was a "beep" that linearly increased in pitch and volume as the PPA increased. A five minute warm up was used to determine baseline PPA and a comfortable running speed. Subjects ran at this speed for the remainder of the test. A target threshold was then set at 50% of the baseline PPA, and was used as the goal for one of the following two running conditions: 1) 5 minutes of visual biofeedback, or 2) 5 minutes of audio biofeedback. The assigned condition for each subject was randomized such that a nearly equal number of subjects received visual biofeedback as opposed to audio biofeedback. Data were collected for ten seconds during the last 30 seconds of each interval without subjects' knowledge. Acceleration data were recorded in LabVIEW. Kinematic data were recorded in Vicon Nexus. Data were analyzed using repeated measures ANOVAs to compare between conditions (Audio & Visual) and across time (Warmup & Biofeedback). Data were determined to be significant if $p < 0.05$ and are presented as Mean ± SD.

RESULTS

There were no significant interactions between biofeedback type and time for PPA. Main effects indicated that PPA values decreased significantly ($p = 0.001$) from the warmup phase to the biofeedback phase for each biofeedback condition (Table 1). Similarly, main effects showed that cadence increased significantly ($p = 0.006$) across time for both audio and visual biofeedback. Kinematic data showed no significant changes between conditions or across time.

DISCUSSION

This study builds upon previous literature that has examined biofeedback as a tool to decrease tibial PPA's. The significant reduction in PPA values from the warmup condition to each biofeedback condition found in the current study is comparable to those decreases found by other authors using visual or audio biofeedback. Crowell and Davis's examination of the effect of visual biofeedback on PPA used a 50% threshold, as performed in this study, and displayed a significant decrease of 48% [1]. In comparison, the current study's averaged data displayed a significant decrease of 18.7%. One reason for this discrepancy may be that Crowell and Davis only accepted runners with initial PPA's above 8g, whereas the current study accepted all heel strikers [1]. As such, those runners in Crowell and Davis' study had more opportunity to decrease their PPA. Furthermore, Wood and Kipp investigated the effect of audio biofeedback on PPA using a threshold of 10-15%, and found a significant decrease in PPA of 11.9% [5]. The greater percent decrease found in the current study is likely due to the lower threshold that is used. Finally, while these two studies presented data regarding changes in PPA in response to biofeedback, this current study is novel in that it also presents data on changes to cadence and kinematics resulting from biofeedback use. This study suggests that an increased cadence without changes in lower extremity kinematics can produce significantly decreased PPA's. Further research is necessary to determine the longitudinal effect of audio biofeedback on tibial PPA's and on the rate of injury in recreational runners who use this biofeedback.

CONCLUSIONS

Subjects were able to successfully decrease tibial PPA values while running with audio and visual biofeedback. No difference in PPA value reduction was found between the two biofeedback types. In order to achieve this reduction, subjects on average increased their cadence without making any other observed kinematic changes to their gait.

INTRODUCTION

For patients with peripheral arterial disease (PAD), the most limiting symptom is physical activity induced pain in the legs known as claudication. Clinically, little is done to assess function other than physicians interviewing them or walking with them to observe the patient's limitations firsthand. Quality of life questionnaires and treadmill and overground maximum walking distance tests are commonly used in research settings. Both types of assessments could potentially be implemented to understand functional limitations in a clinical setting. However, there is no consensus on the best functional walking test to use on these patients[1,2] and neither type of test has been directly compared with gait biomechanics, which is the gold standard for testing functional limitations[3]. Biomechanics testing cannot easily be performed on all patients in a clinical setting due to the cost, time, and equipment restraints. Therefore, this study sought to determine whether common research measures of quality of life and maximum walking distance could accurately predict gait biomechanics measures. We hypothesized that distances and quality of life parameters together would be predictors of gait variables in patients with PAD. If true, clinicians could confidently implement these methods into the clinical setting to better understand functional status in patients with PAD.

METHODS

One hundred and six patients diagnosed with PAD (age: 64.4 ± 6.7 years; ht: 174.3 ± 9.2 cm; mass: 86.9 ± 19.2 kg) were referred to the study by vascular surgeons. Consent was documented and the patients were given two different questionnaires: the Walking Impairment Questionnaire (WIQ)[4] and the Medical Outcomes Survey Short Form 36 (SF-36)[5]. The WIQ is a questionnaire specific to patients with claudication and it includes component scores for pain, distance, stairs, and speed. The SF-36 has been validated in multiple populations as a measure of quality of life and includes eight domain scores. The walking distance scores were determined by having subjects complete the Gardner treadmill test[6]. Subjects walked on a treadmill set at 0.86 m/s (2.0mph) at 0% grade. The grade of the treadmill was increased 2% every 2 minutes. The initial claudicating distance is the distanced walked prior to the first indication of pain and the absolute claudication distance is the distance walked until the patient cannot walk any further and must stop the test. Additionally, the 6 minute walk test (6MWT) was performed, which is the distance patients can walk overground in 6 minutes[6].

For the gait biomechanics testing, 27 reflective markers were placed at anatomical positions[3]. Marker position data was recorded using a twelve camera motion capture system (Motion Analysis Corp., Santa Rosa, CA; 60 Hz). Ground reaction forces were captured by force plates in the overground runway (AMTI, Watertown, MA; 600 Hz). Subjects performed five trials through the overground walkway during a pain free condition. The position data was tracked in Cortex software (Motion Analysis Corp., Santa Rosa, CA) and then processed for gait biomechanics variables in MATLAB (Mathworks Inc., Boston, MA) and Visual3D (C-Motion, Germantown, MD) custom software. Dependent gait biomechanics variables include peak joint angles, moments, and powers of the ankle, knee, and hip during the stance phase. Statistical analysis included a stepwise linear regression analysis using gait variables as the dependents and the quality of life and walking

distances as predictors. For this analysis, the probability level for entry in to the model was set at 0.20 and the significance level of removal from the model set at 0.25. This analysis allowed multiple components of the quality of life measures to be used to predict the gait biomechanics variables. The primary gait outcome variables were ankle plantarflexor moment and ankle plantarflexor power due to previous work in our laboratory identifying the ankle as consistently deficient in patients with PAD. However, prediction models were developed for all ground reaction force, joint angle, joint torque, and joint power peak points from the stance phase.

RESULTS AND DISCUSSION

The models using quality of life questionnaires and walking distances to predict values were significant in 31 of 33 gait parameters tested. Very importantly, the 6MWT was a predictor in 21 of the 31 significant models. For all variables in which the 6MWT was included in the model, as the distance walked increased, the value of the gait parameter was also improved, meaning it moved closer to healthy control values from our previous work[8]. These findings suggest that the 6MWT distances are the best representative of gait parameters from all of the quality of life and walking distance parameters.

An important consideration when interpreting prediction models is the strength of the relationship, or the amount of variance in gait parameters that could be explained by the model. In this study, the significant relationships had r-squared values ranging from .108 to .383, which are not strong relationships. Thus, clinicians should be cautious in thinking that quality of life questionnaires and walking distances could provide the same knowledge as gait biomechanics parameters in patients with PAD. Rather, models of this strength can explain between approximately 10 and 40% of the variance in the specific gait variables and while the models may provide insight into functional status, they are insufficient to describe gait in these patients.

The purpose of this study was to determine whether or not clinicians could rely on quality of life questionnaires and walking distances to evaluate and understand the gait and function of patients with PAD. Previous studies have demonstrated that gait biomechanics are important outcome measures in assessing treatment efficacy in patients with PAD[7,8]. Furthermore, there is an argument in the literature regarding whether the treadmill or 6MWT is optimal for assessing functional outcomes for clinical trials[1,2]. Based on the current study, the 6MWT is the better of the two tests, but neither adequately represents the gold standard for lower extremity function, gait biomechanics. Importantly, this study emphasizes the need for more sophisticated, objective, and accurate methods that could provide stronger models with which to represent function in these patients. Limitations of these studies are they all represent a snapshot in time rather than long-term monitoring of the patient.

CONCLUSIONS

Our results demonstrated that quality of life questionnaires and walking distances can explain between 10-40% of variance in gait biomechanics variables in patients with PAD. Future research should evaluate whether gait parameters assessed through portable devices like accelerometers and inertial sensors are more representative of gait biomechanics in these patients.

INTRODUCTION

Health attitudes regarding quality of life and the potential for recovery of function are related to treatment improvement levels in some populations[1]. Patients with peripheral arterial disease (PAD) experience reduced quality of life and physical function from insufficient leg blood flow. The limited blood flow is caused by atherosclerotic blockages in the arteries in the legs. Muscular ischemia causes pain during walking, eventually forcing patients to stop to rest. The standard treatment to improve blood flow in patients with PAD is surgery. In this population, it is unknown how perceived health status prior to surgery influences surgical outcomes. Thus, this project will determine whether a relationship exists between perceived health status, assessed through questionnaires, and improvement in gait biomechanics and maximum walking distances following surgery. If perceived health status is positively related with improvements post surgery, educational and counseling programs to inform patients about the potential for improved outcomes could potentially lead to better restoration of gait function and walking distances post surgery.

METHODS

Twenty-seven patients diagnosed with PAD (age: 61.8 ± 5.63 years; ht: 174.20 ± 7.35 cm; mass: 84.92 ± 17.14 kg) were consented for this study. Patients were having surgery as the standard of care and they participated in additional research evaluations before and six months following revascularization intervention. Perceived health status was assessed using the Walking Impairment Questionnaire (WIQ)[2] and the Medical Outcomes Study Short Form 36 Healthy Survey (SF-36)[3] The WIQ is a disease-specific questionnaire for individuals with claudication that includes component scores for distance, pain, speed, and stairs. The SF-36 questionnaire evaluates health status across eight physical, emotional, and social domains and has been validated in multiple populations. The scores from each component of the instruments are included as reflective of separate areas of perceived health status.

Walking distance measures included initial and absolute claudication distances as determined by the Gardner treadmill test and the 6 minute walk test (6MWT), the research standards to measure function in patients with PAD. In this test, patients walked on a treadmill set at 0.89 m/s (2.0 mph) and 0% grade, increased by 2% grade every two minutes until patients stopped walking due to claudication pain[4]. The first indication of pain was recorded as the initial claudication distance and the total distance the patients walked on the treadmill before stopping because of pain was the absolute claudication distance. The 6MWT is the maximum distance patients can walk in 6 minutes. For gait biomechanics, five trials of overground walking data were collected using a 12- camera motion capture system (60 Hz; Motion Analysis, Santa Rosa, CA, USA) synchronized with force plates (600 Hz; AMTI, Watertown, MA, USA). Data were collected prior to the onset of claudication pain. Kinematic and kinetic data were calculated using the methods of Nigg et al and Vaughan utilizing Visual 3D (C-Motion, Germantown, MD)[5,6].

Improvements in walking distances and gait biomechanics discrete points were calculated by subtracting baseline data from post surgery data. Pearson's correlations were used to determine the

strength, direction, and significance of relationships between perceived health status variables and gait and walking distance outcome variables.

RESULTS AND DISCUSSION

Significant relationships were found for 7 comparisons ($p < .05$) using Pearson's correlations. Specifically, absolute claudication distance, 6MWT, ankle plantar flexor moment and knee power absorption were related to five of eight domain scores from the SF-36 and one of four WIQ domain scores (Table 1). Only moderate relations were found. Negative correlations mean that as baseline questionnaire scores increase, improvement in the respective gait variable decreases. Positive values indicate that as baseline questionnaire scores increase, gait parameters improved more post surgery.

The direction of the relationships is interesting in that patients who had high baseline scores, meaning fewer perceived physical limitations, did not improve in gait parameters. However, as patients' baseline scores increased in perceived social and general health, increases in absolute walking distances were seen. Perhaps the patients with poor perceived health did not think they would be able to improve. However, they had the most room for improvement and actually benefitted more than patients with positive baseline perceived physical health. Similarly, those who perhaps did not have as severe of symptoms thought they would get a lot better and had a more positive outlook, but the surgery did not help them as much, which could

mean they did not have as much room for improvement in biomechanical parameters.

CONCLUSIONS

The purpose of this study was to examine the relationships between patients' perceived health status and gait and walking distance performance following surgical revascularization. Based on these results we saw differences in level of improvement depending on the area of perceived health. Poor perceived baseline physical health was associated with gait improvements, while positive perceived social and general health was also associated with gait improvements post surgery. Results support the notion that those with poor perceived physical health and those with positive social health can benefit from surgery. Based on the presence of moderate relationships, clinical factors such as restoration of blood flow, extent of muscular myopathy, and presence of co-morbidities are likely greater determinants of surgical outcomes than perceived quality of life in patients with PAD.

PEAK EMG CHARACTERISTICS OF LOWER-EXTREMITY MUSCULATURE INDICATE UPCOMING LOCOMOTOR TRANSITION

[1] Bryson H. Nakamura, [2]Deepak Joshi, and [1]Michael E. Hahn

[1] University of Oregon, Eugene, OR, USA
[2] Graphic Era University, Dehradun, India
email: bnakamur@uoregon.edu, web: http://bssc.uoregon.edu

INTRODUCTION

Transitioning between different forms of locomotion is crucial for functioning in everyday environments. Few studies have identified the characteristic differences in electromyographic (EMG) activation during periods of transition between ramps [1] or stairs [2] and level ground. Recent attempts to develop controllers for classification algorithms in active prostheses have utilized EMG during locomotion [3]. Understanding how locomotor transitions affect peak EMG characteristics would allow for safer ambulation in amputees. The purpose of this study was to determine characteristic difference in peak lower limb muscle activation during transitions between level-ground and ramp/stair locomotive states.

METHODS

Thirteen able-bodied subjects, eleven male (23.5±4.7years; 1.76±0.08m; 76.9±10.kg) and two female (22.5±0.5years; 1.58±0.51m; 59.8±4.3kg), were recruited for this study. Surface EMG data were collected from seven muscles of the right leg. Passive surface electrodes (Ag/Ag-Cl) were placed on the tibialis anterior (TA), medial gastrocnemius (MG), rectus femoris (RF), vastus lateralis (VL), biceps femoris (BF), gluteus maximus (Gmax), and gluteus medius (Gmed), using common placement protocols. Footswitch insoles inserted into the subjects' shoes were used to collect the gait events of foot contact and toe off.

Subjects were asked to complete three successful trials at a self-selected normal walking pace in eight different transition types: LG to ramp ascent (RA), LG to ramp descent (RD), RA to LG, RD to LG, LG to stair ascent (SA), LG to stair descent (SD),

SA to LG, and SD to LG. Three gait cycles per trial were analyzed in this study. Gait cycles were defined from heel-strike to heel-strike of the right leg. The gait cycle beginning three heel-strikes before transition (Pre2), two heel-strikes before transition (Pre1), and one heel-strike before transition (Tr) were analyzed. Each gait cycle was sectioned into one event and two phases: Heel Strike (HS; 0% gait cycle), Stance (ST; first 60% of gait cycle), and Swing (SW; last 40% of gait cycle). The EMG and foot switch data were collected at a sampling frequency of 1500 Hz. The EMG signals were band-pass filtered (3-500 Hz), full wave rectified, and smoothed using a 4th order Butterworth low-pass filter (6 Hz) to generate a linear envelope. Each trial was then amplitude normalized to the maximum peak amplitude of that trial, which was considered to be 100% activation. Relative peak amplitude (AMP) and timing of AMP (GC) were then extracted for each trial, gait cycle and phase.

Two-Way ANOVAs, Phase x Cycle ($\alpha < .05$), were used to determine main effects between cycles and phases of the same transition. Follow-up analyses (adjusted $\alpha < .017$) isolated phases and compared differences between cycles within a single transition.

RESULTS AND DISCUSSION

All eight transitions exhibited significant main cycle effects in either AMP or GC in at least one muscle. Significant changes in shank musculature were found in all transitions. Ramp transitions elicited fewer significant changes than stair transitions.

LGRA: Overall MG AMP increased as subjects moved toward the transition. This may suggest that

MG is increasing overall activation in anticipation of the upcoming RA locomotion which may necessitate increased plantar flexor moments for propulsion.

LGRD: Earlier activation in RF may indicate awareness of the impending transition, while the increased AMP at HS in the VL is utilized to overcome increased external knee flexion moment. In combination, these muscles provide enhanced stability to the subjects as they prepare to transition to RD locomotion.

LGSA: The SW phase showed the greatest evidence of the upcoming LGSA transition. A combination of TA and MG effects suggest a primary goal for toe clearance, followed by stability. The combination of increasing Tr-AMP and earlier Tr-GC during SW was present in VL and Gmax, which may indicate anticipation and manipulation of stride length to transition to stair locomotion.

LGSD: The LGSD transition elicited significant changes to peak activation characteristics in all seven muscles. Shank musculature showed changes during SW phase with earlier TA Tr-GC and increased MG Tr-AMP. The combined effect allows the toe to clear over the edge of the stair and have ample anticipatory activation for stair landing. Further, the combined effects of reduced RF AMP, earlier VL GC, a switch in phase of peak AMP in BF, increase in Gmax AMP at HS, and increase in Gmed AMP during SW, may aid the shank musculature in aiming and control of foot contact.

RALG: The primary change in the RA to LG transition occurred in the gluteal musculature. The Pre1 gait cycle showed a significant, but minimal, change in overall Gmax GC with earlier peak activation.

RDLG: The MG and BF were found to have significant AMP main cycle effects, while TA showed AMP changes in ST phase. In MG, progressive increases in AMP were observed in HS and ST, while AMP in SW remained the same. Similarly in ST, TA increased in Pre1-AMP over Pre2- levels. Alternatively, in BF, progressive increases in AMP were observed in SW, while HS

and ST AMP were not altered. The increases in AMP during the ensuing ST phase may indicate that MG is pushing off the ramp to alter the downward momentum of the body into a more horizontal path, while TA sustains preemptive activation to ensure proper toe clearance during the ensuing SW phase.

SALG: Though part of the same muscle group, the VL and RF acted in opposition. While VL AMP increased in Pre1, RF AMP decreased. This could be a result of bi- vs. mono-articular musculature, which would allow RF to decrease AMP and allow VL to control knee extension.

SDLG: Activation patterns changed during the Tr gait cycle in TA, MG, and Gmax. While subjects were performing SD locomotion, ST phase activation of the MG and Gmax provided sufficient plantar flexor moment and hip extensor moment, respectively. For TA, decreased Pre1-AMP during ST and SW were observed, seemingly in an effort to reduce potential co-activation in the shank and allow the toes to move into a plantar flexed position for ensuing stair contact.

CONCLUSIONS

Peak EMG activation characteristics change as subjects approach a locomotor transition. Unique patterns observed in this study could be used to enhance classification algorithms in active, mechanized prostheses.

VARIABILITY OF SHEAR STRESSES ON THE PLANTAR SURFACE OF THE FOOT DURING GAIT

Marisa Papp[1], Visar Berki[1], Brian L. Davis[1]

[1]Department of Biomedical Engineering, University of Akron, Akron, Ohio 44325, US
Email: mjp117@zips.uakron.edu

INTRODUCTION

Despite the fact that the plantar foot experiences three dimensional force vectors during gait, only the vertical component has been studied thoroughly in association with diabetic neuropathy. There is evidence supporting the existence of a strong association between diabetic neuropathy and higher plantar shear loads that may be responsible for foot ulceration and re-ulceration. No study to date, however, has examined the reliability of shear measurements. For this study, all forces—anteroposterior (AP) and mediolateral (ML) shear, and pressure—were measured simultaneously. The Coefficient of Variation (CV) was then calculated (as the ratio of standard deviation to mean stress) for these groups across multiple regions of the foot.

METHODS

Shear and pressure data during walking were collected on 29 volunteers (16 Males/13 Females) none of whom had gross foot deformities (minor clawing of the toes was permissible), prior foot surgeries, or foot pain. The study included three groups: a control group (CG) that consisted of 16 subjects with no known diabetic symptoms, 7 older diabetic neuropathy patients (ODN), and 6 younger diabetic neuropathy patients (YDN). Subjects walked at a self-selected pace without any sock or shoe apparel on the shear and pressure evaluating camera system (SPECS). The plantar surface was divided into ten areas, based on the schematics of Cavanagh's work in reference to anatomical structures of the foot [1] (Figure 1). The coefficient of variation percentage (CV) was calculated for all plantar pressure and shear variables in order to observe data variability.
Figure 1. Shear and pressure regions of the foot.

RESULTS AND DISCUSSION

The pressure CV values (Table 1) in the current study were consistently lower, indicating less variability, in all areas except for the midfoot (A7 and A8) when compared to Bacarin et al and Cavanagh et al [1]. Reasons for this could include differences in sensor sizes (the SPECS system has sensors 1.6mm x 1.6mm while Cavanagh et al used a 1.0cm x 1.0cm sensor), differences due to gait speed and/or subjects.

Some theories suggest that patients with neuropathy tend to walk with more variability due to their diminished afferent feedback, while others propose that the neuropathic patients adopt a "robot-like" gait pattern with little variability. In the forefoot regions (A4, A5 and A6), the variability values in diabetic patients seemed slightly lower than for the control group, however, in the toe region (A1) the pressure variability is highest in ODN (Table 2). As expected,

among all testing groups the CV of A7 (medial side of arch) was extremely variable.

This study expands upon the previous research of Cavanagh et al., (1998) who showed there was no significant difference in variability of pressure values in neuropathic diabetic patients [3]. In our study, mean lateral shear CV values were significantly higher in region A4 among CG and YDN compared to ODN (p_{A4}= 0.002), while mean medial shear CV in A5 was significantly higher when comparing CG and ODN with YDN (p_{A5}=0.027). Mean anterior shear CV values for the hallux (A1) were significantly higher in ODN and YDN than in control subjects (p_{A1}=0.044). Meanwhile, A5 had significantly lower values among ODN and YDN compared to CG (p_{A5}=0.045). Mean posterior shear CV was significantly lower among CG and YDN in A5 compared with ODN (p_{A5}=0.016).

The heel area did not hold significant variability comparing the diabetic groups to the CG,

most likely because these shear values are more dependent on heelstrike mechanics rather than intrinsic muscle control. The fact that neuropathic diabetic patients have less variability in shear in the medial forefoot region is interesting because this is a high risk area for ulceration. The issue of repetitive moderate shear stresses in this region is a topic that warrants further investigation due to potential implications in the etiology of foot ulceration.

CONTROL STRATEGIES DURING A STEP UP AND OVER TASK IN PATIENTS SIX MONTHS AFTER TOTAL KNEE ARTHROPLASTY AND HEALTHY CONTROLS

[1]Federico Pozzi, [1,2]Adam Marmon, [1]Lynn Snyder-Mackler and [1]Joseph Zeni

[1] University of Delaware, Newark, DE, USA

email: fpozzi@udel.edu

INTRODUCTION

Compared to healthy controls, subjects after total knee arthroplasty (TKA) exhibit less total support moment (TSM), less knee flexion moment, and a greater contribution from the hip when climbing stairs.[1] Similarly, previous work from our lab has shown that patients after TKA perform a step up and over task with reduced knee moment and increased hip joint moment and power generation.[2] After surgery, biomechanical asymmetries during functional tasks are related to poor functional performance and impaired quadriceps strength.[3] Although quadriceps is weaker, and the kinetic and kinematic strategies are abnormal and after TKA, the underlying muscle activation patterns are unknown. Therefore the purpose of this study was to examine the TSM, the relative joint contribution to the TSM, and muscle activation patterns during the step up and over task in patients six months following TKA and healthy older adults.

METHODS

Nineteen patients 6 months following unilateral TKA and 19 healthy older adults participated in this study (Table 1). Participants stepped up and over a wooden box that was mounted to a force plate. They were instructed to step onto the box with one limb, traverse over the step to clear the swinging limb, land on the force plate in front of the box with the contralateral limb, and continue walking.

Table 1. Demographic charcteristics.

	TKA group		Control group	
	Mean	SD	Mean	SD
Sex, male/female	9/11		10/9	
Age, years	69.8	6.2	68.5	7.3
Height, m	1.68	0.7	1.68	0.9
Mass, Kg	85.96	17.39	74.23	16.75
BMI, kg*m^2	30.12	4.96	26.08	3.87

EMG data were collected using double differential preamplified electrodes placed over seven muscles of the lower extremity (lateral hamstring, vastus lateralis, vastus medialis, tibialis anterior, soleus, and the medial and lateral heads of the gastrocnemius). Maximum volitional isometric contractions (MVIC) were performed to determine the maximum levels of voluntary contraction and used for normalization.

Markers trajectories and kinetic were collected at 120Hz and 1080Hz and smoothed using a low-pass filter (6Hz and 40Hz, respectively). EMG data were collected at 1080Hz, bandpass filtered (20-350 Hz), rectified, and low pass filtered (6 Hz) to create a linear envelope. Dynamic muscle activity was normalized to maximal activity either from the MVIC trial or dynamic trials. Kinematic, kinetic, and EMG data were calculated separately for the stance phase of each limb; these data were time normalized to 100% of stance. For each subjects, EMG data were inspected prior to the analysis; signals that were deemed not usable were excluded from the analysis.

Joint moments were calculated using inverse dynamic and normalized to body mass (Kg). TSM represents the magnitude of the extensor synergy, and was calculated by summing the internal extensor moments at the ankle, knee, and hip joints. The stepping portion of the task was divided into two phases (propulsion and lowering) using the peak vertical position of a marker on the pelvis. During the propulsive phase, time to peak TSM was determined using the interval between foot contact on the step and 1st peak of TSM. During the lowering phase, time to peak TSM was determined using the interval between the highest vertical position of the pelvis marker and the 2nd peak of

TSM. During landing, time to peak TSM was calculated using the interval between foot contact on the ground and the 3rd peak of TSM. Average EMG for each muscle was calculated during each interval. Each joint's specific contribution to each peak TSM was calculated by dividing the joint specific moment by the relative TSM peak.

One of the limbs of the control group was randomly assigned as surgical limb. For each phase, TSM, time to peak, specific joint contribution, and EMG average activation were compared between surgical limb of the TKA and control groups using an independent sample t-test.

RESULTS AND DISCUSSION

During the propulsive phase, the TKA group had smaller TSM (-18%, p = 0.01, Figure 1), longer time to peak interval (+0.08s, p < 0.01, Table 2), smaller contribution of the knee joint (-11%, p < 0.01), and greater contribution of the hip join (+8%, p = 0.02) compared to the control group. EMG activation for all muscles was similar between both groups.

During the lowering phase, the TKA group had longer time to peak interval (+0.04s, p < 0.04, Table 2) and smaller contribution of the knee joint (-10%, p < 0.01) compared to the control group. EMG activation for all muscles was similar between groups.

During the landing phase the TKA group had smaller TSM (-22%, p < 0.01, Figure 1), greater contribution of the ankle joint (+8%, p < 0.02, Table 2), and greater average activation of the lateral gastrocnemius (+38%, p < 0.01) compared to the control group. Greater activation was also found for the medial gastrocnemius (+7%) and soleus muscles (+31%), but these results were not significantly different between groups (p > 0.5).
Figure 1. Total support moment during the step up and over task. Error bar represent 1 standard deviation.

CONCLUSIONS

During the step up and over task, patients 6 months following TKA took longer time peak TSM and the peak values were significantly lower than the control group. Factors such as weakness, dynamic stiffness, pain, and slower movement speed may be responsible for the lower TSM. Patients with TKA also exhibited altered joint contribution to the support of the body, as demonstrated by significantly smaller percentage contribution from the knee joint. Similar to stair ascent,[1] the reduction in knee joint contribution is compensated for by increased reliance on the hip. In contrast, during the landing phase, patient after TKA rely more on the ankle joint to support the body, while simultaneously reducing the contribution demands on the knee and hip joints. This landing strategy appears to require greater activation of the triceps surae. Future work should identify the physical impairments that contribute to these altered neuromuscular strategies.

COMPARISON OF THREE PLUG-IN-GAIT PROTOCOL VARIATIONS IN GAIT ANALYSIS

[1] Swithin S. Razu and [1] Trent M. Guess

[1] The University of Missouri, Columbia, MO, USA
email: swithinr@health.missouri.edu, web: www.mizzoumotioncenter.com

INTRODUCTION

Gait analysis is recognized as an important diagnostic tool for the management of patients with gait pathologies. The Vicon® motion capture system is one of the most sophisticated systems used for gait analysis and the Plug-in-Gait (PiG) [1] skeletal model is widely used. As compared to other models, PiG results are reliable in the sagittal plane but show increasing variability in the frontal and transverse planes [2]. The PiG model relies heavily on the capability of the clinician to identify anatomical landmarks and hence is prone to errors. To overcome this drawback, Vicon® has incorporated a functional calibration method (PiG-FJC) to estimate the hip joint center position and knee rotation axes by moving the associated segments through their functional range of motion. This study evaluates the inter-protocol variability of hip and knee angles using three variations of the Plug-In Gait protocol during gait. The first protocol (PiG) is the conventional PiG model based on the original 'Newington model' [1, 3]. The second method, PiG-FJC, uses optimum common shape technique (OCST) [4] to create virtual rigid bodies. The method then uses symmetrical center of rotation estimation (SCoRE) [5] to estimate the hip joint center and symmetrical axis of rotation analysis (SARA) [6] to estimate the knee joint axes. SCORE and SARA are then combined into the conventional PiG model. The third protocol (PiG-MED) uses medial knee and ankle markers to estimate the thigh rotation offset, shank rotation offset and tibial torsion to be adapted into the conventional PiG model.

METHODS

After providing informed consent approved by the institution's human subjects review board, one female (22 years, 1.68 m, 63.7 kg) and two male subjects (23 and 33 years, 1.75 m and 1.83 m, 80.6kg and 94 kg) participated in this study. A comprehensive marker set was designed by combining individual markers and clusters as required by the three protocols to allow simultaneous data capture. The subjects were marked in accordance to the PiG for the lower body with additional markers on the knee (medial epicondyles) and ankle (medial malleolus) which are necessary for the PiG-MED protocol. For the
Figure 1: Marker locations and skeletal model.

PiG-FJC, four-marker clusters were attached to the anterior-lateral aspect of the thigh and shank. 3-D marker trajectories were acquired at 100 Hz by an 8 camera motion capture system (VICON MX-T40S, Oxford Metrics, UK) and the data was processed independently according to each protocol.

The PiG and PiG-MED protocols require the same static calibration to be performed where the subjects stands in a static up-right posture. The medial markers were removed after static capture. The PiG-FJC uses functional calibration to estimate the hip joint center and knee joint axis. To estimate the hip joint center using SCoRE the subjects performed a star arc pattern consisting of flexion-extension, abduction-adduction and internal-external rotation while standing on the contralateral limb. For the SARA procedure the subjects performed a knee flexion movement pattern while standing on the

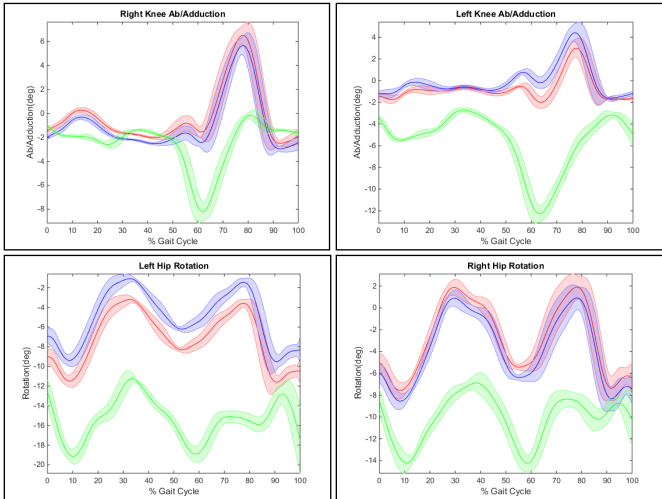
contralateral limb. Relevant anthropometric measures were taken as required by the PiG protocol. The subjects were asked to walk barefoot at their natural speed, and five walking trials were recorded. After data acquisition, 3D marker trajectories were reconstructed and the right and left stride phases identified for all five trials.


Figure 2: Five trial averages and standard deviations for joint angles with the lowest correlation coefficients. PiG (red), PiG-MED (blue) and Pig-FJC (green).

RESULTS AND DISCUSSION

The intra-subject kinematic variability observed was good over the five trials and within a maximum standard deviation of 6.43º for PiG, 6.39º for PiG-MED and 6.64º for PiG-FJC. Good waveform correlation was also observed for hip and knee flexion/extensions for all three protocols.

Table 1: Walk cycle correlation coefficients.

Protocols	Right			Left		
	PiG vs. PiG-MED	PiG vs. PiG-FJC	PiG-MED vs. PiG-FJC	PiG vs. PiG-MED	PiG vs. PiG-FJC	PiG-MED vs. PiG-FJC
Hip flexion/ extension	1.000	0.999	0.999	1.000	1.000	1.000
Hip abduction/ adduction	1.000	0.997	0.997	1.000	0.999	0.999
Hip internal/ external	1.000	0.311	0.311	1.000	0.257	0.257
Knee flexion/ extension	1.000	1.000	1.000	1.000	1.000	1.000
Knee abduction/ adduction	0.998	-0.433	-0.436	0.975	-0.406	-0.543
Knee internal/ external	0.999	0.986	0.989	1.000	0.968	0.968

The PiG and PiG-MED show similar results for all kinematics. Out-of-sagittal plane rotations, especially hip internal/external rotation and knee abduction/adduction revealed poor waveform correlation for PiG-FJC when compared to PiG and PiG-MED as indicated in red (Table 1). The largest variability was observed at the knee abduction/adduction where opposite trends were

observed (Fig. 2). The PiG-FJC hip joint centers were found to be consistently posterior and lateral relative to the PiG hip joint center (Fig. 3). In all three cases the flexion/extension axes for PiG-FJC were externally rotated (Table 2).

BILATERAL VERTICAL STIFFNESS ASYMMETRY DURING A LOW-INTENSITY RUN IN YOUTH MALE ATHLETES

Joong Hyun Ryu, Dino Palazzi

Aspire Academy, Sport Science Dept., Doha, Qatar
email: joong.ryu@aspire.qa, web: http://www.aspire.qa

INTRODUCTION

A stretch-shortening cycle (SSC) during the lower limbs rebound against the ground such as running, jumping, and sprinting is governed by the ability of the musculo-tendon unit to yield against the eccentric stretching of the muscle [1]. Vertical stiffness, calculated as the ratio of the vertical leg spring compression and peak vertical ground reaction force (GRF), often represent SSC mechanically. Although the majority of literature examining vertical and leg stiffness has focused on adults, some studies investigated developmental aspect of neural regulation of stiffness in childhood [2,3]. These studies suggest that as children grow older they improve their ability to use SSC as a result of growth and maturation. The improvement stiffness can be beneficial in sports related tasks performance such as running and jump since we take advantage of the storage and release of elastic energy.

In a developmental context, assessments of bilateral asymmetry, describing functional performance differences between limbs, are also important because the ability to produce stable coordination reflect development of the central controlling structures [4]. In addition, excessive deviations create compensatory movements, modify loading patterns, and may lead to injury or to decline of sporting task performance. Therefore, the aim of current study was to investigate potential age-related difference in bilateral vertical stiffness asymmetry during the running performance as a function of development in adolescent athletes.

METHODS

124 healthy, male student-athletes from 12 to 18 years-old, training up to 8 times a week in 10 different sports, participated for this study. They were well experienced in treadmill running. The age of the participants was calculated on the day of testing. The data allocated into the age range 12-14, 14-16, and 16-18 (table 1).

After warm-up, all participants performed 2-miniutes running at 12 km/h on the instrumented treadmill (ADAL3D-WR, France). Three-dimensional GRF were sampled at 1000 Hz over the 30 seconds at the middle of 2-minutes running period. GRF time series were digitally filtered at 30 Hz cut-off, using a zero phase-lag forth-order Butterworth low-pass filter. Vertical GRF of each contact period (vertical GRF above 10 N) were measured for calculating vertical stiffness of the 40 consecutive steps. Vertical stiffness K_{vert} was calculated as:

$$K_{vert} = F_{max}/\Delta COM$$

where F_{max} is the vertical GRF peak and ΔCOM is maximum vertical displacement of the center of mass (COM), which was calculated by integrating the vertical acceleration twice with respect to time. The symmetry index (SI) of bilateral vertical stiffness was calculated using following formula:

$$SI = \frac{|X_{left} - X_{right}|}{avg(X_{left}, X_{right})} \times 100$$

One-way ANOVA was performed to determine whether there were significant differences among age groups. A post hoc multiple comparison test (Tukey HSD) was performed if as significant main effect was observed. Statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

Significant main effects in vertical stiffness between age group were reported ($F(2,121) = 6.250, p=0.003$). Significantly greater vertical stiffness were reported for the 14-16 age group (39.2 ± 6.7 kN/m) and the 16-18 age group (40.5 ± 6.2 kN/m) in comparison to the 12-14 age group (35.2 ± 7.2 kN/m). There was a significant difference between groups in the SI of vertical stiffness ($F(2,121) = 3.610, p=0.030$). A post-hoc test revealed that the SI of vertical stiffness for the 12-14 age group was significantly higher (10.6 ± 7.4 %) compared to the 16-18 age group (6.9 ± 4.9 %). There was no significant difference between the 12-14 age group and 14-16 age group although a trend towards significance ($p=0.069$). There was no significant difference between the 14-16 age group and 16-18 age group ($p=0.894$).

The results of the current study seem to highlight that the trend in the development of utilizing SSC in multi joint task is dependent on age in youth male athletics. This maybe due to accelerated limb growth during that age and a greater rise in body mass, which is likely to impact on coordination and motor control. Furthermore, the ability to produce stable coordination and to take advantage of using elastic energy stored in the musculo-tendon structures may be acquired during the period between 14 and 16 years of age. If bilateral asymmetry is related to less optimal performance, it maybe important for sport professional to emphasize bilateral movements in training programs for within these periods of growth athletes. In addition, monitoring of bilateral asymmetry in running routinely may help to identify potential running related injuries. Although this finding is from a cross sectional study at present, follow-up longitudinal studies will incorporate in order to confirm finding current study.

GAIT ALTERATIONS IN PERIPHERAL ARTERIAL DISEASE ARE NOT WORSENED BY THE PRESENCE OF DIABETES

INTRODUCTION

Peripheral arterial disease (PAD) is a vascular disease where atherosclerotic blockages restrict blood flow to muscles in the lower extremities. The primary symptom of PAD is intermittent claudication, or pain during walking that results from ischemia of the leg muscles. Claudication is a mechanism not only of pain, but gait dysfunction and those inflicted experience reduced mobility, reduced physical functioning, and decreased quality of life. PAD affects approximately 8.5 million people in the US and 20-30% of those individuals have diabetes [1, 2]. An abnormal metabolic state associated with diabetes affects multiple cell types within the vascular wall adversely and has been found to directly contribute to atherosclerosis [2, 3]. Thus, diabetes is a common co-morbid condition in PAD and has been shown to increase the risk of lower extremity amputation compared to PAD without diabetes [2]. Although there is a clear pathological relationship between diabetes and PAD, the gait mechanics involved remain indistinct. Therefore, the purpose of this study was to determine whether the presence of diabetes in addition to PAD results in greater functional impairment during ambulation. It is hypothesized that the biomechanical adaptations caused by PAD will be to a greater magnitude in individuals also inflicted with diabetes. Additionally, there is an expected effect of condition in PAD groups as the onset of claudication pain will cause further alterations in gait.

METHODS

Twenty-three subjects with PAD and twelve controls consented to participate in the research. The subjects were divided into three groups: PAD and no comorbidities (PAD-NC, 12; age (years): 62.4 ±5.4; height (cm): 178.0± 8.3.; mass (kg): 86.8± 14.8); PAD with diabetes (PAD-D, 11; age: 62.7±5.2; height (cm): 174.63± 5.7; mass (kg): 85.6± 13.9); and healthy controls (12; age (years): 64.4±7.7; height (cm): 178.0± 5.1; mass (kg): 89.8± 16.6). All diabetic patients were without neuropathy. Reflective markers were placed in anatomical locations captured with a 12 camera motion capture system (Motion Analysis Corp, Santa Rosa, CA). Kinematics (60 Hz) and kinetics (600 Hz) were captured using Cortex software (Motion Analysis Corp, Santa Rosa, CA) while subjects walked over ground in pain free and pain conditions. Subjects walked over force plates (AMTI, Watertown, MA, USA) for 5 trials in each condition. After baseline lower extremity biomechanics were captured, subjects performed the 6 minute walk test to induce claudication pain. Following this test, subjects immediately began the pain condition where the walking over the force plates was repeated without rest between trials. Marker position data was exported and analyzed using MATLAB (Mathworks, Inc., Natick, MA) and Visual 3D (Germantown, MD, USA). A mixed ANOVA was used to determine the main effect for group (PAD-NC and PAD-D) and condition (pain free and pain) and Bonferroni was used in the case of significant interactions. Additionally, independent t-tests were used to compare means between control and PAD groups at baseline. Dependent gait variables include spatiotemporal variables (stride time, stride length, step width) and peak kinetic discrete points (ankle plantar flexor, knee extensor, and hip flexor moments; ankle, knee, and hip power generation) affected by PAD[4, 5].

RESULTS AND DISCUSSION

In the comparisons with PAD patients, an effect of condition was found for stride length, ($F_{1, 20}$=4.75, p=0.041), and ankle power generation, ($F_{1, 21}$=8.15, p=0.009) for PAD groups where both values decreased from the pain free to pain condition (Table 1). Contrary to the hypothesis, no main effect of group or any interaction of group and condition were found. PAD has been shown to cause severe myopathy, including altered muscle morphology and mitochondrial function in those afflicted. Therefore, in combination with our findings, it is likely that these problems would dominate any gait deficits caused by diabetes, especially in those without neuropathy.

Regarding the comparisons to controls, ankle power generation was greater in controls with significant differences (M=2.59, SE=.13) from PAD-NC (M=2.04, SE=.42, p=.007) and PAD-D (M=1.96, SE=.58, p=.009). Hip flexor moment was also greater in controls (M=-0.93, SE=0.06) but was only significantly different from PAD-D (M=-0.67, SE=0.08, p=0.012). Another significant difference between controls (M=-0.45, SE=0.05) and PAD-D (M=-0.25, SE=0.06, p=0.017) was found for knee power (Table 1). These results suggest that the PAD-D group has more differences than PAD-NC from healthy controls during pain-free ambulation. The difference in kinetic variables between control and PAD groups are in agreement with previous literature reported by our lab [4, 5].

CONCLUSIONS

Lack of significant group effects between PAD-NC and PAD-D indicates that the mechanisms driving gait deficiencies in patients with PAD are larger than the addition of diabetes on biomechanical variables during locomotion. Significant differences in ankle power generation, hip flexor moment, and knee power between control and PAD groups at baseline in addition to our previous work that found baseline gait deficits prior to the onset of pain further support the idea that gait problems are the results of a known myopathy in these patients. Future research should determine the contribution of these muscular abnormalities to gait alterations and investigate whether improvements in muscular function from treating PAD lead to successive improvements in gait in these patients.

INTRODUCTION

By 2030 there are expected to be over 71 million Americans (19.6% of the population) over age 65 [1], likely resulting in an increased prevalence of chronic diseases, such as coronary heart disease, stroke, and type 2 diabetes. Although walking is the most accessible form of physical activity that can lower the risk of such diseases, 25% of adults over age 55 have difficulty walking one-quarter of one mile [2].

Previous studies have analyzed walking by evaluating muscle function during gait [3-5] (how individual muscles support, brake and propel the body's center of mass (COM)). Only one study has assessed muscle function during gait in healthy older adults rather than young adults [6]. However, their findings may not be representative of all older adults because the walking speed of the older subjects was 1.42 m/s, which is faster than what is typically reported [7].

Older adults walk with altered kinematic and kinetic patterns compared to young adults, even when walking speed is similar [7], which may also suggest altered muscle function in older adults during gait. Thus, the purpose of this study was to determine muscle function during gait in a healthy older adult population and contrast muscle function of healthy older adults with that of a young adult population.

METHODS

Kinematic, kinetic, and electromyography data of the gait of healthy older adults were collected at the University of Wisconsin-Madison as previously described [7]. For this study, a subset of ten healthy older adults (3M, 7F; Age: 73.9 ± 5.3 years; Height: 1.67 ± 0.10 m; Mass: 64.5 ± 10.2 kg) walking at a self-selected speed (1.31 ± 0.11 m/s) was analyzed, based on the suitability of the available data of each subject for simulation analyses.

OpenSim 3.2 [8] was used to generate simulations of one gait cycle for each subject. A generic musculo-skeletal model with 27 degrees-of-freedom and 94 musculotendon actuators [9] was scaled to match the anthropometry of the individual subjects. Joint angle trajectories were determined using inverse kinematics [5]. A residual reduction algorithm [8] adjusted model mass properties and joint kinematics slightly to reduce dynamic inconsistency between the ground reaction forces and body segment accelerations. A static optimization (SO) with an objective function that minimized the sum of squared muscle activations [10] was used to estimate muscle activations and forces in all lower extremity muscles. SO muscle activations were compared to experimental EMG to ensure consistency between the simulated and experimental muscle activation patterns. The instantaneous potential for acceleration (IPA) was calculated to determine the potential of individual muscles to contribute to support and progression of the COM over the gait cycle [5]. To determine individual muscle contributions to support, braking, and propulsion, muscle forces estimated by SO were multiplied by the IPA of each muscle for each subject.

Older adult muscle contributions to support and progression were compared to those of young adults walking at a self-selected speed (1.32 ± 0.13 m/s) from previous work performed at Ohio State [5].

RESULTS AND DISCUSSION

Healthy older and young adults use similar muscles to support (Figure 1), brake and propel (Figure 2) their COM during gait. However, older adults use each muscle to a different degree than young adults. To support their body during the first half of stance, both older adults and young adults primarily use their vasti (VAS) and tibialis anterior (TA). In addition to the vasti, older adults use gluteus medius (GMED) and gluteus maximus (GMAX) for support. Young

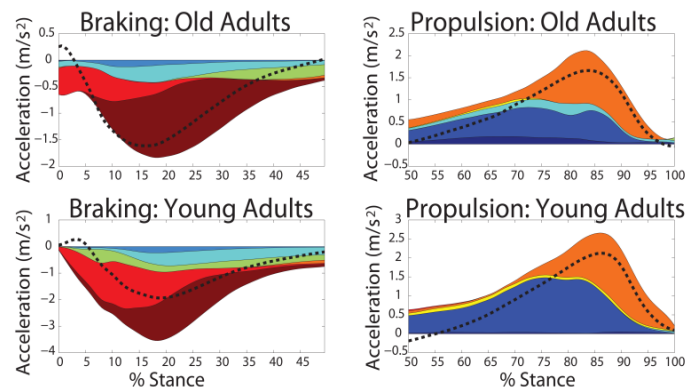
adults primarily use their TA during weight acceptance and their VAS and soleus (SOL) during the rest of early stance. GMED and GMAX also contribute to support during early stance in young adults, but to a lesser degree than observed in older adults. In late stance, SOL provides a majority of the support in older adults while young adults are primarily supported by gastrocnemius (GAS). VAS contributes to support during late stance in young, but not older, adults.
Figure 1: Area plots of muscle contributions to positive support during stance in old and young adults.


Figure 2: Area plots of muscle contributions to braking and propulsion during stance in old and young adults.

To slow the COM during weight acceptance, the TA and VAS primarily contribute to braking in both groups. However, GMED and GMAX contribute more to braking in older adults, while the rectus femoris provides braking in young adults. To propel the COM, young adults use GAS more than older adults. In contrast, older adults rely more on SOL, biceps femoris (BF) and GMED for propulsion.

CONCLUSIONS

The greater use of muscles about the hip (GMED, GMAX, and BF) by older adults reflects a distal to proximal change in neuromuscular control observed previously [11]. These differences in muscle contributions to COM acceleration between the older and young adults may be due to several factors. Although kinematic differences between age groups have been observed in previous studies [6, 7], this finding is not consistent throughout the literature. In this study, although both groups walked at a similar speed, the older adults walked with a more extended hip, greater knee flexion during stance, and greater plantar flexion at toe off compared to the young adults. Kinematic differences could affect muscle moment arms ([R]), a muscle's location on its force-length-velocity curve and thus its force (f), and the orientation and inertial properties of the body segments (the mass matrix: $[M]^{-1}$), which together determine muscle contributions to acceleration ($\ddot{q}$) [3]:

$$\ddot{q} = [M]^{-1} * [R]f$$

However, age-related changes in muscle-tendon parameters, which could affect muscle forces and moment arms, were not modeled in this study. Future studies should examine the effects of age-related changes to neuromuscular properties on muscle function during gait. Finally, the findings of this study suggest a need to better understand the interplay between neuromuscular control, kinematics, and muscle function during gait in older adults.

A NEW METHOD FOR IDENTIFYING TOE-OFF EVENT RUNNING ON A TREADMILL USING KINEMATIC DATA

INTRODUCTION

Many running analysis studies are conducted on a runway with a force plate to identify stance phase events. Although running on a treadmill offers the opportunity to evaluate consecutive steps during an uninterrupted run; in the absence of an instrumented treadmill the stance events must be identified using kinematic data. Therefore, several researchers have developed methods for identifying stance phase events of running on a treadmill using kinematic data [1-3]. Several of the algorithms have been shown accurately identify initial contact, however, accurately identifying toe-off has proven to be more challenging. Therefore, the purpose of this study was to investigate a new kinematic method for identifying toe-off during overground and treadmill running using multi-segment foot model data.

METHODS

Twelve runners ($\geq$ 10 miles/week, 26.3 $\pm$ 4.85 years) volunteered for the study. Six participants conducted overground running trials on a 25 m platform with a force plate (1000 Hz) and six ran on a non-instrumented treadmill. Each participant was equipped with 6.4 mm retroreflective markers identifying the leg and six foot segments: calcaneus, navicular, first and second metatarsal, hallux, fourth and fifth metatarsal, and cuboid. Three-dimensional positions of markers were captured at 200 Hz with a 10-camera Eagle system.

Three different kinematic methods were used to determine toe-off. The new method identified the toe-off event as the maximum MTP joint extension angle after initial contact (SagM). In addition to the new method, the toe-off event was also identified using the minimum vertical position of the toe tip (VTOE) proposed by Maiwald, et al. [2]. The third method proposed by De Witt [1] utilizes the local maximum of the vertical acceleration of the toe tip after initial contact and then linearly interpolates the jerk of the toe tip to determine the time at which jerk is equal to zero (ATOE).

For the overground methods, five successful trials of running at 4.0 ($\pm$10%) m/s were evaluated. Determinations of the toe-off event using the kinematic methods were compared to identification of the event using a force plate (10 N threshold).

For treadmill methods, subjects ran on a treadmill at 3.3 m/s. Ten seconds of running data were captured. Five consecutive steps during the 10 s period were then used to analyze toe-off timing. Because the treadmill was not instrumented, one corner of the treadmill was positioned on the force plate embedded in the runway. For each participant a ground reaction force baseline and toe-off threshold level was determined. The toe-off events using the kinematic methods were then compared to identification of the event using the force plate method.

All three kinematic methods were then compared to the ground reaction force data methods for each trial and the difference in frames was recorded. The differences were then averaged for each subject's five trials and then mean and standard deviations were recorded for the group (overground and treadmill). Positive frame differences indicated that the kinematic method identified an earlier toe-off while negative numbers identified a later toe-off when compared to ground reaction force. Root

mean square differences (RMS) were then calculated to assess error.

RESULTS AND DISCUSSION

For both overground and treadmill running, the SagM method was the most accurate with a frame error that corresponded to 0.007 s and -0.006 s respectively (Table 1). Small RMS values also indicate that this level of accuracy was consistent for all subjects in each group (Table 2). The use of VTOE was moderately accurate for overground running (-0.04 s, RMS=0.04 s), but not for treadmill running (0.22 s, RMS=0.22 s) (Table 1 & 2). The ATOE also had moderately accurate results for both the overground (-0.03 s, RMS=0.03 s) and treadmill running (-0.07 s, RMS=0.07 s) (Table 1 & 2). The results from the previously published ATOE method is similar to results found by De Witt [1] which reported a difference in contact time of approximately 0.02-0.05 s when using the ATOE toe-off prediction. However, both overground and treadmill results when using the VTOE method were much higher than reported by Maiwald, et al. [2] with overground running.

Although, the maximal MTP extension method provided the most accurate estimate for the toe-off event during running overground and on a treadmill, a disadvantage of the method is that it requires a foot model that defines a first MTP joint/complex. The other methods, VTOE and ATOE, do not require the additional joint/complex, however, they do not appear to be as accurate and VTOE does not seem adequate for estimating toe-off with treadmill running. One limitation of this study was comparing treadmill running toe-off event via kinematic methods to the ground reaction force data of the treadmill on a force plate rather than the runner. However, error between the ground reaction force and kinematic methods were similar for overground and treadmill running, suggesting that the ground reaction force data from the treadmill on the force plate was an adequate measure.

CONCLUSIONS

Various kinematic methods for determining toe-off during running gait have been developed and found to have varying levels of accuracy. For studies using a multi-segment foot model that identifies a first metatarsophalangeal joint/complex, using maximal extension angle may provide a very accurate option for identifying toe-off when running overground and on a treadmill.

Naval Medical Center San Diego, San Diego, CA, USA
email: katherine.sharp.ctr@med.navy.mil

INTRODUCTION

Preparing a traumatically injured service member for return to high-level functional activities is arguably important to promote wellness and improve quality of life. Patients incorporate recreational activities, such as running, into their daily lives, driving the need for more research on the topic. While many studies have been conducted utilizing treadmills, previous research has found significant differences between overground and treadmill running [1]. Due to the disparities between the two, the focus of this effort is on overground running, specifically a comparison between the running biomechanics of patients wearing the Intrepid Dynamic Exoskeletal Orthosis (IDEO) and patients with unilateral, transtibial amputations (TTA). This current work presents initial findings in regard to power, work, and mechanical efficiency calculated from data collected on an outdoor, overground motion capture system.

METHODS

Eight patients (ages 28±6 yrs; height 1.8±0.1 m; weight 89.7±12.9 kg), who had been previously cleared for high-level functional activity by their providers, were studied. Five of the eight patients had undergone limb salvage procedures and wore the IDEO while running. The remaining three were TTA patients using the Össur® Flex-Run™ prostheses.

Kinematic and kinetic data were collected outdoors on the straightaway of a 100m track using 12 Raptor-E infrared cameras (Motion Analysis Corp., Santa Rosa, CA, USA). Frontal and sagittal high-speed videos (Nikon Corp., Tokyo, Japan) were taken for reference purposes. Four portable Kistler force plates (Kistler Group, Winterthur, Switzerland) were embedded into a portable walkway so they were flush with the running surface. Analog data were sampled at 1800Hz and a fourth order Butterworth filter with a cut-off frequency of 30Hz was applied. After suiting a patients' lower body with 34-reflective markers on specific anatomical landmarks, they were asked to repeatedly pass through a 30m capture volume at their self-selected jogging speed. For IDEO patients, shank clusters were placed on the lateral portion of the proximal cuff of the orthosis. On the affected limb of TTA patients, shank clusters were placed on the lateral portion of the prosthetic socket, and the ankle joint was defined as the apex of the curve on the running prosthesis. Testing ended with successful collection of a minimum of three clean force plate hits per leg and at least six full gait cycles per leg. Kinematic, kinetic, and temporal-spatial data were processed using Visual 3D software (C-Motion Inc., Germantown, MD, USA). Power, work, and mechanical efficiency were calculated using the unified deformable (UD) segment model [2].

RESULTS AND DISCUSSION

Descriptive statistics on initial results can be found in Table 1. Initial results indicate differences between the affected and unaffected limbs of the observed IDEO users. The affected limb generated less positive work and less maximum power compared to the unaffected limb. In this same group, the affected limb was less mechanically efficient than the unaffected limb. There were no large differences in minimum power or negative work between limbs for patients running in the IDEO. Differences between the affected and unaffected limbs of TTA patients were minimal for all UD segment model calculations.

When comparing across groups, initial results also indicated differences. The affected limb of IDEO patients produced less positive work and reduced mechanical efficiency compared to the affected limb of TTA patients. Figure 1 demonstrates how the peak minimum and maximum powers of the affected limbs in each group differ in timing and magnitude with IDEO patients displaying diminished peaks that occur later in stance. Conversely, the power absorption and power generation of the unaffected limb for both patient groups follows a similar pattern. TTA patients within this particular sample appear to be more dynamic runners because they display a more equal distribution of absorption and generation of power compared to IDEO patients.
Figure 1: UD power of each limb (Un = unaffected, Aff = affected) presented by IDEO and TTA patients over stance phase of the gait cycle while running.

The main limitation of this initial study is an insufficient sample size. A post-hoc power analysis calculation determined that a sample size of 12 (six patients per group) is necessary to achieve 80%

power. Therefore, the primary immediate goal is to study additional IDEO users and patients with amputation in order to determine if significant differences exist. Future work will also look at kinematics and kinetics of these two patient populations while running.

Presented here are initial findings of running data collected on IDEO and TTA patients in an overground, outdoor environment, the first of its kind for the Navy. Assisting in the transition of our wounded warriors back to high levels of functional activity and increasing their quality of life is a priority. Hopefully, by equalizing the efficiency ratio between affected and unaffected limbs, future overuse injuries and/or injuries due to poor mechanics can be avoided.

INTRODUCTION

Lower limb trauma (LLT) leads to significant loco-motor impairments [1]. Lateral movements are especially difficult for these individuals [2-3]. Rapid lateral movements are a common occurrence in everyday locomotion, from navigating a crowded sidewalk to avoiding other shoppers at the grocery store. Yet, these specific movements are under-trained and under-researched in clinical populations. Thus, we determined how functional deficits due to LLT affected lateral walking transitions using a virtual reality obstacle course. We hypothesized that individuals with greater functional deficits would require greater time to execute the transitions and would exhibit less smooth transition trajectories.

METHODS

Two able-bodied controls (AB) and 7 individuals with varying levels of LLT (including limb salvage, transtibial amputation, knee disarticulation, and transfemoral amputation) participated. The protocol consisted of a functional assessment and navigating a virtual obstacle course in the Computer Assisted Rehabilitation Environment (Fig. 1A-B). We used the four square step test as a clinically relevant measure of movement function [4]. The obstacle course consisted of the participant walking at 0.9 m/s while navigating an avatar through a series arches in one of 4 lanes projected on the screen with the goal of hitting as few arches as possible (Fig. 1C). Though participants made 1 and 2 lane transitions, here we only analyzed the more challenging 2 lane transitions.
Figure 1: A) Patient walking in the CAREN, B) Example of obstacle course VR scene, C) Pelvis trajectory during typical obstacle course trial.

To measure the timing of the transitions, we calculated the amount of time from exiting the final arch of a set to crossing midway to the next arch set. We quantified the smoothness of the transitions as the sum of the squared jerk across the entire transition zone between arch sets.

To identify how functional abilities influenced lateral transitions, we correlated 4SST times with total number of arches hit, time to midpoint, and summed squared jerk. We tested what differentiated successful and unsuccessful transitions using paired t-tests. We also used paired t-tests to identify differences in transitions toward and away from the injured leg.

RESULTS AND DISCUSSION

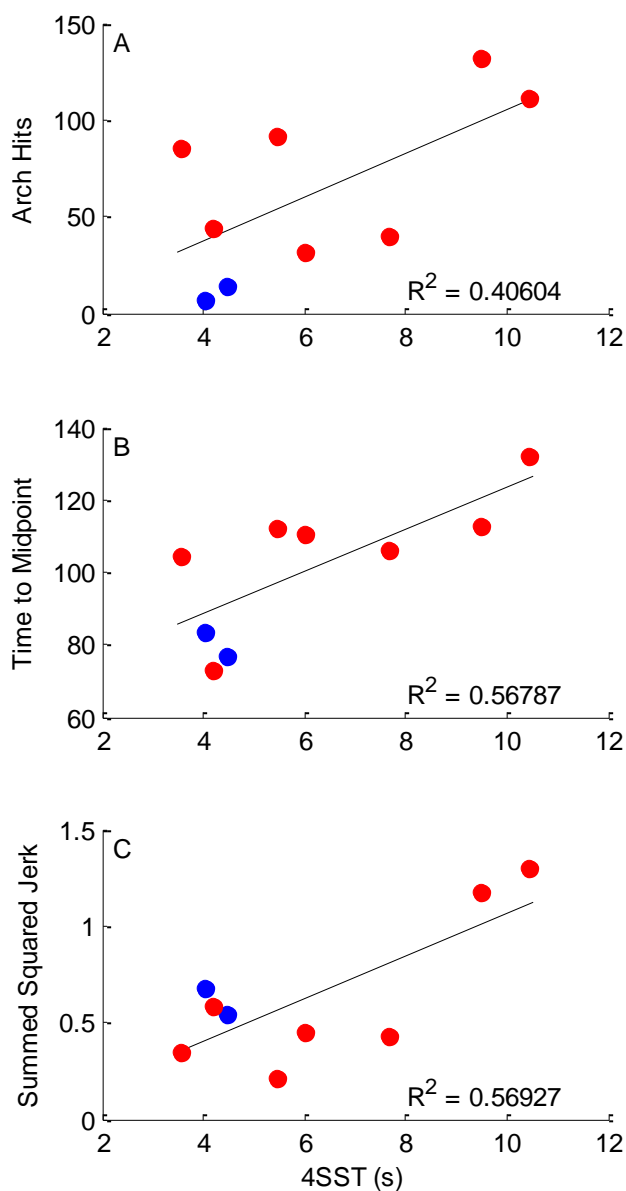
As hypothesized, 4SST was positively correlated with total arch hits, time to midpoint, and summed squared jerk (Fig. 2). Thus, more impaired individuals, as measured by greater 4SST times, had a more difficult time completing the transitions.


Figure 2: Correlations between 4SST and transition characteristics for AB (blue) and LLT (red) participants. Transition performance worsened with greater lower limb functional deficits.

The only significant difference between successful and unsuccessful transitions was the time to midpoint (Table 1). This suggests that, though more impaired individuals had less smooth trajectories, the ability to quickly move laterally was an important determinate of successful lateral transitions.

Contrary to our hypothesis, there were no significant differences between strategies when transitioning towards or away from the injured leg for the dependent measures quantified here (Table 1). This is likely due to the fact that lateral transitions place large demands on both legs regardless of direction, with one producing a large lateral force to initiate the transition and the other producing a large, opposing force to slow the lateral movement and return to straight steady walking.

Table 1: Comparison of time to midpoint and summed square jerk for transition success and transition direction. Bold values indicate significant difference at $p<0.05$.

	Successful	Unsuccessful	Uninjured	Injured
Time to Midpoint	**99.44**	**128.00**	111.65	102.95
Summed Squared Jerk	0.64	0.63	0.61	0.67

CONCLUSIONS

LLT significantly impairs the ability to make successful lateral walking transitions and alters the movement patterns used to make them. Due to the ubiquity of these types of movements in everyday life and the potential implications for maintaining stability (i.e., for fall risk), it is important to include lateral transitions in both clinical assessments and in rehabilitation programs. Based on the variables we investigated, the ability to quickly move laterally appears to be an important factor in successful lateral transitions. However, more detailed analyses of these movement patterns may yield additional insights into the strategies these patients use to achieve successful transitions.

ATTENTION ALLOCATION ABILITY IN DUAL TASKS AMONG DIFFERENT AGES

Meng Liu, Jerod Post, Ka-Chun Siu

Clinical Movement Analysis (C-MOVA) Laboratory, Physical Therapy Education,
University of Nebraska Medical Center, Omaha, NE, USA
Email: mandy.liu@unmc.edu; web: http://www.unmc.edu/alliedhealth/research/cmova/

INTRODUCTION
A growing body of literature investigates the ability to multi-task and to allocate attention between tasks at different age groups [1-3] with a common goal of reducing fall incidences in older population. Increasing complexity of secondary task has more effects on the gait control for older than young group [2,3]. However, middle-aged subjects are not usually tested even though they are the major workforces of our modern society.

Therefore, this study investigated the ability of attention allocation between two tasks among different age groups. We hypothesized that (1) the ability to allocate attention between two tasks would be varied depending on age and complexity of secondary task; (2) dual task performance of middle age subjects would lie between that of young adults and older subjects.

METHODS
Twelve young (19-34), six middle-aged (35-64) and three older healthy subjects (65-80) were included in this study. Subjects crossed two obstacles and performed a secondary task while the gait information was recorded through a pressure-mapping walkway (ProtoKinetics, Havertown, PA). Gait velocity was computed using ProtoKinetics Movement Analysis Software. Secondary task included an easy (7 items) and a hard (20 items) symbol recall test. Number of Responses was recorded. Instructions of five different percentages of attention allocation conditions between walking and secondary task were randomly given to all subjects: 0-100%, 25-75%, 50-50%, 75-25% and 100-0% respectively on walking to secondary task (Conditions 1-5).

Dual Task Cost, DTC = [(Dual task–single task)/ single task] was calculated from gait velocity. The Attention Allocation Index (AAI) of gait was computed using AAI = (P-S)/N where P, S and N represent the conditions with 100-0%, 0-100% and 50-50% of attention allocation respectively on walking to secondary task. The AAI of number of responses was computed as AAI = (S-P)/N. Three-way repeated measures ANOVA (3 age groups x 5 conditions x 2 tests) was conducted to compare all gait parameters, number of responses of secondary task and DTC of all measures.

RESULTS AND DISCUSSION
The ANOVA indicated that significant interactions between age groups and attention allocation conditions existed in gait velocity (F=2.728; p=0.04) and the DTC of gait velocity (F=5.697; p=0.001). Older subjects walked more slowly while focusing more on walking (Figure 1) and their DTC of gait velocity decreased across conditions 1-5. Middle-aged and young subjects did not show such trend in gait, but the dual-task performance of middle-aged group did lie between young and older groups. The reduction of gait performance could be due to the "stiffening strategies" of elder people [4]. When older participants were instructed to allocate more attention to walking, they strategized to slow down their gait. These results indicate that healthy older adults are capable to allocate their attention, but possibly with a paradigm shift using different attention allocation strategies. Such paradigm shift is further confirmed in Figure 2.

The AAI captured the ability to allocate attention between two tasks. Figure 2 illustrates the allocation attention paradigm shift from a positive relation in young adults to a negative relation in elderly. Most

young participants were able to speed up their gait when they allocated their attention to walking and were able to increase the number of responses when they allocated their attention to the secondary symbol recall test. However a paradigm shift begins in middle-age group that the ability of attention allocation becomes less profound. A reversed relation (paradigm shift) was shown in our small sample of older adults.
Figure 1. Gait velocity in 5 conditions among three different age groups.

Results of the number of responses showed that significant interactions exist between attention allocation conditions, age groups and tasks (F=2.8, p=0.016). Young subjects recalled the most numbers in both secondary tasks. Secondary task performance of middle-aged subjects was at the middle level among three groups (Figure 3). This supports our hypothesis and agrees with the result of previous study [5]. The number of responses was similar in older participants regardless of instruction (Figure 3). Older adults might prioritize their attention on walking to reduce the risk of falling [5].

We conclude that the ability of attention allocation varied at different ages. The dual task performance of middle-aged group was at the middle level among three groups. Although the attention allocation instructions (e.g. 25-75%) between two tasks were abstract or even ambiguous, all subjects were able to shift their attention based on instructions, with a paradigm shift of allocation attention ability starting at the middle-aged group. More healthy older subjects are currently studying to confirm our important interpretation.
Figure 2. The AAI between gait velocity and number of responses among three different age groups in the easy symbol recall test.

INFLUENCE OF HEEL TYPE ON STRIDE LENGTH

Lorraine Smallwood, Adam Jadgodinsky, Christopher Wilburn and Wendi Weimar
Auburn University, Auburn, AL, USA
email: weimarwh@auburn.edu

INTRODUCTION

The introduction of high heeled shoes in the 1600's started a major trend in women's fashion that continues to this day. A myriad of styles including stiletto heeled and wedge heeled shoes have entered the marketplace. Many studies have shown that kinematic changes occur in gait while wearing high heeled shoes. Esenyel et al., found that stride length decreased from 137 to 131 cm when wearing a 6 cm high heeled shoe [1]. Barkema et al., noted women had a significantly shorter stride length while wearing a 9 cm heel when compared to wearing 1 and 5 cm heels when walking at a self-selected pace [2]. When women wore high heels (5 cm) for at least 40 hours per week, Cronin et al., found step length to be significantly shorter than for those who did not habitually wear high heels [3]. These studies looked only at barefoot and stiletto style high heeled shoes. Wedge heeled shoes have been part of the fashion world for many years, but there is little research on the effects of wedge heeled shoes on gait. Walking barefoot while in plantar flexion mimics gait while wearing high heeled shoes, except there is no support for the foot that is normally found in shoes. The purpose of this study is to examine the effects of different styles of high heeled shoes as well as walking barefoot in plantar flexion on spatial gait parameters.

METHODS

Four healthy adult females (age 22.6 years ± 2.21; height 1.62 m ± 0.04; weight 63.28 kg ± 4.48) who were comfortable wearing high heeled shoes and with no lower limb injuries for the past six months volunteered for this study. The participants walked on a 4.75 m instrumented walkway under four randomized conditions: barefoot, barefoot while in plantar flexion (tip toe), stiletto heeled shoes and wedge heeled shoes. Each condition involved three trials of walking at a self-selected pace. Stride length was compared over the four conditions. Participants wore B-flexible by Bandolino BDINSPIRE stiletto heeled shoes and Forever Doris-22 wedge heeled shoes in the appropriate size. Both styles of shoes were marketed as 3" (7.62cm) heels and were similar in style. The only major difference between the shoes was the heel type. Kinematic data was sampled via Vicon T-Series T40S at 100 Hz, (Denver, Colorado, USA). Reflective markers were placed on the first metatarsophalangeal joint, heel, cuboid, navicular, medial and lateral malleolus, medial and lateral knee, and trochanter on each leg. Kinematic data were extracted from Vicon Nexus. Stride length was calculated through Excel 2013. Prior to statistical analysis stride length was normalized to body height.

RESULTS AND DISCUSSION

Results from the 1 (participant) x 4 (footwear condition) one-way ANOVA failed to reach statistical significance (barefoot to stiletto, p=0.191; barefoot to tiptoe, p=0.206; barefoot to wedge, p=0.136; stiletto to tiptoe, p=0.956; stiletto to wedge, p=0.818).
Figure 1. Stride length normalized to body height.

The purpose of this study was to determine if wearing high heeled shoes or walking barefoot while in plantar flexion would influence spatial gait parameters. It was hypothesized that stride length for barefoot gait would be greater than when shod or when walking while in plantar flexion (Figure 1). While not significantly different, stiletto heeled gait did yield a slightly longer stride length. This finding is in contrast to Esenyel et al., who found a decrease in stride length when walking with high heels [1]. Next, it was hypothesized that tip toe gait would result in shorter stride length than barefoot gait since the smaller area of foot contact with the floor leads to a smaller area for the body's base of support. The trend shows a larger stride length while walking in plantar flexion, however, this is not significantly different. Wearing wedge heeled shoes during gait was also hypothesized to result in shorter stride length than when walking barefoot. While not significantly different, the difference between barefoot and wedge heeled gait is the largest amongst all conditions. This leads to question if the additional surface area of the wedge heeled shoe's sole allows the individual to feel more secure in their gait and thus increase their stride length.

Stiletto heeled shoes have a heel surface area of 1 cm^2. Hence, the surface area of the shoe's sole that makes contact with the ground during gait is greatly reduced when compared to barefoot. It was hypothesized that tiptoe gait would produce a smaller stride length than walking on stiletto heels since walking on tiptoe resulted in even smaller amount of surface area of the foot in contact with the ground than while shod in stiletto heeled shoes. Stride length for both conditions were nearly identical (Figure 1). Since there is more surface area of the wedge heeled shoe's sole making contact with the ground than when wearing stiletto heeled shoes, it was hypothesized that stride length while walking in wedge heeled shoes would differ from walking in stiletto heeled shoes. While no significant differences were found between these conditions, an increase in stride length was seen when individuals shod with wedge heeled shoes were compared to stiletto heeled shoes. Continuing research with a larger population should clarify the trends seen in this pilot study.

MODELING THE LEAN RELEASE, LEAN RELEASE WITH WAIST PULLS AND WAIST PULL WHILE WALKING PERTURBATIONS WITH AN INVERTED PENDULUM

INTRODUCTION

Moglo and Smeesters [1] compared large forward lean releases, lean releases with waist pulls and waist pulls while walking in both younger and older adults. Thiaux et al. [2] compared large forward lean releases and surface translations in younger adults. Both showed that the angular positions and velocities at reaction time of the threshold of balance recovery trials formed a perturbation threshold line separating falls from recoveries, regardless of the postural perturbation. The perturbation threshold line also declines with age, shifting down and to the left [1].

Thiaux et al. [3] showed that a two-dimensional thin rod inverted pendulum mounted on a horizontally moving skid could accurately model the outcome of lean releases and surface translations for younger adults: an unavoidable fall (above perturbation threshold line) or balance recovery (below line).

The purpose of this study was to determine if the inverted pendulum model by Thiaux et al. [3] could also simulate the lean releases with waist pulls and waist pulls while walking experiments by Moglo and Smeesters [1] for both younger and older adults.

METHODS

Experimental procedure: The maximum forward initial lean angle from which 10 younger (YA: 20-25yrs) and 10 older (OA: 62-73yrs) healthy adults (50% women) could be suddenly released and still recover balance was determined for 3 waist pull forces including zero [1]. The maximum forward waist pull force that the same participants could suddenly sustain and still recover balance was also determined for 2 walking velocities [1]. The initial lean angle was increased from 5deg in 2.5deg increments while the waist pull force was decreased from ~600N in ~25N increments, until participants failed to recover balance twice at a given initial lean angle or succeeded in recovering balance at a given waist pull force, respectively. Balance recovery was successful if participants used no more than one step and less than 20% body weight was supported by the safety harness. Angular position (or lean angle), angular velocity, waist pull force and walking velocity were measured from onset of perturbation (OP) to reaction time (RT) using 3 force platforms, 3 load cells and 2 optoelectronic position sensors with 24 markers.

Inverted pendulum model: The maximum perturbations were simulated in Matlab using the inverted pendulum on a skid model by Thiaux et al. [3], immobilizing the skid by setting its mass $M=\infty$, pull force $F_2=0$ and coefficient of friction $\mu=0$. The inputs were the mass of the participant (m), height of the participant (h), gravity ($g=9.81m/s^2$), waist pull force (F_1) and ankle torque ($\tau=0$). The outputs were the angular position (θ), velocity (ω) and acceleration (α) from OP to RT. The initial conditions were θ_o and $\omega_o \approx 0$ for lean releases, and $\theta_o \approx 0$ and ω_o for waist pulls while walking.

Data analysis: The error between the experimental and theoretical angular positions ($\delta\theta$) and velocities ($\delta\omega$) was calculated from OP to RT for trials at the maximum lean angles or pull forces. Single sample t-tests then determined if the errors were different from zero, while repeated measures analyses of variance determined the effect of the postural perturbations on the errors. Linear regressions were also used to establish the relationships between the angular positions and velocities at reaction time for the threshold of balance recovery trials.

RESULTS AND DISCUSSION

For both YA and OA, all RMS errors and errors at RT were significantly different from zero (p≤0.008), except for $\delta\omega$ errors at RT for waist pulls while walking (p≥0.190). Nevertheless, errors were all 5% or less of the experimental perturbation threshold line intercepts for YA, except for $\delta\omega$ errors for lean releases with waist pulls which were still 13% or less (Table 1). All RMS errors and nearly all errors at RT were greater for lean releases with waist pulls compared to lean releases and waist pulls while walking (p≤0.049). Only $\delta\omega$ errors at RT for OA were not significant for postural perturbation effects (p=0.081). The experimental ($\theta_{YA} = -0.250\omega_{YA} + 40.9$, r²=0.946 and $\theta_{OA} = -0.202\omega_{OA} + 28.1$, r²=0.874) and theoretical ($\theta_{YA} = -0.219\omega_{YA} + 35.7$, r²=0.885 and $\theta_{OA} = -0.177\omega_{OA} + 24.1$, r²=0.732) angular positions and velocities at RT for the maximum perturbations formed very similar disturbance threshold lines (Figure 1).

CONCLUSIONS

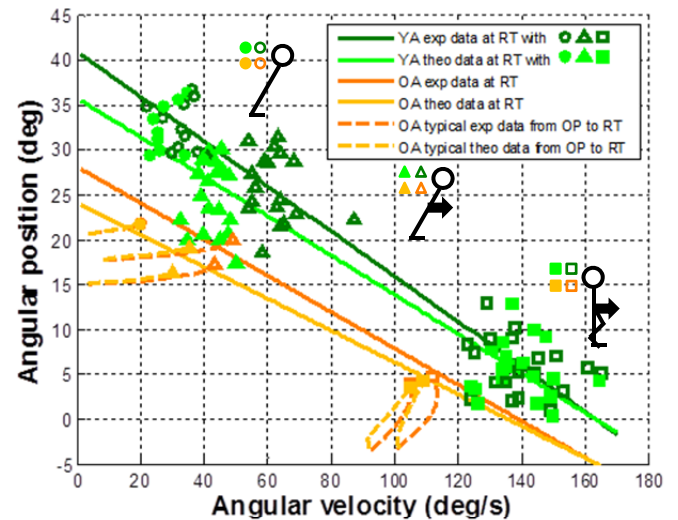
The inverted pendulum on a skid model by Thiaux *et al.* [3] can not only accurately model the outcome (fall or recovery) of lean releases and surface translations for YA, but can also accurately model the outcome of lean releases, lean releases with waist pulls (to a lesser extent) and waist pulls while walking for both YA and OA. This reduces the need for time consuming and dangerous experiments,


Figure 1: Perturbation threshold lines. For clarity, typical data from OP to RT lines for YA and data at RT points for OA are not shown.

especially if large postural perturbations are used and avoiding a fall is not always possible.

The Sensitivity of Predicted Knee Contact Mechanics during Gait to Variations in Ligament Properties

[1] Colin Smith, [1] Rachel Lenhart and [1] Darryl Thelen

[1] University of Wisconsin-Madison, Madison WI, USA
email: dgthelen@wisc.edu, web: http://uwnmbl.engr.wisc.edu/

INTRODUCTION

Subject-specific multibody models of the knee joint provide valuable insight into the mechanics of the healthy and pathologic knee during movement. However, the quality of the predictions of these models is directly dependent on the accuracy of the model parameters. While knee model geometries can be segmented from magnetic resonance (MR) images, other parameters such as ligament stiffness and reference strains must be estimated. As a result, the uncertainty in these ligament parameters can propagate into the predicted knee mechanics. The objective of this study was to use a probabilistic approach to evaluate the propagation of variations in ligament properties onto knee kinematics and cartilage contact pressures.

METHODS

A three body, 12 DOF knee model was developed from MR images of a healthy adult female (1.65 m, 61 kg). Fourteen ligaments were represented by bundles of nonlinear elastic springs, with wrapping surfaces included to prevent penetration of bony geometries. Articular cartilage surfaces were segmented from the MR images and represented by high resolution meshes. Cartilage contact pressures were calculated by detecting overlap between the articulating surfaces and using an elastic foundation model to determine pressure based on the depth of penetration. The knee model was integrated into an existing lower extremity musculoskeletal model [1], which included 43 muscles acting about the hip, knee and ankle joints. The predictive capacity of the model was validated by comparing simulated passive and active knee kinematics with *in vivo* 3D knee kinematics measured with dynamic MRI [2].

Whole body kinematics and ground reactions were recorded while the subject walked overground in a motion analysis laboratory. At each frame of a gait cycle, an enhanced static optimization (ESO) routine [3] was used to calculate muscle forces, patellofemoral kinematics and secondary tibiofemoral kinematics that minimized a weighted sum of squared muscle activations while satisfying overall dynamic constraints. The constraints required that the muscle forces and internal knee loads (contact pressures, ligament forces) produced by the optimized knee kinematics generate the measured hip, knee (flexion) and ankle accelerations.
Figure 1: Multibody 12 degree of freedom knee model and representative pressure map

We performed a monte carlo analysis to evaluate the propagation of uncertainty in ligament stiffness and reference strain values into predicted joint mechanics. Nominal values were determined from previous models [4] and tuned to ensure predicted passive kinematics reproduced measured passive kinematics. In the probabilistic analysis, ligament stiffness and reference strains were represented by normal distributions centered at the nominal values with standard deviations of 30% of the mean and 0.2, respectively [5]. A total of 2000 simulations were performed using a high throughput computing grid using randomly selected values from the parameter distributions.

RESULTS AND DISCUSSION

The predicted tibiofemoral kinematics showed variability in each of the degrees of freedom. Internal-external rotation showed the most variability with the maximum standard deviation (5.6°) occurring during swing phase. The superior-inferior translation and medial-lateral translations showed similar variability to the anterior-posterior translation.
Figure 2: Anterior translation and internal rotation of the tibiofemoral joint during gait. The black line and shaded area represent the mean ± 2 standard deviatons of the monte carlo simulations.

Metrics of articular contact such as mean pressure and contact area also showed substantial variability. The mean pressure on the medial and lateral tibial plateaus had a maximum standard deviation of 0.52 MPa and 0.86 MPa, respectively. The medial and lateral contact areas showed maximum standard deviations of 45.9 mm^2 and 48.0 mm^2.

Further analysis will reveal the individual ligaments which contribute the most to the variability in the predicted results. This will provide valuable insight into the function of specific ligaments during walking.
Figure 3: Mean pressure and contact area of the medial tibial plateau over a gait cycle. The blue line and shaded area represent the mean ± 2 standard deviatons of the monte carlo simulations.

CONCLUSIONS

The probabilistic analysis showed that variations in ligament stiffness and reference strains produce substantial variability in the predicted tibiofemoral kinematics and contact mechanics. This indicates that future work is required to accurately determine the values of the ligament parameters.

ASB 2015 Meeting Chair
asb2015@osu.edu

CONCLUSIONS

Abstracts for the 39th ASB meeting must be submitted electronically via our website and received by March 15, 2015. Recall the old adage (slightly modified) that "Failure to plan on your part does not constitute an emergency on ASB's part". In the event that a submission is incomplete or received after the submission deadline, the abstract will not be reviewed and considered for the conference program.

At the time of submission, please indicate your preference for a podium, poster or thematic poster presentation. Thematic posters involve presenting a research poster, providing a short (3 min or less) summary of the research and participating in an active discussion among the audience participants. If we are unable to accommodate your preference, your abstract will still be considered for other presentation types. Also, if a student is the first author, please indicate this on the abstract submission page of the website.

JOINT MOMENT PATTERNS DURING A FATIGUING RUN

Nathaniel I. Smith and Brian R. Umberger

University of Massachusetts, Amherst, MA, USA
email: nathanis@umass.edu, web: http://www.umass.edu/locomotion

INTRODUCTION

The vast majority of research on running biomechanics involves brief runs of moderate intensity, such that participants experience minimal fatigue. Because fatigue is an inevitable consequence of strenuous running, addressing its effects naturally leads to a more complete understanding of "real world" running scenarios. Previous work has found that when fatigued, runners use altered kinematics and experience reduced impact attenuation, increased metabolic cost and greater susceptibility to overuse injuries [e.g., 1-3]. In addition, the capacity of leg muscles to produce force is impaired after runs as short as twenty minutes [4]. Research in this area has thus far not addressed gait variables that lie functionally between muscle forces and kinematics.

A better understanding of the kinetic changes that underlie these fatigue effects could lead to improved training and rehabilitation protocols. As a first step toward achieving these goals, the current investigation aims to characterize changes in lower extremity joint moment profiles occurring over the course of an exhaustive run.

METHODS

Participants were eight recreational runners (four male, four female; 24.6 ± 5.8 years; 1.70 ± 0.10 m; 69.6 ± 15.1 kg; 42 ± 14 km/wk). All participants were habitual rearfoot strikers and were uninjured for at least three months prior to testing. All methods were approved by the university's Institutional Review Board.

In order to standardize the speed of the exhaustive run, participants' speed at lactate threshold was determined by means of a speed-based incremental treadmill test, conducted three to seven day prior to the exhaustive run. Speed of lactate threshold, determined by two independent reviewers, was defined as the speed of the fastest stage prior to a sharp and sustained increase in blood lactate concentration.

Exhaustive runs were completed on the same force-instrumented treadmill used for the incremental tests (Bertec Corporation, Columbus, OH). The speed of the run was set such as to elicit 95% of the oxygen consumption recorded at lactate threshold. Three-dimensional (3-D) kinematics were recorded using a motion capture system while force data were measured using the instrumented treadmill. Marker trajectories and force data were recorded for ten seconds each minute, and perceived exertion (Borg scale) was reported by participants every two minutes throughout the test. Due to the varied durations of the exhaustive runs, trials coinciding with 20, 40, 60, 80 and 100% of the run duration were selected for analysis.

3-D joint angles and moments were calculated using Visual 3-D, and dependent variable values were calculated using custom-written Matlab software (The MathWorks, Natick, MA).

Statistical analysis was conducted using SAS software (SAS Institute Inc., Cary, NC). One-way analyses of variance were used to test for significant differences in variable values across percent of run duration. Trends in variables that showed significant change were described with linear or polynomial regression curves.

RESULTS AND DISCUSSION

Despite a significant increase in rate of perceived exertion ($p < 0.001$, 12.2 ± 0.6 at 20% vs. 19.1 ± 0.8% at 100%), no significant changes in joint moment or joint angle variables were seen between
Figure 1: Group mean sagittal knee joint moments at 60, 80, and 100% of run duration. Vertical line indicates toe-off.

the beginning and end of the run. Figure 1 exemplifies the remarkable consistency in the joint moment profiles evaluated. Temporal variables indicated that participants maintained their stride length (p = 0.79) and stance time (p = 0.56). Frontal plane kinematics and kinetics were also relatively unaffected by fatigue, as participants used similar peak hip abductor moments (p = 0.80) to achieve similar peak adduction angles (p = 0.13). The standard deviation of gait variables within individual trials was evaluated as a means of detecting changes in variability accompanying fatigue, but these measures did not change significantly during the exhaustive run.

The changes in peak joint moments between the middle and end of the run for the two fastest runners (lactate threshold speeds of 4.30 and 4.57 m/s) and the two slowest runners (lactate thresholds at 3.27 and 3.21 m/s) are presented in Table 1. These groups demonstrated similar changes in peak moments during this period with the exception of the hip flexion moment. This difference could suggest that as their hip flexors fatigued, faster runners adjusted their patterns of muscle activation in order to reduce peak muscle force demands while maintaining the hip range of motion necessary to prepare the foot for ground contact. Alternatively, psychological differences between faster and slower runners could have resulted in higher levels of muscular fatigue before faster participants reached volitional exhaustion. Reductions in peak moments occurring non-uniformly across joints may imply

differences in the rates at which fatigue develops between muscle groups.

Table 1. Changes in selected peak joint moments occurring between 60% and 100% of run duration in the fastest and slowest participants.

	Fastest Runners	Slowest Runners
Peak Hip Flexion Moment	- 8.3%	+ 1.4%
Peak Hip Abduction Moment	+ 6.6%	+ 4.3%
Peak Knee Extension Moment	- 0.8%	- 0.8%
Peak Ankle Plantarflexor Moment	+ 0.5%	+ 1.3%

The duration and relative intensity of the exhaustive run utilized in the present study likely impaired the force-producing capacity of participants' leg extensor muscles [4]. The lack of change in the present results may imply that the muscle forces required to accomplish submaximal running gait are moderate enough to remain unaffected by mild muscular fatigue. Alternatively, net joint moments could be maintained while reducing individual muscle forces by altering patterns of co-contraction, which could be addressed in future studies using electromyography. Lastly, it should be acknowledged that motion capture during an exhaustive run introduces many factors which may have increased somatic stress and caused participants to end the test for reasons other than fatigue, including but not limited to the enforcement of a constant running speed and the hardness of the treadmill, itself.

Effects of Transcutaneous Electrical Nerve Stimulation on Gait Kinetics in Individuals with Experimentally Induced Knee Joint Pain

Seongjun Son, Hyunsoo Kim, Matthew K. Seeley, and J. Ty Hopkins

Brigham Young University, Provo, Utah, USA
Email: seongjunson@gmail.com

INTRODUCTION

Knee joint pain (KJP) is a very common problem in the United States. KJP alters motor function, muscle coordination, and gait mechanics. These alterations may contribute to the progression of structural knee joint disease [1]. Restoration of neuromuscular function and KJP relief is a primary goal for rehabilitative clinicians. While transcutaneous electrical nerve stimulation (TENS) mitigates motor function deficits, due to KJP, it is unclear how TENS might acutely affect ambulatory mechanics in the presence of KJP. The purpose of this study was to examine (i) the effects of experimental KJP on ankle, knee and hip frontal plane joint moments during walking, and (ii) the immediate effects of TENS on the aforementioned joint moments. We hypothesized that (i) experimental KJP would reduce ankle eversion, knee valgus, and hip abduction moments during loading response and push-off, and (ii) TENS treatment would mitigate these mechanical alterations effectively.

METHODS

Participants: Two groups of 30 asymptomatic volunteers participated in the study (10 men, 5 women per group). We randomly selected 15 participants from an initial 75 volunteers for the TENS group (Mean ± SD; age = 24 ± 3 yrs, mass = 71 ± 12 kg, height = 178 ± 7 cm). For the placebo group, 15 participants were matched to the TENS group by gender, age, mass and height, selected from the remaining 60 volunteers (age = 23 ± 2 yrs, mass = 72 ± 14 kg, height = 177 ± 9 cm). The study was approved by the appropriate institutional review board, and informed consent was obtained prior to participation. **Experimental KJP Procedures:** Two groups of all 30 participants underwent 3 different experimental sessions (hypertonic, isotonic, control)

in a counterbalanced order, two days apart. Session order was blinded to investigators and subjects. A 20-gauge flexible catheter was inserted into the right infrapatellar fat pad, and a portable infusion pump infused a continuous saline solution flow of 0.154 mL·min^{-1} for 50 min (total = 7.7 mL). No infusion was administered during the control session. **Therapeutic Intervention:** A TENS protocol was set at a continuous asymmetric biphasic square-pulse wave with a pulse width of 120 μs and a pulse rate of 180 Hz. The treatment session lasted 20 min in a seated upright position. TENS treatment was given to all 15 participants in the TENS group, consistently across all 3 different experimental sessions. In order to blind placebo treatment, all 15 participants in the placebo group was told that an electrical stimulation had been set to sub-sensory level, and the indicator light was on during the placebo treatment. **Gait kinetics:** Synchronized high-speed video (240 Hz) and an instrumented treadmill (1200 Hz) were used to measure gait mechanics throughout the first five observed stance phases of walking at each time interval (baseline, infusion, treatment). **Statistical Analysis:** Functional analysis of variance (FANOVA) were used to evaluate mean differences between TENS and placebo groups over each time interval for joint moments. To perform the FANOVA, the mean curve is represented by polynomial functions, showing us the entire gait cycle, rather than identifying isolated one or two peak joint moments as required for traditional parametric analyses of variance (ANOVA) [2]. Pairwise comparison functions, with 95% confidence intervals were plotted to determine specific differences during the stance phase of gait. If 95% confidence intervals did not cross the zero line in red, statistical significant difference existed ($P < 0.05$; Fig. C and F).

RESULTS AND DISCUSSION

Hypertonic saline infusion (i) increased knee varus moment during 0-7% of stance (Fig. A), (ii) decreased knee valgus moment during 14-48% and 69-82% of stance (Fig. A and B), and (iii) reduced hip abduction moment during 12-42% of stance (Fig. D and E; $P < 0.05$). No statistical difference was found at the ankle joint between baseline and hypertonic saline infusion (KJP). In addition, there were no statistical differences in other sessions (isotonic saline, no infusion). Group × treatment interactions showed that, compared with the placebo treatment, TENS treatment (i) increased knee varus moment during the first 10% of stance (Fig. C), (ii) increased hip adduction moment during 8-15% of stance (Fig. F), and (iii) increased hip abduction moment during 57-79% of stance (Fig. F; $P < 0.05$).

Figure 1. The black lines represent normal gait mechanics, with 95% confidence intervals (shaded areas). If a dotted curve in red or blue does not overlap with the shaded area, statistically significant difference existed ($P < 0.05$). Group × Treatment Interactions = difference between a "Baseline" and "Treatment" mean curve in the TENS group subtracts difference between a "Baseline" and "Treatment" mean curve in the placebo group.

These findings show that experimental KJP acutely changes frontal knee and hip kinetics during gait. TENS treatment acutely and effectively mitigated the alterations, due to KJP, for frontal-plane knee and hip moments. Since it is difficult to induce chronic KJP, our novel experimental KJP model could allow us to evaluate neuromechanical gait adaptations to KJP. Experimental KJP caused by the hypertonic saline infusion leads to release of substance P, a substance that is released through the c-fiber pathways from sensory nerve terminals in the brain and spinal cord, which is commonly seen in musculoskeletal pain [3]. As we observed decreased knee valgus moment during painful walking, similar gait strategies were also reported in previous literature using patients with early stage of knee osteoarthritic pain [4]. These similar reducing moment gait strategies may result from the immediate gait adaptations to KJP through (i) an unloading strategy [5], (ii) muscle inhibition [5,6], and/or (iii) altered muscle coordination [6]. If altered motor strategies persist, it may increase the risk of changes in normal gait mechanics over the long-term, and possibly accelerate structural changes in knee articular cartilage [1], by shifting the normal load to a location of the knee that does not typically bear load [7]. The present results indicate that TENS treatment might work as a rehabilitation tool to control mechanical alterations due to KJP. Attempting to increase motor neuron excitability through TENS might promote gains in muscle force production and motor neuron activation, which in turn, help overcome deficits in knee and hip joint moment.

DANCE ALTERS SUBJECTIVE AND OBJECTIVE BIOMECHANICAL GAIT AND BALANCE MEASURES IN PARKINSON'S DISEASE: A CASE STUDY

Kristen L. Sowalsky, Jill Sonke, Lori Altmann, and Chris J. Hass

The University of Florida, Gainesville, FL, USA
email: ksowalsky@hhp.ufl.edu

INTRODUCTION

Parkinson's disease (PD) is a progressive neuro-degenerative brain disorder leading to motor and non-motor deficits. Characterized by an overall paucity of movement, PD is classified as a hypokinetic disorder in which there are four hallmark motor signs; tremor, rigidity, bradykinesia, and postural instability. These impairments manifest into gait and balance disturbance which affect mobility and may ultimately lead to a decrease in quality of life [1]. Current treatments including pharmacological therapies, surgery, and physical therapy aim to alleviate symptoms and potentially slow the progression of the disease [2]. Dance training is a relatively new, yet increasingly popular therapy for people with PD [3, 4]. Aside from being an enjoyable activity, dance combines a number of factors already known to benefit those with PD; auditory cueing, aerobic exercise, strengthening exercise, stretching, and a supportive social community. A recent review of the literature demonstrates that dance has been shown to improve UPDRS motor scores, berg balance, gait speed, and quality of life in persons with PD [3]. It was our goal to add to this body of literature by investigating the effects of dance training on various objective and quantitative biomechanical parameters of balance and gait in addition to subjective measures. This case study is to be used as pilot data for a larger and more comprehensive study on the effects of dance therapy on gait, balance, and ultimately mobility in PD.

METHODS

The participant was a 66 year old male with a diagnosis of PD from a fellowship-trained movement disorders neurologist. He was diagnosed at the age of 53 with his symptoms predominantly on the right side of his body. Intake forms and assessments included an IRB approved informed consent, medical history questionnaire, Activities-specific Balance Confidence Scale (ABC), Tinnetti's Falls Efficacy Scale, Functional Gait Assessment, 6 Minute Walk test, and Timed Up and Go gait task. Balance testing was performed on a Bertec force plate for 3 conditions, 3 trials per condition at 360 Hz: 1) Eyes Open (120s), 2) Eyes Closed (20s), and 3) Narrow Stance (60s). Gait performance was captured using an 8 camera Vicon motion capture camera system. Spatiotemporal gait parameters were assessed bilaterally while walking over ground; forward, backward, and while counting (a dual-task activity). After testing, the participant completed a 16 week "Dance for Life" training intervention at the UF Center for Arts in Medicine. Dance training occurred in three 75-minute sessions per week for 16 weeks. Each session included a 15 minute seated warm-up, 15 minute barre segment, 5 minute break, 15 minute floor segment, 20 minute performance or social dance, and 5 minute cool-down. Upon completion of the 16 week dance intervention program, the participant was re-tested in all of the assessments and conditions described above. SPSS software program was used for statistical analysis.

RESULTS AND DISCUSSION

The results for the clinical assessments and gait task (Table 1) were mixed with an improvement in falls efficacy, 6 minute walk distance, and timed up and go speed. Significant differences were found between pre and post balance parameters (Table 2). Center of pressure path length, velocity, sway area, and approximate entropy increased for all balance conditions. As bradykinesia and reduced complexity of movement are associated with PD [5], the increase in the above balance measures may

plausibly be considered an improvement. Pre and post gait assessment (Table 3) revealed significant improvements in both spatial and temporal parameters for forward and backward walking. In the counting condition, a dual-task activity, there were mixed results.

CONCLUSIONS

This case study demonstrates the potential impact dance training may have on persons with PD. There were significant measureable changes in clinical assessments, balance measures, and gait parameters. Future research on a larger sample size is warranted.

LOW STRENGTH INCREASES FUNCTIONAL DEMAND DURING WALKING IN OLDER WOMEN

INTRODUCTION

Walking is the most performed activities of daily living and is a complex motor task, which requires an integration of motor, sensorial and cognitive information [1]. The age-related strength loss has been pointed as one of the main factors which leads to biomechanical abnormalities during walking [2].

Also, the lower limb strength loss increases the functional demand (FD) during mobility tasks, which may result in an elevated cost of walking, increased perception of effort and the early onset of fatigue [3]. Increments on FD in older adults are also associated with a reduction to produce maximum strength and it has an important impact on mobility, specially, when it affects the lower limb muscles, such as knee extensor muscles [4].

Thus, the objective of the present study was to identify the FD of lower limb joints (ankle, knee and hip) during the gait in older adults with lower strength and normal strength.

METHODS

Data of thirty older adult women, recruited from community-based physical activity groups, between the ages of 60 and 80 years were considered for this study. The participants were separated into two groups: group with normal strength (knee extensor maximal voluntary isometric torque > 1.5 Nm.kg^{-1}) and group with lower strength (knee extensor maximal voluntary isometric torque < 1.5 Nm.kg^{-1}), based on having knee extensor maximum voluntary isometric strength higher than 1.5 Nm.kg^1 [5].

Maximal voluntary joint torques were measured isometric for the hip, knee, and ankle for both flexion and extension movements using a isokinetic dynamometer (BIODEX®, New York, USA). The order of joint testing was randomized. Three submaximal repetitions were performed for familiarization purposes, and three maximal repetitions were collected for analysis. Strong verbal encouragement to obtain maximal effort was provided.

The biomechanical assessment of gait was recorded using a 3-D motion analysis system (Vicon®, Oxford, UK) synchronized with a force plate (AMTI®, Watertown, USA). The gait assessment was held on a walkway measuring 14 meters length and 2 meters wide. The volunteers were instructed to walk on the walkway at the speed that they perform their activities of daily living. Each volunteer walked on the walkway for 10 consecutive times.

Data were processed using a fourth-order Butterworth filter with a cut-off frequency of 6 Hz. A purpose written program in Excel was used to amalgamate the data on the knee, ankle and hip angles and moments produced during the gait.
The muscle strength data were combined with the biomechanical moment and angle data to determine the FD placed on the muscles during the gait. FD for a muscle group was defined as the muscle moment required at a particular joint angle, divided by the maximum isometric muscle strength available at that joint angle (expressed as a percentage) [6].

PASW 18.0 (SPSS Inc.) was used for statistical analyses and means and standard deviations were

used to summarize participant characteristics. Then, the comparison of FD between groups was tested using a MANOVA and the significance level for statistical tests was set at p < 0.05.

RESULTS AND DISCUSSION

MANOVA demonstrated a significant main effect on the FD between groups (F = 15.190, p < 0.001). The pos hoc analysis showed that older adults with lower strength had 36 and 67% higher FD of knee flexor and extensor than older adults with normal strength (p = 0.003 and p < 0.001). Also, the older adults with lower strength had 36% higher FD of hip flexor than older adults with normal strength (p = 0.004; Table 1).

Our findings demonstrated that lower limb joint (knee and hip) FD during flexion and extension movements is higher in older adults with lower strength. All subjects that composed the group of older adults with lower strength had knee extensor weakness, which predispose then to have higher knee extension FD than older adults considered with normal strength. However, what deserves to be highlighted in the current study is that the subjects with knee extensor muscles weakness also had increased FD at knee and hip flexor.

The according Reeves et al. (2008) and Samuel et al. (2012), older adults those perform their mobility activities in high levels of lower limb FD have a reduction on their physiological muscular reserve, which represents that if a balance perturbation occurs these people are unable to generate strength to correct the position of the center of mass. Also,

Rowe et al. (2005) suggested that the threshold for an acceptable FD is lower than 80%. In the present study both groups had FD higher tan 80% for several joint movements. Thus, based on our results the older women of our sample, especially people with lower strength, may have an increased risk of falling.

CONCLUSIONS

The older women with lower strength had higher hip and knee FD during walking. Our findings demonstrated that older adults with lower strength might be at an increased risk for the early onset of fatigue and falls.

WALK-TO-RUN TRANSITIONS ON A SPLIT-BELT TREADMILL

Jan Stenum and Julia T. Choi

University of Massachusetts Amherst, Amherst, MA, USA
email: jtchoi@umass.edu, web: https://blogs.umass.edu/jtchoi/

INTRODUCTION

The walk-to-run transition in humans has been studied extensively using a range of methods and theoretical perspectives [1, 2, 3, 4]. However, the exact nature of the transition, or the trigger for the transition, has proved elusive so far. Here we present a novel paradigm for studying the walk-to-run transition in humans using a split-belt treadmill. The speed and direction of each leg can be controlled independently, thus allowing us to decouple the normal inter-limb relationship, and probe direction- and leg-specific effects on gait transitions. We studied how subjects walk and run with one leg forward and one leg backward (i.e., hybrid locomotion). The walk-to-run transition speeds were measured for three different conditions: forward locomotion, backward locomotion and hybrid locomotion.

METHODS

Subjects. 4 subjects (2M/2F; 24.5 ± 2.6 yrs; average leg length 0.90 ± 0.03 m) were tested.

Experimental setup. A split-belt treadmill (Bertec) was used to test 3 different conditions: forward, backward and hybrid locomotion. In the hybrid condition the left and right treadmill belts moved in opposite directions (e.g., left leg moved backward and right leg moved forward).

Data collection. Qualisys Track Manager was used to collect and process kinematics data. 11 reflective markers were attached to left and right fifth metatarsal, malleolus, tibial plateau, greater trochanter and anterior superior iliac spine and C7. Ground reaction forces for each leg were sampled at 2000 Hz, and synced to kinematics data sampled at 100 Hz.

Walk-to-run transition. To determine the *preferred* walk-to-run transition speed, subjects walked at increasing belt speeds. The initial treadmill speed was set at 0.8 m/s. Subjects were instructed to use the preferred gait (most comfortable) at each speed as the belt speed was increased, in steps of 0.1 m/s for forward and backward conditions and 0.05 m/s for the hybrid condition. The process was repeated until the walk-to-run transition occurred. The duration for each belt speed step was 15 seconds. After the transition, the belt speed was increased for three additional steps. The order of the three conditions and the direction of each belt for the hybrid condition were randomized across subjects.

We defined walking as an inverted-pendulum gait, and running as a "bouncing" gait (spring-loaded inverted pendulum). We verified the recorded walk-to-run transition speeds by visual inspection of kinetics data offline, identifying a single peak in the vertical ground reaction forces as running.

RESULTS AND DISCUSSION

The walk-to-run transition occurred at different belt speeds across the three conditions. On average, subjects transitioned at speeds of 2.00 ± 0.20 m/s during forward walking and 1.47 ± 0.15 m/s during backward walking. When one leg walked forward, and one backward, both legs transitioned to running together at a lower speed. We did not observe walking on one leg, and running on the other leg during hybrid locomotion for the tested speed combinations. The average walk-to-run transition speed in hybrid locomotion was 1.17 ± 0.16 m/s.

The joint kinematics of the forward leg in hybrid walking resembled a forward walking pattern (i.e., both legs walking forward), while the backward leg in hybrid walking resembled a backward walking pattern (i.e., both leg walking backward). **Figure 1** shows overlaid trajectories of hip, knee and ankle angles at a walking speed of 1.0 m/s, comparing the joint kinematics of the backward leg during

backward walking and hybrid walking (**Fig. 1A**), and the forward leg during forward walking and hybrid walking (**Fig. 1B**).

percent stride time

B Forward Leg

percent stride time
Figure 1: Mean (±SD) hip, knee and ankle angles plotted as a function of stride time for a typical subject walking at 1.0 m/s. **A:** The backward leg showed similar kinematics during backward (green) and hybrid (cyan) gait conditions. **B:** The forward leg during forward (blue) and hybrid (cyan) gait conditions.

We calculated peak hip extension, peak hip flexion, peak knee flexion, and peak ankle plantarflexion. **Figure 2** shows the group averaged peak angles across speeds, relative to the walk-to-run transition speed for each gait condition. To average data across subjects, the two walking speeds before the walk-to-run transition in each condition and the two running speeds after the transition in each condition were included.

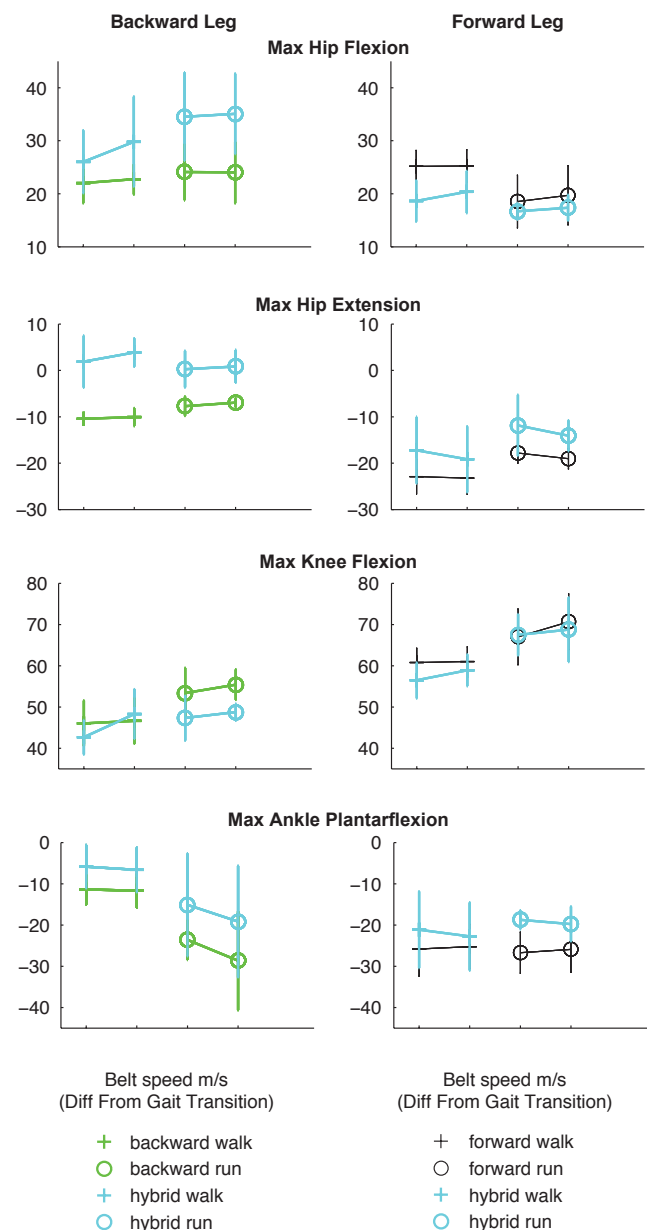
In summary, our preliminary data suggests that walk-to-run transition speeds are direction-specific. Moreover, the transition speed depends on differences in inter-limb directions. However, intra-limb kinematics for a given walking direction was less dependent on the direction of the opposite leg.


Figure 2: Mean (±SD) max hip flexion, hip extension, knee flexion and ankle plantarflexion across subjects for the backward leg during backward and hybrid gaits and for the forward leg during forward and hybrid gaits for walking before the walk-to-run transition and for running after the transition.

FRACTAL SCALING EXPONENT OF SPATIO-TEMPORAL VARIABLES DUE TO THREE TYPES OF BELT SPEED CONTROL MODES DURING TREADMILL WALKING

INTRODUCTION

Long-range correlation of stride time has been used in gait dynamics studies. The scaling exponent α of detrended fractal analysis (DFA) is widely used for quantifying the relationship [1]. Previous study reported that long-range correlation of stride time during metronomic walking disappeared while that of stride velocity during treadmill walking disappeared [2]. This result indicated that the constant rhythm with a metronome and fixed treadmill belt speed limited the stride time and stride velocity, respectively. Recent study using a feedback-controlled treadmill reported that long-range correlation was persisted in the stride velocity as well as stride time and stride length [3]. These results are similar to those of the ground walking condition [4]. Therefore, the purpose of this study was to evaluate and compare the changes in fractal scaling exponent in spatiotemporal variables when the treadmill walking speed was controlled by the visual presentation and the feedback-controlled treadmill.

METHODS

Nine male healthy subjects participated in this experiment (age: 23.3±2.3years, height: 175.6±3.1cm, weight: 66.4±4.0kg). All subjects walked on the treadmill with three kinds of belt speed control modes for 10 minutes or more, such as conventional treadmill (CTM, fixed belt speed), feedback-controlled treadmill (FTM, automatically controls its belt speed depending on the walking speed of the walker, i.e. self-paced) [5], and FTM+Vision (FTM walking while showing current subject's walking speed and target speed on the screen) (Fig. 1). All subjects were asked to maintain the target speed (pre-determined subject's preferred walking speed) throughout the experiment and were also asked to keep their eyes focused straight ahead.

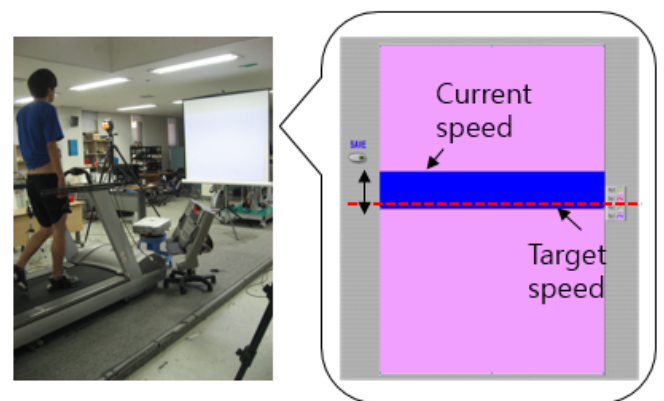
To acquire spatiotemporal gait variables (stride time, stride length, stride velocity), three-dimensional motion capture system (Motion Analysis System Inc. USA) was used. The mean and fractal dynamics of all variables were calculated. The fractal dynamics were represented by using the scaling exponent α of the detrended fluctuation analysis [1].


Figure 1: Experimental setup and composition of the screen for presenting subject's current walking speed (The blue bar that moves up and down, and red dotted line represent current speed at each moment and target speed for reference, respectively.)

Asymmetric index (SI) was used to compare asymmetry of gait variables (SI=0: perfectly symmetry, larger SI is the more asymmetry) [6].

$$SI(\%) = \left| \frac{X_R - X_L}{X_R + X_L} \right| \times 100$$

X_R and X_L are right and left data, respectively. Matlab R2013b (Mathworks, Inc., USA) were used for calculating all variables.

RESULTS AND DISCUSSION

There was no significant difference in the mean of all variables among three kinds of treadmill walking conditions (average stride time 1.11~1.18sec, average stride length 0.96~1.01m, average stride velocity 0.83~0.92m/sec). Their asymmetric indices were also small values of about 0.5% or less. In results of fractal dynamics, the scaling exponent α from DFA of all variables of CTM and FTM+Vision walking were very similar. Especially the scaling exponent α of stride velocity in both conditions were close to 0.5 value (in other words, long-range correlation of stride velocity in both conditions almost disappeared). The scaling exponent α of stride length and stride velocity in both conditions showed large asymmetry (SI>9% and SI>15%, respectively) as shown in Table 1. On the other hand, in FTM walking, all variables showed long-range correlation (α>0.5) like a case of ground walking and represented that the asymmetric indices (SI<5%) were lower than those of the other two conditions.

CONCLUSIONS

The results of this study showed that although the control mechanism of walking speed was different in CTM and FTM+Vision (changing belt speed itself and adjusted self-paced by looking at current walking speed, respectively), the characteristics of gait dynamics in spatiotemporal variables were quite similar to each other. This result might be due to the same purpose of walking, regardless of the way or variable to control. Further study is necessary to identify the effect of the constrained and unconstrained walking by using various limitations and conditions.

ANTERIOR LAXITY IN HEALTY YOUNG WOMEN WITH KNEE HYPEREXTENSION

INTRODUCTION

Knee hyperextension, an underrepresented and insidious condition mainly seen in women [1-4], can contribute to abnormal accumulated knee stressors resulting in pathology. Movement of the knee into hyperextension of more than five degrees, is associated with a ground reaction force vector that acts anterior to the knee joint[5]. The anterior location of the ground reaction force vector places increased contact stress on the tibiofemoral cartilage [6] and considerable tension stress on the passive restraining structures that resist further knee extension (e.g. posterior knee capsule and Anterior Cruciate Ligament)[5]. Chronic hyperextension may stress connective tissues resulting in adaptive lengthening of the structures that resist knee hyperextension and consequently contribute to a more unstable joint. The purpose of this study was to investigate joint laxity in women with and without knee hyperextension. We hypothesized that knee laxity, measured by the anterior displacements at specific loadings and the stiffness changes in the knee joint, were different among women with and without hyperextension.

METHODS

Healthy female, 18-39 years of age, with and without knee hyperextension greater than 5° at rest were invited to participate. Participants were screened for: knee extension passive range of motion (PROM); lower limb muscular strength; and general joint laxity using the Beighton and Horan Joint Mobility Index (BHJMI). To determine leg dominance, participants were instructed to kick a ball. The knee ligament arthrometer KT-2000 (MedMetric Co., San Diego, CA, USA) was used to evaluate knee laxity by measuring anterior displacement of the knee joint. Participants were placed in a supine position. KT-2000 device was placed on participant's lower leg and knee was positioned in 30° of flexion. EMG electrodes were attached to selected lower limb muscles to ensure participant's complete relaxation during the KT-2000 testing. Three successful trials of laxity were obtained to calculate the mean value of anterior displacement bilaterally. Data was collected on knee joint laxity in anterior direction applying 45, 67, 89, and 134 N. The applied force and corresponding displacement data were continuously recorded into a computer via an acquisition card (DaqCard 216b, IOtech, USA) at 1,000 Hz. Intra and inter-session tester reliability was determined (ICC=0.9) prior to data collection.

The recorded force and displacement output data were analyzed using Excel to identify the anterior displacement in millimeters (mm) at each load for further analysis. Stiffness was defined as the ratio of the force to the displacement. The initial stiffness was the stiffness calculated in the initial loading phase (45-67N) and the terminal stiffness was in the terminal loading phase (89-134N). All statistical testing was performed using SAS 9.3 (SAS Institute Inc., Cary, NC, USA).

RESULTS AND DISCUSSION
Figure 1: The dominant leg of women with hyperextension showed greater displacement.

Twenty two healthy women: twelve women (mean + SD age, 20.4 ± 2; mass, 59 ± 6 kg; height, 1.6 ± 0.1 m) with knee hyperextension greater than five degrees at PROM and ten women (mean + SD age, 21 ± 3; mass, 59.3 ± 10 kg; height, 1.7 ± 0.1 m) took part in this study. Mean + SD knee passive range of motion was 8.5°+ 1.7° (range 6° to 11°) and 3.4°+ 1.5° (range 0° to 5°) in women with and without knee hyperextension, respectively.

The results of this study showed that the dominant side of the hyperextension group had significant greater anterior displacement that that of the no-hyperextension group ($p < 0.05$) (Figure 1). No significant difference was found in the non-dominant side. Pearson correlation coefficients (Figure 2) showed a moderate correlation between the degree of knee extension at PROM and anterior displacement. The dominant side of the hyperextension group had significantly smaller initial stiffness than that of the non-hyperextension group (Figure 3).
Figure 2: There was a weak correlation between PROM and anterior displacement in the dominant leg across in both groups.

CONCLUSIONS

The results of this study seem to indicate that knee hyperextension places the posterior capsule of the knee joint and Anterior Cruciate Ligament under considerable tension stress. Chronic knee hyperextension may stress connective tissues

resulting in adaptive lengthening of the structures that resist knee hyperextension and consequently contribute to a more unstable joint. These findings may explain why hyperextension knees are at greater risk of injury. Further investigation on knee mechanics in women with knee hyperextension should be performed.
Figure 3: The dominant leg of women with hyperextension had significantly smaller initial stiffness.

Differences in Synergistic Control of Muscles During Treadmill Walking in Anterior Cruciate Ligament Reconstructed Legs

INTRODUCTION

Individuals who have suffered an anterior cruciate ligament (ACL) injury and undergone a surgical reconstruction show a high incidence of reinjury and osteoarthritis even with extensive physical therapy and return to sports [1, 3]. The progression to further joint issues highlights the need to investigate possible changes in the muscular control of the reconstructed leg to better understand the underlying reasons for these risks. This understanding can help to develop and improve rehabilitation strategies. One study has looked at the complexity of movement patterns of ACLR knees as compared to healthy knees during treadmill walking showing deviations from healthy knee that could underlie progressive joint issues [2]. However, in order to investigate more deeply the neural control mechanisms behind these differences we looked at the synergistic organization of muscle control in ACL-R legs versus healthy legs using muscle synergy decomposition analysis techniques. We hypothesized the total variability accounted for (VAF) by using these synergies would be higher for ACL-R versus healthy legs at the comparable number of modules which would indicate reduce complexity in the ACL-R leg. We also hypothesized that that the ACL-R legs would exhibit altered activation timing of these synergies compared to the healthy legs.

METHODS

In this study we collected electromyography (EMG) (sampled at 1200 Hz) on 16 lower body muscles (eight each leg) in six unilateral ACL-R post rehabilitation individuals while they walked on a treadmill at 1.5 m/s for five minutes. The EMG signals were demeaned, rectified, and filtered using a 6 Hz butterworth filter. Each gait cycle was separated using ground reaction forces to identify foot contact events. The data for each cycle was normalized to a percent of the gait cycle. Nonnegative matrix factorization (NMF) was used to decompose these eight EMG signals across the gait cycles into lower dimensional components (modules/synergies each with a paired activation profile) for each leg separately [4]. We analyzed our data first assuming three distinct muscle modules, then four muscle modules, and then five muscle modules. Instead of setting a threshold of 95 percent VAF to determine the number of synergies present, we instead compared the VAF at three, four, and five modules. We compared the VAF between the healthy leg and the ACL-R leg of the individuals using independent t-tests. We also calculated the effect size on the timing and magnitude of the main peak in each activation profiles of the synergies under the assumption of three modules.

RESULTS AND DISCUSSION

Our results suggest that there may be altered control of lower body muscles during treadmill walking in persons after ACL-R… The analyses revealed important differences in VAF at 3 modules between healthy legs and ACL legs and effect of ACL-R on the peak timing and magnitude of the activation profile for selected modules.

The convergence of VAF between the ACL-R and the healthy leg as more muscle synergies are assumed is expected. The notable result is that there is significant difference in total VAF at three modules. As shown in Fig. 1 ACL-R legs demonstrate a larger amount of VAF which indicate diminished complexity in coordination of muscle activations during walking.
Figure 1: Total VAF of the healthy and ACL-R legs when assuming three, four, and five muscle synergies. * P< 0.05

Because of the significant difference in VAF between ACL-R and Healthy legs at three modules, we further investigated the activation profiles for the assumption of three modules. The results of this analysis are shown in Table 1. When evaluating the effect size of ACL-R on the timing and magnitude of the most prominent peak in the activation of each module, Module 1 showed a large effect size on the timing of the peak, Module 2 showed a large effect size on the magnitude of the peak, and Module 3 showed large effects on the timing of the peak. The results point to an altered usage of muscle synergies

that may reveal one way in which deficits in ACL-R legs persist.

CONCLUSIONS

The differences in the total VAF at three modules and the effect of ACL-R on the synergy activation profiles indicate differences in the control of walking movement in the ACL-R leg. It is possible that recruiting more subjects could help detect differences under the assumption of a higher number of modules as well as differences in the VAF for each specific muscle. Although these early results point towards altered control of muscle synergies in ACL-R legs, further investigation of these differences is required to fully characterize changes in neuromuscular control and understand why specifically these individuals are at heightened risk of further joint problems in the reconstructed knee.

CO-CONTRACTION INDEX DURING GAIT AND RELATIONSHIP TO QUADRICEPS STRENGTH IN INDIVIDUALS WITH FOCAL CARTILAGE DEFECTS IN THE KNEE

Louise M. Thoma, Michael P. McNally, Ajit M.W. Chaudhari, Robert A. Siston, Thomas M. Best, David C. Flanigan, Laura C. Schmitt

The Ohio State University, Columbus, OH, USA

email: thoma.24@osu.edu

INTRODUCTION

Greater muscle co-contraction about the knee has been commonly reported in individuals with knee pathology such as anterior cruciate ligament injury and osteoarthritis. Previous work indicates co-contraction is higher in individuals with more severe osteoarthritis [1], and increases potentially injurious compressive forces in the knee. [5] Despite being younger in age, individuals with focal cartilage defects (FCD), or isolated articular cartilage lesions, of the knee present with impairments similar to osteoarthritis, including considerable quadriceps weakness. [2] To our knowledge, there are no reports of muscle activation strategies in individuals with FCDs during dynamic activity. The primary purpose of this exploratory study in individuals with FCDs was to test the hypotheses that (1) co-contraction index (CCI) is higher on the involved limb than the uninvolved limb during gait and (2) weaker quadriceps strength is correlated with greater CCI during gait. We also explored when during the gait cycle CCI is the highest, to inform future research questions.

METHODS

Fourteen individuals (7F:7M, 29.5±6.0 years old, 25.8±3.5 kg/m^2) with FCDs in the knee (Grade 3-4) provided IRB-approved informed consent prior to participation. Defect location varied per participant: 5 patellofemoral only, 6 tibiofemoral only, 3 mixed.

Quadriceps strength was quantified as the peak torque produced during 3 maximal isometric knee extensions at 60° knee flexion (Biodex System 3, Shirley, NY), normalized to mass and height.

Five gait trials at each subject's self-selected speed were captured with three-dimensional motion capture (10-camera, Vicon MX-F40, Oxford, UK) and electromyography (EMG) concurrently. Ground reaction force data were collected for two consecutive foot strikes by independent force plates (Bertec FP4060, Columbus, OH). Motion capture and forces plate data were used to identify initial contact and toe-off to define the stance phase.

A 16-channel telemetric surface EMG system (Noraxon Telemyo DTS, Scottsdale, AZ) measured muscle activation of the right and left vastus lateralis (VL), vastus medialis (VM), biceps femoris (BF), and semitendinosus (ST). EMG signals were filtered using a 50-500Hz 4th order band-pass Butterworth filter and rectified. A 50 millisecond running average was used to create a linear envelope and normalized to the highest signal amplitude during a maximal volitional isometric contraction (MVIC). The normalized linear envelopes for VL and VM, and for BF and ST, were summed to create a single activation curve for the quadriceps and hamstrings respectively.[5] CCI was calculated for each time point during stance phase with Equation 1.[3,4]

Equation 1

$$CCI_i = \frac{lower\ EMG_i}{higher\ EMG_i} \times (lower\ EMG_i + higher\ EMG_i)$$

The stance phase of gait was divided into ten 10% epochs (ie. subdivision of stance phase) for analysis (Epoch 1-10 consecutively, with Epoch 1 beginning at heel strike, and Epoch 10 ending at toe off). The average CCI was calculated over each Epoch. We evaluated the average CCI with a 2x10 repeated measures analysis of variance, with Limb (involved, uninvolved) and Epoch (Epochs 1-10) as within-subject factors (α=0.05). Limb, Epoch, and the Limb*Epoch interaction violated the sphericity assumption (Mauchly's test), thus the Greenhouse-Geisser correction was used. Significant interactions or main effects were evaluated post-hoc with pairwise comparisons and a Bonferroni correction. Spearman's Rank Order Correlation was used to

evaluate the relationship between quadriceps strength and the average CCI for the stance phase, as quadriceps strength was non-normal.

RESULTS AND DISCUSSION

There was a main effect for limb (Figure 1, p = 0.013). CCI was higher in the involved than the uninvolved limb, supporting the first hypothesis. There was also a main effect for epoch (p < 0.0005). Post-hoc pairwise comparisons between phases indicated CCI was highest in early stance. Phase 1 was significantly different than Phases 2-9 (p = 0.000-0.005) and Phase 2 was different than Phases 1, 4, 5, 9, and 10 (p = 0.005-0.042). All other phases were similar to each other. There was no interaction effect of between limb and phase (p = 0.065).
Figure 1: Average CCI per epoch during the stance phase of gait for the involved and uninvolved limb

Our second hypothesis was also supported. Involved limb quadriceps strength was negatively correlated to average CCI during the stance phase (Figure 2, ρ = -0.73, p = 0.003). There was no relationship on the uninvolved side (ρ = -.27, p = 0.4).

Previous work suggests co-contraction is a harmful muscle activation strategy, as it increases tibiofemoral compressive forces [5], which may further damage compromised knee cartilage. However, this assertion is dependent on the assumption that muscle activation is related to muscle force production. The common practice of normalizing EMG during gait to MVICs may be inappropriate in individuals with quadriceps inhibition [6], and may lead to an over-estimation of muscle activity. It is likely that many individuals with FCDs also demonstrate quadriceps inhibition.

With future studies, we will investigate if the high CCIs resulted in increased joint compressive forces, or were over-estimated resulting in minimal impact on compressive forces. This study was limited by a small sample size and heterogeneous FCD location.
Figure 2: Scatterplot of involved quadriceps strength vs. involved CCI

CONCLUSIONS

Individuals with FCDs demonstrate higher CCI on the involved compared to the uninvolved limb. Given the inverse relationship between quadriceps strength and CCI, future work considering the detrimental effect of higher CCI, especially in early stance, on compressive joint forces must consider the potential over-estimation of CCI in individuals with quadriceps strength deficits.

Cognitive Influence on Obstacle Avoidance: Auditory and Structural Interference

[1] Lori Ann Vallis, [1] Matthew Mendes, [1] Timothy A. Worden and [1] Pratham Singh

[1] University of Guelph, Guelph, ON, Canada
email: lvallis@uoguelph.ca, tworden@uoguelph.ca

INTRODUCTION

Throughout our daily lives we are constantly interacting with and moving through our environment, completing concurrent motor and cognitive tasks in a smooth and efficient manner [1]. While gait was once thought of as an automatic task, we now know that use of the cognitive system, and more specifically executive function [2], is vital for the successful planning and executing goal directed actions, e.g. obstacle avoidance [3]. The ability to perform more than one task at a time has been well studied using dual task paradigms, some of which involve cognitive tasks that result in structural interference [e.g. tasks requiring assessment of visual information for task completion; 4] and other tasks which result in capacitance interference [e.g. tasks requiring rapid/intense mental processes; 5].

The **purpose** of this study was to investigate how each type of interference (structural and capacitance) affects executive function strategies used to plan the adaptive locomotor patterns for a complex motor task, obstacle avoidance.

METHODS

Thirteen healthy university students were recruited (aged 20.6 ± 1.6 years) for this study. Exclusion criterion included visual perception problems (e.g. strabismus), hearing problems and history of recent musculoskeletal injuries (e.g. sprain within last 2 months). The experimental paradigm is outlined in Figure 1. Gait velocity, minimum foot clearance, takeoff and landing distance from the obstacle were calculated. Data was analyzed at the instant of heel contact 2 steps before (OBS-2), 1 step before (OBS-1) and at crossing (OBS-xing) the obstacle. Response accuracy and response time for the auditory and visual Stroop task was calculated from a microphone fixed to the subjects' thorax.

Dual task cost (DTC) was also processed for both kinematic and cognitive measures [5]:

$$\frac{(Dual\ task - Single\ task)}{Single\ task}$$
Figure 1(A). Subjects were instrumented with rigid triads of iREDs (100 Hz) and anatomical points were digitized (e.g. heels, toes). A lapel microphone recorded participants audio response times (3000 Hz). **(B).** First, participants completed 10 baseline walking trials where they stepped over an obstacle set to a height of 30% of their lower limb length with *no cognitive task*. They then completed 4 different blocks of experimental trials (seated trials always preceded walking over obstacle trials). Half of the participants completed the visual Stroop task prior to the auditory Stroop task (*10 congruent/10 incongruent*).

A Pearson Chi Square was performed to examine if cognitive accuracy and response time differed between cognitive tasks. A multivariate ANOVA (Stroop Condition X Trial Type) was conducted on mean and variability of obstacle avoidance parameters. A single variable ANOVA was conducted for cognitive measures and another single variable ANOVA was conducted for dual task cost. Significance level was set to $p < 0.05$.

RESULTS AND DISCUSSION

Cognitive task performance. An effect of accuracy for Stroop type was observed with subjects significantly less accurate at identifying the auditory Stroop cue compared to the visual Stroop cue. There was no effect for congruency. For mean response latencies, a main effect of Stroop test was observed; subjects identified the visual Stroop cue significantly faster than the auditory Stroop cue (Figure 2), however no changes in DTC were detected.
Figure 2: Response latency (s) for the two Stroop tests; visual Stroop cue responses were significantly faster than auditory Stroop responses.

Dual Task performance. Recall that a larger dual-task cost is indicative of an increase in a given obstacle parameter compared to baseline values. Interestingly, there were no detectable differences in gait velocity or takeoff distance across conditions, though a main effect of trial type was observed for *minimum lead foot clearance* DTC (Figure 3).
Figure 3: Significantly larger dual-task costs for the visual Stroop cue were observed for minimum lead toe clearances (p<0.05).

Similarly, a main effect of cognitive task was observed for *trail toe clearance*; larger dual-task costs were observed for the visual Stroop cue compared to the auditory Stroop cue (Figure 4).

Figure 4: Significantly larger dual-task costs for the visual Stroop cue were observed for trail toe clearances (p<0.05).

For landing distance, a trend for greater dual-task cost caused by the visual Stroop task was also observed, although this was not statistically significant (p=0.069). It appears that a secondary visual task caused subjects to adopt a more cautious obstacle crossing strategy.

CONCLUSIONS

Our results indicate that a more cautious control strategy is used when performing tasks involving visual (structural) interference compared to tasks involving auditory (capacitance) tasks. These results highlight that researchers should carefully consider the impact of structural interference when selecting cognitive tasks for dual task paradigms during gait.

Foot Pressure Masking Differences With and Without Kinematic Data for Unilateral Clubfeet

INTRODUCTION

The use of pedobarography has been proven to be a reliable measure when assessing normal and pathological feet [1, 2]. When using pedobarography to assess clubfoot deformity, the accuracy of foot pressure data is dependent upon the software's ability to identify regions of interest (ROI) on the foot print. However, built-in software is not always precise when masking the ROI when foot deformity is present. Inaccuracies in masking ROI can be due to the severity of the foot deformity and/or the absence of plantar pressure in different regions of the foot due to problems such as dynamic supination. Therefore, manual corrections have to be made to the ROI in order for data output to be accurate for both clinical and research applications [2]. Differences seen within the data will depend on the experience and subjective interpretations of the data collector [1, 2].

Recent research has reported that the use of 3D kinematic multi-segment foot models in conjunction with pedobarography is a valid and reliable outcome tool to evaluate typically developing and pathological feet [1]. Using kinematic assessment simultaneously with pedobarography may allow for more precise ROI masking and negate the variability that is present in ROI masking for feet with deformity that require manual correction. Therefore, the purpose of this study is to assess the differences between a 10 area pedobarographic ROI mask in children with unilateral clubfeet with and without the use of kinematic data.

METHODS

Twenty-six children, ages 2.6-12.9 years, diagnosed with unilateral clubfoot underwent simultaneous pedobarographs and kinematic data collection. Foot pressure analysis was collected for both the involved and uninvolved sides using Novel emed-x

platform and Novel Database Pro M v.23.3.52. Kinematic data was collected for both feet using 12 Motion Analysis Eagle cameras and Cortex software v.5.0.1.1496. Three trials per subject per side were collected for a total of 156 foot pressure trials. Nine markers were placed on each foot according to the Oxford foot Model [1]. Kinematic data was exported as a .c3d format and loaded into the Novel Automask program where marker coordinates were projected onto the transverse plane [3]. Post processing of the data consisted of masking the foot into 10 ROI with and without the kinematic data using the Automask; hallux, 2nd toe, 3rd-5th toes, 1st metatarsal, 2nd metatarsal, 3rd-5th metatarsal, medial midfoot, lateral midfoot, medial heel and lateral heel [3]. One investigator, with 5 years' experience using Novel software, performed all post processing and evaluation of foot pressure ROI differences.

Differences in masking techniques were expressed as a percentage of the total number of trials that would have required manual corrections. The decision for manual corrections was based on visual assessment of the 10 ROI superimposed onto the maximum pressure picture. If a trial was deemed to need manual corrections it was rated as inaccurate. Manual corrections were based on the following criteria: 1. ROI was misidentified: Ex. Big toe was included in the 1st metatarsal mask; 2. ROI was displaced laterally/medially: Ex. The 1st metatarsal was not in contact with the ground due to dynamic supination; therefore the 1st metatarsal mask was superimposed laterally onto the 2nd metatarsal; 3. The ROI was externally rotated about the vertical (Z) axis. The line dividing the heel was rotated medially and the medial/lateral heels were not divided accurately based on the predefined parameters [3]. In addition to visual differences in ROI, t-tests were used to assess significant

differences between the peak pressure (PP) and contact area (CA) of the total foot and the 10 ROI with and without the kinematic data (p<.05).

RESULTS AND DISCUSSION

Of the 156 total pedobarographic trials, 2 were discarded due to the inability to post process kinematic data, resulting in 154 usable trials for data analysis. Differences in masking ROI and changes in CA and PP were assessed in the involved and uninvolved sides of 26 children with unilateral clubfoot.

When masking the foot without kinematic data, compared to the uninvolved side the ROI of the involved side demonstrated a significant increase in PP in both the lateral midfoot and the 3rd-5th metatarsals. When masking ROI with kinematic data these ROI are no longer significantly different between sides (Table 1). For CA in ROI masked without kinematic data the involved side demonstrated significant decreases in the medial midfoot, 1st metatarsal and hallux. When masking ROI with kinematic data the 1st metatarsal difference is lost and new differences are noted in the lateral hindfoot (Table 1). More statistical differences are noted in the medial and lateral feet when masking the ROIs without kinematic data than with kinematic data (Table 1).

When visually assessing the ROI differences between masking techniques, more trials required manual correction when applying kinematic data to the pedobarograph. Masking ROI without kinematic data on the uninvolved side required manual corrections in only 4% of trials, whereas the involved side required manual corrections in 25% of the trials. When masking the ROI with kinematic data, the uninvolved side required manual corrections in 50% of trials and the involved side required manual corrections in 55% of trials. For both masking techniques the involved side required more manual corrections to the ROI. This is contrary to previous research conducted on masking with and without kinematic data which reported kinematic data was more reliable when masking the foot using a 5 area ROI mask for typically developing children and children with clubfeet [1]. However, the 5 area ROI mask previously utilized is not as widely used in the clubfoot population as the more complex 10 area ROI mask utilized by Jeans et al [2].

We believe the primary reason our findings are not consistent with previous research is that we defined more ROI's (10 as opposed to 5), resulting in smaller regional areas and increased variability due to their definitions. However, the 10 area ROI mask used in this study is more clinically relevant in assessing changes in clubfeet over time and due to surgical intervention since it provides a greater number of detailed regions of interest that we believe are necessary for adequate pre-post intervention comparisons [2].

EFFECTS OF CUSTOMIZED KNEE REPLACEMENT SURGERIES ON WALKING MECHANICS

Henry Wang, Jonathan Foster, Natasha Francksen, Jill Estes, and Lindsey Rolston

Biomechanics Laboratory, Ball State University

INTRODUCTION

It is reported that 70% of the Knee OA patients have cartilage degeneration isolated to the medial and patellofemoral compartments [1]. Majority of these patients undergo total knee replacements (TKR). The iDuo system is a customized, individually made bi-compartmental knee replacement (BKR) treating OA at medial/lateral and patellofemoral compartments [2]. The BKR features the following benefits: an intact contra-lateral compartment, retained anterior and posterior cruciate ligaments, anatomical knee geometry, and a good knee alignment. It is surmised that the BKR knee will have similar knee mechanics to that of a normal healthy knee during daily activities. To date, there is no information regarding the knee mechanics during level walking with a BKR. There are no *in vivo* biomechanical comparisons between a BKR limb and a limb with an off-the-shelf TKR. The purpose of the study was to examine the differences in knee mechanics between three groups of participants during level walking: (1) patients with customized BKRs, (2) patients with off-the-shelf TKRs, and (3) healthy controls.

METHODS

23 participants were recruited in the study. Seven patients (63±10 yr.; 100±43 kg; 1.73±0.12 m) received TKRs (Persona, Zimmer Inc.) (post-op: 14±5 mo.). Four patients (63±7 yr.; 93±18 kg; 1.66±0.06 m) received BKRs (iDuo, ConforMIS Inc.) (post-op: 19±4 mo.). Twelve healthy participants (57±6 yr.; 82±12 kg; 1.75±0.11 m) served as controls. Participants walked at a self-select speed in a gait laboratory. A VICON motion capture system was used to collect 3D walking motion at 100Hz. Three AMTI forceplates were used to collect ground reaction forces at 2000Hz. Visual 3D was used to perform model based computations. Knee joint kinematics and kinetics were calculated during the stance of walking. MANOVA was performed. $\alpha = 0.05$.

RESULTS AND DISCUSSION

Table 1 shows the means and SDs of the walking speed, knee mechanics in the sagittal, frontal, and transvers planes of the three groups. No significant differences in walking speed between the BKR and control group (P>0.05). No significant differences were observed in peak knee extensor moment, peak knee power absorption and production, peak knee abduction moment, and peak knee internal and external moments between the BKR and control groups (P>0.05). In addition, the peak internal rotation angle was not significantly different between the BKR and control knees (P=0.096). Compared to the control group, the TKR group showed slower walking speed, less peak knee extensor moment, less peak knee power absorption and production, smaller peak internal rotation angle, less peak knee abduction moment, smaller peak external and internal rotation moments (P<0.05); Compared to the BKR limbs, the TKR limbs demonstrated less peak knee power absorption and production, less peak knee abduction moment, smaller peak external and internal rotation moments (P<0.05); In addition, the TKR group showed a trend of less peak knee extensor moment than that of the BKR group (P=0.08).

Close to normal walking speed and 3D knee mechanics appear to be achievable outcomes with customized BKR surgeries. In this study, the BKR patients demonstrated comparable walking speed and peak knee extensor moment and power to the healthy control participants during stance of walking. Off-the-shelf TKR patients walked significantly slower than healthy controls with less knee extensor moment and power produced. In addition, compared to the BKR knees, the off-the-shelf TKR showed deficits in peak knee extensor moment and power during walking. It is possible that the reduction in TKR knee strength may be associated with the traditional off-the-shelf TKR design. Furthermore, when secondary plane knee mechanics were examined, the BKR limbs revealed

no differences in key variables of knee mechanics from the healthy limbs. On the contrary, the TKR limbs exhibited reductions in the peak internal rotation angle, peak abduction moment, and peak internal and external rotation moments when compared to the control limbs. The deviations in secondary plane knee mechanics displayed by the TKR limbs may be related to alterations of the knee geometry introduced by the off-the-shelf TKRs. Future studies should examine the long-term effects of the customized BKR on knee biomechanics during daily activities to establish its long-term benefits and functionality.

CONCLUSIONS

A customized BKR design could provide adequate support to knees to perform normal walking.

EFFECTS OF WALKING SPEED ON THE STUMP-SOCKET INTERFACE IN TRANSTIBIAL AMPUTEES

INTRODUCTION

The number of amputees continues to rise in the United States, and it is expected that by 2050 there will be 3.6 million people with limb loss [1]. The most common pathway for limb loss is dysvascular pathology, such as diabetes [1]. People with diabetes have difficulties maintaining skin integrity and skin breakdown is a common problem experienced by amputees due to the motion and forces between the stump and socket. The stump soft tissues were not designed to withstand the forces they are exposed to inside of the socket, which can lead to pressure ulcers.

The motion and forces of greatest concern are socket pistoning and flexion-extension. Pistoning refers to translation in the axial direction, while flexion-extension is the rotation that occurs about a mediolateral axis due to a bending moment created by the ground reaction force. Studies have utilized various x-ray and motion capture techniques to statically and dynamically quantify pistoning, with reported values from 1.1 to 7.5 cm, depending on the type of socket [2]. However, the actual magnitudes and patterns of loading at the stump-socket interface (SSI) over a continuous gait cycle have not been fully characterized. The SSI is typically considered to be a rigid connection in musculoskeletal modeling studies [3]. Knowledge of the actual motions and forces at the SSI would lead to more realistic and informative simulations. Our long-term goal is to develop new prostheses that reduce SSI loads and decrease the incidence of soft tissue injury. The specific purpose of this study was to examine the stump-socket kinematics and kinetics during walking across a range of speeds in transtibial (TT) amputees.

METHODS

Data were collected for three subjects, two with a left-side TT amputation and one with a right-side TT amputation. Each subject had a shuttle lock connecting the sleeve and socket, standard pylon and a split toe flex foot. The subject demographics and walking speeds are listed in table 1.

Table 1: Subject demographics and speeds of trials.

Subject	1	2	3
Height (m)	1.88	1.70	1.80
Mass (kg)	104.3	80.7	68.0
Preferred (m/s)	1.26	1.35	1.27
Slow (-20%)	1.02	1.14	1.05
Fast (+20%)	1.47	1.67	1.57

Data analysis was performed using a three-dimensional unilateral TT amputee model that we created [4] by modifying one of the standard gait models provided with OpenSim (gait2354). A residual tibia/fibula (stump) segment articulated with the socket via a joint at the most distal aspect of the stump, representing the SSI. The socket and pylon were connected to a model of a split-toe flex foot via a pin joint. The entire model has 25 degrees of freedom, including pistoning and flexion-extension at the stump-socket joint.

Kinematic data were captured using a full-body marker set and were synchronized with ground reaction forces measured using three force platforms. Inverse kinematics and inverse dynamics analyses were performed in OpenSim and results were averaged over three trials per subject for each speed, and then averaged across subjects within a speed. Data from some non-consecutive gait cycles were joined, resulting in a small discontinuity at approximately 80% of stance (Figure. 1).

RESULTS AND DISCUSSION

The amount of pistoning ranged from 2.42-2.69 cm which is within the range reported in the literature [2] (Figure 1, Table 2). The peak pistoning force occurred in the first half of stance and ranged from 0.94-1.05 bodyweights (Table 2). The peak pistoning force occurred earliest and had the greatest magnitude at the fast gait speed (Figure 1). There was 11-16° of socket flexion-extension at the SSI, with the greatest amount of motion occurring with the fast gait speed (Figure 1, Table 2). The peak extension moment occurred at approximately 80% of stance and was greatest for the slow gait speed (Figure 1). At the slower speed, the subjects limited the amount of socket flexion moment at the beginning of stance (Figure 1). At the preferred speed there was the greatest flexion moment at the beginning of stance, but the smallest extension moment at the end (Figure 1).

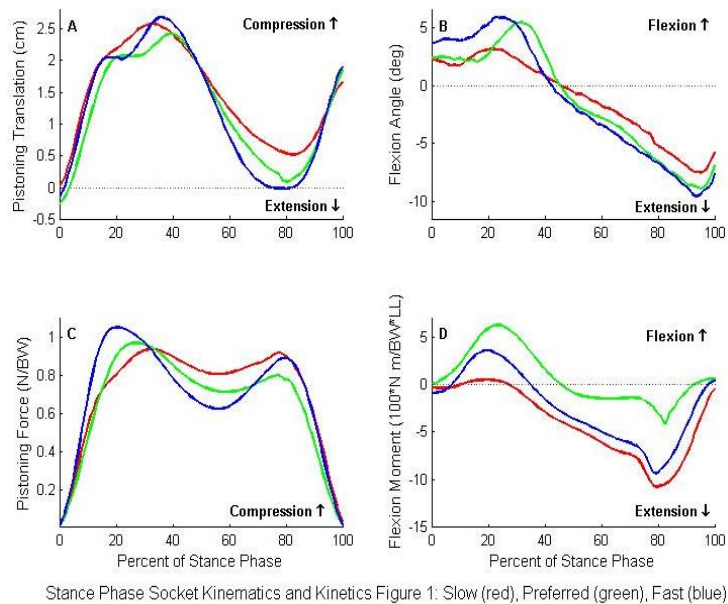
Stance Phase Socket Kinematics and Kinetics Figure 1: Slow (red), Preferred (green), Fast (blue)


Figure 1: Stance phase socket kinematics and kinetics. Slow speed (red), preferred speed (green), and fast speed (blue).

The pistoning force was around one body weight and the bending moment at the SSI exceeded typical hip and knee joint moment magnitudes. Unlike the case for typical joint kinetics (e.g., knee joint forces and moments), the relatively large pistoning force and bending moment at the SSI are borne by a small area of soft tissue that was not meant to withstand such loading. Interestingly, the peak extension moment, which will correspond with a high pressure concentration on the proximal anterior stump, had the smallest magnitude at the preferred speed (Figure 1, Table 2). Amputees may have difficulty coordinating their movement patterns in such a way as to minimize this loading when walking at non-preferred speeds.

The data demonstrated amputees potentially make compensations with the amount of motion and loading at the SSI when walking at non-preferred speeds. The compensations made may increase stump loading at a susceptible site for skin lesions in late stance. More subjects with different types of prosthetics and diverse preferred speeds need to be collected to increase the generalizability of the findings.

INDIVIDUALS USING AN ANKLE-FOOT ORTHOSIS HAVE MINIMAL GAIT DEVIATIONS WHEN ACCOMMODATING TO WALKING ON A CROSS SLOPE

INTRODUCTION

Individuals regularly negotiate non-level terrain during their daily activities. Walking on non-level surfaces, such as cross slopes, requires altered lower extremity biomechanics compared to level ground walking [1]. Dixon and Pearsall [1] observed that while walking on a cross slope healthy individuals increased downslope limb extension and upslope limb flexion in order to functionally lengthen and shorten the downslope and upslope limbs, respectively. Additionally, they observed that the downslope ankle was more inverted while the upslope ankle was more everted to allow the foot to conform to the cross slope walking surface.

Walking on a cross slope may be more difficult for military personnel who are often required to traverse non-level surfaces while carrying loads. The task may become increasingly more challenging for military personnel who have sustained a lower extremity injury resulting in the use of a semi-rigid passive dynamic ankle-foot orthosis (AFO) [2]. AFO use may limit the ability of the foot/ankle to accommodate to the cross slope walking surface. The purpose of this study was to characterize lower extremity kinematic responses made by uninjured individuals and identify gait deviations in individuals utilizing a passive dynamic AFO when walking on a cross slope during a simulated military patrol task.

METHODS

Eleven uninjured service members (33.2±7.0yrs, 1.80±0.06m, 87.9±7.9kg; CONT) and twelve service members prescribed a custom AFO for a unilateral lower extremity musculoskeletal injury (35.4±5.8yrs, 1.83±0.08, 90.0±16.5kg; AFO) participated. All participants wore a standard issued military kit consisting of a Kevlar vest and helmet and carried a mock M4 rifle. Participants walked in a Computer Assisted Rehabilitation Environment (Motek Medical, Amsterdam) on a 6-degree-of-freedom platform with embedded treadmill during a reality-based simulated patrol. They walked for one minute at a controlled speed, based on leg length, during three platform conditions: 1) level ground, 2) 5° tilt to the left, and 3) 5° tilt to the right (Fig. 1).
Figure 1. Representative illustration of a cross slope with the platform tilted to the left.

A 24 camera motion capture system (120 Hz; Vicon Peak, Oxford, UK) tracked 61 markers located on 13 body segments, the helmet, and rifle. Marker data were filtered with a low pass Butterworth filter (6 Hz) and lower extremity kinematics were calculated within Visual 3D (C-Motion Inc., Germantown, MD). AFO data was grouped by a tilt toward the AFO limb or the uninjured limb, and compared to the right limb of CONT during the same platform condition. A 2x2 ANOVA compared between groups and within limbs ($p<0.05$). Paired t-tests were used to compare the right limb during each platform condition within the CONT group ($p<0.05$).

RESULTS AND DISCUSSION

Similar to previous reports of cross slope walking, CONT functionally lengthened their downslope limb while shortening their upslope limb. Compared to level ground walking, the downslope limb was more extended throughout the gait cycle to include reduced midstance and swing ankle dorsiflexion ($p<0.03$), greater push-off ankle plantarflexion ($p<0.001$), reduced swing knee and hip flexion ($p<0.03$), and greater late stance hip extension

(p=0.003). Alternately, the upslope limb was more flexed to include greater midstance ankle dorsiflexion (p<0.001), reduced push-off ankle plantarflexion (p=0.002), greater stance and swing knee flexion (p<0.02), reduced late stance knee extension (p=0.013), greater early stance and swing hip flexion (p<0.001), and reduced stance hip extension (p<0.001) (Fig. 2).
Figure 2. Sagittal plane ankle, knee, and hip kinematics during level walking in CONT and the upslope and downslope limb for both CONT and AFO.

Additionally, the frontal plane tilt of the treadmill elicited kinematic changes within the frontal plane when CONT walked on a cross slope. Compared to level ground walking, CONT had greater downslope limb ankle inversion (p<0.001) and greater upslope limb ankle eversion (p<0.001). Throughout the gait cycle the pelvis was more rotated in the frontal plane toward the downslope limb than during level walking (p<0.05) (Fig. 3).

However, the AFO group did not make the same biomechanical changes at the ankle to the cross slope. AFO had significantly less movement at the AFO ankle in all planes (p<0.05) compared to CONT during all platform states due to the semi-rigid nature of the device and the medio-lateral support that the device is designed to provide. As a compensatory response to the reduced AFO ankle mobility the AFO group had greater frontal plane pelvic rotation towards the AFO limb regardless of platform state than was observed in CONT. The limited AFO ankle motion

did not result in differing sagittal plane responses at the ipsilateral knee and hip or the contralateral limb to the cross-slopes between groups (Fig. 2).
Figure 3. Frontal plane ankle angle and pelvic inclination angle during level walking in CONT and the upslope and downslope limb for both CONT and AFO.

CONCLUSIONS

Both injured and uninjured military personnel used greater downslope limb extension and greater upslope limb flexion while walking on a cross slope during a simulated military task. Service members with traumatic lower extremity musculoskeletal injuries requiring a passive dynamic AFO had limited ankle motion in all three planes. The limited motion at the ankle joint did not result in any significant differences in the sagittal plane at the ipsilateral knee and hip or contralateral limb between injured and uninjured participants. However, the inability of the AFO foot to conform to the tilted surface because of limited frontal plane ankle motion elicited changes in frontal plane pelvic motion.

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is a syndrome characterized by expiratory airflow limitation; however, the effects of the disease reach further than just the respiratory system. For example many patients report muscle fatigue as the main limiting factor to activity as opposed to dyspnea, indicating muscular limitations [1]. Another possible limitation may be gait; however, an investigation of biomechanics of gait in COPD patients revealed only moderate changes to their ankle mechanics as compared to healthy controls [2]. Moreover, COPD patients walk with a more periodic step length and step width at their preferred walking speed than healthy controls [3]. COPD patients walk with greater mediolateral variability than healthy controls and this walking variability was associated with functional capacity [4]. Therefore, it is feasible that variability measures of gait may be more sensitive to discriminating gait dysfunction in patients with COPD versus healthy controls.

Variability is an inherent characteristic in all physiological systems and the level of variability has two extremes. On one end of the spectrum, a highly variable, yet irregular system is uncoordinated; whereas a highly regular, invariable system is unable to adapt to perturbations. According the optimal movement variability theory, a healthy system is a highly variable system, in which the fluctuations have deterministic properties [5]. A diseased physiological system is characterized by a level of variability away from the optimal level, either too variable and irregular or too periodic. Thus, healthy physiological systems present a moderate level of predictability (i.e. regularity) and a high level of complexity.

Therefore, our aim was to compare the joint angle variability in patients with COPD to healthy, older control subjects using the Lyapunov exponent. It was hypothesized that patients with COPD would exhibit an increase in variability of the ankle joints compared to healthy controls as deficits in ankle mechanics in patients with COPD have been determined previously [2].

METHODS

A total of nine healthy controls (70.2±7.1 yrs; 176.9±8.7 cm; 80.1±17.0 kg) and nine patients with COPD (66.3±9.3 yrs; 176.2±14.3 cm; 101.8±36.5 kg) participated in this study. A spirometry test revealing a FEV_1/FVC >0.7 categorized the subjects into the COPD group. Both groups reported no lower extremity injuries or pathologies that would alter normal gait. The groups were speed matched (post hoc) to attenuate speed as a factor (COPD = 0.88±0.21 m/s; Control = 1.00±.27 m/s).

Subjects walked for four minutes at a self-selected speed on a treadmill while three dimensional marker trajectories were recorded (MAC, Santa Rosa, CA; 60Hz). The kinematic data were tracked in Cortex (MAC, Santa Rosa, CA) and were unfiltered, providing the true fluctuations over time. Visual 3D (C-Motion, Germantown, MD) was used to calculate the joint angles. Using Wolf's algorithm [5], the Lyapunov exponent of the ankle, knee, and hip joints was calculated in MatLab (MathWorks, Natick, MA). The Lyapunov exponent was calculated from 14400 frames of continuous joint angle data. The lag and embedding dimension used for each subject's Lyapunov exponent calculation was specific to each individual. Lag ranged from 9-53 in the COPD group and 8-30 in the control group, while the embedding dimension ranged from 5-9 in the COPD group and 5-8 in the control group. Group mean Lyapunov

exponent values for each joint were compared using an independent t-test.

RESULTS AND DISCUSSION

Contrary to our hypothesis, the Lyapunov exponent for the ankle angle was not different between the two groups (p=0.99; Table 1). In fact, no significant differences were found between the groups at any joint (knee: p=0.40; hip: p=0.35). The ankle angle demonstrated the greatest Lyapunov exponent value across all three joints. The Lyapunov exponent quantifies the rate at which an attractor is diverging. A larger Lyapunov exponent value indicates larger stride-to-stride fluctuation in the joint angles, while a smaller Lyapunov exponent value represents a more organized and consistent system. As can been seen in Figure 1, although there were no significant differences in the group means, a few patients with COPD did demonstrate a less consistent attractor. It is feasible that some patients with COPD have greater variation in movement and some have less, this is consistent with heterogeneity and the presentation of phenotypes in the patient population.

Although not significant, it is interesting to note that the patients with COPD exhibited decreased knee and hip Lyapunov exponent values as compared to the controls. A smaller number would indicate that the attractor is diverging at a slower rate and possibly maintaining a more consistent pattern. This would indicate an altered organization of the neuromuscular system compared to older healthy control, with the possibility of the knee and hip compensating for the ankle.

CONCLUSIONS

These results do not support our hypothesis that COPD patients would exhibit an increase in ankle joint angle variability compared to older, healthy controls. Although COPD patients alter gait in the mediolateral direction [4], these results suggest that it does not affect joint angles in the anteroposterior plane. Although no significant differences were found in this study, further investigation into the effects of COPD on gait variability should be done due to variability's association with functional capacity.

INTRODUCTION

Elevated tibiofemoral joint (TFJ) and patellofemoral joint (PFJ) contact forces are believed to contribute to the etiology and exacerbation of knee joint symptoms [1, 2]. To promote participation in regular exercise it is important to minimize or avoid these symptoms. Evaluation and treatment of knee joint injuries that are sensitive to elevated knee joint contact forces may be facilitated by development of methods to estimate these parameters in a clinical setting. In this way, clinicians could identify individuals who are likely to benefit from interventions to reduce knee joint contact forces as well as evaluate the effectiveness of their interventions. Kinematic gait analysis is a feasible clinical assessment that is routinely performed in many settings. The purpose of this study was to test for a set kinematic measurements to predict total TFJ and PFJ contact force (impulse) during running.

METHODS

A total of 56 individuals (26 males, 30 females: 22.6 years) participated in this study. All participants reported regular participation in recreational activities that include running or jumping at least twice per week. Three-dimensional lower extremity joint kinematics (200 Hz) and ground reaction forces (1000 Hz) were recorded as participants ran at 3.3 m/s using their preferred foot strike pattern. These data were used to derive hip, knee, and ankle sagittal plane angles, net internal joint moments, and joint reaction forces using an inverse dynamics approach. Muscle cross sectional area, line of action, and moment arms as a function of joint position at each joint were derived from the literature to estimate quadriceps, hamstrings, and gastrocnemius muscle forces during the stance phase of 5 steps for each participant [3]. Patellofemoral joint contact force was determined using quadriceps force after adjusting for co-contraction of the knee flexors. Tibiofemoral joint contact force was estimated as the sum of knee joint reaction forces and muscle force components parallel with the long axis of the tibia. Total PFJ and TFJ force (impulse) per step was calculated as the integral of these forces curves. Estimated TFJ impulse using this model is within 7% of *in vivo* TFJ joint impulse recorded from an instrumented prosthesis during walking [4].

Six different kinematic measurements during running were evaluated as possible predictors of average TFJ and PFJ impulse: peak trunk flexion angle, peak knee flexion angle, peak ankle dorsiflexion angle, vertical excursion of the participant center of mass during stance, knee angle at initial contact, and step length. Following tests for multicollinearity among the predictor variables, the most parsimonious set of kinematic predictors was determined using separate stepwise multiple linear regressions to predict TFJ and PFJ impulse with a bidirectional elimination approach.

RESULTS

Mean TFJ impulse of the sample was 1.24 (0.17) BW*s. Five kinematic variables (all except peak trunk flexion angle) were found to predict over 75% of the variability in TFJ impulse (Adj R^2 = .76, P < .001). Using these kinematic predictors it is possible to predict TJF impulse to within 0.165 BW*s, resulting in an estimate that is expected to be within 13% of the measured TFJ impulse (Figure 1).
Figure 1. Predicted tibiofemoral joint (TFJ) impulse during running using only kinematic data (predicted) and TFJ impulse estimated using a biomechanical model with kinematic and kinetic inputs (measured).

Mean PFJ impulse of the sample was 0.51 (0.13) BW*s. Peak knee flexion, vertical excursion of the center of mass, and peak ankle dorsiflexion were found to predict over 75% of the variability in PFJ impulse (Adj R^2 = .76, P < .001). These kinematic variables alone predicted PJF impulse to within 0.13 BW*s, which is within 25% of the mean PFJ impulse in our sample (Figure 2).
Figure 2. Predicted patellofemoral joint (PFJ) impulse during running using only kinematic data (predicted) and PFJ impulse estimated using a biomechanical model with kinematic and kinetic inputs (measured).

DISCUSSION

The purpose of this study was to test for a set of kinematic variables that could be used to predict TFJ and PFJ impulse during running. We determined that sagittal plane kinematic data alone can be used to generate fair estimates of both TFJ and PFJ impulse during running. Efforts to refine and improve model accuracy in the future may incorporate frontal and transverse plane kinematics, as these also affect TFJ and PFJ impulse and are often implicated in running related injuries.

The accuracy of the TFJ impulse prediction exceeded that for PFJ. This suggests that sagittal plane kinematics may be particularly suitable for analysis of TFJ disorders during running. In light of the growing popularity of running as exercise among people with TFJ OA and people with risk factors for TFJ OA, these results offer some clinical utility. PFJ impulse prediction was less accurate and would benefit from further refinement of the kinematic predictors. It should be noted that increased peak knee flexion, vertical excursion of the center of mass, and peak ankle dorsiflexion made significant contributions to the prediction of both PFJ and TFJ impulse. Further refinement of the kinematic predictors may improve prediction of both PFJ and TFJ impulse.

Towards clinical utility of biomechanical models, further testing of these predictor variables, acquired with three dimensional motion analysis, is needed. Two dimensional technologies are more pervasive in clinical settings. Theoretically, each predictor variable used in this study could be quantified using a single video camera positioned lateral to a standard treadmill, representing an area for future study.

CONCLUSIONS

Kinematic variables alone produce a fair prediction of TFJ impulse and, to a lesser extent, PFJ impulse during running. The ability to estimate knee joint loads using kinematic data offers promise as a clinical tool for analysis of interventions to reduce TFJ and PFJ loads during running as well as in the identification of people at risk for injury associated with elevated joint loads. Identification of kinematic variables to increase the predictive validity of the model will further improve the clinical utility of these results.

INTRODUCTION
Temporal-spatial, kinematic, and kinetic asymmetries during gait in persons with unilateral amputation have been well documented [1]. Existing evidence suggests split-belt treadmill based interventions have potential to improve gait symmetry. Specifically, a single session case study of a split-belt treadmill walking intervention showed improved gait symmetry in an individual with a transfemoral amputation [2]. The potential of a multi-session training study to improve gait symmetry in persons with an amputation can be substantiated by research in stroke survivors [3]. However, descriptions of potential training benefits beyond temporal-spatial symmetry are lacking.

Research to quantify the adaptive responses of persons with lower limb amputation when exposed to a split-belt treadmill walking intervention is needed to inform the design of a potential training intervention. Therefore the overall goal of this study was to examine adaptability to a split belt treadmill walking intervention for persons with lower limb amputation. This report focuses on the ankle kinematic strategies used when uninjured participants and those with transtibial amputation (TTA) walk during a split belt treadmill intervention. We hypothesized that participants with TTA would use different strategies at the ankle to walk on a split belt treadmill, specifically indicating greater reliance on the intact limb as defined by peak flexion angles.

METHODS
Eight participants, 4 TTA and 4 uninjured, were enrolled in the study. All participants provided written informed consent, and all study procedures were approved by the local IRB.

Participants were fit with up to 70 retro-reflective markers and data was collected with a 27 camera motion capture system (Vicon, Oxford UK). Participants were asked to walk on a split-belt instrumented treadmill (Bertec, Columbus, OH) for 4-minute to serve as an acclimation period. Foot marker data from the acclimation period were used to quantify step length (heel strike to contralateral heel strike) of each limb which was used to assign belt speeds during the subsequent split-belt intervention conditions; the limb with the shorter step length was assigned to the fast pace (1.5 m/s) condition whereas the limb with the shorter step length was assigned to the slow pace (0.5 m/s) condition [3]. Participants then completed 4 walking conditions in order: belts tied at a slow pace for 5 minutes, belts tied at a fast pace for 2 minutes, belts split at a slow and fast pace for 15 minutes, and belts tied at a slow pace for 5 minutes. Ankle kinematics and stance times were created using Visual 3D (C-motion, Germantown, MD).

RESULTS AND DISCUSSION
TTA had a step length difference of greater than ±4 mm (two standard deviations outside of uninjured population [4]). All uninjured participants had slightly shorter step lengths on their left limb, while all TTA had shorter step lengths on their intact limb.

The stride length of the intact limb for participants with TTA is very consistent with the left limb of uninjured participants. During the split condition, the intact limb plantar flexion prior to toe-off was slightly increased in the TTAs (-16.7{7.4} vs. -13.8{6.2} degrees). Additionally, the TTA spend less time in stance compared to the uninjured group (Table 1).

Table 1 – Stance time (s) for uninjured participants and TTA while walking in 4 conditions

Condition	LEFT / INTACT		RIGHT / PROSTHETIC	
	Control	TTA	Control	TTA
Before Split 0.5 m/s	1.06s±0.06s	1.20s±0.07s	1.07s±0.05s	1.15s±0.05s
Before Split 1.5 m/s	0.62s±0.02s	0.61s±0.03s	0.62s±0.02s	0.60s±0.02s
Split Belt Condition	0.62s±0.03s	0.60s±0.03s	0.91s±0.05s	0.84s±0.08s
After Split 0.5 m/s	1.11s±0.13s	1.19s±0.08s	1.13s±0.13s	1.13s±0.07s

TTA prosthetic limb differences appear to be limited when compared to uninjured participants. TTA prosthetic dorsiflexion setting was at 6.9{2.1} degrees. TTA tended to have higher peak dorsiflexion during fast walking compared to uninjured participants (22.2{3.7} vs. 16.9{3.5} degrees), while this trend was reversed in the split belt condition (18.6{3.6} vs. 21.2{3.6} degrees).

Limited differences were seen in the sagittal ankle kinematics of uninjured participants and TTA when walking on a split belt treadmill. This may have occurred because the intact limb of the TTA was assigned to the fast belt in the split condition for all participants. The results may have been different had the prosthetic foot had to compensate to greater belt speeds. When examining the stance times however, this paradigm may provide a potential training benefit as it forces increased stance times on the prosthetic limb. However, this result does not carry over once the split belt condition is removed, implying that repetitive training would be required for retention.

CONCLUSION

Ankle kinematics change in a similar manner for TTAs and uninjured participants when exposed to split-belt walking. Mechanical limitations of the prosthetic device (decreased range of motion compared to the intact limb) have a greater effect than any potential difference in adaptive capacity. Kinetic changes at the ankle should be further explored to determine strategies that may be occurring in the intact limb to aid in walking.

The Effects of Longitudinal Training on Walking Navigation Through a Complex Environment

[1] Timothy A. Worden and [1] Lori Ann Vallis

email: tworden@uoguelph.ca, lvallis@uoguelph.ca

INTRODUCTION

Dual-task interference occurs when the cognitive resources shared between two attentionally demanding tasks (e.g. concurrent walking and backwards counting) exceed the available capacity of attentional resources. Research indicates that the amount of dual-task interference increases as tasks require more attention (such as navigating a complex and sensory rich environment) [1]. Dual-task training has been shown to improve dual-task performance in simple reaction time paradigms [2] likely due to optimization of cognitive processes, however the effects of training on complex dual-task situations remain unknown.

The **purpose** of this study was to examine the efficacy of training healthy young adults with concurrent walking and cognitive tasks to improve dual-task performance in a complex environment. We hypothesized that the concurrent training of walking while performing cognitive tasks would improve the sharing efficiency of attentional resources, and thus improve dual-task performance. Furthermore, we believed that duration of training would affect results, with individuals who receive training for a longer duration (four weeks) demonstrating larger improvements than shorter training sessions (one week) or no training at all.

METHODS

Healthy young adults were randomly assigned to either a no training control group (N=9), a one week training group (N=10) or a four week training group (N=12). Participants were tested at baseline (Visit A), one week following the cessation of training (Visit B) and again 6 weeks later to test for learning retention effects (Visit C). Each testing session was the same design, with participants performing a total of 40 randomized dual-task trials. The cognitive task performed was an auditory Stroop task, and the walking task involved stepping over a dynamic obstacle scaled to 50 % of lower leg length that either moved from a low to high position as subjects approached, or remained stationary [1]. Training was twice a week for 30 minutes; and involved walking tasks (e.g. walking in a pattern) while simultaneously performing various cognitive tests (e.g. backwards counting).

Kinematic data was collected at 60 Hz to quantify stepping patterns. Kinematic outcome measures calculated were minimum lead foot clearance (MLC), minimum trail foot clearance (MTC), take off distance (TOD) and landing distance (LD). Furthermore, mediolateral (ML) dynamic margin of stability (MOS) was calculated for two steps before obstacle crossing, one step before obstacle crossing and the obstacle crossing step [3]. Accuracy for correctly answering the cognitive task was also recorded. A Pearson's Chi Square test was performed to determine differences in cognitive test accuracy. A between-groups repeated measures ANOVA design was performed to identify any changes in outcome measures across the three Visits; statistical significance level was $p < 0.05$.

RESULTS AND DISCUSSION

Participants in the four week training group improved their response accuracy from Visit A to Visit C (92 % to 95 %), while the other training groups showed no change in their ability to accurately answer the auditory Stroop task. In contrast to expected results, improvements in cognitive task performance were not observed directly following training in any group.

Examining MLC, there were no significant differences between groups or testing sessions. For MTC, there was an effect of group, with both

training groups significantly increasing MTC for Visit C as compared to Visit A, while the control group decreased MTC on Visit C, as illustrated in Figure 1. These results indicate that all trained participants adopted a more cautious obstacle clearance strategy with the trailing foot.
Figure 1: MTC values for the three groups; MTC was increased for all trained individuals in Visit C compared to Visit A ($p < 0.05$).

When examining foot placement before obstacle crossing, the Control group maintained a consistent TOD over the three testing sessions, while both training groups significantly increased their TOD from Visit A to Visits B and C (Figure 2; $p < 0.05$). However, due to differences between groups in takeoff distances in Visit A, it is difficult to conclude if training increased TOD or if, by chance, the control group naturally began with an more optimal takeoff distance, which both trained groups converged upon following training.
Figure 2: TOD values for the three training groups; TOD increased for all trained individuals in Visits B & C compared to Visit A ($p < 0.05$).

There were no significant effects, for landing distance measures indicating participants landed at the same distance from the obstacle regardless of testing session and training group.

ML MOS increased in only the trained groups, and only for two steps before the obstacle crossing. There was a trend for increasing MOS at obstacle crossing, although it was not significant. These results suggest that training can improve stability in less challenging steady state walking, however when stability becomes more challenged (as is the case for the step before obstacle crossing and the crossing step), training durations of one or four weeks were unable to increase dynamic stability.

CONCLUSIONS

Through short-term training, we were able to alter the performance of individuals as they navigated a complex environment by adopting a more cautious obstacle stepping strategy. Furthermore, trained individuals adapted a more stable walking strategy during over-ground walking, however stability returned to Visit A values during the more challenging obstacle avoidance and cognitive test. Interestingly, only the four week training group improved cognitive test accuracy, suggesting that as participants were trained, prioritization went to implementing more cautious locomotor strategies, with no significant improvements in the cognitive tests (until Visit C with the four week training group). These results suggest participants prioritized the adoption of strategies to improve postural efficiency with our training protocol, with no real improvements in cognitive task performance [4].

WALKING PATTERN IN CHILDREN WITH AND WITHOUT DOWN SYNDROME VIA AN FORCE-DRIVEN HARMONIC OSILLATOR MODEL

[1]Jianhua Wu, [1]Matthew Beerse, [2]Toyin Ajisafe, and [1]Huaqing Liang

[1]Georgia State University, Atlanta, GA, USA. Email: jwu11@gsu.edu
[2]Texas A&M University, Corpus Christi, TX, USA

INTRODUCTION

Children with Down syndrome (DS) display poorer kinematic and kinetic patterns of walking than children with typical development (TD). It is generally suggested that low muscle tone and joint laxity contribute to motor deficits in children with DS. However, little is known on neuromuscular control in children with DS during locomotion. A force-driven harmonic oscillator (FDHO) model sheds light on general muscular activation with respect to the gravitational load of the thigh-shank-foot system. The *K/G* ratio derived from this model represents a scaling between the elastic restoring torque from muscles and soft tissues and the gravitational torque from the weight of the leg during walking. Clinically, this ratio was previously used to show different muscular function in infant walkers [1] and children with cerebral palsy [2]. This study aimed to compare the *K/G* ratio between children with and without DS while walking overground and on a treadmill.

METHODS

Participants: Twenty six children with and without DS aged 7-10 years completed overground walking at lab visit #1, and 20 children completed treadmill walking at lab visit #2. Of the 26 subjects, the DS group was 9.0 ± 1.3 years in age, 1.24 ± 0.08 m in height, and 30.6 ± 5.6 kg in body mass; the TD group was 9.1 ± 1.4 years in age, 1.33 ± 0.07 m in height, and 29.6 ± 5.1 kg in body mass.

Experimental design: At the first visit, participants walked barefoot overground at two speeds: normal (NS) and the fastest speed (FS). At the second visit, participants walked barefoot on a treadmill at 75% (NS) and 100% (FS) of the preferred overground speed. Two load conditions were manipulated at both visits: no load (NL) and ankle load (AL) that

was equal to 2% of body weight on each side. Average AL condition was 6.0 N in the DS group and 5.9 N in the TD group.

Data collection:
A total of four conditions (2 treadmill speed by 2 ankle load) were tested at both lab visits. The order of condition presentation was mostly randomized across the two groups. A 7-camera Vicon motion capture system was used to register reflective markers attached bilaterally to the subjects. Four trials were collected for each condition during overground walking. A Zebris FDM-T instrumented treadmill was used to register vertical ground reaction force during treadmill walking. Two 60-second trials were collected for each condition.

Data analysis: Customized Matlab programs were used to determine gait events such as heel contact and toe off for overground and treadmill walking trials. An FDHO model [3] represents a hybrid pendulum-spring system that consists of a single pendulum and a spring attached to the pendulum. The simple pendulum represents the gravitational contribution of the thigh-shank-foot system facilitating the passive dynamics of the system, and the spring represents the contribution of muscles and soft tissues facilitating the active dynamics of the system during walking. When ankle load is added, it becomes the thigh-shank-foot-ankle load system. For small amplitude of oscillation during walking, the periodic duration (i.e., stride time) can be predicted as below:

$$\tau = 2\pi \sqrt{\frac{mL^2}{mLg + kb^2}}$$

where τ is stride time, m is the mass, L is equivalent leg length of the system, g is gravitational acceleration (9.81 m/s^2), mL^2 is the moment of inertia of the system about the hip joint, mLg is the gravitational restoring torque associated with the

size and mass of the system, and kb^2 is the elastic restoring torque from muscles and soft tissues. This equation can be reduced as below:

$$\tau = 2\pi \sqrt{\frac{L}{g + \frac{kb^2}{mL}}} = 2\pi \sqrt{\frac{L}{(1 + K/G)g}}$$

Statistical analysis: Two 3-way (2 group x 2 speed x 2 load) ANOVA with repeated measures on the last two factors were conducted on the *K/G* ratio for overground and treadmill walking separately. Post-hoc pair-wise comparisons with Bonferroni adjustments were conducted when appropriate. Statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

During overground walking, the *K/G* ratio across the two groups was 1.07 in the NS condition and 3.02 in the FS condition. In other words, the ratio between the elastic and gravitational torques was about 1:1 in the NS condition and 3:1 in the FS condition for the two groups regardless of external ankle load (Fig. a). There was a speed effect on the *K/G* ratio ($p < 0.001$) such that both groups increased the *K/G* ratio from the NS to the FS condition.

(a)

Overground K/G ratio
During treadmill walking, the *K/G* ratio across the two groups was 0.85 in the NS condition regardless of external ankle load. In the FS condition, the DS group produced a lower *K/G* ratio of 1.14 compared to 1.47 in the TD group without ankle load, but a similar *K/G* ratio of 1.44 compared to 1.43 in the TD group with ankle load (Fig. b). There was a speed effect on the *K/G* ratio ($p < 0.001$) such that both groups increased this ratio from the NS to the FS condition. Also, there was a group by load interaction on the *K/G* ratio ($p = 0.007$). No

difference in the *K/G* ratio was observed in the NS condition between the two groups. However, in the FS condition, the DS group increased the *K/G* ratio from the NL to the AL condition while the TD group maintained the *K/G* ratio regardless of external ankle load. The DS group produced a lower *K/G* ratio at the fast speed of treadmill walking without ankle load, but the inclusion of ankle load helped children with DS produce a similar *K/G* ratio as their healthy peers.

(b)

Treadmill K/G ratio
Although no specific muscle was identified, the FDHO model demonstrates that children with DS are able to produce a similar general muscular activation as their healthy peers while walking overground, an important daily motor activity. However, children with DS may have difficulty in performing a novel task such as walking on a treadmill at a fast speed due to the limitations of their physical characteristics.

CONCLUSIONS

The inclusion of external ankle load appears to improve general muscle activation in children with DS, and it may be a promising training component when designing an intervention protocol to improve motor function in children with DS.

INTRODUCTION

Regulation of locomotion is highly related to control of gravitational load. While external load is added during locomotion, humans increase the activation of extensors during stance and suppress the initiation of flexors during swing [1]. External load at the ankles, rather than on the waist or thigh, elicits higher activities from ankle extensors, and increases stride length and decreases cadence in adults [2]. In contrast to many studies with adults, few have studied the effect of gravitational load on gait patterns in children. It is generally recognized that spatiotemporal and kinematic patterns become adult-like in children aged 5-8 years. However, little is known if children show adult-like kinetic patterns while walking with additional load. A frequency domain analysis of vertical ground reaction force (GRF) helps reveal gait abnormalities in children with cerebral palsy and Down syndrome. The purpose of this study was to investigate differences in kinetic patterns between children and adults while walking with external ankle load using both time- and frequency-domain analyses.

METHODS

Participants: Twenty two children and 20 adults participated in this study. The children group was 11M/11F, 9.2 ± 1.3 years in age, 1.33 ± 0.09 m in height, and 28.8 ± 5.5 kg in body mass. The adult group was 10M/10F, 23.7 ± 2.4 years in age, 1.69 ± 0.11 m in height, and 68.9 ± 12.9 kg in body mass.

Experimental design: Each subject walked three times across the 10-m walkway at their self-selected preferred speed and the average speed was used for treadmill walking. Treadmill speed was normalized to the subject's leg length: $\hat{v} = v/\sqrt{gl_0}$, where g is gravitational acceleration and l_0 is leg length.

Three bilateral ankle loads were manipulated: no load, low load (2% of body mass on each side), and high load (4% of body mass on each side). The order of load presentation was randomized across the two groups. A Zebris FDM-T instrumented treadmill was used to register vertical GRF during treadmill walking. Two 60-second trials were collected for each load condition.

Data analysis: Vertical GRF data were normalized to the subject's body weight (BW). Customized Matlab programs determined gait events (heel contact and toe off), and the timing and magnitude of the first peak force F_{Z1} after heel contact and the second peak force F_{Z2} before toe off. The timing was presented in % of stance and the magnitude was in multiples of BW.

A Fourier transform mathematically transforms vertical GRF into harmonics and each harmonic represents the contribution of certain anatomical components [3]. A discrete periodic signal $F(t)$ can be presented as the sum of a finite number of sine and cosine terms:

$$F(t) = A_0 + \sum_{n=1}^{N/2} [A_n \cdot \cos(n\omega_0 t) + B_n \cdot \sin(n\omega_0 t)]$$

where N is the total number of data points, A_0 is the mean value of the signal, n is harmonic number, A_n and B_n are harmonic coefficients, and ω_0 is fundamental frequency which is equal to 2π divided by the period of the signal. Stance time was used to define the periodicity of vertical GRF. The Matlab programs calculated power of the harmonics in each stance phase. We compared the power of the first five harmonics between the two groups as these harmonics reconstruct the shape of the GRF curve.

Statistical analysis: Average treadmill speed was 1.3 m/s across the two groups. Normalized treadmill

speed $\hat{v}$ was 0.54 ± 0.04 m/s in children and 0.45 ± 0.04 in adults. Since GRF variables show a linear correlation with $\hat{v}$, 2-way ANCOVAs (2 group x 3 load) with repeated measures and a covariate of $\hat{v}$ were conducted on GRF variables. Post-hoc pairwise comparisons with Bonferroni adjustments were conducted when appropriate. Statistical significance was set as $p < 0.05$.

RESULTS AND DISCUSSION

Children produced a similar timing and magnitude of peak vertical GRFs as adults in each condition after adjusting for $\hat{v}$ (Table 1). There was a group by load interaction on F_{Z1} timing (p=.005) and a load effect on F_{Z2} timing (p<.001). There was a load effect on F_{Z1} magnitude (p<.001) and a group by load interaction on F_{Z2} magnitude (p<.001). Children at the age of 7-10 years display adult-like spatiotemporal control of foot falls and foot-floor kinetic interaction during walking with ankle load.

(a) No load
Children produced a lower power from the 2nd harmonic than adults in each condition after adjusting for $\hat{v}$ (Fig. a-c). Both groups had the highest power from the 2nd harmonic and increased this power with ankle load. There was a group by load interaction on the 2nd harmonic power (p = .004), where children increased the power to a greater extent than adults from no load to both load conditions. There was a load effect on the first five harmonics (all p<.001). Both groups increased the

2nd to 5th harmonic power, but decreased the 1st harmonic power with the load.

(b) Low load

(c) High load
CONCLUSIONS

Children aged 7-10 years display adult-like kinetic pattern in the time domain but not in the frequency domain. A frequency analysis helps reveal kinetic differences between children and adults. Neuromuscular development continues into adolescence.

2DOF EXTERNAL FIXATOR AND SURGICAL SYSTEM FOR CLUBFOOT CORRECTION

[1] Ying Ying Wu, [2] Anton Plakseychuk, and [1] Kenji Shimada

INTRODUCTION

Clubfoot is a complex three-dimensional (3D) deformity of the foot presented at birth. The deformed foot is rigidly held in supination and equinus (an inwards and downwards twist). In the US, clubfoot affects 1 in 1,000 live births and may affect only one or both feet. Even though most recover with initial soft tissue manipulation (Ponseti method), between 11% to over 30% of *fully treated* clubfeet relapse during early childhood [1, 2]. Relapsed and neglected clubfoot is a persisting issue within and beyond the United States.

External fixation is a less destructive and highly effective technique for clubfoot correction [3, 4]. An *external fixator* is a frame that surrounds the leg and is attached to the tibia, first metatarsus and calcaneus via bone pins in a minimally invasive surgery. Adjusting joints on this frame pushes the bones into the correct pose. After surgery, the patient is discharged and instructed to adjust the joints *gradually* (2mm/day) to prevent soft tissue damage. The fixator is worn for another 4-12 weeks to maintain the correction. Although complications such as pin infections were observed, they were mild and without lasting effects [3]. Studies that simultaneously correct angulations in all three planes did not observe "rocker bottom" [5, 6].

Current external fixators are bulky and obstruct patient mobility for the entire treatment period of about 12-18 weeks. Constructing a fixator for 3D deformity based on 2D radiographs is a complex task and surgeons face a steep learning curve [7]. Thus, surgeries tend to be long, averaging 2.5hours and up to 4.5hours or even 8hours for less experienced surgeons [8]. Errors in fixator setup may result in residual deformities that require the whole process to be repeated.

We propose a fixator system consisting of a compact two degrees of freedom (2DOF) external fixator and a surgical system, to correct a *full 3D clubfoot deformity*. This system will improve patient outcome by enabling patient mobility, and reduce surgery time and learning curve by assisting the setting up of the fixator during surgery.

METHODS
Figure 1: Axis-angle representation.

We define clubfoot deformity correction as a *3D rigid body transformation* of the first metatarsus. The 6DOF bone deformity problem is simplified to only 2DOF: (1) translation along the vector sum of the x, y, z translations, and (2) rotation by θ about an equivalent axis, $\overline{\omega}$, as shown in Fig. 1:

$$\theta = \text{acos}\left(\frac{trace(R)-1}{2}\right), \qquad (1)$$

$$\overline{\omega} = \frac{1}{2\sin(\theta)}\begin{bmatrix} r_{3,2} - r_{2,3} \\ r_{1,3} - r_{3,1} \\ r_{2,1} - r_{1,2} \end{bmatrix}. \qquad (2)$$

where R is the desired 3x3 rotation matrix, and $r_{i,j}$ is the element in the i-th row and j-th column of R.

To achieve a compact configuration for patient mobility, the magnitude of translation was minimized to minimize the size of the prismatic joint and thus the overall size of the fixator. Fixator components were also constrained to above the foot.

To optimize the rates of adjustment of each joint so that soft tissues are stretched by approximately

2mm/day, we fit Bezier curves to the foot and interpolated intermediate splines during the correction so that the length of neighboring splines differs only by 2mm. Bezier curves are used as they give naturally changing curves. The positions of the first metatarsus across the interpolated splines form the ideal path. Joint adjustments are optimized by minimizing the error between actual and ideal paths.

RESULTS AND DISCUSSION
Figure 2. (a) Prototype of our 2DOF external fixator. (a) Before correction. (b) After correction.

A computer-assisted design (CAD) model of clubfoot was created based on our knowledge of clubfoot deformity. The axis-angle representation was applied and the fixator configuration was optimized for the correction of this clubfoot. On a sawbone foot model, we built a compact prototype. Fig. 2 shows the correction on sawbone model.

Using Bezier curves to approximate tissue stretch, we achieved a soft tissue stretch of 2mm/day on both the medial and lateral sides (figure not shown).
Figure 3. (a) CAD design of passive positioning linkage. Insert: close up of a single joint of linkage. (b) Prototype of a single joint.

The key to this method is to place these joints accurately at the calculated poses. To achieve this, we are designing a passive positioning linkage, as shown in Fig. 3, with no motors, but with electromagnetic brakes that can hold the joints in place while the surgeon set up the fixator.

CONCLUSIONS

We developed a compact 2DOF external fixator that is able to correct a full 3D clubfoot deformity. Our surgical system is able to optimize the joint adjustments to avoid soft tissue damage. Further verifications using real patient data or via patient testing are necessary to fully validate the system.

SHOD VS. BAREFOOT WALKING: WHY DO HUMANS CHANGE THEIR STEP FREQUENCY?

Matthew B. Yandell, Karl E. Zelik

Vanderbilt University, Nashville, TN USA
email: matthew.yandell@vanderbilt.edu, karl.zelik@vanderbilt.edu, web: https://my.vanderbilt.edu/batlab/

INTRODUCTION

Humans value economy of locomotion and seem to adopt a step frequency while shod that minimizes metabolic cost at a given walking speed [1]. It has also been observed that humans increase their step frequency when walking barefoot (as compared to shod) [2,3]; however, the reason for this increase has not been explained.

Taken together, these empirical observations indicate that either: (1) removing the shoes changes gait dynamics sufficiently such that it shifts the metabolic minimum step frequency for a given walking speed, or (2) humans adopt a new step frequency when walking barefoot that does not minimize metabolic expenditure.

The goal of this study was to determine which of these two possibilities better explains the shift in step frequency when walking barefoot versus shod. We performed an experiment that compared shod versus barefoot walking, and estimated metabolic power as well as the relative effects of shoe-specific properties (e.g., mass, height) on step frequency. A secondary goal was to investigate changes in center of mass (COM) mechanics for shod versus barefoot gait.

METHODS

We studied 5 subjects (mean ± SD, 23 ± 4.3 years old, 72.3 ± 16.0 kg, 177.4 ± 11.0 cm height) during level walking on an instrumented split-belt treadmill (Bertec). All subjects gave informed written consent prior to participation. Three footwear variants were tested: shod (using each subject's personal athletic shoes), barefoot, and weight-matched (WM) barefoot (ankle mass was added to match shoe mass). Each subject performed acclimation trials at 1.25 m/s to determine their baseline self-selected step frequency for each footwear variant.

Next, each subject was asked to walk at 1.25 m/s while matching a metronome frequency for the five testing conditions in Table 1. A Cosmed K4b^2 system measured metabolic data for six minutes, and ground reaction force (GRF) data was collected during the last minute of each trial. Average metabolic power during the last 2.5 minutes of each trial was calculated from the equation given by Brockway [4]. GRF data was low-pass filtered at 25 Hz (Butterworth, 3rd order, zero lag) and used to compute individual limb COM power [5] for each limb. Statistical comparisons between conditions were performed using analysis of variance with Holm-Sidak step down correction (alpha = 0.05).

Table 1: Conditions for each footwear variant

Step Frequency	Footwear Variant		
	Shod	**Barefoot**	**Barefoot WM**
Shod SS	X	X	X
Barefoot SS		X	
Barefoot WM SS			X

We also estimated the effect of leg length difference (barefoot vs. shod, due to shoe height) on step frequency using regression equations reported in literature [2,6].

RESULTS AND DISCUSSION

We found that the barefoot and barefoot WM self-selected step frequencies were significantly higher than the shod self-selected frequency (P < 0.01, Table 2). No significant difference in step frequency was observed between barefoot and barefoot WM (P = 0.62). Mean shoe mass in this study was 296 g.

We observed from metabolic data that 4 out of 5 subjects exhibited a lower gross metabolic power when walking barefoot at the shod self-selected step frequency (~112 steps/min, Table 2) than barefoot at the barefoot self-selected frequency (~121 steps/min). This difference did not reach statistical significance, likely due to the low number of subjects. However, through ongoing testing of additional subjects we will attempt to distinguish if sta-

tistically significant differences exist.

The height of the shoe sole added 20 ± 6 mm (mean ± SD) to each participant's leg length, as compared to walking barefoot. Based on the published speed-step length relationship [2,6], we estimated this 20 mm decrease in leg length when walking barefoot would result in a 1.9 step/min increase in step frequency. The predicted increase in step frequency was substantially smaller than the empirical increase of 8.4 step/min (Table 2) observed in this study.

Differences were also observed in COM power for barefoot vs. shod gait, specifically in terms of a reduced transient immediately following heelstrike during barefoot walking.

Table 2: Self-selected (SS) step frequency for each footwear variant

Variant	**Subject SS Step Frequency (steps/min)**					
	1	**2**	**3**	**4**	**5**	**AVG**
Shod	112	123	103	112	111	**112.2**
Barefoot	118	130	118	119	118	**120.6**
Barefoot WM	117	130	118	120	117	**120.4**

There are multiple factors which could contribute to the increase in step frequency when a person transitions from shod to barefoot walking. In this study we sought to determine if properties of the shoe could account for the altered dynamics.

We found that the addition of shoe mass to barefoot walking had little to no effect on self-selected step frequency, and thus did not account for the observed barefoot vs. shod changes. Similarly, we estimated that the reduction in leg length when walking barefoot (due to the loss of shoe height) was only expected to lead to a small increase in step frequency (~1-2 steps/min), but this accounted for less than 25% of the observed barefoot vs. shod step frequency increase, which was >8 steps/min.

Since these intrinsic shoe characteristics failed to account for the observed change in step frequency, other factors must be considered. One of these is shoe length (and its effect on effective foot length), which will be investigated in ongoing/future trials. Another factor may be related to the subjective comfort/discomfort experienced as a result of not having shoe cushioning when walking barefoot.

Although it is difficult to define comfort, the lack of cushioning when walking barefoot could have a marked effect on a user's subjective preference and lead to altered behavior.

In summary, we found indications that when walking barefoot, people may choose a self-selected step frequency that is metabolically sub-optimal. The increased step frequency observed for barefoot (as compared to shod) walking was not well explained by the mass or height properties of the shoe. We speculate that cushioning provided by the shoe and/or subjective user comfort may be significant factors in the choice of self-selected barefoot walking frequency, factors which are generally not integrated into biomechanical walking models or our theoretical understanding of gait. Shoe characteristics could potentially be manipulated to encourage desired locomotor behaviors, such as more favorable biomechanics or reduced joint loading associated with long-term injury risk.

BODY MASS AND HEIGHT ARE NOT GOOD PREDICTORS OF PLANTAR SHEAR STRESS

INTRODUCTION

Peak pressure has been long considered a risk factor for diabetic foot ulceration. Recent studies also indicated shear as a significant pathological factor. Cavanagh et al (1991) demonstrated a significant correlation between body mass and peak pressures in diabetic patients [1]. However, Ahroni et al (1987) claimed that peak pressure values of heavier individuals may not necessarily be abnormally high [2].

Another physical body attribute, body height, has been associated with step length [3] and step length depends on anteroposterior ground reaction forces [4].

To our knowledge the literature does not contain any reports that discuss a potential correlation between peak plantar shear stress and body measures such as body mass and height or presence of neuropathy. The purpose of this study was to explore these relationships in three subject cohorts.

METHODS

The study was approved by the Institutional Review Board at Kent State University and UNT Health Science Center. Subjects gave informed consent before participation. We studied three groups: (DN) consisted of 14 diabetic neuropathic patients, second - (DC) comprised 14 diabetic patients without neuropathy and third - (HC) healthy control group, which included 11 subjects. Peripheral neuropathy was tested with a Biothesiometer. Vibration perception threshold (VPT) was measured in terms of voltage on a 0-50 volt scale. Each subject walked multiple times at self-selected speeds on the custom-built Cleveland Clinic stress plate, which was installed on a 12-ft walkway and set flush. Data from three trials were averaged and used in statistical analysis. Two shear stress and pressure variables were identified in each subject; peak shear (PS), peak shear time integral (STI),

peak pressure (PP) and peak pressure time integral (PTI). These were correlated against the patients' body mass, height and vibration perception threshold (in DN subjects only).

RESULTS AND DISCUSSION
Figure1: PS-Body Mass correlation graphs.
Figure2: PS-Body Height correlation graphs.

Normality assumption was satisfied. Shapiro-Wilk values for the stress variables were >0.1. Pearson correlation analysis was carried out for each group and each stress and pressure variable. No correlation was statistically significant. Body mass and body weight could not account for any degree

of variance in PS, STI, PP and PTI. This indicated that plantar shear and pressure under the foot do not depend on body mass or height. In addition, plantar shear and pressure variables do not correlate with VPT in DN subjects. Table 1 displays the calculated r and respective p values.

The reason to the lack of a strong relationship might be variations in the structure of the foot. For example, in diabetic patients with peripheral neuropathy, compromised plantar fat may lead to bony prominent areas, where high stress values can be seen. Also, the proportional dimensions of the human body and foot may present great variation, which would also lead to substantial variations in the plantar surface area. This study revealed that, PS, PP, PTI and STI may vary regardless of body mass and body height. These results also confirm an earlier report that showed that plantar shear stresses cannot be easily predicted based on normal plantar loads [4]. It was also found in this study that PS, PP, PTI and STI may vary independent of VPT in DN patients.

It is thought that effective load bearing area, gait speed, muscle activity, frictional properties and moisture content of the skin, and other intrinsic factors might influence local shear stresses as well as body mass and height. Such a complicated relationship needs to be further investigated in a large sample study. The purpose of this study was to present preliminary data on the potential association of plantar shear stress and plantar pressures and physical body measures.

CONCLUSIONS
Thus, plantar shear stresses do not depend on body weight and body height and they need to be measured rather than estimated.

MORE ULCERS DEVELOP AT PEAK SHEAR LOCATIONS THAN AT PEAK PRESSURE LOCATIONS. A CALL TO REVISIT ULCERATION PATHOMECHANICS

[1]Metin Yavuz, [1] Linda Adams, [1]Hiral Master, [1]Allan Garrett, [2]Georgeanne Botek

INTRODUCTION

Approximately 100,000 lower extremity amputations need to be performed every year in the US due to diabetic foot ulcers (DFU). In the world, a foot is lost to diabetic ulceration every 20 seconds. Estimated cost of DFU and related amputations to the US Healthcare System is $30 billion. Amputations place a substantial burden on the quality of lives and families of patients. Foot ulceration has long been associated with plantar pressures. However, only 38% of DFU occur at the location of peak pressure (PP) [1]. Moreover, ulcers may not develop at high pressure values that are considered harmful or they may develop at pressures that are not considered harmful. Therefore, sensitivity and specificity of foot pressure is not high enough to accurately predict developing ulcers [2].

Rationale for DFU prevention is centered on pressure relief. However, studies have revealed limited results from the use of pressure-reducing preventive footwear [3]. Studies from the past decade have shown increased plantar shear in diabetic patients with neuropathy when compared to non-neuropathic diabetic patients and healthy individuals [4, 5]. In addition, peak plantar pressure and shear do not usually occur at the same site in diabetic and healthy subjects [6]. Pollard and Le Quesne reported that peak pressure and shear occurred at the same sites, which were also the sites of a previous ulceration in 100% of the patients (N=5) [7]. However, the equipment used by the authors had major drawbacks such as attachment of thick sensors on the plantar surface and a need for separate sensors for pressure and shear components. The purpose of this ongoing study was to investigate a site-wise association between healed ulcers and plantar shear loading, using the Cleveland Clinic pressure and shear device.

METHODS

Four neuropathic diabetic subjects (3 F, 1M) with 5 recently healed plantar ulcers were recruited after signing an IRB approved consent form. The ulcers had healed within the past three months of study participation. Peripheral neuropathy was tested by a Biothesiometer and 5.07 Semmes-Weinstein monofilaments. The foot was examined and any calluses noted. Subjects walked on the Cleveland Clinic device, which can quantify triaxial plantar stresses. The stress plate was set flush in the middle of a 4-meter walkway. Data were collected implementing the two-step method, and were analyzed after determining averages from three trials. Locations of peak pressure and resultant shear stress were identified based on the averaged data. The data was then compared to ulcer site locations for descriptive analysis.

RESULTS AND DISCUSSION

In 2 subjects, locations of PS and PP didn't overlap, and the PS site coincided with an ulcer (Figure 1). A third DFU coincided with the location of PP. In the remaining 2 subjects, PS and PP overlapped and coincided with the ulcer site. In summary, 40% of the ulcers had occurred at peak shear site only and 20% had occurred at peak pressure site only. Furthermore, 80% of ulcers had occurred at a location coincident with PS, half of which were coincident with PP as well.

A)

B)

C)
Figure 1: A) Peak plantar shear on the right hallux of a neuropathic diabetic patient, B) Peak pressure in the midfoot and C) Representative foot placement on the stress plate. Note: peak shear had a magnitude of 24 kPa and peak pressure was 167 kPa. Peak shear and pressure sites did *not* coincide and peak shear occurred where a diabetic ulcer had healed a month before assessment.

CONCLUSIONS

The preliminary results of this ongoing study support the previous findings that indicate the clinical significance of plantar shear in diabetic ulceration. The biphasic character of plantar shear stresses is believed to play a major role in ulceration pathomechanics, subjecting soft tissue to cyclic loading that may result in fatigue failure. Shear stresses were also shown to cause hyperkeratosis and hence callus formation in soft tissue. It is a clinical fact that many ulcers are preceded by callosities. Blood occlusion also occurs faster if a soft tissue is subjected to both pressure and shear simultaneously. High temperatures in the diabetic foot are thought to further contribute to ulcer development by increasing metabolic rate of the tissue; this increased metabolic rate might not be compensated by impaired blood circulation which is

often seen in diabetic patients. Frictional shear stresses contribute to elevated plantar temperatures particularly in the presence of kinetic friction. Shear stress couplings observed on the foot-ground interface, such as bunching, twisting and stretching may further damage plantar tissue. Interestingly, one ulcer occurred at a site that experienced only 167 kPa of pressure and 24 kPa of shear stress (Figure 1). This also indicates that other factors might be in play along with plantar stresses that make a foot susceptible to ulceration.

Diabetic ulceration has a multifactorial etiology and oversimplifying the pathology by focusing on only certain factors such as foot pressure will most likely hamper the provision of effective healthcare to patients who are at risk for ulceration. Given that most diabetic ulcers do not develop at peak pressure locations and pressure-reducing therapeutic footwear cannot effectively reduce ulcer incidence, it is crucial to further explore the clinical implications of plantar shear as well as other factors such as physical activity. Better understanding of these factors will lead to designing more effective preventive footwear and methods.

INTRODUCTION

Many foot disorders have a biomechanical etiology. Ground reaction forces and related stresses that act under the foot are associated with complications such as diabetic ulceration, rheumatoid foot, hallux valgus and foot blistering. The normal component of the 3D plantar stresses, i.e., pressure, can be easily quantified by commercially available barefoot or in-shoe systems. However, few investigators have access to equipment capable of measuring 3D loading under the foot since measuring plantar shear stresses remains to be quite challenging.

Brand has suggested that temperature can be used to predict tri-axial loading under the foot [1]. Studies have also revealed that diabetic patients have increased plantar temperatures when compared to control subjects [2]. It is thought that diabetic feet experience elevated stresses that lead to inflammation within the foot, which can be observed as temperature increase on the plantar aspect of the foot. Unfortunately, this theory has not been validated before. The purpose of this study was to explore a site-wise association between peak plantar temperature and peak pressure and shear stresses obtained from diabetic patients using a thermal camera and a custom-built pressure-shear plate. In addition, peak pressure and shear magnitudes were correlated against peak temperature in order to reveal a magnitude-wise association. The study examined these factors in both diabetic neuropathic patients (DN) and diabetic non-neuropathic control patients (DC).

METHODS

The study was approved by the Institutional Review Board. Subjects gave informed consent before participation. Group DN consisted of 14 diabetic neuropathic patients (2 F, 64.8±6.8 years, 32.0±5.1 BMI). The second group (DC) comprised 14 diabetic patients (9 F, 52.4±12.9 years, 28.9±7.4 BMI) without neuropathy. Vibration perception threshold (VPT) was tested using a Biothesiometer. 5.07 Semmes-Weinstein monofilaments were used to assess presence of sensation. Each subject waited ten minutes while barefoot in order to ensure the plantar temperatures reached steady-state conditions. After this period, resting plantar temperatures were recorded using an infrared thermal camera. Subjects then walked at self-selected speeds on the stress plate, which was installed on a 12-ft walkway and set flush. Data from three trials were averaged and used in statistical analysis. Data were collected implementing the two-step method. Subjects' feet were masked into five forefoot (FF) regions; hallux, lesser toes, medial forefoot (1st metatarsal head), central forefoot (2nd and 3rd MTH) and lateral forefoot (4th and 5th MTH). Four major stress variables were identified in each subject; peak pressure (PP), peak shear (PS), peak pressure-time integral (PTI) and peak shear-time integral (STI). Peak values of the stress variables and peak temperature (PT) were found in five forefoot regions. Separately, locations of global peak values of all variables were determined for each person. Linear regressions were used to explore the value of temperature in predicting pressure and shear. Differences in temperature by group and site were analyzed by ANOVA. For all analyses alpha was set at 0.05.

RESULTS AND DISCUSSION

Mean temperatures were significantly higher in the DN group by 1.3 °C (31.1 °C vs 28.8 °C, SD=3.3 vs 3.9, p=.001). Temperatures were not different by group and site (Table 1). Significant linear regressions were observed between PS and

temperature at the hallux, but not at other regions. Peak plantar temperature sites matched the site of peak shear in 57% of the DN subjects and in 71% of the DC subjects (Table 2). Figure 1 displays the peak shear stress plantar temperature profiles of a representative DN subject.

Table1. Measured plantar temperature values (°C). Values are means (standard deviations).

Site	DN	DC
Hallux	30.7 (4.0)	28.2 (4.4)
Lesser Toes	30.1 (4.2)	27.7 (4.2)
Medial FF	31.2 (2.7)	29.5 (3.7)
Central FF	31.7 (2.4)	29.5 (3.4)
Lateral FF	31.6 (2.9)	29.2 (3.6)

Table 2: Site-wise correlation percentage values for peak stress and temperature.

	Group DN	Group DC
PP - PT	14% (2/14)	86% (12/14)
PS - PT	57% (8/14)	71% (10/14)
PTI - PT	14% (2/14)	71% (10/14)
STI - PT	57% (8/14)	50% (7/14)

Figure 1: Resting plantar temperature (left) and peak plantar shear (right) profiles of a representative DN subject. Note the match between the sites of peak temperature and peak shear (first MTH)

Results indicated that plantar temperature can predict triaxial plantar loading at the hallux but not at other foot sites. As revealed by this study, temperature alone is not an excellent predictor of plantar pressure and shear stress. Plantar temperature values may vary depending not only on plantar loading, but also blood circulation, internal loading and the presence of kinetic friction at the foot-ground interface. Compromised fat layer in diabetic feet, which is a natural heat insulator, might also influence how heat is dissipated on the plantar surface. On the other hand, particularly in group DC, peak temperature values achieved a moderate success in identifying the location of peak stress values. This success was quite lower in group DN.

In a previous study we observed a 5.3 °C increase on the plantar foot of healthy subjects, after ten minutes of walking [3]. This increase may be higher in DN subjects given that elevated stresses are experienced by such feet. Whether caused by activity or inflammation, high temperatures in the diabetic foot are thought to further contribute to ulcer development by increasing metabolic rate of the tissue; this increased metabolic rate might not be compensated by impaired blood circulation which is often seen in diabetic patients.

We believe that the potential relationship between the magnitudes of stresses and temperature has a complicated, non-linear character. Appropriate modeling schemes can be implemented to explore such complicated potential relationships. The results of this study are thought to warrant further investigation on this topic.

Gait Patterns Following Anterior Cruciate Ligament Reconstruction Differ With Graft Type

[1] Ryan Zarzycki, [2] David Logerstedt, [1] Lynn Snyder-Mackler

[1] University of Delaware, Newark, DE, USA
[2] University of the Sciences, Philadelphia, PA, USA

INTRODUCTION

After anterior cruciate ligament reconstruction (ACLR), subjects demonstrate persistent altered movement asymmetries during gait that may increase the risk of osteoarthritis (OA) development[1] and predict re-injury[2]. Graft type can influence kinematics and kinetics during gait although most studies have only explored sagittal plane movement[3]. The purpose of this investigation was to determine if differences in sagittal, frontal, and transverse plane kinematics and kinetics exist between subjects undergoing ACLR with hamstring (HS) autograft and subjects with bone-patellar tendon-bone (BPTB) autograft.

METHODS

Thirty five subjects following ACLR were included in this analysis. Twenty six subjects underwent ACLR with a HS autograft (mean age 19.1 years, 17 male, 9 female) while 9 underwent ACLR with a BPTB autograft (mean age 20.8, 8 males, 1 female). Subjects were enrolled after they met the following criteria following post-operative physical therapy (mean 22.5 weeks post surgery, standard deviation (SD) 7.7 weeks): full joint range of motion, greater than 80% quadriceps index, minimal/no effusion, and the subjects must have started a running progression. Standard motion capture was performed during gait at the subject's preferred walking speed. Knee and hip joint angles and moments were calculated through inverse dynamics in all three planes of motion at initial contact (IC), peak knee flexion (PKF), and peak knee extension (PKE). A 2 x 2 analysis of variance was utilized to detect differences between limb and group (HS, BPTB).

RESULTS

Significant group x limb interactions were found with knee adduction angle at peak knee flexion (see table 1 for all means, SD's, and p values). The BPTB group had greater asymmetry resulting from a greater mean adduction angle of the uninvolved limb. There was no significant interaction with external knee flexion moment at peak knee flexion although the mean difference between limbs was greater than the minimal clinically important difference of .04 Nm/kg*m. The BPTB group's knee flexion moment asymmetry was .08 Nm/kg*m greater than the HS group. There were no significant interactions with all other variables.

DISCUSSION

In this analysis the BPTB group displayed greater asymmetry between limbs in external knee flexion moment and knee adduction angle at peak knee flexion compared to HS group. The BPTB group were likely underloading their surgical knee as evident by the decreased external knee flexion moment at PKF. Furthermore, the uninvolved knee in the BPTB group had an increase in knee adduction angle at PKF, likely reflecting compensation due to underloading their surgical side. Altered loading following ACLR may increase the likelihood of knee OA. Based on these findings, subjects with BPTB autograft may be more likely to develop knee OA. Special attention during rehabilitation should be given to restoring symmetrical loading.

INTRODUCTION

Total knee replacement (TKR) is commonly used to correct end-stage knee osteoarthritis (OA) of the knee joint. Unfortunately, difficulty with stair climbing often persists and prolongs the challenges of TKR patents. Stair climbing is a common activity of daily living and utilized in all clinical recovery assessments after a TKR.

Experimental studies of stair ambulation after TKR reported that peak knee extension moment appears to be reduced following TKR compared to healthy subjects during stair ascent [6]. Studies utilizing an instrumented TKR have shown that compressive loads at the knee during stair ascent were ranged between 2.5 and 3.1 bodyweight (BW) in stair ascent [2, 3]. Only a limited number of studies have utilized musculoskeletal simulations to investigate knee joint loading in stair negotiation in healthy subjects. However, no studies have investigated the knee joint loading and muscle forces in TKR patients during stair ascent using musculoskeletal simulation. Therefore, the purpose of this study was to determine if the knee joint reaction force (JRF) following TKR are recovered to the level of healthy individuals, and determine the differences in muscle forces causing those loadings during stair ascent.

METHODS

Five patients (63.6 ± 8.7 yrs, 1.7 ± 0.1 m, 87.0 ± 8.9 kg, 14.6 ± 3.4 months post-surgery) who received a posterior stabilized TKR and five healthy participants (57.8 ± 10.0 yrs, 1.8 ± 0.1 m, 89.0 ± 6.6 kg) participated in the study. A 9-camera motion analysis system (240 Hz, Vicon Motion Analysis), and two force platforms and an instrumented staircase (1200 Hz, AMTI) were used to obtain 3D kinematic and ground reaction force data for five trials during stair ascent at a self-selected speed.

Kinematic and kinetic data were initially processed in Visual3D (C-Motion, Inc.) and then exported to OpenSim (3.0.1, SimTK, Stanford, CA, USA) to perform musculoskeletal simulations. A generic musculoskeletal model (Gait 2392 Model) was scaled to the height and weight of each individual participant to generate subject-specific models. In order to improve the accuracy of the simulations a residual reduction algorithm (RRA) was used to minimize virtual residual forces added to the model to account for dynamic inconsistency. Kinematic changes from RRA were all kept below 5.5 cm of translation and 3.5 degrees of rotation. Peak residual forces and moments were each kept below 14% of body weight and 1.6 Nm/kg, respectively. Individual muscle excitations and resulting muscle forces were calculated using computed muscle control to drive simulations of the stair ascent trials. Joint reaction forces were computed using the JRF Tool in OpenSim.

In order to compare differences between TKR patients and healthy individuals, a paired samples t-test was used for each variable (21.0, IBM SPSS, Chicago, IL) with an alpha level set at 0.05 a priori.

RESULTS AND DISCUSSION

Peak knee extensor moment was reduced in TKR patients compared to healthy controls (Table 1), which is consistent with findings reported in the literature [1, 5]. Although no differences of both earlier and late peak knee joint compressive forces were found, the late-stance peak compressive knee contact force showed a trend of elevated compressive JRF for TKR patients compared to controls (p = 0.051). The magnitudes for compressive JRF seen in this study were elevated slightly over those seen in the literature for stair ascent [2, 3, 4].

The late stance peak rectus femoris muscle force was reduced while the late stance peak vastus medialis force was greater in TKR patients compared to healthy controls (Table 1). No differences were found for the late stance peak hamstring muscle forces. However, the peak late stance medial gastrocnemius muscle force was smaller and the late stance peak lateral gastrocnemius muscle force was greater in TKR patients compared to controls.

It appears a different strategy was utilized by TKR patients to produce similar levels of muscle forces compared with to healthy controls. It can be seen that the majority of muscle force during the push-off phase is from the rectus femoris in healthy individuals. However, TKR patients utilized the vastus medialis more during push-off than healthy controls. Similarly, TKR patients utilized the medial and lateral gastrocnemius differently than healthy individuals. The underlying biomechanical factors causing these differences and the influence they have on JRF remain unclear. TKR patients may be utilizing the muscles differently as a compensatory strategy for the reduced knee extensor strength that remains after rehabilitation. It is possible that gait compensation strategies seen in knee OA patients to relieve pain linger after the TKR rehabilitation is completed.

CONCLUSION

TKR patients showed a trend of having higher late stance peak compressive JRF. Some muscle force compensatory strategies appear to be present in the push-off phase; however, the differences in muscle forces do not clearly explain the trend present in compressive JRF during the second half of stance. Future research utilizing musculoskeletal modeling and simulation is necessary to investigate differences in muscle forces dependent on rehabilitation strategies and differences existing at the ankle.

VALIDITY OF THE TWO-DIMENSIONAL SAGITTAL PLANE ASSUMPTION IN MODELING THE STANDING LONG JUMP

[1] Lauren J. Hickox, [1] Blake M. Ashby, and [1] Gordon J. Alderink

[1] Grand Valley State University, Grand Rapids, MI, USA
email: ashbybl@gvsu.edu, web: http://www.gvsu.edu/engineering

INTRODUCTION

Most standing jumping studies include the assumption that jumping is a sagittal plane activity in order to use a two-dimensional model (2D) instead of a three-dimensional (3D) model. However, the 2D assumption may not always be acceptable for jumping activities, particularly those that include arm movements. To investigate the validity of this assumption, a human subject study was designed that compared the results of kinematic and inverse dynamic analyses using both 2D and 3D full-body models.

METHODS

A Vicon motion capture system (Vicon Motion Systems Ltd., Los Angeles, CA) was used to record positions of markers on the bodies of six adult male volunteers (mean ± standard deviation, mass: 90.3 ± 12.0 kg and height: 182.0 ± 6.3 cm). Reflective markers were placed on the upper and lower body in locations that allowed for the creation of both 2D and 3D models. The 2D model was single-sided and contained seven segments: foot, shank, thigh, pelvis, trunk, upper arm, and forearm. The 3D model contained 12 segments, including upper and lower extremities on both sides of the body. The anatomical reference frames for the 3D model were based on Ren et al. and recommendations by the International Society of Biomechanics (ISB) [1-3].

The participants performed leg and arm rotations that were collected for determination of the hip and shoulder joint centers using the SCoRE method [4]. Two in-ground force plates (Advanced Mechanical Technology Inc., Watertown, MA) were also used to collect 3D force and center of pressure data during takeoff. For the jumping trials, the subjects were instructed to stand with one foot on each force plate. After familiarizing themselves with the motion, the participants performed eight standing long jumps for maximum distance with no restrictions on takeoff position or arm motion during the jump. The participants were allowed to rest as long as desired between jumps.

Inverse dynamics analyses were performed for the 2D and 3D models and joint moments, powers, and work values were found using Matlab R2013a (Mathworks, Natick, MA). The use of force plate data resulted in an over-determined system for both models. In order to solve the systems, the trunk equations were not used and the models were solved from the ground up to the lower back and from the hands "down" to the shoulders. The differences between these models were compared using a one-way ANOVA model in SAS JMP 10.0 (SAS Institute, Cary, NC).

RESULTS AND DISCUSSION

The results from this study showed good agreement between the 2D and 3D models for the lower body, with only insignificant differences in the moments, power (Figure 1), and work for the ankle, knee, and lower back. The 2D hip analysis resulted in a slightly higher peak power than the 3D analysis. For the upper body joints, the differences between the two models were more significant, particularly in power generation. The differences at the hip and shoulder were expected as they are ball and socket joints that are not physically constrained to sagittal plane motion, and the planar assumption in the 2D model caused the effects of adduction-abduction to be ignored at these joints. Differences at the elbow are explained in part by the planar assumption's inability to account for the elbow axis of rotation often not being perpendicular to the sagittal plane.
Figure 1: Comparison of Net Joint Power about the Flexion-Extension Axes for 2D and 3D Analyses for the Right Side (+ extension/plantarflexion).

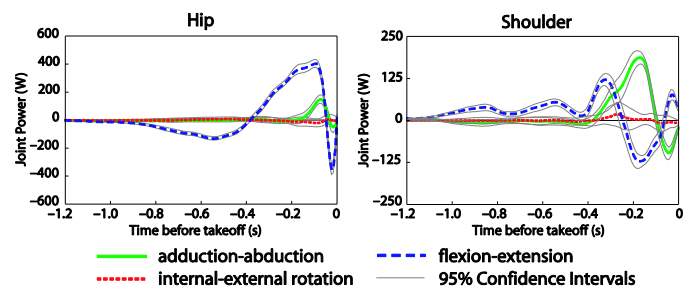
In order to further analyze any non-planar activity that occurred during the jumps, the components of the 3D moments, power, and work were determined. The moments and power generation about the flexion-extension axes were found to be dominant in the lower body, confirming the agreement between the 2D and 3D models. The hip was the only joint in the lower body that showed significant moment and power generation (Figure 2) about the adduction-abduction axis, however flexion-extension was still overwhelmingly the dominant motion. In the upper body, significant moments and power generation were seen about both the adduction-abduction and flexion-extension axes at the shoulder joint (Figure 2). This was expected as more out-of-plane motion was observed in the upper body than in the lower body during the jump trials. Separating the total work at the right shoulder into components, 45.3% was found to be performed about the adduction-abduction axis and 53.6% was found to be performed about the flexion-extension axis. This distinction is not possible with a 2D analysis.


Figure 2: Components of Joint Power for the 3D Analysis for the Right Side Hip and Shoulder (+ abduction, extension, and external rotation).

CONCLUSION

3D models may more accurately represent the motion being studied but add complexity that comes at the cost of processing and analysis time. Gaining a better understanding of the differences between the two types of models should help with correct model selection for specific applications in future studies. When choosing a model for the analysis of the standing long jump, the value added by a 3D model needs to be considered with respect to the goals of the study. The results of this study showed that a planar motion assumption with a 2D model should be appropriate for most studies of the standing long jump, particularly when overall performance is considered and details of the upper body motion are not a concern. In cases where upper body motion is being studied or small increases in performance are vital, a 3D model may be more appropriate as it more accurately represents the motion of the upper body.

Using a Dynamic Musculoskeletal Model to Explore Human Pinch

email: abarry@hawk.iit.edu

INTRODUCTION

The act of pinching is fundamental to a variety of everyday tasks. The act of pinching involves a transition from dynamic movement to application of a precise isometric force at the tip of the digit. The transitions from movement to force and force to movement are complex [1] and incompletely understood. Computer modeling could help to identify important parameters in the pinching task. This information would further knowledge of hand motor control and guide rehabilitation.

Thus, building on previous models of the index finger [2] and thumb [3-5], we are developing a dynamic model of pinch. This study describes development of the model and preliminary validation testing of isometric force production of individual muscles. Simulation values are compared with cadaver results.

METHODS

The model was developed using OpenSim (SimTK, Stanford, CA).To replicate the structure of the hand in OpenSim the bone geometry was first imported from the OpenSim website [3]. The muscle attachment points and wrapping surfaces for the muscles were adapted from a previous study [2]. The thumb in this simulation was represented as a 5 DOF system, which has not been done before for this kind of simulation. The 5 DOF observed were abduction/adduction (A/A) at the Carpometacarpal (CMC) and Metacarpal (MCP) joints, and there was flexion/extension (F/E) at CMC, MCP, and Interphalangeal (IP) joints.   These joints were represented using non-orthogonal axes as found by Hollister [6-7]. The index finger was represented by a 4 DOF system, with A/A at the MCP joint only, and F/E at MCP, Proximal Interphalangeal (PIP),

and Distal Interphalangeal (DIP), represented by non-orthogonal axes [2]. Each joint was provided with limits, to ensure that the joints did not rotate outside of their range during simulation.   Initial joint angles were represented in the key or lateral pinch posture for the individual muscle activation simulations. These angles are defined by Valero-Cuevas 2003, to be: CMC A/A=0°, CMC F/E=-30°, MCP A/A=0°, MCP F/E=17°, and IP F/E=23°. For the Index finger the joints were set at: MCP F/E=30°, MCP A/A=0°, PIP F/E=45°, and DIP F/E=15° to coincide with previous studies [2]. Figure 1 provides a visual representation of the model used in simulation.
Figure 1: OpenSim model of hand with muscle attachments of the index finger and thumb

Individual muscle properties, specifically the peak force, optimal fiber length, and pennation angle, were obtained from previous studies [2,8]. These values were then used to calculate the tendon slack lengths for each muscle, assuming a 0.033% strain. All 8 muscles were included for the thumb: extensor pollicis longus (EPL), abductor pollicis longus (APL), flexor pollicis longus (FPL), Extensor Pollicis Brevis (EPB), Abductor Pollicis Brevis (APB), Flexor Pollicis Brevis (FPB), Opponens Pollicis (OPP), and Adductor Pollicis (Add). Six muscles were included for the index finger: flexor digitorum profundus (FDP), Flexor Digitorum Superficialis (FDS), Extensor Digitorum Communis

(EDC), First Palmar Interosseous (FPI), Extensor Indicis (EI), and Lumbrical (LUM).

For the individual thumb muscle simulations an activation was applied to produce a force of 10N for each muscle, i.e., if the muscle's peak force were 100N, the activation level would be 10%. This was done to allow a comparison with reported values in literature [8]. For the index finger an activation of 10% was used in every simulation to compare with previous studies [2]. With these activation levels and the initial angular positions a Forward Dynamics Simulation was performed to compute the motion of the model. Obtaining the isometric forces was accomplished by placing a small massless sphere on the fingertip and creating a contact with a ground oriented in the direction of the distal phalanx.

RESULTS AND DISCUSSION

The magnitudes of the forces produced were compared to the values from previous cadaver studies for the thumb [8] and index finger [2].
Figure 2: Comparison of the forces simulated in OpenSim to those from a cadaver study [Towles], all forces were generated from 10N of muscle force. Bars represent 95% confidence interval.
Figure 3: Comparison of force magnitudes from OpenSim and a cadaver study [Dan] in the index finger with 10% activation.

It can be seen that the thumbtip force magnitude closely matches (within 95% confidence interval) the magnitude seen in cadavers for EPL, FPL, EPB, and Add (Fig. 2). Those magnitudes are also shown to be a more accurate representation of the force than the old mathematical model. The forces for APL, FPB and OPP are not significantly close to the cadaver values which may be due to anatomical variations between the cadavers and the definition of the muscle insertions in the model.

For the index finger, the greatest deviations between the model and cadaver results were seen in the long flexors (Fig. 3). Model performance may be improved in the future by adjustments to the contact surfaces used to obtain the forces in the OpenSim model and by routing of the flexor tendons.

CONCLUSIONS

OpenSim can generate an accurate model of the forces generated in the human thumb and index finger. Increasing the accuracy of the model may be accomplished with different muscle wrapping surfaces, improved muscle insertion points, or by adding damping components to each of the joints. Putting these two components together gives a very promising possibility for the simulation of dynamic pinching.

INVESTIGATION OF THE STRESSES INDUCED IN BONE DURING WALKING AND STAIR CLIMBING PRE AND POST THR

INTRODUCTION

The total hip replacements (THRs) present a high clinical success rate but it presents a number of complications as well especially among the younger patients. The main complication is attributed to the loosening of the stem due to osteolysis and stress shielding, both leading to bone resorption [1]. The stress shielding is defined as bone density loss due stress reduction following THR. While many solutions attempted to minimize the stress reduction between the intact and prosthetic case by exploring, amongst other on the effects of the stem material and shape. The influence of physical activities on the stress shielding reduction is not yet sufficiently explored. The aim of this study is; first, to explore the effect of two common daily activities, walking and stair climbing, on the stress distribution in the femoral bone before and after THR and second, to investigate whether the performance intensification of a particular physical activity reduces the stress shielding rate or not.

METHODS

Series of CT-scan images of a left intact femoral portion of a healthy female subject have served as an essence of the three-dimentional (3D) computer assisted design (CAD) model. The segmentation procedure performed in MIMICS 14.0 has aimed to isolate in a predefined mask only pixels that represent the cortical bone layer. Within this layer, the bulk of the cancellous bony tissue is intuitively determined based on CT images and anatomical data. The design of the femoral stem geometry is inspired from an anatomical cementless commercial design that has neck-shaft angle of about 130°, an oval cross-section proximally and an almost circular one distally. The prosthetic CAD model is then generated by sectioning the head of the intact femur to accurately house the prosthesis.

A 3D finite element (FE) model is developed to predict the stress induced in the bone during walking and stair climbing. As shown in figure 1, the cortical, cancellous and prosthesis part instances were all meshed with quadratic hexahedral elements.
Figure 1: FE hexahedral meshes of the intact (In) and prosthetic (Pr) models showing the zones A1-4 and B1-4 repeatedly and accurately demarcated in both models for comparison purposes.

Orthotropic material property was assigned to the cortical bone and isotropic material properties were assigned to the cancellous bone and the prosthesis (Ti–6Al–4V) [2]. A bounded contact is considered to simulate the fully osseointegration condition that rises between the prosthesis and bone as well as the junction of the cortical and cancellous bone tissues. While the distal face of the cortical bone was set fixed in the subsequent nonlinear FE analyses, the loading applied consists of the action of up to four hip muscles as well as their resulting hip contact forces during walking (Wk) and stair climbing (Sc) loading cases, respectively. The lines and points of applications of the above-mentioned loads were

derived from the study of Heller et al. [3] considering a body weight of 700N. The stress shielding rate η was calculated based on the equation $1 - \sigma/\sigma_0 \times 100\,\%$, where σ and σ_0 correspond to the maximum of Von-Mises stress in each zone, A1-4 and B1-4, before and after THR, respectively. The analyses were performed using ABAQUS 6.10 FE package program.

RESULTS AND DISCUSSION

The response of the femoral cortical bone shows that the maximum Von-Mises stress increase substantially from Wk and Sc loading cases in both intact and prosthetic cases in the all zones except in the A4 and B4 regions where only a slight variation was predicted (Figure 2). The maximum Von-Mises stress was predicted to be in the intact case under Sc loading case in A1, A2, B1 and B2 regions ranging from 81.3 - 85.7 MPa. The max Von-Mises stress in the A4 zone after a THR is the only one that it decreases from the Wk to Sc case.
Figure 2: Von-Mises stress in the cortical bone for the Prosthetic and Intact cases for both walking (Wk) and stair climbing (Sc) loading cases.

In regions A1-4, the stress shielding rate increased from the A1 to A4 zones for the both considered loading cases. In Wk and Sc loading cases, the rate of stress shielding (η) reaches in A4 the highest magnitudes of 58% and 70%, respectively (Figure 3). Under the two loading cases, the stress shielding rate is maximum in A4, then in B3 and A3 regions. From B1-B4, the B3 region is the only one that it presents a rate of stress shielding greater than 30% equivalent to the rate in A3.
Figure 3: Stress shielding rate η calculated for the different zones and loading cases walking (Wk) and stair climbing (Sc) loading cases.

The zone A4 is found to be the most vulnerable region in the femur post THR. If we consider that walking is the most common daily activity before THR, the stair climbing activity after THR cannot increase the stress in the A4 region, where η is maximum, to its level in this region before the THR. However, stair climbing activity after a THR may be beneficial to reduce the stress shielding in A3 and B3 zones since the max Von-Mises stress in those zones under Sc loading activity is in the same order of magnitude of those recorded under the Wk loading before THR. This study may be of great benefit to provide a comprehension on how the femoral bone responds under common daily activities and how the stress shielding rate is going to be affected by activity intensification.

EFFECT OF JUMP IMPACT LOAD ON MENISCII, FEMORAL, TIBIAL AND PATELLAR CARTILAGES DURING FULL JOINT KNEE FLEXION

INTRODUCTION

Menisci and Cartilage degeneration in the knee joint is mainly caused by elevated stress level and high contact forces resulting from impacts. Landing from a jump impact on the knee joint muscles and ligaments has been discussed in previous studies [1]but there was no thorough investigation of its effect on the femoral, tibial and patellar cartilages, as well as menisci, which is presented in this study. The objective of this study is to investigate the effect of ground reaction force due to landing from a jump impact on the knee joint cartilages and menisci and compare results with those before impact to determine the elevation in stress and contact values.

METHODS

A Full Finite Element knee joint model was used to conduct this study. The model was created based on MRI scans of the right knee (Male:45 yr-70 kg) which were used to extract the 3D geometry of the knee joint model. The 3D geometry of the skeletal knee skeletal was built using Mimics and Abaqus. Articular cartilages and menisci were considered to behave as linear elastic isotropic as reported in the literature [2]. Ligaments and Quadriceps muscles were modeled as axial spring connectors which have an elastic nonlinear behaviour [3]. Muscles orientation and insertions were adapted from Sakai et al [4].Since bone stiffness is much higher than the soft tissues, bones are modeled as rigid bodies represented by a reference node and meshed with tetrahedral elements. Menisci and cartilages were meshed with 8 node hexahedron elements. Frictionless non-linear contact with finite sliding was assumed in all articulations. Model was validated using results reported in previous studies [3] and [5] as shown in (Figure 1) for ACL forces at Quadriceps load of (3N). Boundary conditions of

the presented study was to flex the femur to 33 degrees then apply load of 1265 N to the tibia to simulate the vertical ground reaction force first peak as illustrated in the study of Pflum et al [1]. Parameters of interest are contact pressure, contact area and patella tendon forces at the moment of impact and comparing it with results just before impact. Total contact forces after impact will be measured as well.

RESULTS AND DISCUSSION

As shown inTable (1), contact pressure increased substantially after the impact loading was applied. It was noticed that more contact pressure resulted in the lateral compartment as shown in the contour plot of femoral cartilage (Figure 3). Contact Area results showed the same trend except for medial menisci which remained almost the same. Patella tendon forces before applying the load (5N) reflected the forces given to the Quadriceps muscles (3N) in addition to forces resulted from rotation, however after at the moment of impact load, patella tendon forces increased to (65N). At the moment of impact, total contact forces were (1200N), (320N) and (310N) for the tibial cartilages, menisci and patella cartilage respectively.
Figure 1: Presented model validation curve
Figure 2: Rotated Model showing contact pairs, Patella tendon and Quadriceps muscles connectors
Figure 3: Contact Pressure contour plot on femoral cartilage at 33 degrees flexion and impact loading of 1265 N.

CONCLUSIONS

Results show that most of the load bearing was concentrated on the lateral compartment which requires more investigation. Contact forces results shows the tibial cartilages to be the most impacted in the knee joint at the moment of load impact which indicates more prone to injury and degeneration. The excessive increase in contact pressure due to landing from a jump and impacting with ground reaction force can cause meniscal and cartilage failure. Future work should focus on the design of safer landing technique to avoid joint degeneration.

MODELING THE AGING ACHILLES TENDON: INTER-FASCICLE ADHESIONS AND TENDON COMPLIANCE AFFECT PLANTARFLEXOR BEHAVIOR DURING WALKING

INTRODUCTION

The Achilles tendon (AT) consists of distinct fascicle bundles arising from the gastrocnemius and soleus muscles that intertwine and twist before inserting onto the calcaneus [1]. Current musculoskeletal models simplify this architecture by representing the gastrocnemius and soleus as independent muscle-tendon actuators [2], which may be an appropriate assumption if the fascicles freely slide relative to one another. However, this assumption may not hold with aging, as inter-fascicle adhesions form and reduce sliding between adjacent tendon fascicles [3]. This adaptation could explain our recent finding that depth-dependent variations in AT deformations during walking are much smaller in old vs. young adults (Fig. 1A) [4]. A reduced capacity for sliding in old tendons may couple gastrocnemius and soleus muscle-tendon behavior, which could in turn alter muscle force production.

Tendon also undergoes microstructural changes with aging that are believed to increase its compliance, consistent with ultrasound imaging studies of the Achilles tendon in walking [4,5]. Tendon compliance systematically influences muscle fiber kinematics and mechanical power production [6], and could modulate the effects of inter-fascicle adhesions in the aging Achilles tendon. Thus, we developed simple models of the plantarflexor muscle-tendons (Fig. 1B) to investigate the independent and combinatory effects of inter-fascicle adhesions and tendon compliance on plantarflexor muscle fiber kinematics and the performance of mechanical work in walking.

METHODS

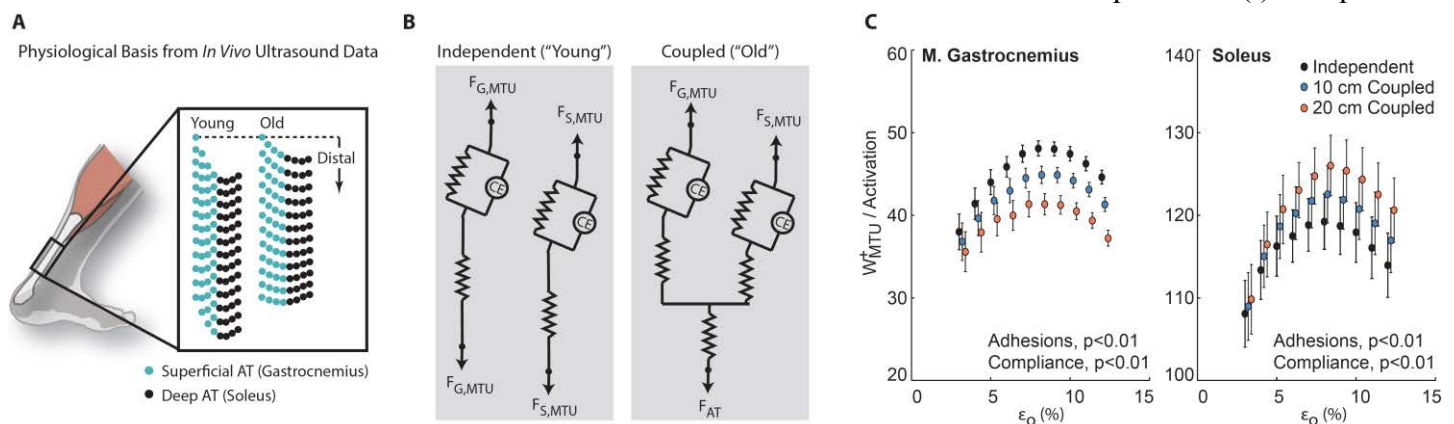
10 young adults walked at their preferred speed down a 10 m walkway (mean, 1.33 m/s). 3D motion capture recorded pelvis and lower extremity kinematics at 200 Hz. For each subject, we estimated gastrocnemius and soleus muscle-tendon unit (MTU) lengths over one stance phase from scaled, seven segment, 18 degree-of-freedom musculoskeletal models [2]. MTU lengths then served as boundary conditions in models composed of (*i*) independent


Figure 1. (A) Superficial and deep free AT tissue displacements, tracked using 2D speckle tracking, reveal smaller depth-dependent variations in AT deformations in old vs. young adults [4] which may arise from inter-fascicle adhesions. (B) We simulated inter-fascicle adhesions by coupling the gastrocnemius (G) and soleus (S) via a shared AT of two lengths (10 cm, 20 cm) across range of compliances. (C) Simulating tendon adhesions redistributed stance phase positive work (mean ± SE) from the gastrocnemius to the soleus, with progressively larger changes observed with increasing tendon compliance.
