based on the individual's "top of backswing" and "follow-through" phases (Figure 1).

Repeated measures ANOVA analyses were used to determine if there were differences in the peak knee adduction moment and swing velocity between the stance conditions. When the ANOVA was significant, planned contrasts between the self-selected condition and each of the other stance conditions were conducted.

## RESULTS AND DISCUSSION

Preliminary results show that variations in a golfer's stance have significant effects ( $p < 0.01$ ) on loading at the knee (Table 1). Specifically, the planned contrasts revealed that both the 30° external rotation ( $p < 0.01$ ) and the wide stance width ( $p < 0.01$ ) conditions resulted in a significantly lower peak knee adduction moment compared to the self-selected stance. Therefore, increasing a golfer's foot angle or stance width are both potential mechanisms to reduce the typical external knee adduction moment a player experiences during the golf swing.

Although previous literature has also reported a reduction in the peak knee adduction moment when the feet are placed in greater external rotation, the magnitude of the change differed slightly from our findings. Specifically, Lynn et al. [3] found a 0.09 Nm/kg reduction in the peak knee adduction moment when the feet were externally rotated 30°, while we found a reduction of 0.40 Nm/kg between the 30° and self-selected conditions (Table 1). Considering

**Figure 1:** Ensemble mean of frontal plane moments for lead limb knee joint. Percent swing is normalized from "top of backswing" to "follow through". Vertical dashed line represents "impact".

participants in the present study used a driver for all golf shots (previous research utilized a 5 iron), we attribute our greater reduction of the knee adduction moment to the typically greater exertion associated with using a driver.

The second purpose of this study was to analyze the effect altering a golfer's stance has on performance. Our data show that altering the golfer's stance resulted in no significant changes ( $p = 0.06$ ) in swing velocity (Table 1). This suggests that the externally rotated foot position and the wider stance were both successful in terms of decreasing the peak knee adduction moment without hindering performance.

**Table 1:** Mean  $\pm$  SD for peak knee adduction moment and swing speed for golf stance conditions

Stance Condition	Peak Knee Adduction Moment (Nm/kg)	Swing Speed (mph)
Self-selected	1.49 $\pm$ 0.58	102.13 $\pm$ 7.59
0 degree	1.43 $\pm$ 0.46	100.37 $\pm$ 7.89
30 degree	*1.09 $\pm$ 0.53	100.57 $\pm$ 8.25
Narrow	1.55 $\pm$ 0.53	99.60 $\pm$ 6.81
Wide	*1.10 $\pm$ 0.51	101.23 $\pm$ 7.57

\* Significantly different from Self-selected ( $p < .01$ )

## CONCLUSION

The preliminary results demonstrate two modifications of the golf stance that can decrease the peak knee adduction moment without altering performance. Considering the prevalence of injury to the lead limb knee joint, modifying a golfer's stance could be used to increase the longevity of their playing career.

# LEG MUSCLE FUNCTION OF FRONT ROW RUGBY UNION SCRUMMING

<sup>1</sup> Mostafa Yaghoubi, <sup>1</sup> Sally Lark, <sup>1</sup> Philip Fink, and <sup>1</sup> Sarah Shultz

<sup>1</sup> School of Sport and Exercise, Massey University, Wellington, New Zealand

## INTRODUCTION

The purpose of the rugby scrum is to restart play quickly, safely, and fairly after a minor infringement. The scrum is created by eight players from each team, known as front-row pack, who compete for ball possession by binding together in three rows (World Rugby, 2010). The Rugby union scrum comprises of three phases before the ball is introduced: crouch, bind and set. It is important that the front row (comprised of loose head and tight head props, and a hooker) players act in unison, particularly at the bind and set stages. They train for this synchronicity throughout the season, using both live scrimmages and machine-based drills. However, we do not know if the scrum machine simulates live play to the extent that the desired synchronicity is achieved in training. Therefore the purpose of this study was to compare the muscle activation patterns between scrum machine drills and live scrimmages.

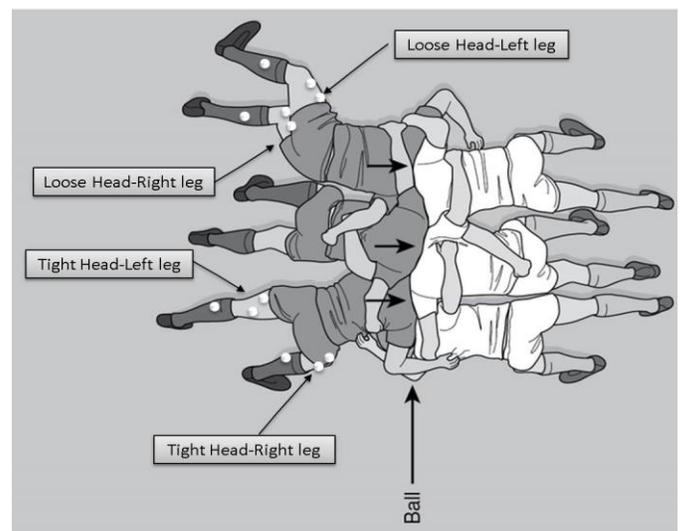

## METHODS

Male front row players (N=76; age: 23.6±3.5 years; mass: 104±10.6kg; height: 185±9.5cm) participated in this study. The scrum testing was performed on a scrum sled (Scrum Machines, POWA, New Zealand) and during a live scrum. A 16 channel Noraxon Telemetry DTS EMG telemetry unit, Model 542 DTS EMG (Noraxon US Inc., Scottsdale, AZ) was used to measure bilateral muscle activity of rectus femoris, vastus lateralis and gastrocnemius of tight head and loose head props during scrum (Fig. 1). A digital camera was also synchronized with the EMG system to record the rugby scrum (60Hz) and determine the referee 'set' call while they performed scrum. To normalize the EMG signals during the scrum, participants performed maximal voluntary isometric contractions (MVIC) for each muscle in a randomized order.

All raw EMG signals were rectified and filtered using a 4<sup>th</sup> order Butterworth bandpass filter (frequency band: 5-500Hz). The onset point of muscle contraction was initially identified. The muscle reaction time was calculated as the duration of time from EMG onset to the set call and was normalized to the entire duration of scrum [2]. The rate of muscle recruitment from onset to peak amplitude was calculated using the following equation:

$$V = \frac{\text{Peak amplitude}}{\text{Onset to peak duration}}$$
 To ensure that the data were normally distributed, a log transformation was applied to the rate of muscle recruitment data.

The muscle reaction time, rate of muscle recruitment, and muscle amplitude (as a percentage of MVIC) were analyzed during engagement phase of the scrum. Tests for normality revealed abnormally distributed data for muscle reaction time; thus, comparisons between groups and trials were assessed using Mann-Whitney. Paired t-tests compared muscle recruitment and activity between trials. Statistical significance was set at p<0.05.

**Figure 1:** Positions of the EMG electrodes on front row of rugby union scrum.

## RESULTS AND DISCUSSION

The muscle reaction time to ‘set’ call was faster when scrummaging live than during the scrum machine drills for all muscles. This quicker reaction time could be due to pre-neuromuscular activation of the musculature. By pre-activating the muscles, they can fire optimally against unpredictable oppositions. Scrumming against the machine operates under an open loop control while a live situation requires close loop control [3], where no adaptations to changing or developing opposing forces are required.

However, the rate of muscle recruitment was significantly higher in the quadriceps muscles when using the scrum machine than in the live situation. Additionally, the muscle amplitude was greater in the vastus lateralis and gastrocnemius during scrum machine drills, compared to live situations. As there is no early push back and no dynamic and opposing front row forces from the scrum machine, the need to pre-activate the musculature becomes irrelevant. Furthermore, the requirement for additional muscle activation for stabilisation purposes is not accounted for when using a scrum machine (Table 1).

## CONCLUSIONS

The scrum machine is ideally suited for functional muscle strengthening during practice. However, scrum training should simulate the live situation as much as possible, to ensure muscle firing patterns can match opposing forces in the most efficient and accurate manner in a game situation.

## INTRODUCTION

Soldiers simultaneously execute physical and cognitive tasks during military activities. During these activities, soldiers don body borne loads that often exceed 30% of their body weight, altering lower limb biomechanics and decreasing their physical ability. Performing dynamic military activities, such as a single-leg cut, requires a forceful change in direction and produces biomechanical patterns that increase musculoskeletal injury risk [1]. These biomechanical alterations may be further exaggerated with the addition of body borne load or during the performance of a reactive, unanticipated movement. Executing a dual task (combined physical and cognitive) leads to negative performance of either task [2], by producing alterations of lower limb biomechanics [2, 3]. Yet, the impact of a dual cognitive task during dynamic, loaded military activities, such as cutting, is currently unknown. The purpose of this study was to quantify how a dual task impacts the lower limb biomechanics exhibited when performing anticipated and unanticipated single-leg cuts with body borne load.

## METHODS

Twenty-four males ( $20.2 \pm 3$  yrs,  $1.8 \pm 5.2$  m,  $80.3 \pm 11.1$  kg) had hip and knee biomechanics quantified during a series of single-leg cutting tasks. Each participant performed the cuts with three body borne load conditions: no load (NL), medium load (ML, 15% body weight), and heavy load (HL, 30% body weight). During the NL condition, participants wore combat equipment (helmet, boots, and mock weapon) that weighed  $\sim 6$  kg. For ML and HL conditions, participants wore a weighted vest (WeightVest.com Inc. Rexburg, ID, USA) that was adjusted to have the total load (vest plus combat equipment) equal either 15% or 30% of their body weight. With each load, participants performed three anticipated (AN) and unanticipated (UN) cuts with

(DT Cut) and without (Cut) a dual cognitive task. Each cut required participants run at 4.0 m/s down a 10-m walkway and respond to an external light stimulus, by planting their dominant limb on a force plate (Optima, AMTI, Watertown, MA, USA) and cutting at  $45^\circ$  to their non-dominant side. The AN cuts required participants respond to the light stimulus prior to initiating the trial, while UN cuts required participants responded to the light stimulus approximately 500 ms prior to contact with the force platform. The dual task required participants verbally subtract by three from a random number announced at the beginning of each cutting trial.

Hip and knee joint biomechanics of each cut were quantified from 3D trajectories of 36 reflective markers recorded with twelve high-speed (240 fps) optical cameras (Opus, Qualysis AB, Gothenburg, Sweden). A kinematic model with seven skeletal segments (bilateral foot, shank and thigh, and pelvis segments) and 24 DoF was created from a stationary recording. During each cut, synchronous GRF data and marker trajectories were low pass filtered with a fourth-order Butterworth filter (12 Hz). The filtered marker trajectories were processed to solve for the hip and knee joint rotations at each time frame, and filtered kinematic and GRF data were processed to obtain joint moments using Visual 3D (C-Motion, Rockville, MD).

For analysis, subject-based means of hip and knee peak stance (0% - 100%) joint angles and moments were quantified and submitted to a repeated measures linear mixed model. Alpha was set at 0.05.

## RESULTS AND DISCUSSION

The addition of load increased hip and knee joint moments during the single-leg cut. Specifically, the soldiers exhibited greater hip flexion ( $p = 0.001$ ) and internal rotation ( $p = 0.018$ ), and knee flexion ( $p = 0.016$ ) and abduction moments ( $p = 0.001$ ) with the

HL compared to NL, and greater hip flexion moment ( $p = 0.006$ ) compared to ML. Increased knee abduction loads can result in excessive valgus - a risk factor for knee joint injury. To maintain lower limb stability and help attenuate the elevated joint moments that occur with the addition of body borne load, soldiers altered their hip posture during the cut. Soldiers exhibited increased hip flexion ( $p = 0.003$ ) posture with the HL compared to NL, and internal rotation posture ( $p = 0.038$ ) compared to ML. The addition of a body borne load produced no significant adaptation of knee posture. Further research is warranted to determine if adaptations of hip posture are adopted to maintain lower limb stability without compromising the performance of the cut.

Both anticipation and dual task had an impact on lower limb biomechanics during the cut, but did not further exaggerate the lower limb biomechanical adaptations that occur with body borne load. During the UN cuts, soldiers exhibited significantly greater hip ( $p = 0.040$ ) and knee flexion posture ( $p < 0.001$ ), and smaller hip adduction ( $p = 0.001$ ), and knee abduction ( $p = 0.005$ ) and external rotation moments ( $p = 0.026$ ) compared to the AN cut. These findings contradict the existing literature on UN cutting. Reportedly, participants increase frontal plane hip and knee joint motions and loads [4], and potential injury risk, during UN cuts. The current participants, however, adopted hip and knee biomechanical patterns that may decrease injury risk when performing UN cuts with body borne load. Conversely, adding a dual task to the cut may

increase injury risk. Participants significantly decreased hip flexion moment ( $p = 0.027$ ) and knee flexion posture ( $p < 0.001$ ), and increased knee external rotation posture ( $p = 0.034$ ) during DT Cut compared to the Cut (Table 1). The extended knee posture may increase the strain on the musculoskeletal system by reducing the lower limb musculature's ability to absorb and generate energy during the cut [5]. Further work is needed to determine if the knee adaptations evident during the dual task cuts impact soldier performance during such dynamic military activities.

## CONCLUSIONS

The addition of body borne load increased hip and knee joint moments and altered hip posture during the cutting task. But, neither anticipation nor a dual task further exaggerated those biomechanical adaptations. During the UN cuts, participants adopted a biomechanical pattern, including smaller hip and knee frontal plane moments, that are associated with reduced injury risk. However, with the addition of a dual task, soldiers adopted an extended and externally rotated knee that may increase risk of injury.

# BALL RELEASE VELOCITY AND PRE-RELEASE RANGE OF MOTION FOR FIVE TYPES OF SOFTBALL PITCHES

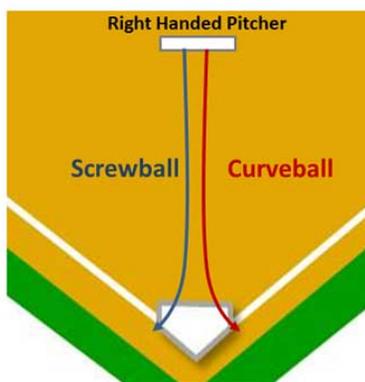

Ben W. Meyer

Shippensburg University, Shippensburg, PA, USA  
[bwmeyer@ship.edu](mailto:bwmeyer@ship.edu)

## INTRODUCTION

Recent analyses of softball pitching have focused on the fastball, change-up, and screwball pitch types [1,2]. However, in order to succeed at higher levels of play, softball pitchers must also be proficient using other types of pitches such as the curveball and riseball techniques. Figure 1 shows the distinction between a screwball and a curveball for a right-handed pitcher. The focus of several previous investigations has been on pitch counts, injuries, and/or comparisons between novice and expert athletes. This investigation includes the curveball and riseball pitch types, with a focus on the mechanisms of the generation of ball velocity.

Ball velocity is one of the key elements in a pitcher's level of success. One of the factors that may contribute to the generation of a large ball velocity is the pre-release range of motion (ROM). The ROM refers to the distance traveled by the ball from the start of the windmill motion until release.

**Figure 1:** Differences between screwball and curveball pitches.

Previous work has assessed the influence of ROM on overhead back (OHB) throw distance [3]. For the

OHB throw, the use of a large ROM did not guarantee a large throw distance in a sample of undergraduate students. The study participants were novices with the OHB technique, and so the present study expands upon this previous work by analyzing a population of subjects who are highly skilled with a variety of softball pitch types.

The purpose of this study was to build upon previous findings for the fastball, change-up, and screwball pitches by adding information about ball release velocity (VR) and pre-release range of motion (ROM) for the curveball and riseball techniques.

## METHODS

Five female NCAA Division II softball pitchers (age =  $20 \pm 1$  yr) participated in the study. Participants performed five pitches for each of the following pitch types: fastball, change-up, screwball, curveball, and riseball. The pitches were performed in a practice session during the spring competitive season. Participants threw for both velocity and accuracy during all trials.

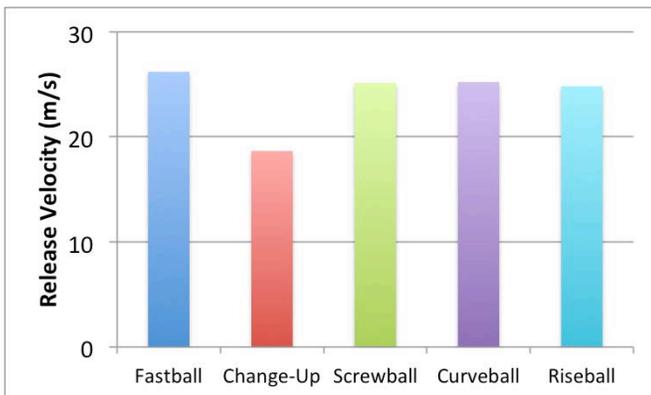

Each trial was recorded with a Casio Exilim EX-F1 camera at a sampling rate of 300 frames per second. Digitizing targets were placed in the plane of motion to calculate reference distances. The center of the ball was digitized in every 3<sup>rd</sup> frame of the video files using Logger Pro software to give data at 0.01 s intervals. The onset of the pitch was determined to be the frame in which the pitcher's hand made its first movement on a continuous trajectory.

The ROM and ball velocities were computed using standard kinematic analysis techniques [2,3]. The three best attempts (for each pitch type) based on

velocity at release (VR) were used in the analysis. Differences between measures were assessed using ANOVA tests with a cut-off for statistical significance set at  $\alpha = 0.05$ .

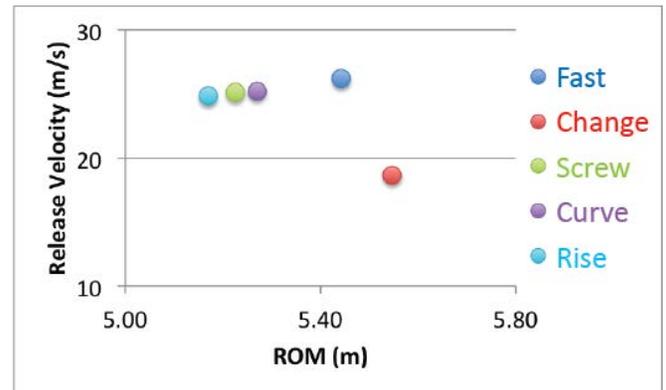

## RESULTS AND DISCUSSION

Figure 2 shows that pitchers achieved the largest VR values using the fastball ( $26.2 \pm 1.4$  m/s) and curveball ( $25.2 \pm 1.3$  m/s), while the smallest VR values were obtained using the change-up ( $18.7 \pm 1.6$  m/s). The fastball, screwball, curveball, and riseball VR values were not significantly different from each other, but VR values for the change-up technique were significantly smaller than all the other techniques. Recent studies [4,5] have shown that female collegiate pitchers throw fastballs in the 22 to 27 m/s range, so the athletes in the present study fall in the higher end of this range.

**Figure 2:** Ball release velocities for the five pitch types analyzed in the study.

Figure 3 shows the relationship between ball release velocity and ROM for all pitch types. Subjects used the largest ROM in the change-up technique ( $5.55 \pm 0.34$  m) and the smallest ROM in the riseball technique ( $5.17 \pm 0.32$  m). Although the fastball technique produced the largest release velocity, the ROM values were not the largest among the pitch types ( $5.44 \pm 0.22$  m). Excluding the change-up technique, results show that an increase in ROM leads to an increase in VR.

**Figure 3:** Relationship between ball release velocity and pre-release range of motion.

## CONCLUSIONS

The results of this project indicate that for a small sample of NCAA Division II softball pitchers, release velocities are very similar (24-26 m/s) for the fastball, screwball, curveball and riseball pitch types. The change-up pitch has distinct VR and ROM characteristics and future studies should investigate other factors that make the change-up such a unique pitching style.

# THE INFLUENCE OF MODERN CLIMBING HOLDS ON FINGER FORCES AND FORCE DISPERSION PATTERNS

Dylan Herman-Dunphy and Deborah L. King

Ithaca College, Ithaca, NY, USA  
email: [dherman2@ithaca.edu](mailto:dherman2@ithaca.edu), web: <http://www.ithaca.edu/hshp/depts/ess/>

## INTRODUCTION

Climbing is one of the fastest growing sports in the world and this growth has evolved with the addition of sport climbing into the 2024 Olympic games. Most research done on the biomechanical effects of climbing holds has focused on the effects of holds on finger forces. How a climber's fingers grab a climbing hold may have a greater effect on finger forces than the depth of the objects being held [1]. However, changing grip position does not affect finger force magnitudes when gripping a simulated climbing hold [2]. Nonetheless, finger forces are unequal across the fingers when using climbing hold grip positions [1,2]. No studies, though, have used modern climbing holds and instead used simulated holds (wood ledges) or outdated style holds.

The purpose of this study was to determine if, when using modern climbing holds, the type of hold affects finger forces as measured by maximum normal and average normal forces. A secondary purpose was to understand the positioning of the fingers on the holds by measuring center of force distance between each finger.

## METHODS

The 19 volunteer subjects were a mix of climbers and non-climbers. Subjects were required to hang onto 7 holds (H1-H7), made by Atomik Climbing Holds, for 1-2s with a 10-minute break between each hang. H1 was a sloper hold at 90 degrees sloping, H2 was a sloper hold at 110 degrees

sloping, H3 was a pinch hold that is 4.5cm wide, H4 was a pinch hold that is 7.0cm wide, H5 was an edge hold that is 60 degree in-cut, H6 was an edge hold that is 70 degrees in-cut, and H7 was an edge hold that is 90 degrees in-cut.

A Tekscan pressure sensor (3000E F-Scan System), designed for insole-shoe pressures, was used to collect data at 63 Hz. After a pilot study to validate the F-Scan system with finger forces, the pressure films were adhered to a thin piece of foam and the climbing holds. Subjects directly held onto the film over the climbing hold for each grip. Average (avg) and maximum (max) normal forces and center of force (COF) distances were collected using the F-Scan analysis software.

Data were analyzed using three, two-way repeated measures ANOVAs and post hoc analysis were done for significant main effects and interactions. Alpha = 0.05.

## RESULTS AND DISCUSSION

There was a significant finger main effect for avg force ( $F_{2,204, 83.738} = 140.132, p = 0.000$ ). The middle finger avg force was 18% greater than index, 29% greater than ring, and 53% greater than pinky. Avg force had a significant hold ( $F_{4,163, 158.189} = 3.394, p = 0.010$ ). For max force there was a significant finger main effect ( $F_{2,166, 80.146} = 131.662, p < 0.001$ ) and a significant hold main effect ( $F_{4,128, 152.750} = 5.562, p = 0.000$ ). H5 was 18% > H4, 16% > H6, and 19% > H7. Similar results were observed for max force for the finger main

effect ( $F_{2,166}$ ,  $80.146 = 131.662$ ,  $p < 0.001$ ) with the middle finger greater than the index, ring, and pinky by the same percentages. For the hold main effect ( $F_{4,128}$ ,  $152.750 = 5.562$ ,  $p < 0.001$ ) though H5 was greater than H1, H4, and H6. .

The limited number of differences in finger forces on the different types of holds supports previous literature [1,2] that grip type or hold type has little effect on finger forces. Surprisingly, though, H5, the 60-degree in-cut edge, repeatedly had greater finger forces for both avg and max force. This indicates there is some effect of climbing hold type on the finger forces. Since H5 had the largest degree of in-cut, it is hypothesized that the angle of the gripping surface may influence finger forces to a significant effect as opposed to grip surface width or depth, for example.

COF analysis showed a COF distance finger main effect ( $F_{1,689}$ ,  $52.372 = 14.781$ ,  $p = 0.000$ ) with COF distance from index to middle finger greater than the distances between the ring and middle fingers or ring and pinky fingers. A COF hold main effect ( $F_{4,024}$ ,  $124.754 = 3.357$ ,  $p = 0.012$ ) suggest that the distances between adjacent fingers vary substantially on the different holds, which was not surprising given the large range in size of each hold. Interestingly, this difference in COF finger distance on the different holds did not affect the pattern of individual finger forces as the middle finger always had the greatest force followed by the index, ring, and pinky.

## CONCLUSION

Regardless of hold type, the distribution of force between the fingers follows the same pattern with the middle having the greatest force and pinky the least. The type of the modern climbing hold, however, has little effect on finger forces; though, the angle of in-cut may affect the finger forces with an inverse relationship between the degree of in-cut

and the magnitude of finger forces. Further research into the biomechanical effects of climbing holds on finger forces should focus on the role that in-cut angle plays in determining finger forces and how that relates to risk of injury.

## INTRODUCTION

Modern warfare requires warfighters to carry increasingly heavy loads that include essentials like body armor, gear, food, and water. Optimizing the load and configuration is critical for maximizing the probability of mission success. The Marine Corps Load Effects Assessment Program (MC-LEAP) was developed to reveal variations in soldier performance due to clothing and individual equipment (CIE) [1]. The program consists of an obstacle course representative of tasks warfighters encounter in combat. Performance for any obstacle is frequently defined by the time required to complete the obstacle. Using this sole measure of performance, we hypothesize that performance on several obstacles are correlated; meaning a decrease (or increase) in performance for one predicts a decrease (or increase) in performance in another. For example, we hypothesize correlated performance in the sprint and agility run since subjects sprint between cones during the agility run. In addition, we expect high correlation in performance between window and wall obstacles since both require upper body strength. If performance on obstacles are highly correlated, one may conclude they do not provide independent measures of performance.

## METHODS

We tested 44 subjects (17 females, 27 males; age =  $20.1 \pm 1.9$  years; body mass =  $74.1 \pm 14.9$  kg; height =  $1.76 \pm 0.12$  m; mean  $\pm$  standard deviation). A subset of 24 subjects (8 females, 16 males) completed the obstacle course a total of four times while carrying 0% (twice), 15%, and 30% of their body weight. All subjects carried a mock-rifle (3.4 kg). The University of Michigan IRB approved the study, and all subjects gave informed consent. The

investigator held an inertial measurement unit (Opal sensors, APDM, Portland OR) with an embedded binary switch that was used to time-stamp the beginning and end of each obstacle, essentially serving as a timing gate. The course (Figure 1) was an abbreviated version of the MC-LEAP containing 10 obstacles. A linear fit and Pearson correlation coefficient was calculated from the data for each possible pair of obstacles. The additional loading conditions produced a wide range of performance, strengthening the validity of these results depicted in Figure 2. If the 95% confidence interval for the slope from the linear fit includes zero, then the correlation between the two obstacles is negligible.

**Figure 1:** Abbreviated MC-LEAP obstacle course.

## RESULTS AND DISCUSSION

The only pair of obstacles that had negligible correlation was the window and casualty drag. If performance in an obstacle was not highly correlated ( $R < 0.7$ ) with any other obstacle, then it could be considered an independent measure of performance. Two obstacles that met this criterion were the vertical jump and balance beam. By contrast, the two

obstacles exhibiting the greatest performance correlation were the vertical transfer and casualty drag ( $R=0.80$ ). These obstacles also had the strongest correlations with subject height ( $R=0.64$  and  $R=0.66$ , respectively), suggesting height could be a confounding variable. As expected, performance in the window and wall obstacles were correlated ( $R=0.79$ ), and variability could derive from differences in subject flexibility or technique since the window obstacle represents a constrained wall [2]. Additionally, performance in the high crawl and bounding rush were highly correlated ( $R=0.76$ ), as both require significant coordination of limbs while in a prone position. Finally, performance in the sprint and agility run were correlated ( $R=0.72$ ) as anticipated from [3] where high performers sprinted in straight lines between cones during the agility run.

## CONCLUSIONS

The overall number of obstacle pairs with highly correlated performance (4) is much less than the total possible number of pairs (54). Thus, this subset of obstacles from the MC-LEAP sufficiently assesses different variables of performance. However, since performance in a few obstacles are significantly correlated (e.g., window and wall), one

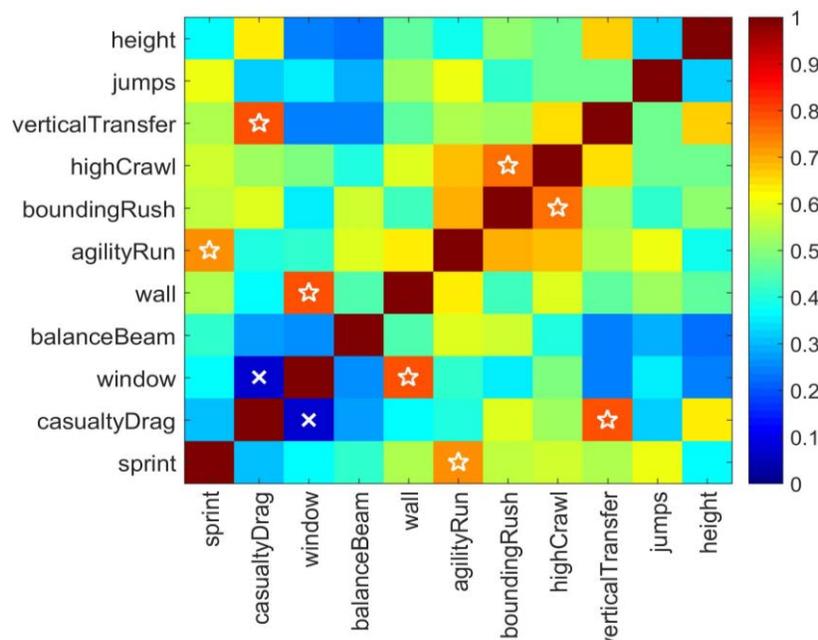

obstacle in such a pair might be eliminated without compromising conclusions regarding subject performance. Furthermore, this suggests there is likely a subset of performance variables (i.e., speed, strength, agility, etc.) that contribute to all obstacles to varying degrees depending on the obstacle. It should also be noted that effectively only speed was considered. Other measures of performance would highlight a different skill/technique and generate different correlations. Thus, removal of an obstacle should be considered based on metrics of interest.

## INTRODUCTION

The FIFA11+ is an injury prevention program designed as a dynamic warm-up program targeting commonly occurring injuries in soccer, such as anterior cruciate ligament injury [1]. The program is simple to learn, does not require specialized equipment, can be completed in approximately 20 minutes, is progressive so can be used across a range of skill levels, and is very easy to implement. The common goals of injury prevention programs, including the FIFA11+, are to improve core stability, balance and neuromuscular control. The FIFA11+ also incorporates exercises designed to improve the participants' ability to maintain proper joint alignment. Recommendations from the program development team are that the participants should perform the dynamic warm-up at the start of training session at least twice per week. The FIFA11+ has been shown to effectively reduce injury rates [2,3] and increase dynamic balance [4], however, it is unclear if biomechanical changes can be identified that may be contributing to the reduced injury rates. The purposes of this study were 1) to characterize the distribution of energy absorbed by the lower extremity during a deceleration task and 2) to determine if participation in the injury prevention program leads to changes in the distribution of energy absorbed across the joints in the lower extremity. Via the training with the FIFA11+, we hypothesized a reduction in energy absorption at the knee during a deceleration task, which may be compensated for by the more proximal joint (e.g. hip).

## METHODS

Twenty-seven female soccer players (age= 20.3 ± 1.23 yrs; height 1.66 ± .06 m; mass 63.9 ± 5.0 kg) from two Division I Collegiate soccer teams

participated in this study. Participants underwent motion analysis of a deceleration task (Decel) prior to (Pre) and following (Post) a competitive season during which the teams utilized the FIFA 11+ Injury Prevention Program.

The Decel task was completed by having subjects run approximately ten meters, plant their foot on the force plate and decelerate their body, then pushing backward, and running backwards to the initial starting position. Three successful trials were collected from each limb; a trial was deemed successful when the participant cleanly planted the entire foot on the force plate, with no shifting of the foot during the deceleration, and completed the maneuver without any loss of balance.

Motion capture data were acquired via Vicon Nexus software (Vicon Motion Systems, Oxford, United Kingdom) where 22 retro-reflexive markers affixed to anatomical landmarks and 23 markers affixed to rigid, thermoplastic shells were utilized to generate subject specific models. Kinematic and kinetic data were collected at 240 and 1080 Hz, respectively, via 8 cameras and an imbedded forceplate. Kinematic and kinetic data were low-pass filtered using a second-order, zero-phase-lag Butterworth filter with a cutoff frequencies of 6 and 40 Hz, respectively. Visual-3D (C-Motion, Germantown, MD) software was used to calculate kinematic and kinetic variables. The dependent variables for this study include joint power for four constituents of the lower limb (distal foot, ankle, knee and hip) calculated using a 6 degree of freedom method [5]. Negative work was then calculated as the integration of power from initial contact (vertical ground reaction force exceeding 5N) through peak knee flexion angle (PKF). All values were normalized by body mass. Work performed by each constituent was calculated as a

percentage of total (summed distal foot, ankle, knee, and hip) work.

A 2x4 repeated measures ANOVA was completed to assess change in the distribution of negative work performed across the four joints over time. Paired t-tests were used to assess difference in the presence of a significant joint by time interaction. Alpha levels were set at  $p=0.05$ . Huynh-Feldt corrections were applied if the assumption of sphericity was violated.

## RESULTS AND DISCUSSION

There was a significant constituent by time interaction (Figure 1;  $p= 0.011$ ). Paired t-tests indicated significant reduction in the proportion of energy absorbed by the knee (Pre  $47.8 \pm 7.6\%$  and Post  $45.0 \pm 7.1\%$ ;  $p= 0.008$ ) and an increase in the proportion of energy absorbed by the hip (Pre  $34.3 \pm 1.2\%$ , Post  $37.2 \pm 1.5\%$ ;  $p= 0.024$ ). These findings support our hypothesis that after participating in the FIFA11+ program, the hip compensated for the reduce energy absorbed by the the knee. While there were significant differences observed at both the knee and the hip, the effect sizes were large (Cohen's  $D = 0.937$ ). The inherent variability of biomechanical measures, combined with the relatively small sample size available here suggest that a larger data set may be needed before drawing more definitive conclusions.

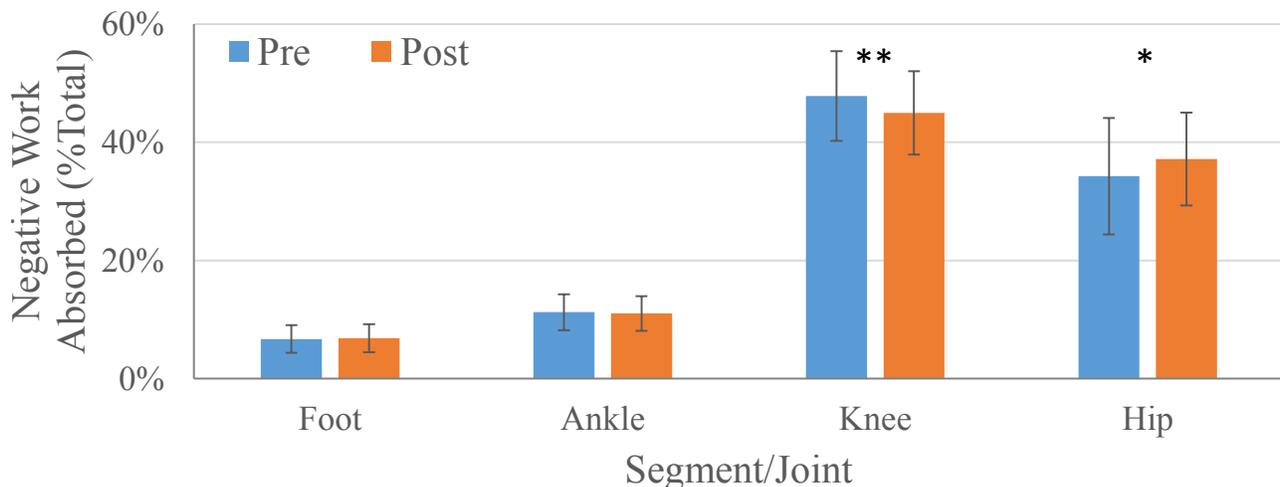

Figure 1. Distribution of negative work for the foot, ankle, knee and hip Pre and Post a season utilizing the FIFA11+ Injury Prevention Program. Significant differences over time  $*p<0.05$ ;  $**p=0.01$ .

## CONCLUSIONS

As a focus of the intervention to improve core stability, balance and neuromuscular control, it is reasonable to expect that participation would lead to reduced energy absorption by the knee, which also led to increased energy absorption by the proximal hip. Participating in the FIFA11+ program has successfully reduced injury, which may be attributed to a shift in energy absorption during deceleration to more proximal muscular. This redistribution of energy absorption at the knee and hip may be a positive result of the FIFA11+ program.

# KNEE ADDUCTION MOMENT AND MUSCLE ACTIVATION DURING A SIDECUT ON A RAISED SURFACE

Lauren E. Schroeder, Kevin A. Valenzuela, Songning Zhang, John G. Orme, and Joshua T. Weinhandl

## INTRODUCTION

Fast-pitch softball has increased in popularity, with 19,628 NCAA Division I female athletes participating in the 2014-15 season [1]. However, increased participation results in increased chance of injuries. Base running is a major component of the sport, occurring in almost every play of the game. To get from one base to the next, players have to “round the base” by performing a sidecut to the left by planting their right foot on a raised base. Unfortunately, this specific movement has resulted in approximately 187 game-day injuries [2].

This dynamic sidecut movement has been shown to place large loads on the knee ligaments, potentially resulting in anterior cruciate ligament (ACL) injuries [3]. Noncontact ACL injuries account for nearly 31% of all game-day softball knee injuries [2]. Certain biomechanical and neuromuscular abnormalities are common in noncontact ACL injuries. Specifically, increased frontal plane loading [4] and unbalanced quadriceps-to-hamstring co-contraction indices (Q:H CCI) [5] have been identified as primary risk factors for noncontact ACL injuries.

To date, no study has analyzed effects of rounding a base on noncontact ACL injury risk factors in softball players. Therefore, the aim of this study was to determine the effect of a raised surface (i.e. base) during a sidecut on frontal knee loading and muscle activation in recreational softball players.

## METHODS

Nine recreationally active females (age:  $21.8 \pm 2.0$  yrs,  $1.70 \pm 0.03$  m,  $63.7 \pm 5.0$  kg) completed two base running conditions. In the first condition, a sidecut simulating rounding first base was performed with no base (NB) present on the force plate. For the second condition, the same route was performed with a base (WB) present on the force plate. Participants were instructed to stay within a range of  $90^\circ$ - $120^\circ$

during the entrance of the sidecut. Entrance and exit speeds were monitored at  $4.0 \text{ m/s} \pm 0.25 \text{ m/s}$  and  $3.75 \text{ m/s} \pm 0.25 \text{ m/s}$ , respectively. During each trial, right leg 3-D kinematics and kinetics were collected using a 12-camera Vicon motion capture system (200 Hz), ground reaction forces (GRF) were collected with one AMTI force plate (2000 Hz), and muscle activations were measured using the Delsys Trigno wireless electromyography (EMG) system (2000 Hz). Muscles included biceps femoris (BF), semitendinosus (MH), vastus lateralis (VL), and vastus medialis (VM).

Raw EMG data were pre-amplified and band-pass filtered using a 4<sup>th</sup> order Butterworth filter (10 Hz, 350 Hz), full-wave rectified and low-pass filtered (5 Hz) to create a linear envelope. Peak maximum voluntary isometric contraction values for each muscle were used to normalize filtered EMG signals for comparisons (%MVIC). Raw 3D marker coordinate and GRF data were both low-pass filtered using a 4<sup>th</sup> order, Butterworth filter (20 Hz). Q:H CCI was defined as average quadriceps activation divided by average hamstrings activation. A time frame of 50 ms prior to initial contact (pre-contact) and 100 ms after initial contact (post-contact) were used during EMG analysis. Peak internal knee adduction moment was computed in the joint coordinate system and normalized to body mass (Nm/kg).

Paired-samples *t*-tests were used to compare differences between NB and WB initial contact knee abduction angle, peak knee abduction angle, and peak knee adduction moment. A repeated measures 2x2 ANOVA was used to compare Q:H CCI between the conditions (NB and WB) and contact times (pre- and post-contact). The alpha level was set at  $p \leq 0.05$ .

## RESULTS AND DISCUSSION

This study compared frontal knee loading during two base running conditions. It also compared muscle

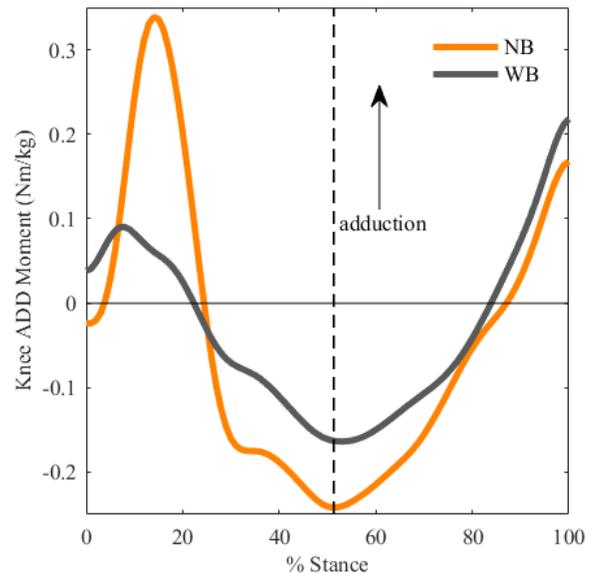

activations during two base running conditions pre- and post-contact. Our results suggest that performing a sidecut with a raised surface does not significantly alter both peak and initial contact knee abduction angle. Peak knee adduction moment was significantly greater in the NB condition compared to the WB condition (Table 2). A main effect involving contact time was identified for Q:H ratio, indicating a greater Q:H ratio post-contact than pre-contact ( $F_{1,7} = 16.113, p = 0.005$ , Table 1).

It is interesting to note that while participants landed with somewhat larger initial contact and peak knee abduction angles in the WB condition, peak knee adduction moments were significantly larger in the NB condition (Figure 1). These findings contradict what McLean et al. [4] found regarding the causal link between increased initial contact knee abduction angles and the subsequent increased peak knee adduction moments. This suggests contacting a raised surface may provide a more optimal surface to perform and complete the sidecut, causing the GRF to potentially shift more medially compared to cutting on a flat surface.

Q:H CCI#s showed that prior to initial contact, activation between the two muscle groups were somewhat balanced (Table 1). Previous literature has shown that reduced hamstring pre-activation places the ACL at an increased risk of injury due to the inability to properly scale the hamstrings to the same level as the quadriceps [6]. Significantly greater quadriceps activation was seen post-contact. The quadriceps act to prevent the knee from collapsing during any sort of dynamic task, thus explaining the increased activation. Unfortunately, an unbalanced Q:H ratio, with significantly greater quadriceps activation, creates a large anterior shear force, thus increasing the stress on the ACL [5]. Neuromuscular training to improve Q:H CCI could decrease the load applied to the ACL and decrease the risk of injury.

## CONCLUSIONS

These findings suggest that rounding a base, with a controlled foot placement, may reduce ACL injury risk by decreasing the knee adduction moment. Examining movement patterns at the ankle and abnormal foot strikes may provide a better explanation for ACL injuries that occur when rounding a base.

# COMPARISON OF BARBELL KINEMATICS IN THE HANG CLEAN AND HANG CLEAN HIGH PULL: IMPLICATIONS FOR SPECIFICITY OF TRAINING

Scott Light, Stephen Henderson, Melissa Mache

California State University, Chico, CA, USA

email: mmache@csuchico.edu

## INTRODUCTION

The ability to generate power has been previously associated with greater vertical jump heights and faster sprint times [1]. Multi-joint weightlifting exercises, such as the hang clean, that are performed at high speeds and mimic sport specific movements are commonly implemented to help athletes develop power [2, 3]. The hang clean is often broken down into its various components to simplify the movement and help athletes learn and improve specific portions of the lift. For example, the hang clean high pull can be used to help athletes improve technique and triple extension in the hang clean [4]. Independent investigations of the hang clean and hang clean high pull suggest there are similarities in the biomechanics of the two lifts, however, a direct comparison of these lifts is lacking [2, 3]. Furthermore, there are few existing descriptions of Olympic lift performance by women; it remains to be seen if men and women perform these tasks in a similar manner. Thus, the purpose of this study was to compare barbell kinematics of the hang clean and hang clean high pull as a function of sex, with the intent of examining the specificity of the hang clean high pull as a training tool for improving hang clean performance.

## METHODS

Ten men [mean (SD) age: 23 (2) yrs; height 1.76 (0.08) m; mass: 80.9 (10.2) kg] and nine women [mean (SD) age: 23 (1) yrs; height 1.66 (0.06) m; mass: 63.8 (9.5) kg] provided informed consent to participate in this study. All participants were recreationally active individuals with formal training in Olympic lift technique.

Testing took place on two separate occasions, separated by 2 to 10 days. The first testing session

began with a modified version of the Burgener warm-up for Olympic weight lifting. Following the warm-up participants completed a series five repetition hang clean sets to estimate their one repetition maximum (1RM), which was calculated using the Brzycki Formula.

On day two of testing kinematic data were collected during two randomized blocks of trials: five hang cleans and five hang clean high pulls. All lifts were performed at 70% of the participant's 1RM. After the participant completed a modified Burgener warm-up, retroreflective markers were applied to the barbell. Data collection then began with hang clean or hang clean high pull trials. A minimum of 90 seconds of rest was provided between trials and blocks of trials.

Kinematic data were collected at 120 Hz using a 6-camera motion capture system (Motion Analysis). Data were low pass filtered at 8 Hz and used to compute barbell kinematic variables. Vertical bar displacement was analyzed from the instant bar velocity began to increase in the positive direction to maximum barbell height. Maximum vertical velocity, time to maximum vertical velocity, maximum vertical acceleration, and time to maximum vertical acceleration were analyzed from the instant the bar velocity began to increase to the instant of peak vertical velocity of the bar. Values were averaged across trials of the same type. Effects of task and sex on the dependent variables were tested using a 2-way repeated measures ANOVA. Significant interaction effects were explored using t-tests as appropriate. The alpha level was set at 0.05 for the ANOVA and 0.025 for all post-hoc analyses.

## RESULTS AND DISCUSSION

Independent of sex, participants exhibited similar barbell kinematics when performing the hang clean

and hang clean high pull (Table 1). Specifically, there were no differences in the maximum vertical velocity ( $p = 0.513$ ), time to maximum vertical velocity ( $p = 0.151$ ), maximum vertical acceleration ( $p = 0.182$ ), and time to maximum vertical acceleration ( $p = 0.052$ ). The only variable, that differed between the two tasks was the vertical displacement of the bar, which was greater in the hang clean than the hang clean high pull ( $p = 0.007$ ). It is not clear why vertical displacements differed between lifts, however, it is likely that further investigation of the biomechanics of the respective skills could shed light on this difference. That being said, the barbell kinematics indicate that the hang clean high pull is specific to the hang clean and could be an effective tool for improving hang clean performance.

Similarities in barbell kinematics were also present when comparing the performance of men and women during the two lifts (Table 1). Specifically, the vertical displacement ( $p = 0.141$ ), maximum vertical velocity ( $p = 0.090$ ), time to maximum vertical velocity ( $p = 0.0785$ ), and time to maximum vertical acceleration ( $p = 0.792$ ) did not differ between sexes. The only observed difference between sexes was a greater maximum vertical acceleration among men when compared to women ( $p = 0.045$ ). Despite the many similarities between sexes, the difference in acceleration suggests women may benefit from lifting a lighter load to increase vertical acceleration and potentially maximize the development of power.

## CONCLUSIONS

In the current study hang cleans and hang clean high pulls were performed with strikingly similar barbell kinematics. Thus, the present evidence supports the

use of the hang clean high pull as an exercise for improving hang clean performance. Additionally, men and women in the present study performed the two lifts with great similarity. However, researchers should continue to examine the importance of the observed difference in maximum acceleration between sexes. In general, the similarities between tasks and across sexes in the present study suggest that the hang clean high pull is specific to the hang clean and therefore an appropriate training tool for both men and women wishing to improve hang clean performance.

The present results should be interpreted in light of the following cautions: (1) The current study included recreational athletes rather than elite Olympic lifters. Though the present participants had formal training in Olympic lift technique, individuals that are more skilled may perform the lifts differently. (2) We chose to focus on the kinematics of the barbell. The observed similarities in barbell kinematics are telling, however, it is important that future research examine the kinematics and kinetics of the mover to further support the present findings and current strength and conditioning practices.

# EFFECT OF LEG-DRIVE ON UPPER EXREMITY MUSCLE ACTIVITY DURING A BENCH PRESS

Justin Chia, Kelsey Miller, and Jacob Gardner

Biola University, La Mirada, CA, USA  
email: jake.gardner@biola.edu

## INTRODUCTION

The bench press is one of the most popular and iconic upper body strength exercises. From competitive to casual, all types of lifters are looking for ways to optimize their bench press. Anecdotal claims from competitive powerlifters suggest that a method known as “leg drive” may allow the bench presser to lift more weight than a standard leg position. One study that examined variability of muscle activity for the bench press in power lifters compared to untrained individuals made an observation that the muscle activity in the vastus lateralis was greater among experienced power lifters compared to untrained lifters [1]. Besides this observation, practically no peer reviewed studies exist regarding how leg activity might affect upper extremity performance in the bench press.

The purpose of this study was to determine if muscle activity of upper extremity muscles differed depending on the involvement of the legs during a bench press exercise. We hypothesized that no differences in upper extremity muscle activity would exist with respect to leg involvement.

## METHODS

Preliminary data from 10 participants (6 male: age  $22.0 \pm 2.1$  yrs, height  $1.71 \pm 0.04$  m, mass  $74.7 \pm 6.4$ , BMI  $25.5 \pm 2.5$  and 4 female: age  $20.5 \pm 1.3$ , height  $1.63 \pm 0.07$ , mass  $60.1 \pm 11.3$ , BMI  $22.4 \pm 2.1$ ) are reported. All participants were recreationally trained and had at least 6 months of regular bench press experience. Additionally, participants were injury free for at least 1 year prior to the start of the study.

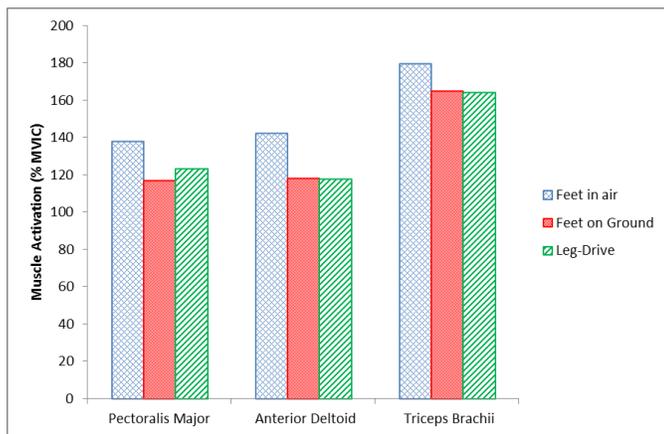

Participants attended two testing sessions. The first session served as a test for the participant’s 1-repetition maximum (1RM) for the bench press as well as a familiarization with the leg-drive protocol.

The second session was conducted 1 week later to minimize the potential effects of fatigue or muscle soreness. For this session, surface electromyography electrodes (Noraxon Ag/AgCl Dual EMG, Noraxon USA Inc.) were placed on the right side of the body over the muscle bellies of the sternal fibers of the pectoralis major, the anterior deltoid, and the lateral head of the triceps brachii. A maximal voluntary isometric contraction (MVIC) was performed at mid bench press position (elbows at 90 degrees) for normalization of the three muscles. Participants then performed 3 repetitions in the bench press with a load of 75% of their 1RM in three testing conditions: 1) neutral placement of the feet for stabilization (i.e. standard bench press [2]), 2) feet placed behind the line of the knee on the ground with the instruction to perform leg drive, 3) legs in the air with hips and knees flexed to 90 degrees. For the leg stabilization and leg-drive conditions, vertical and anteroposterior ground reactions forces (GRF) were recorded for the right leg to determine if the subjects were pressing with their legs (AMTI BP600600, 1000 Hz). The three conditions were randomized for each participant.

EMG data were collected through Biopac’s Acknowledge software using BioNomadix wireless transmitters/receivers (Biopac Systems Inc.) collecting at 1000 Hz. The normalized average of the peaks of the three reps for each muscle were analyzed using a repeated-measures ANOVA. A Bonferroni pos-hoc analysis was conducted when applicable to determine where, if any, differences occurred. Because of the low number of participants in this preliminary work, male and female gender groups were combined for statistical analysis. An alpha level of 0.05 was set a priori.

## RESULTS AND DISCUSSION

Graphically, there appears to be a trend for the feet in the air condition to result in greater muscle activations for each of the three muscles analyzed (Figure 1). However, the repeated measures ANOVA revealed no statistically significant differences across conditions for the pectoralis major ( $p = 0.191$ ) or the anterior deltoid ( $p = 0.231$ ). The ANOVA did reveal a statistically significant difference across conditions for the triceps brachii ( $p = 0.046$ ), but the post hoc analysis found no significant pairwise comparisons.

**Figure 1:** Average peak muscle activation of the pectoralis major, anterior deltoid, and triceps brachii muscles across the three leg positions. Mean values are shown in percentage of the peak muscle activation during the 1RM.

When comparing a standard bench press exercise to a bench press performed with leg-drive, our results indicate that a similar amount of motor units are recruited for the task regardless of the leg condition. This begs the question as to what actually lifters are experiencing when they state that it feels easier while using leg-drive. Something to note about the present study is that we required our participants to maintain 5 points of contact with the bench (head, shoulders, buttocks, right and left foot) at all times throughout the lift. In this way, we wanted to eliminate the possibility of an “easier” lift simply by lifting the hips off the bench to effectively change the inclination angle at which the lift is being performed or to shorten the range of motion.

Feasibly, if the lift truly were easier from a muscle activation standpoint, we may actually see less motor unit recruitment during the leg-drive. Less muscle activation would indicate a less demanding task for the central nervous system (CNS) with the same amount of weight being lifted. On a similar note, it is possible that since the weight being lifted was the same across all conditions (75% of 1RM), the CNS only recruited the motor units necessary to perform that task and no more or no less. However, since we did not find a difference in muscle activation between the two conditions, it is clear, at least from a muscle activation standpoint, that leg-drive did not lead to a reduction in motor unit recruitment and thus, the task demand was the same.

While not statistically significant, it is interesting to note a trend appeared for a higher level of motor unit recruitment during the feet in the air condition compared to the other two conditions. Previous research has found that electromyographic activity of trunk stabilizer muscles are increased when performing an unstable compared to a stable bench press [3]. It is possible that the results of the present study may be a similar finding; indicating that not having the feet placed on the ground for stability could result in increased neuromuscular demand by the CNS.

## CONCLUSIONS

Preliminary data from this work indicates that using leg-drive during a bench press does not reduce the demand placed on the central nervous system and thus does not result in decreased muscle activation compared to a standard bench press exercise.

# COORDINATION OF THE ANKLE AND TOE JOINTS IN DANCERS

<sup>1</sup> Danielle N. Jarvis and <sup>2</sup> Kornelia Kulig

<sup>1</sup> California State University Northridge, Northridge, CA, USA

<sup>2</sup> University of Southern California, Los Angeles, CA, USA

email: danielle.jarvis@csun.edu

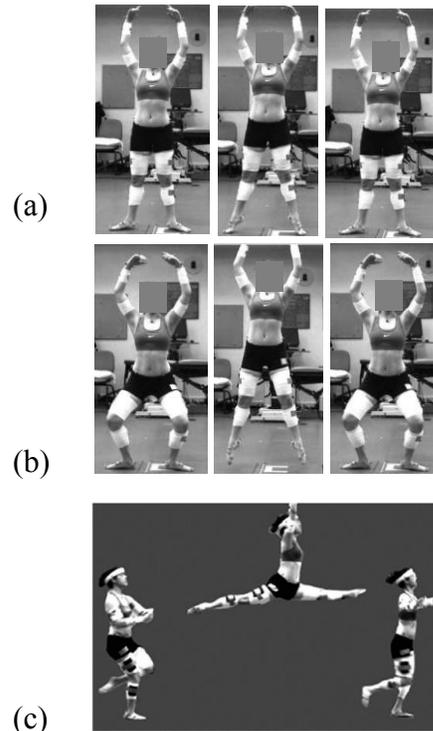

## INTRODUCTION

Dance training emphasizes specialized use of the foot and ankle joints and requires a large range of motion at these joints [1]. Dancers are taught to ‘roll through the foot’ in several types of movements, including jumping. This motion involves allowing the metatarsophalangeal (MTP) joints to stay on the ground as the ankle plantar flexes, then flexing the toes at the end of jump takeoff. Conversely, dancers are taught to land by contacting the ground with the toes first, extending the MTP joints prior to dorsiflexing the ankle.

While dance teachers commonly focus attention on foot and ankle movements, few studies have quantified foot and ankle motion in dancers [2,3], and no study has examined coordination of the ankle and MTP joints during dance movements. Therefore, the purpose of this study was to examine sagittal plane coordination of the ankle and MTP joints during several common dance movements, including relevés, sautés, and saut de chat leap takeoffs.

## METHODS

Ten healthy female dancers (age=27.6±3.2 years; weight=56.3±6.9 kg; height= 1.62±0.06 m) with an average 21.7±4.9 years of dance training were recruited for this study. A three-dimensional motion analysis system was used to collect kinematic data. Participants performed relevés (rising up onto the toes), sautés (vertical bipedal jumps) and saut de chat leaps (split jumps involving both vertical and horizontal movement) (Fig. 1).

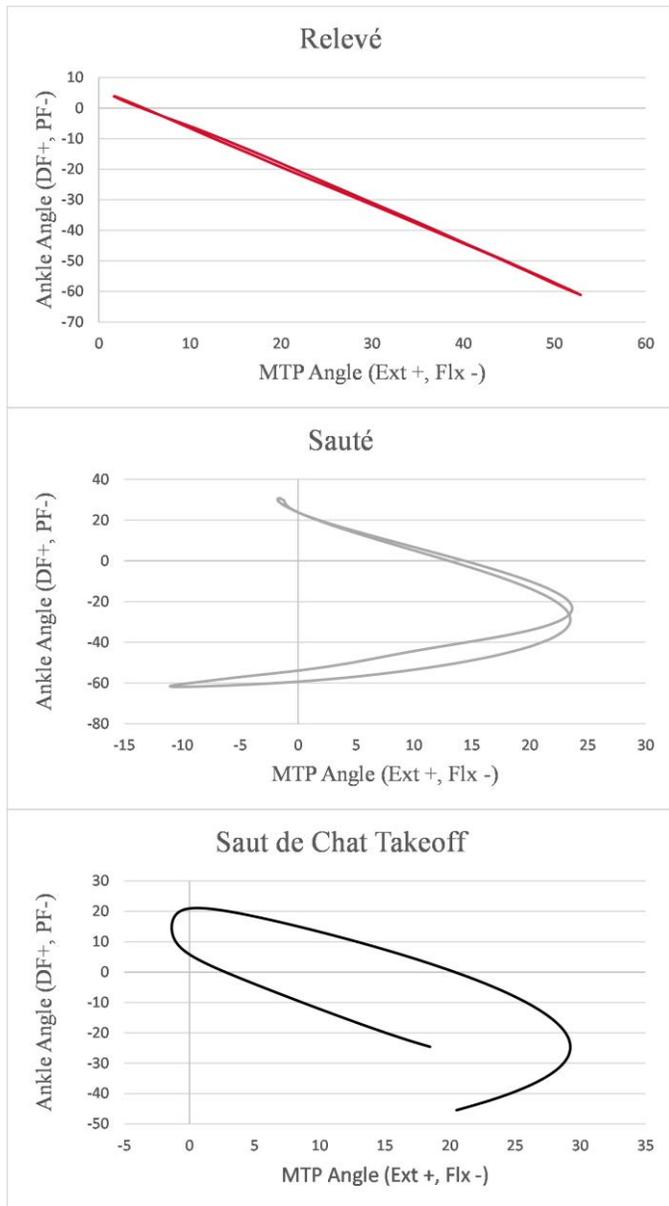

**Figure 1.** Body positioning during dance movements: (a) relevés; (b) sauté jumps; (c) the saut de chat leap, including takeoff, flight, and landing.

The movements were analyzed using a four-segment lower extremity model, which included thigh, shank, foot, and toe segments; the foot was divided at the MTP joints [3]. Sagittal plane kinematics of the ankle and MTP joints were calculated. Angle-angle diagrams of ankle and MTP joint motion were created to examine sagittal plane coordination patterns in the three movements. Based on the angle-angle diagrams, coordination can be described as in-phase, anti-phase, primarily ankle movement, or primarily MTP movement [4].

As the purpose of this study was to examine and describe coordination patterns amongst common dance movements, no statistical analyses were performed at this stage.

## RESULTS AND DISCUSSION

**Figure 2.** Angle-angle plot of mean ankle and MTP displacement for relevé, sauté, and saut de chat.

In the relevé, the movement is anti-phase throughout the entire rising and lowering portions. As the ankle plantar flexes, the MTP joints extend, and as the ankle dorsiflexes, the MTP joints flex (Fig. 2, top).

In the sauté, the movement starts off anti-phase as the ankle plantar flexes and the MTP joints extend. The pattern then shifts to in-phase as the dancer starts to leave the ground, where the ankle continues to

plantar flex while the MTP joints flex to provide additional propulsion off the floor and then achieve the desired aesthetic line while in the air. This pattern is then reversed in landing as the MTP joints first extend as the ankle begins to dorsiflex showing in-phase coordination, then the ankle continues to dorsiflex while the MTP joints flex in an anti-phase coordination pattern (Fig 2, middle).

In the saut de chat leap takeoff, an anti-phase coordination pattern is present as the ankle dorsiflexes and the MTP joints flex while the dancer absorbs weight and prepares to push-off into the air. The anti-phase pattern stays present as the dancer begins to propel off of the ground; the ankle is plantar flexing while the MTP joints extend. Near the end of takeoff, this coordination pattern shifts as the ankle continues to plantar flex and the MTP joints flex to push off of the floor (Fig 2, bottom).

## CONCLUSIONS

This examination of foot and ankle coordination patterns in dancers illustrates the specialized motion of the foot and ankle typically emphasized in dance training. Dancers do in fact move through the foot in both jump takeoffs and landings, demonstrating anti-phase movement of the MTP and ankle joints.

The results of this study provide descriptive evidence of coordination patterns used by trained dancers. Future research could quantify these coordination patterns more specifically using vector coding techniques. The learned coordination patterns at the foot and ankle joints that are seen in trained dancers may be important for successful performance as well as for avoiding injuries. This initial dynamic analysis of sagittal plane MTP and ankle coordination patterns in dancers demonstrates how dancers achieve the aesthetics of foot and ankle motion that are encouraged during training.

# KINEMATIC ANALYSIS OF TRUNK COORDINATION THROUGHOUT THE ROWING STROKE SEQUENCE

McDarragh R. Minnock, Songning Zhang, David R. Bassett, Joshua T. Weinhandl  
The University of Tennessee, Knoxville, TN, USA  
email: mminnock@vols.utk.edu

## INTRODUCTION

Rowing at the elite level requires a high level of physical strength and endurance, as well as technical proficiency. Accurate kinematic sequencing of the rowing stroke (i.e. catch position, drive phase, finish position, and recovery phase) enables the rower to produce powerful and efficient strokes, while also protecting the body from injury [1]. Considering the ‘closed-chain’ and cyclic load-unload nature of rowing, chronic and overuse injuries are the most prevalent of all injuries. Specifically, lower back injuries account for 25% of all rowing related injuries [1, 2].

Previous studies have shown during prolonged sub-maximal ergometer rowing, the total range of lumbar-pelvic motion was markedly increased by about 5° [3]. Similar changes in spinal kinematics were also observed during incremental and maximal effort rowing studies [4-6]. It is important to understand spinal kinematics at different intensities, because the trunk acts as a cantilever and helps in transferring forces throughout the stroke sequence.

There is limited research available on rowing and trunk coordination throughout the rowing stroke sequence. In related coordination studies, angle-angle diagrams were analyzed to assess how two segments move relative to one another at one point in time and determine the variability in movement patterns [7]. Variability in movement is thought to negatively influence the system and potentially lead to injury. However, other studies have shown that variability in movement is essential for the body’s response to complex tasks [7, 8].

The purpose of this study was to observe the influence of rowing stroke intensity on pelvis-lumbar-thoracic coordination. First we hypothesized that the rower would deviate from proper form at 90% split intensity. Secondly, the variability in

pelvis-lumbar-thoracic coordination would increase as the rowing stroke intensity increases.

## METHODS

Ten female rowers from the University of Tennessee, Knoxville Varsity Rowing Team (20.7±2.2yrs, 1.74±0.05m, 69.12±6.2kg) were recruited to participate in this study. They performed an incremental step test on a Concept II model D rowing ergometer (Concept Inc., Morrisville, VT) to measure rowing form at increasing intensities. Intensities were determined from the rower’s average 2,000-meter split time from the previous season. The test began at 70% intensity and increased by 2.5% until reaching 100% intensity. Trials were collected for 30 strokes at the given intensity, followed by 30 seconds rest between trials.

Delsys Trigno wireless inertial measurement unit sensors (IMU) were used to record orientation data throughout the trial (148 Hz). Three sensors were placed on the sacrum, L4, and between shoulder blades. The IMUs recorded the orientation of each segment and XYZ Cardan angles were analyzed.

Data were processed using a customized Matlab code (Mathworks, Inc., Natick, MA) to identify the catch and finish of the 30 strokes. The middle 10 strokes were selected as strokes that best represent rowing form at a given intensity. Data were time normalized to 101 data points to allow for comparison between intensities and participants. A vector coding technique from Needham et al. [7, 8] was used to analyze the coupling angles (CA) and coupling angle variability (CAV) between the pelvis-lumbar and lumbar-thoracic spine at increasing intensities.

Repeated measures ANOVA were used to assess the differences between coupling angle variability at four intensity levels of interest: 70%, 80%, 90%,

and 100%. Follow-up independent t-tests for post hoc comparisons between consecutive intensities were used to identify the point of significant change in rowing form.

## RESULTS AND DISCUSSION

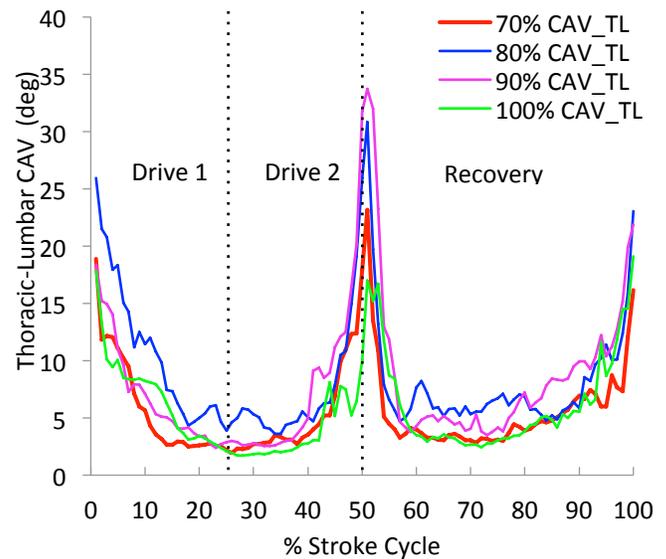

This study measured the coupling angle and coupling angle variability of the pelvis-lumbar and lumbar-thoracic spine at increasing rowing intensities. All participants successfully completed the incremental step-test protocol.

Significant changes in lumbar-thoracic CAV were observed among all participants between the 90%-100% intensities during the second half of the drive phase ( $p < .01$ ). There were changes in the lumbar-thoracic CAV at the other intensity levels (Fig. 1); however, they were found to be not significant. Non-significant changes in lumbar-pelvis coupling angle were observed between 90-100%. There were no significant changes in lumbar-pelvis CAV throughout the incremental step test.

There was significant variability in the lumbar-thoracic spine between 90-100% during drive 2 (Table 1). According to Needham et al. [8] our results suggest that there is more motion in the lumbar spine relative to the thoracic spine. This could indicate earlier extension of the trunk at an earlier point in the drive phase in order to meet performance standards. Although currently there is no research on rowing specific coordination at increasing intensities, we can infer from these results and previous studies that there is more variability in the form of lumbar-thoracic spine when performing at near maximal intensity [4-6]. Increased coordination variability of rowing form may influence the risk of developing lower back injuries.

## CONCLUSIONS

This study addressed movement variability in the rowing stroke sequence at increasing rowing intensities. These results suggest that there is variability in trunk coordination as rowing intensity increases. The repetitive motion of the rowing stroke sequence, in combination with the cyclic loading and unloading of the spine can be harmful to the spinal structure and surrounding tissues. However, further research is warranted to observe the influence of training types, such as prolonged submaximal training or maximal effort tests on trunk coordination

**Figure 1:** Lumbar-thoracic CAV for each of the given intensities across a complete rowing stroke sequence.

## INTRODUCTION

Within the context of contact sports, a greater capacity to rapidly increase the stiffness of the neck against an impact may lower the risk for concussion and upper cervical spine injury [1]. In this regard, the contractile rate of force development (RFD) is an important variable, as it determines the potential static strength capacity of the neck that could be developed over the early phase of force application [2]. Static contractions performed with ballistic intent have been shown to facilitate the neural drive necessary to increase contractile RFD [3].

Therefore, our aim was to evaluate the effectiveness of repetitive maximum voluntary static efforts (MVEs) of the neck, performed with ballistic intent, in improving the contractile RFD of the neck and the associated static force capacity available within the first 100 ms of force application.

## METHODS

Twelve physically active males were enrolled, with relevant characteristics as follows: age, 18.6-24.8 years, neck circumference, 36.7-39.5 cm; and neck-to-head ratio, 0.6-0.7

Ballistic intent training and measurement of outcome variables of static force were performed using a Multi-Cervical Unit™. Two blocks of five ballistic intent MVEs were performed along right and left planes of neck flexion, oriented at 45° from the midsagittal plane, with a 3-min rest between blocks and 5-min rest between directions. Visual and auditory feedback of applied force was provided.

Three variables of the moment of static force of the neck were calculated at the level of C3: peak moment of force ( $\vec{M}_{Res}$ , N·m), defined as the largest magnitude

of the moment-time curve developed during each 3-s trial; RFD ( $N \cdot m \cdot s^{-1}$ ), calculated as the rise in the slope of the moment-time curve over the first 100 ms after force onset; and the impulse of static force (ISF,  $N \cdot m \cdot s$ ), defined as the area under the moment-time curve over the first 100 ms after force onset. Facilitation of the neural drive with training was measured from the surface electromyography signal of the sternocleidomastoid (SCM), splenius capitis (SPL) and upper fibers of trapezius (UFT) muscles, bilaterally. Signals were integrated over the 50 ms *prior to* force onset ( $iEMG_{PRE}$ , mV·s).

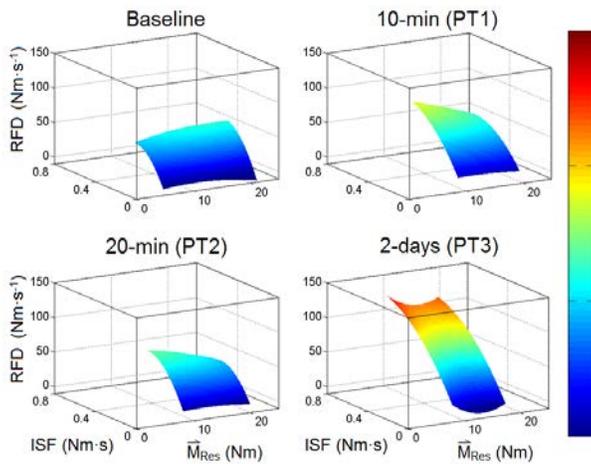

Outcome variables were measured at baseline, and at 10 min (PT1), 20 min (PT2) and two days (PT3), post-training. Effects of training on the relationship between  $\vec{M}_{Res}$ , RFD and ISF, and the contribution of neural facilitation to RFD, were evaluated using linear regression analyses. The effect size (Cohen's *d*-value) of training on outcomes was calculated.

## RESULTS AND DISCUSSION

Among our twelve participants, peak  $\vec{M}_{Res}$  at baseline ranged between 4.5 and 21.3 N·m, with no between-side difference (paired *t*-test,  $P \geq 0.06$ ). Across all participants and time points of measurement, ballistic-intent training produced a medium-to-large effect on RFD (Cohen's *d*, 0.54 to 0.75; 114-166% increase from baseline) and ISF (Cohen's *d*, 0.51 to 0.66; 133-176% increase from baseline), with a coefficient of variation of the standard error ( $CV_{SE}\%$ ) of 22-24%. The effect size of training on peak  $\vec{M}_{Res}$  was small (Cohen's *d*, 0.20-0.24;  $P \geq 0.07$ ).

Multiple regression plots, relating the effect of training on the three force variables, are shown for all time points of measurements in Figure 1. At baseline, greater magnitudes of RFD and ISF were associated with greater magnitudes of peak  $\vec{M}_{Res}$ .

Training produced a selected increase in RFD and ISF among participants with a lower peak  $\vec{M}_{Res}$  at baseline, with this effect persisting to PT3. A probabilistic sensitivity analysis (PSA), performed using a simulated mean based on the lowest  $\vec{M}_{Res}$  value at baseline (4.5 N·m), indicated that training can be expected to produce an increase in RFD at PT1, that exceeds the upper 95<sup>th</sup> percentile of the proportional increase in RFD for the mean peak  $\vec{M}_{Res}$  of our study group at baseline of 11.2 N·m in 63% of trials.

**Figure 1:** Linear regression plots relating the change in RFD and ISF as a function of peak  $\vec{M}_{Res}$ , N·m. The color scale is calibrated to the peak magnitude of RFD across all time-points of measurement.

Training-induced changes in RFD and ISF were associated with a 28.7-71.7% increase in  $iEMG_{PRE}$  of the SCM and SPL at PT1 to PT3 (one-way ANOVA,  $P \leq 0.01$ ), with only a discrete increase for the UFT at PT3 ( $P=0.004$ ). Based on PSA results, participants were classified into low and high baseline peak  $\vec{M}_{Res}$  groups using the mean group value of 11.2 N·m as

the cutoff. Training facilitated an increase in stabilizing  $iEMG_{PRE}$  (Table 1) for the high group (contralateral SCM and ipsilateral SPL;  $P \leq 0.001$ ;  $R^2$ , 0.65), with no effect identified for the low group ( $P=0.59$ ;  $R^2$ , 0.08).

A single bout of ten repetitive ballistic intent MVEs was effective in producing an acute increase in the RFD of the neck, along the direction of training, with an associated increase in ISF capacity at 100 ms. The proportional change in RFD and ISF, across all time points of measurement, was significant at a power of 0.91-0.97 (two-sided). The effects of ballistic intent training were modulated by the underlying coordination of ISF, with a facilitation of the ipsilateral SCM for participants in the low baseline peak  $\vec{M}_{Res}$  group, compared to a facilitation of ipsilateral SPL and contralateral SCM for the high group, this latter pattern of facilitation likely to provide the neck stability necessary for greater magnitudes of ISF and peak  $\vec{M}_{Res}$  to be generated.

## CONCLUSIONS

Ballistic-intent training could provide an easy-to-administer stimulus to enhance the static force capacity of the neck, which could have meaningful application for concussion risk management in contact sports. Learning of effective coordination strategies for individuals with low baseline static force should be considered.

# BIOMECHANICAL DIFFERENCES BETWEEN A SPLIT-STEP AND SIDESTEP CUT IN FEMALE TENNIS PLAYERS

<sup>1</sup> Adrienne Hamada, <sup>1</sup>Henry Wang, <sup>1</sup>D. Hankemeier and <sup>1</sup>D. Clark Dickin

<sup>1</sup> Biomechanics Laboratory, Ball State University, Muncie, Indiana, USA  
email: amhamada@bsu.edu

## INTRODUCTION

A sidestep cut is a common change of direction movement in sports but is also a common mechanism for anterior cruciate ligament injuries (ACL) [1, 2]. Injuries to the ACL are common in sports such as basketball, soccer and lacrosse but much less common in tennis despite the constant cutting, pivoting and sudden decelerations [3]. The majority of these injuries occur during initial contact with the knee flexed less than 30° and in an abducted (i.e. knocked-kneed) position with the foot rotated outwards [4].

Studies have shown that the use of a split-step could decrease knee loading and injury risk when compared to a sidestep cut [1, 5]. The populations used in these previous studies were not familiar with a split-step. A split-step is a common movement used by tennis players and allows for a quicker reaction time [6]. The landing position of a split-step allows for the body to be more stable as compared to body positioning just before a sidestep cut and allows performers to share forces between feet decreasing peak knee adduction and external rotation [1, 5]. Therefore the purpose of this study was to investigate the differences in joint loading and overall risk factors between a sidestep and split-step cutting maneuver in female tennis players.

## METHODS

Four healthy young females (age: 19.25 ± 1.25 years; mass: 65.6 ± 8.20 kg; height: 1.680 ± 60.69 m) performed two different cuts (sidestep and split-step cuts). Participants were excluded if they had any previous anterior cruciate ligament injuries, other ankle or knee surgeries, current lower extremity injuries, pain, neurological or physiological problems that would prevent them from running and cutting. Participants with a history

of participating in tennis at a USTA 3.0 level or higher with experience playing high school tennis or junior tournaments or adult tournaments or league were included. A sidestep cut in which participants planted one leg and moved in the direction opposite of that leg was performed, along with a split-step cut in which participants performed a bilateral hop with a simultaneous double leg landing then proceeded to perform a sidestep cut. The two cuts were randomized and performed under unanticipated conditions to simulate a game like situation. This was done using a set of timing gates, controlled by a custom program producing images of direction arrows or stop signs. The cutting maneuver was captured using a 12-camera (VICON, Inc., Denver, CO, USA) collecting at 200Hz and two AMTI force Platforms (AMTI, Watertown MA, USA) embedded in the floor sampling at 2000Hz. A modified Plug-in Gait model that included marker clusters on the thigh and shank of each leg was used. Sagittal, frontal and transvers plane joint kinematics were calculated using Visual 3D software (Version 5.0, C-Motion, Germantown, MD, USA). A paired samples t-test was run comparing a sidestep to a split-step with an alpha of p<.05.

## RESULTS AND DISCUSSION

Table 1 shows knee joint angles in all three planes at initial contact for both split-step and sidestep cuts in both directions. Analysis was run on the plant leg comparing the sidestep and split-set cuts in the same direction. During a split-step cut a significant increase in initial contact knee flexion angles were observed compared to the sidestep cut (p<.05). There was also an increase in knee internal rotation at initial contact when performing a split-step as compared to a sidestep cut (p<.05). There were no other significant differences observed between a sidestep cut and split-step cut at the knee joint.

Table 2 shows ground reaction forces during a sidestep and split-step cuts. A significant decrease in peak ground reaction forces were seen during a right split-step cut ( $p < .05$ ). There is was a decrease in breaking forces but was not significant.

The results demonstrate the potential benefits to the use of a split-step cut. The knee flexion angles at initial contact were larger during a split-step cut as compared to a sidestep cut. These angles were observed to be greater than  $30^\circ$  which can decrease the risk of ACL injuries. The decrease in peak ground reaction forces can also decrease the risk of ACL injuries. This decrease in ground reaction forces can be attributed to the ability to share forces between two feet rather than having all of the force being put into one leg. Trewartha et al. (2007) observed that subjects who were better able to share the forces between the two feet show a trend towards decreasing the load placed on the ACL.

## CONCLUSIONS

The preliminary results of this study show that there is the potential of a split-step cut to decrease the risk of ACL injuries by increasing knee flexion angles at

initial contact and decreasing peak ground reaction forces. Since this is a fundamental movement in tennis it is possible that the differences seen are attributed to the experience of the movement. There is the potential for this movement to be translated into other sports but other populations should be trained and tested to see if similar results are achieved.

# ENERGY FLOW IN YOUTH BASEBALL PLAYERS IN RELATION TO PITCHING PERFORMANCE AND EFFICIENCY

<sup>1</sup> Jacob Howenstein, <sup>2</sup> Kristof Kipp, <sup>1</sup> Michelle Sabick

<sup>1</sup> Saint Louis University, MO, USA

<sup>2</sup> Marquette University, WI, USA

email: jhowens2@slu.edu

## INTRODUCTION

In baseball pitching, shoulder and elbow injuries are prevalent given the ballistic nature of the motion. These injuries, once predominantly seen in older pitchers, have begun to permeate to younger athletes. Because repetitive micro-trauma may lead to acute injuries, understanding how youth pitchers can achieve high performance levels with minimal joint loads could yield important information to help reduce the risk of injury in these athletes [1,2].

Pitchers generate mechanical energy in the lower extremities and transfer it through the trunk and into the upper extremity, ultimately propelling the ball toward home plate. Optimal transfer of energy between segments is critically dependent on the correct muscle activation and timing of sequential steps during the pitching motion [2]. Energy flow (EF) is a measure that quantifies how energy is both generated and transferred among body segments [3]. An optimal, or more efficient, pitching technique would be characterized by larger energy generation and transfer along with smaller joint loads at the shoulder and elbow.

Most pitching studies have focused on the upper extremities and have largely ignored the role of the lower extremities and trunk in relation to pitching performance. Additionally, multiple studies have identified athlete size and pitch velocity as contributors to the magnitude of elbow and shoulder loading [1,4]. Although important, these findings provide limited insight into how to decrease joint loads without a compromise in pitch performance. Therefore, investigation into joint loads with respect to pitch velocity (i.e. joint moment/mph) would likely provide an indicator of pitch efficiency and the trade-off between performance and surrogates for risk of injury [2]. The purpose of this study was

to investigate the relationships between measures of full body energy flow and pitch performance and pitch efficiency.

## METHODS

Fourteen youth baseball pitchers (age:  $11.6 \pm 1.3$  years, height:  $1.59 \pm 0.12$  m, mass:  $48.5 \pm 13.4$  kg, velocity:  $56.6 \pm 6.9$  mph, 11 right-handed/3 left-handed) were recruited for this study. All testing occurred in an indoor research lab equipped with a custom built pitcher's mound with two embedded force plates; one under the rubber and one under the landing area. Reflective markers and marker clusters were attached to each pitcher's upper and lower body. Kinematic data were recorded with a 14-camera motion capture system at 250Hz. Kinetic data of the drive (rear) and stride (front) leg were sampled at 1000Hz, and a radar gun was used to record velocity. Each pitcher threw 15 maximal effort fastballs toward a hanging strike zone 46ft from the rubber. The fastest strike thrown for each pitcher was chosen for analysis.

Elbow valgus and shoulder internal rotation moments were calculated with an inverse dynamics procedure. Energy flow was quantified with a full-body segment power analysis [5]. The rate of work done on each segment by the joint forces (JFP; eqn. 1) and muscle moments (STP; eqn. 2) were summed at the proximal and distal ends of each segment to calculate the total segment power (SP; eqn. 3).

$$\text{JFP} = (\text{joint reaction force}) \cdot (\text{linear joint velocity}) \quad (\text{eqn. 1})$$

$$\text{STP} = (\text{joint moment}) \cdot (\text{segment angular velocity}) \quad (\text{eqn. 2})$$

$$\text{SP} = \text{JFP}_{\text{prox}} + \text{STP}_{\text{prox}} + \text{JFP}_{\text{dist}} + \text{STP}_{\text{dist}} \quad (\text{eqn. 3})$$

When the SP is integrated over a specified interval of time, the result is net energy transfer into or out of the segment. The SP for each segment was thus integrated over the period that it was positive to

calculate the energy it gained and integrated over the period that it was negative to calculate the energy it transferred. EF was normalized to body-mass, whereas upper extremity moments were normalized to body-mass, height, and pitch velocity to calculate pitch efficiency.

Selected EF variables were compared to pitch performance (i.e. ball velocity) and efficiency (i.e. velocity-normalized joint loads) with simple linear regressions.

## RESULTS AND DISCUSSION

A considerable number of the correlations between selected EF variables, pitch velocity, and elbow valgus and shoulder internal moments were significant (Table 1). Pitch velocity was strongly correlated to EF into the drive hip and hand as well as out of the pelvis, shoulder, and humerus. Velocity-normalized elbow valgus and shoulder internal rotation moments were strongly correlated with EF into the drive hip, and out of the pelvis and humerus. Collectively, these correlations point to the importance of energy production and transfer in relation to both velocity and pitch efficiency.

In addition, linear energy toward home plate was strongly related to pitch velocity and efficiency. The four linear energy variables all showed consistent and significant correlations with both pitch velocity and efficiency. In comparison, peak rotational trunk energy had a significant relationship with pitch velocity but not efficiency. No rotational energy

variable had a significant correlation with pitch efficiency. Rotational energy thus appears more important for pitch performance than for pitch efficiency. This study provides evidence that pitch efficiency is not only dependent on an athlete's size and pitch velocity, but also how they generate and transfer energy between body segments.

## CONCLUSIONS

The results of this study highlight the relationships between energy flow and both performance and efficiency measures of baseball pitching. Linear energy from the drive leg and trunk are strongly correlated to pitch velocity and upper extremity loading. Future research should expand the use of energy flow analysis to populations of different ages and larger subject pools. In addition, identifying kinematic predictors of energy flow variables would allow researchers to apply these techniques to athletes in the field without the needing specialized equipment.

## INTRODUCTION

The Pro-agility test (“20-yard shuttle” or “5-10-5”) is used by football coaches and scouts to assess player acceleration and agility. It is one of the tests administered during the NFL Combine, and draft status is tied to its effective execution.

Athletes begin in a three-point stance with either hand touching the ground. Upon starting, the athlete sprints toward his right (if the right hand was down to start) or left to touch a ground marker five yards away. Then, the athlete turns to sprint ten yards in the opposite direction, touching another marker. Last, he turns again to sprint five yards through the finish line, which is the original start (see Figure 1).

**Figure 1:** The route run during the Pro-agility test. The sequence of moves is labeled  $t_1$ ,  $t_2$ ,  $t_3$ .

Traditionally, players use a crossover step (CS) to start, avoiding a “false” step. However, a “rhythm”, or “drop” step (DS), is natural and has been shown to produce better sprint times for short distances [1,2]. The purpose of this study was to compare a CS start to a DS start in the Pro-agility test to determine which, if either, produces better times.

## METHODS

Study procedures were reviewed and approved by the university IRB, and all subjects provided informed consent. Thirteen Division I football players volunteered to run the test four times in counterbalanced order: twice using a CS start and twice using a DS start. A high-speed video camera

captured each trial at 100 Hz from a position 25 m away from and perpendicular to the line containing the ground markers. Video frames were used to measure the time from start to the first marker touch ( $t_1$ ), from first marker to second marker ( $t_2$ ), and from second marker to finish ( $t_3$ ). Total time ( $t_{TOT}$ ) was the sum of these times. The times from the two DS trials were averaged together, as were the times from CS trials.

Full-body digitization and custom software were used to calculate the center of mass (COM) position, velocity, and acceleration during  $t_1$ . The body’s lean ( $\theta_{LEAN}$ ) with respect to vertical was measured using the vector from the athlete’s trail-foot toe to the top of the trunk. Paired t-tests ( $\alpha = 0.05$ ) were used to find technique differences for times, maximum  $\theta_{LEAN}$ , maximum acceleration ( $a_{COM}$ ), and time to reach both max  $\theta_{LEAN}$  and  $a_{COM}$ .

## RESULTS AND DISCUSSION

Descriptive statistics for all variables are presented in Table 1. Several of the compared variables were shown to be significantly different between trials using a DS start and trials using a CS start.

Specifically,  $t_{TOT}$  was 0.10 s faster, with  $t_1$  taking 0.07 s less time, using a DS start ( $p = 0.02$  and  $p < 0.01$ , respectively). Maximum  $a_{COM}$  in  $t_1$  was the same in both conditions, but subjects reached  $a_{COM}$  0.08 s sooner using the DS start ( $p < 0.01$ ). Even though max  $\theta_{LEAN}$  was similar between techniques, the time to reach it trended significantly less using the DS technique ( $p = 0.06$ ).

A time savings of 0.10 s may seem unimportant, but it can affect an athlete’s ranking in the test heavily. For example, in the 2016 NFL Combine, 51 defensive linemen completed the test, with scores ranging from 4.21 - 5.13 s, and a median of 4.56 s

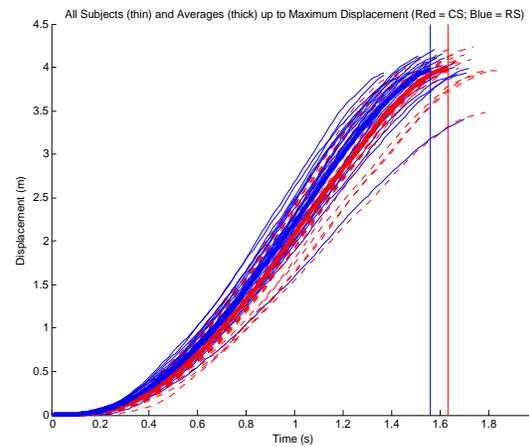

[3]. If the median player improved his score by 0.10 s, he would have moved up 12 places in rank. This has draft position and related financial implications for the athlete.

The bulk of the time savings occurs during  $t_1$ , and kinematic differences during that portion of the run should be examined. Previous work has indicated that the advantages of the DS stem from two factors. First, a better location of the foot behind the COM allows for bigger horizontal forces. Second, the ballistic placement of the dropped foot leads to an enhanced stretch-shortening cycle (SSC) of propulsive muscles [1,2].

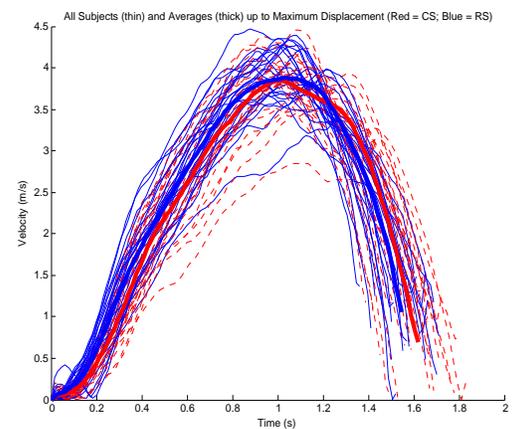

The first of these factors relates to  $\max \theta_{LEAN}$ . Though it was not bigger with the DS start, athletes probably achieved  $\max \theta_{LEAN}$  sooner, meaning that propulsive forces could get bigger sooner. This is supported by their reaching  $\max a_{COM}$  sooner when using the DS start. Though not significantly, athletes continued to gain time during  $t_2$  and  $t_3$ , eventually growing the total advantage to 0.10 s. This may be due to enhanced SSC action at the changes of direction due to carrying slightly more speed at each turn, crating a more ballistic stopping and re-direction (see Figures 2 & 3).

## CONCLUSIONS

When preparing athletes for the Pro-agility test, practitioners seek any potential advantage. The DS start results in a time savings of 0.10 s in this sample, which could help vault players to better rankings and draft positions. Trainers and coaches should try both techniques to see if better times can be achieved using the less-traditional DS start.

## INTRODUCTION

Baseball pitchers generate mechanical energy in the lower extremities and transfer it from proximal to distal segments, through the trunk and upper extremity, to ultimately propel the ball towards home plate [1]. Energy flow (EF) is a measure that refers to how energy is both generated and transferred through the body [2]. The pelvis and trunk link the lower extremities to the arm, thus greater magnitudes of energy flow through the trunk should allow for more energy to be transferred from the lower extremities and core musculature to the throwing arm. Greater magnitudes of EF into the dominant arm from the shoulder have previously been shown to increase serve speeds in tennis players [2]. Little research, however, has applied EF analysis to baseball pitching and no study has applied it to the lower extremities and trunk.

Although information on EF is useful, it is difficult to quantify outside of a research lab. Therefore, the identification of kinematic variables that correlate with greater magnitudes of EF would improve the translation of EF research to the coaching of athletes. The purpose of this paper was to identify kinematic variables that correlate with the magnitude of EF during pitching in youth baseball players.

## METHODS

Fourteen youth baseball pitchers (age: 11.6±1.3 years, height: 1.59±0.12 m, mass: 48.5±13.4 kg, velocity: 56.6±6.9 mph, 11 right/3 left) were recruited for this study. All testing occurred in an indoor research lab equipped with a custom built pitcher's mound with two embedded force plates; one under the rubber and one under the landing area. Reflective markers and marker clusters were attached to each pitcher's upper and lower body.

Kinematic data were recorded with a 14-camera motion capture system at 250Hz. Kinetic data of the drive (rear) and stride (front) leg were sampled at 1000 Hz, and a radar gun was used to record velocity. Each pitcher threw 15 maximal effort fastballs toward a hanging strike zone 46 ft from the rubber. The fastest strike thrown for each pitcher was chosen for analysis.

Energy flow was quantified with a full-body segment power analysis [3]. The rate of work done on each segment by the joint forces (JFP; eqn. 1) and muscle moments (STP; eqn. 2) was summed at the proximal and distal ends of each segment to calculate the total segment power (SP; eqn. 3). The joint between the pelvis and trunk was defined as the midpoint between the two iliac crests.

$$\text{JFP} = (\text{joint reaction force}) \cdot (\text{linear joint velocity}) \quad (\text{eqn. 1})$$

$$\text{STP} = (\text{joint moment}) \cdot (\text{segment angular velocity}) \quad (\text{eqn. 2})$$

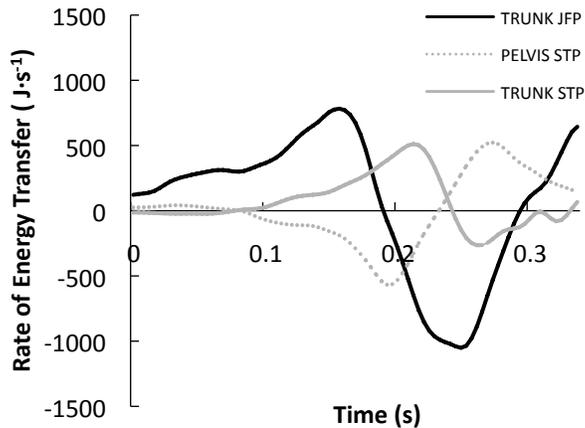

$$\text{SP} = \text{JFP}_{\text{prox}} + \text{STP}_{\text{prox}} + \text{JFP}_{\text{distal}} + \text{STP}_{\text{distal}} \quad (\text{eqn. 3})$$

For this paper, we focused on the EF between the pelvis and trunk (Figure 1), as well as the EF out of the trunk through the shoulder joint. The JFP and STP between the pelvis and trunk were analyzed separately while the EF out of the shoulder joint was calculated as the sum of the JFP and STP at the distal end of the trunk. When a component of segment power is integrated over an interval of time, the result is net EF into or out of the segment by that method. The JFP and STP for the pelvis and trunk were integrated over the period each was positive to calculate the energy transferred into them and integrated over the period that they were negative to calculate EF out.

The EF variables of the pelvis and trunk were compared to selected kinematic variables with simple linear regressions. When compared to kinematic parameters, EF was normalized to body mass.

## RESULTS AND DISCUSSION

Multiple kinematic variables had significant relationships with the magnitude of EF through the trunk (Table 1). The maximum linear velocity of the pelvis and trunk and the velocity of both segments at the time of stride contact had significant relationships to the magnitude of JFP between the two segments. These relationships, however, were expected since JFP is the dot product of the force and velocity at a joint. An interesting observation is the stronger relationship between JFP and the peak linear trunk velocity compared to the relationship between JFP and trunk velocity at stride foot contact. The likely explanation for this finding is that the increase in velocity of the trunk, from stride contact to its peak value, is due to the EF from the pelvis via the joint force between the segments.

**Figure 1.** Sample energy flow between the pelvis and trunk from stride foot contact to ball release.

Peak trunk flexion angular velocity and the angular velocity of the pelvis relative to the shoulders both had significant relationships to STP out of the pelvis, STP into the trunk, and total EF out of the

trunk at the shoulder joint. Peak trunk angular velocity had a significant relationship with STP out of the pelvis and STP into the trunk. The strong relationship between EF and the angular velocity of the pelvis relative to the trunk underscores the importance of the pelvis leading the rotation of the trunk and creating an angle of separation between the segments. The strong relationship between angular trunk flexion velocity and EF indicates that trunk flexion is an important way to transfer rotational energy up the kinetic chain, even more than axial rotation of the trunk, which had no significant relationship to EF magnitude. Peak angular trunk velocity had the strongest relationship with STP into the trunk, but did not correlate with EF out of the trunk through the shoulder.

## CONCLUSIONS

The best kinematic predictors of energy flow through the pelvis and trunk were peak linear velocities of the pelvis and trunk, angular velocity of the pelvis relative to the trunk, and peak angular trunk flexion velocity. Future research should expand this investigation to larger subject populations and more experienced pitchers with more consistent mechanics.

# KINETICS OF STEEPLECHASE HURDLING PERFORMANCE

<sup>1</sup> James Tracy, <sup>1</sup> Spencer Baker, and <sup>1</sup> Iain Hunter

<sup>1</sup> Brigham Young University, Provo, UT, USA  
email: [iain\\_hunter@byu.edu](mailto:iain_hunter@byu.edu), web: <http://biomechanics.byu.edu/>

## INTRODUCTION

The 3000m steeplechase event requires athletes with a unique combination of endurance, strength, and athleticism. Studies have been completed in recent years focused on kinematics of the steeplechase event, but very little exists on the kinetics.<sup>1,2</sup> Kipp found steeplechase hurdling forces are greater than treadmill running.<sup>3</sup>

This study aimed to determine a kinematic and kinetic analysis of steeplechase hurdling related to horizontal velocity gained or lost upon takeoff and landing.

## METHODS

Eight male collegiate steeplechase athletes were brought to the biomechanics lab. After signing an informed consent approved through the university's institutional review board, they did their typical warmup routine followed by marker placement according to the Vicon Plugin Gait model. A hurdle was placed prior to a 0.6 x 0.9m force platform to measure two hurdle landings, one with the left leg leading and one with the right. Force data were collected at 1000 Hz with motion at 250 Hz. A successful trial was determined when the foot landed completely on the force plate and the designated speed of 4.73 m/s was attained within 5%. This is a little slower than their typical race pace, but constraints of the lab limited us from faster running.

Various characteristics of hurdling technique were measured or calculated using outputs from the Plugin Gait Model. Measurements are illustrated or listed in Figure 1. Change in horizontal velocities were calculated through A/P impulse calculations.

A stepwise linear regression tested for correlations between the loss of velocity during contact with the

ground and the various measures of technique. Correlations were tested between all combinations of predictor variables individually. Some variables were not used in the final regression model based upon them being closely correlated with other potential predictor variables. Separate analyses for takeoffs and landings were completed with alpha set at 0.05. The separation of takeoff and landing trials were needed since the force plates were not in positions that allowed for measurements of both ground contacts in a single jump.

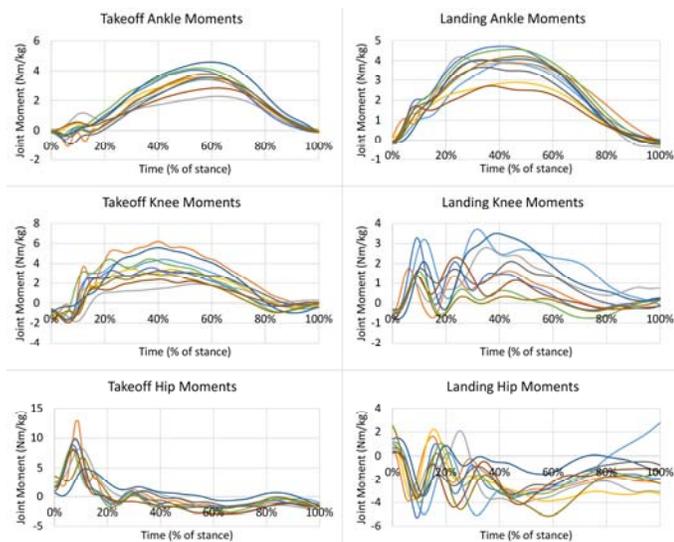

**Figure 1:** Measurements used in analysis are labeled in image. Others included peak vertical force and vertical impulse at takeoff and landing, high point of center of mass, trunk lean at takeoff and landing, and energy during contact with the ground for the hip, knee, and ankle, at takeoff and landing.

## RESULTS AND DISCUSSION

Only takeoff vertical impulse predicted the loss of velocity during takeoff contact. Other measures were non-significant. The horizontal distance between the landing toe and the person's center of mass and the horizontal distance between the landing toe and the hurdle predicted the loss of velocity at landing.

Joint energies during time in contact with the ground were non-significant in the regression analyses.

Graphs of each subject's joint moment profiles for descriptive purposes are included in Figure 2.

**Figure 2:** Joint moments for takeoff and landing. No significant differences were observed in joint kinetics (specifically joint energy).

Some aspects of steeplechase hurdling technique do not affect the loss or gain of velocity at takeoff and landing. The final model included takeoff vertical impulse, takeoff toe to hurdle distance, knee extension of the lead leg, landing peak vertical force, landing ground time, landing toe to hurdle distance, and landing center of mass to toe distance.

Avoiding large vertical impulses during takeoff allows the athlete to better maintain their horizontal velocity. A forward lean at takeoff was correlated with a smaller peak vertical force at takeoff. This forward lean may be part of the reason vertical impulses were lower. Since both measures were highly correlated with each other, only vertical

impulse was included in the regression. Applying the forces correctly may be more important than body positioning for takeoff, although the one is not independent of the other. A greater vertical impulse was also correlated with a greater high point. Greater takeoff distance was correlated with a center of mass high point farther back from the hurdle. Since the lead leg is farther in front of the center of mass than the trail leg is behind, a high point farther back from the hurdle is desirable.

Correlations of independent variables at landing included: landing closer to the hurdle with longer ground time and a greater forwards lean, a greater forwards lean on landing with a smaller center of mass to toe distance, and a smaller peak force at landing with a smaller toe to hurdle distance. Thus, methods for landing closer to the hurdle and having a smaller center of mass to landing toe distance are connected with more ground time, a greater forwards lean, and a lower peak force.

## CONCLUSIONS

During takeoff, correctly applying forces was more significant than body positioning to successfully maintain horizontal velocity. During landing, the body positioning was more significant than the forces involved to predict obstacle navigation success. However, the kinematics and kinetics are interconnected.

## INTRODUCTION

Anterior cruciate ligament (ACL) injuries are common sports injuries that impact 1 in every 3,000 individuals [1]. An ACL injury results in the loss of dynamic knee stability, which is critical for the successful execution of movements like single-leg jump landing (SLJL) [2]. Discrete measures are often used to evaluate dynamic knee stability but these measures may not fully capture the altered joint biomechanics. To better capture the changing dynamics, we will implement an empirical based modeling (EBM) approach to quantify dynamic knee stability.

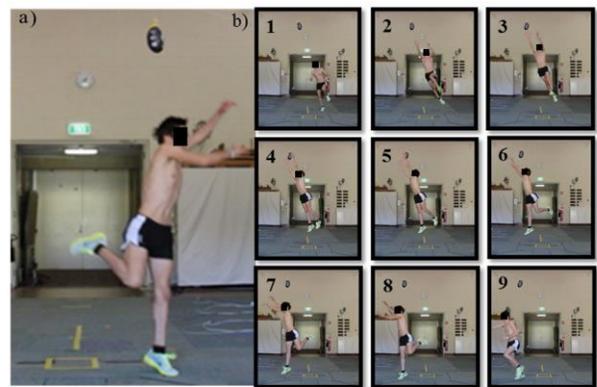

Previous work has assessed dynamic gait stability via methods such as; Lyapunov exponents [3, 4]. This method uses experimental (empirical) gait waveform data to derive models to evaluate gait pattern stability [3, 4]. The EBM approach employed here will use experimental jump landing data to derive a transfer function to evaluate dynamic joint stability via bode stability analysis. A transfer function is the ratio of the models' output response to the input perturbation [5]. Previous studies have used waveform data to develop transfer functions [6, 7]; however, they did not use the transfer function to assess stability.

Thus this study combined multiple techniques to evaluate dynamic knee stability from sagittal plane knee kinematic data in athletes during a SLJL task [3-5, 8]. Surface electromyography (sEMG) data was also analyzed to determine how changes in joint stability relate to changes in muscle coordination. We hypothesize that this technique will be able to differentiate between stable and unstable knee biomechanics and that greater knee flexor-extensor co-contraction will be exhibited during stable jump landings.

## METHODS

Five Australian Football players (age  $20 \pm 1$  yrs;

mass  $87.1 \pm 5.4$ kg; height  $1.90 \pm 0.1$ m) were randomly selected from a larger cohort to perform the six SLJLs each as part of the SLJL protocol (Fig. 1). Sagittal plane knee kinematics were obtained from experimental kinematic marker trajectories. And ground reaction force (GRF) and sEMG data were also synchronously recorded. The sEMG data was collected for six muscles: medial and lateral vasti, hamstrings and gastrocnemii.

**Figure 1:** Series of images of an individual performing the experimental single-leg jump landing protocol in the laboratory.

The EBM transfer function was developed using the sagittal plane kinematic and GRF waveforms during the weight-acceptance (WA) phase of SLJL. Here the sagittal plane kinematic waveform represented the output response and the GRF waveform represented the input perturbation (Eq. 1).

$$\text{Transfer Function} = \frac{\text{Sagittal plane knee kinematics}}{\text{Ground reaction force waveform}} \text{ Eq. 1}$$

The Laplace transform converted the ratio from the time to frequency domain for the Bode analysis. The gain and phase margins obtained from the Bode stability analysis were used to quantify the individuals' dynamic knee stability. If both the gain margins (GM) and phase margins (PM) were positive, the individual was stable; otherwise they were unstable [5].

The sEMG data was normalized to each muscles peak activation. Directed co-contraction ratios (DCCR) were also calculated for the medial/lateral and flexion/extension muscle groups. The DCCR provides a value between -1 and 1 that indicates the role the agonist (flexor and medial) compared to the antagonist (extensor and lateral) muscles. We computed the integral of the sEMG data during the WA phase for the three muscles and the knee flexors (hamstrings and gastrocnemii) muscle group. A one-way ANOVA and Tukey's post hoc analyses determined if differences between the stable and unstable groups' PMs, sEMG DCCRs and area means were significant ( $\alpha=0.05$ ).

## RESULTS AND DISCUSSION

Twenty-one SLJL trials were classified as stable while nine were classified as unstable and the resulting stable and unstable GM and PM means were significantly different ( $p<0.01$ ;  $p=0.04$ , respectively) (Table 1). The DCCR analysis found that individuals exhibited a more balanced knee flexor-extensor co-contraction during the stable trials than the unstable trials, although the difference was not significant. Overall, all three muscle groups exhibited greater muscle activation during the unstable trials than the stable trials (Table 1). Individually, the gastrocnemii muscles generated significantly greater activation during the unstable trials ( $85.7 \pm 34.1$ ) than the stable ( $57.8 \pm 24.8$ ) ( $p=0.02$ ). Neither the quadriceps nor the hamstrings increase in muscle activation were significant.

The results indicated that the EBM approach successfully assessed and quantified dynamic knee stability during the WA phase of SLJL. And that the stable landings exhibited greater knee flexor-

extensor co-contraction. The gastrocnemii produced a significantly larger increase in activation during the unstable trials, potentially to compensate for the smaller increase in muscle activation by the hamstrings. Previous research has shown that knee flexors and extensors function synergistically to stabilize the knee via joint compression [9]. The disproportionate increase in muscle activation exhibited by the muscle groups during the unstable SLJLs supports this concept. Furthermore, the larger increase in gastrocnemii muscle activation during the unstable landings could represent the muscle activation strategy individuals adopt in attempt to stabilize the knee during unstable SLJLs.

## CONCLUSIONS

This study offers an alternate approach for evaluating dynamic knee stability. The results also provided insight the muscle activation strategies individuals adopt during stable and unstable SLJLs. Future work will investigate how muscle activation timing influences dynamic knee stability.

## INTRODUCTION

It is easy to accurately measure mechanical power output using a stationary cycle ergometer but stationary cycling is different than actual road cycling. On an ergometer, there is no need for balance and there are no hills. With the advent of inexpensive, on-board, power-measuring hubs, pedals and cranks, it is possible to measure power output in the field on real bicycles. However, some of these devices are of dubious accuracy. Further, outdoor cycling is “noisy” due to variations in road surfaces, incline, velocity and wind. Overcoming air resistance is the major determinant to the power demand in overground cycling yet absent during treadmill cycling but treadmill cycling against resistance eliminates the confound of varying wind experienced during outdoor cycling.

Thus, we explored if a large, inclined motorized treadmill could allow realistic simulation of overground cycling under highly controlled conditions. We were inspired by the great Swedish exercise physiologist, P.O. Åstrand who studied treadmill bicycling in 1953 [1] and humorously noted that his measurements remained particularly consistent “so long as the rider remained on the treadmill”.

Here, we describe our method for using a treadmill to measure mechanical power output and then highlight its utility with three application examples. First, we compared the power required for riding uphill in a seated vs. standing climbing position. Then, we quantified the mechanical power losses due to a novel road bike suspension system. Finally, we used the treadmill to validate a crank-based power measuring device.

## METHODS

On an inclined treadmill, the mechanical power for lifting the mass of the rider and bicycle against gravity,  $P_{\text{vert}}$ , the “vertical power” is calculated as:

$$P_{\text{vert}} = (M + m) g v \sin \vartheta$$

Where  $M$  is the mass of the rider (kg),  $m$  is the mass of the bicycle,  $g$  is  $9.81 \text{ m/s}^2$ ,  $v$  is the treadmill belt velocity (m/s) and  $\vartheta$  is the angle of incline.

The rolling resistance power is calculated as:

$$P_{\text{RR}} = (M + m) g C_{\text{rr}} v \cos \vartheta$$

where  $C_{\text{rr}}$  is the coefficient of rolling resistance. We measure  $C_{\text{rr}}$  by having a subject balance on a bicycle without pedaling while a cord pulls forward on the bike, parallel to the inclined treadmill (Figure 1). The cord passes over a low-friction pulley and we hang weights until the rider remains at one spot on the treadmill in force equilibrium.

$$C_{\text{rr}} = F_{\text{hang}} / F_{\text{N}}$$

where  $F_{\text{N}}$  is the normal component of the weight of the rider + bicycle:  $(M+m) g \cos \vartheta$

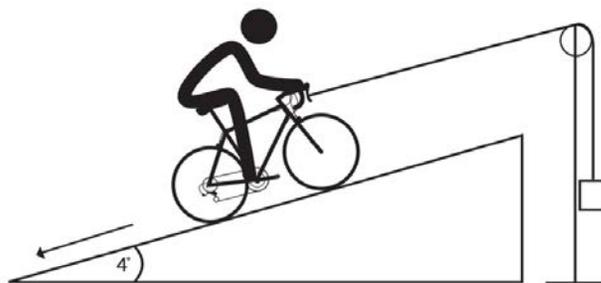

Figure 1. Method for measuring  $C_{\text{rr}}$ .

Finally, we multiply the sum of  $P_{\text{vert}}$  and  $P_{\text{rr}}$  by 1.02 to account for typical drivetrain losses [2].

## RESULTS AND DISCUSSION

We first investigated differences in metabolic and mechanical power output during bouts of seated and standing uphill cycling (n=11). Testing was conducted at 4° at an average power output of 2.85±0.03 W/kg while riding a rigid-framed road bicycle (9.02kg) equipped with a Quarq® crank-based power meter. We averaged rates of oxygen consumption ( $\dot{V}O_2$ ), carbon dioxide production ( $\dot{V}CO_2$ ) for the last 2 minutes of each trial and calculated metabolic power. Metabolic power was ~8 % greater for standing (13.11±0.57 W/kg seated vs. 14.23±0.77 W/kg standing, p <0.001) but there was no significant difference in the mechanical power between the two conditions. (Figure 2).

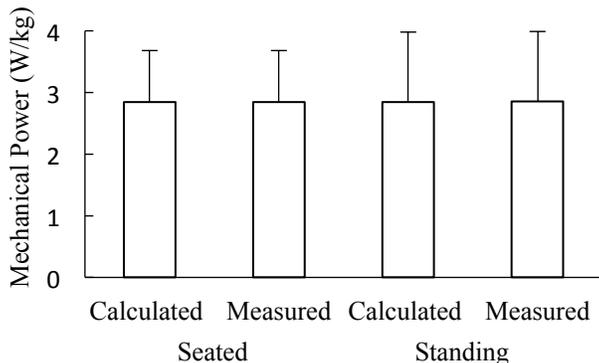

Figure 2. Mechanical power (W/kg) means ± S.D. comparing seated vs. standing.

Next, we investigated differences in metabolic and mechanical power output between a rigid-frame road bicycle without and with a novel front suspension element in the head tube during seated uphill cycling (n=11). The bicycle was designed for rider comfort. However, possible negative effects of the suspension are metabolic and/or mechanical power penalties. Given the extreme repeatability of the treadmill, we were able to discern no differences in either calculated or crank-measured mechanical power (2.85 ±0.05 W/kg) (p = 0.71) between conditions. Metabolic power was not significantly different (13.11 ±0.57W/kg rigid vs. 13.21 ±0.57W/kg compliant, p=0.23). Thus, head tube

suspension system did not require significantly more mechanical or metabolic power compared to riding with the suspension rigidly locked out.

Third, we evaluated the accuracy and precision of six individual units of a newly developed crank-based power meter. We inclined the treadmill to 4.1° degrees and adjusted treadmill speed to achieve 5 power outputs starting at 150W and incrementing 50W every 2 minutes up to 350W. We compared the crank-measured mechanical power to our reference calculated power. We determined an average absolute error of 1.56% (Table 1).

Table 1. Error for crank-power measurements. Difference from Calculated (%)

Meter	% difference
A	+1.16
B	+3.49
C	+0.85
D	-2.06
E	-1.32
F	-0.50

## CONCLUSION

Treadmill bicycling is a realistic and useful simulation of outdoor riding that controls for multiple environmental factors which facilitates collection of accurate and reproducible data.

## INTRODUCTION

An estimated 1.6 - 3.8 million concussions occur annually in the United States [1]. Approximately 30% of sport-related concussions (SRC) experience postural instability immediately post-injury, while 75.6% report dizziness as a debilitating symptom [2,3]. Postural instability post-SRC has been well documented using numerous methods [3]. Kinetic quiet stance measures observed that concussed athletes have elevated postural sway magnitude and greater sway velocity within 24-48 hours post-SRC [4]. In addition, postural instability has been noted within 48-96 hours post-SRC using complex dual-task and dynamic assessments [5]. However, very little is known about the diagnostic validity of these postural assessments post-SRC.

The purpose of this study is to investigate the diagnostic validity of two postural stability methods, quiet upright stance and a sport-like postural task, within 24-48 hours post-SRC.

## METHODS

Twenty-four NCAA Division I athletes with concussions (CON) (12 female, 12 male; age:  $19 \pm 1$  years) and twenty-four matched controls (NON) (12 female, 12 male; age:  $18 \pm 1$  years) participated in this study. All CON were diagnosed with a concussion by the team physician and evaluated within 24 to 48 hours post-SRC. The NON group consisted of NCAA Division I athletes matched to each CON by gender, sport and sport position with no history of concussion or neurological disorder within the past six months. The NON group was measured during preseason participation screening.

All participants completed three trials of eyes open and eyes closed quiet stance for thirty seconds. Additionally, participants completed a sport-like postural task, the Wii Fit Soccer Heading Game (WFS). The WFS uses a Wii Balance Board (WBB) to control an onscreen avatar via an augmented reality environment, and uses internal center of pressure (CoP) measurements to guide the on screen avatar. With the WBB placed on top of the force platform, the athlete swayed their body in an anteroposterior (AP) and mediolateral (ML) direction to move their avatar in a similar fashion to intercept a series of soccer balls while dodging distraction objects.

During both postural tasks, kinetic data was collected from a single force platform (1000 Hz, AMTI, Model OR-6, Watertown, MA.). Raw CoP time-series data in the AP and ML directions were collected using Vicon Motion Capture software (Vicon Motion Ltd., Version 1.8.5, Oxford, England) and further analyzed using custom software (MATLAB 2010, MathWorks, Inc., Natick, MA). Youden's J Statistic, an empirical measure of maximizing the area under the curve, was used to determine performance of the sensitivity (Sn) and specificity (Sp) of Root Mean Square (RMS), Peak Excursion Velocity (PEV), and Sample Entropy (SampEn) in both the AP and ML directions based off the classification of concussion.

## RESULTS AND DISCUSSION

The Youden's J index revealed that during quiet stance, eyes closed PEV in the AP direction ( $y_i = 0.58$ ) had the highest Sn (0.74) and Sp (0.84) in the classification of concussion. During the WFS, RMS in

the ML direction ( $y_i = 0.79$ ) had the highest Sn (0.84) and Sp (0.94), followed closely by RMS in the AP direction ( $y_i = 0.78$ , Sn = 0.89, Sp = 0.89). When quiet stance and WFS were combined, a total Sn of 0.89 and Sp of 0.95 was observed for the above CoP variables (Table 1). No other CoP variables significantly contributed to the diagnosis of concussion. These findings suggest that in a closely matched sample, eyes closed upright stance PEV in the AP direction has good diagnostic validity when attempting to classify concussion. However, the WFS RMS in the AP and ML direction indicated excellent diagnostic validity. This could be due to the sport-like dual-task components of the WFS. This dual-task paradigm may require the athlete to use increased cortical resources to appropriately meet the demands of the postural task more so than quiet upright stance. Therefore, it is recommended that postural stability assessments include both a static quiet stance and sport-like dual-task component in order to maximize the ability to confirm a concussion diagnosis.

## INTRODUCTION

Bat velocity has been identified as a key indicator of batting performance. Increased bat velocity allows for the batter to have increased decision time on whether or not to swing, decreased swing time, and increased batted ball velocity. Coaches and trainers stress the importance of a strong core and the ability to generate rotational velocity during a swing and its relation to faster bat speeds; however, previous research has shown conflicting results. It has been suggested that because youth batters have less body mass or inertia, they are able to move their segments faster compared to adults (1). Conversely, Escamilla et al. (2) reported adult batters had faster pelvis rotational velocities compared to their youth counterparts. Since rotational velocity does not take into account the subject's mass and energy transfer, there may be a more appropriate measure that is related to batted ball velocity. A more useful relationship might be rotational energy – that is, kinetic energy due to rotation. However to date, no batting research has investigated the relationship between pelvis rotational energy and bat velocity. The purpose of this study was to investigate pelvis rotational energy and its potential relationship to bat swing velocity.

## METHODS

A retrospective review identified 200 baseball batters who had previously been tested in the Motus Global lab, including professional, college, high school, and youth batters (Table 1). During testing subjects were instrumented with 45 reflective markers on anatomical land markers. Kinematic data were collected at 480 Hz using an eight-camera 3D motion capture system (Motion Analysis Corp., Santa Rosa, CA, USA). Each participant was allowed unlimited time to warm-up. A standard batting tee was placed in the middle of the capture

volume and the participant was instructed to swing at a baseball placed on the tee. The batting tee was placed 5 cm in front of the lead foot during the stride of the swing and the height of the tee was set at the mid-height of the thigh. The participant was instructed to hit the ball 'up the middle' with a 'game-effort' swing. Testing was completed once the participant successfully hit eight balls. Kinematic data were calculated as previously described (1). Additionally, pelvis rotational energy was computed by modelling the pelvis as a cylinder, and using anthropometric data to calculate inertial properties of the pelvis. The inertia of the pelvis was computed using equation:

$$I_{pelvis} = \frac{mass_{pelvis} * radius\ of\ gyration_{pelvis}^2}{2}$$

The mass of the pelvis was defined as 14.2% of total body mass and the radius of gyration was defined as 34% of the length of the pelvis. The length of the pelvis was defined as 19.1% of the total body height. Rotational energy of the pelvis was computed using the equation:

$$Rot.\ Energy_{pelvis} = \frac{1}{2} I_{pelvis} \omega_{pelvis}^2$$

Per-participant means for the eight swings were computed for each variable and then group mean and standard deviation were computed. Differences between levels of competition (youth, high school, college, and professional) were analyzed using one-way analysis of variance (ANOVA). When the ANOVA indicated significant differences, post hoc paired *t* tests were performed and a Bonferroni correction for multiple comparisons. Additionally, Pearson correlation coefficients were calculated to evaluate the relationship between bat velocity and both pelvis rotational velocity and pelvis rotational energy. The level of significance was set at  $p < 0.05$ .

## RESULTS AND DISCUSSION

Body height, weight, and bat velocity increased significantly with level of play (Table 1). However, there were no differences in pelvis rotational velocity (Table 1) across the competition levels. Even though rotational velocities were not significantly different across levels, there was a trend of decreasing pelvis rotational energy between competition levels with youth batters having the greatest amount. Similar relationships were shown in Escamilla et al.'s (2) study that found no difference in pelvis rotational velocity between adult and youth batters. Conversely, Dowling et al. (1) indicated youth batters had faster pelvis rotational velocity but slower bat velocity.

Pelvis rotational velocity had no correlation to bat velocity within the total group ( $r = 0.12$ ), but was significantly correlated to the professional subgroup ( $r = 0.52$ ) (Table 2). Professional batters were able to transfer more energy to the bat, creating increased bat velocity. The authors of the current investigation believe that the muscle mass about the pelvis, which is involved in the stretch shortening cycle of the lower body during rotation, is essential in transferring energy to the core and upper body during rotation. When comparing batters of different skill level but the same height and weight, researchers established skilled batters had faster bat velocity compared to the unskilled group (3,4). Pure segment rotational velocity may not play as significant a role as initially thought in contributing to bat velocity, although it may still be important once ideal muscle mass is achieved. Therefore, velocity might not be the best measure for bat performance.

Table 1. . Comparison of demographic and kinematic data between competition groups (mean±SD)

	Youth (n=50)	HS (n=50)	College (n=50)	PRO (n=50)	Significance
Age (years)	12±1	16±1	21±1	21±2	*a,b,c,d,e
Body height (cm)	157±12	176±7	180±6	184±5	*a,b,c,d,e,f
Body weight (kg)	48±14	76±20	84±10	91±8	*a,b,c,e,f
Bat velocity (m/s)	25±3	29±3	34±2	36±2	*a,b,c,d,e,f
Pelvis rotational velocity (°/s)	690±88	684±66	673±59	650±71	
Pelvis energy (J)	5±2	10±3	11±2	12±3	*a,b,c,e

Note: HS= high school; PRO= professional. \* Significant differences ( $p < 0.05$ ) among levels. Post-hoc differences between (a) youth and high school, (b) youth and college, (c) youth and professional, (d) high school and college, (e) high school and professional, and (f) college and professional.

When the same breakdown was conducted with pelvis rotational energy, there was a higher correlation to bat velocity ( $r=0.76$ ). Even when batters were separated into competition levels, the correlations are still moderate-strong ( $r = 0.34-0.76$ ). This current study is the first study to investigate the relationship between segmental energy and bat velocity and the authors were able to ascertain a high correlation between the two. Adopting the use of this measurement to further understand how pelvic energy contributes to bat velocity may better describe the differences seen across age groups and different level of play. Further research is needed to understand how this model would apply to other body joints (elbow and knee) and segments (trunk) within the kinetic chain.

## CONCLUSION

Bat velocity had greater correlation to pelvis rotational energy than to pelvis rotational velocity across all batters and within sub-groups. Pelvis rotational energy may be a better measure for understanding a batters ability to generate bat velocity.

# Does the Fibonacci Sequence Predict Segmental Velocities of the Overhand Throw?

Wendi Weimar, Jessica Washington, Brandi Decoux, Sarah Gascon, Gretchen Oliver

Auburn University, Auburn, AL, USA

email: weimawh@auburn.edu, web: <http://www.education.auburn.edu/kinesiology>

## INTRODUCTION

In 1202 Leonardo Pisano published his writing on mathematics in a text entitled *Liber Abaci*. Amongst other topics, he discussed how rabbits multiply in an idealized environment. This sequence, later labeled as the Fibonacci Sequence, is a numerical series in which the resultant sum is a computation of the previous two numbers of the sequence. Specifically, the equation is:

$$X_{n+1} = X_n + X_{n-1}$$

A fundamental representation of this mathematical sequence is 0,1,1,2,3,5,8,13, etc... Further, a mathematical ration of the successive numbers in the aforementioned sequence has often been referred to as the Golden Ration (1.618). While the Golden Ratio has provided aesthetic pleasure in nature and artistic expressions, such as the Golden Spiral seen in spiral galaxies and the quantity of flower pedals, it has also been observed in the human body. Specifically, this ratio has identified the relationship between the lengths of several adjacent anatomical segments, such the upper arm to the forearm, the metacarpals to the phalanges and the upper leg to the lower leg. Additionally, this relationship has also been found in the temporal components of the human gait cycle [1]. However, the identification or correlation of this sequence on various complex movements and the performance outcomes of those motions remain limited. Therefore, the purpose of this project was to determine if the segmental linear velocities during the overhand throw increased in a manner predicted by the Fibonacci Sequence.

## METHODS

The utilized in this project was not collected for the purposes of this project. Instead the data was collected as part of a normative softball study

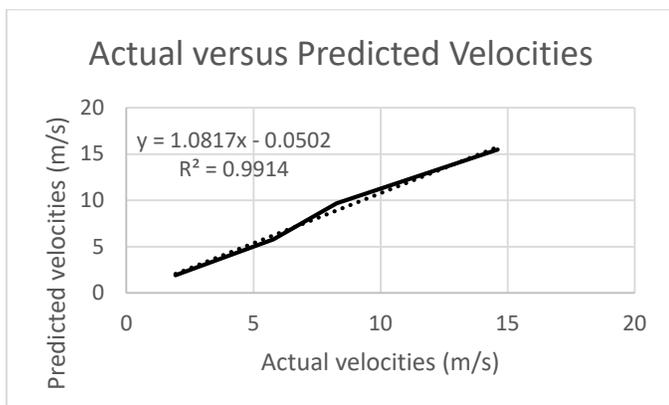

currently being undertaken in the Sports Medicine and Movement Laboratory at Auburn University in an attempt to identify pathomechanics and improve injury prevention in softball athletes. The throwing data used in this project was from six NCAA Division I collegiate softball players ( $165.3 \pm 6.2$  cm;  $67.1 \pm 5.0$  kg;  $20.8 \pm 1.2$  years). Kinematic data were collected using The MotionMonitor™ motion capture system (Innovative Sports Training, Chicago IL) at a rate of 100Hz. Prior to testing, participants had 15 electromagnetic sensors attached at the following locations: (1) the posterior/medial aspect of the torso at C7, (2) posterior/medial aspect of the pelvis at S1, (3-4) bilateral distal/posterior aspect of the upper arm, (5-6) the bilateral flat, broad portion of the acromion of the scapula, (7-8) bilateral distal/posterior aspect of the forearm, (9-10) bilateral distal/posterior aspect of the lower leg, and (11-12) bilateral distal/posterior aspect of the thigh, (13) superior aspect of the midfoot, (14) superior aspect of the throwing hand at the second metatarsal, (15) and the occipital protuberance. Each participant executed five maximal effort throws to a teammate located at a distance of 60 feet.

To investigate if the summation of speed principle [2] follows a Fibonacci Sequence during the proximal to distal sequencing of the overhand throwing motion, linear velocity of the pelvis, upper arm, lower arm and hand were extracted for analysis. While the trunk was not included in this sequence, due to different computations in segment velocity, it should be noted that the trunk was included as a component of the Fibonacci Sequence. Therefore, the pelvis velocity was chosen as the beginning of the Fibonacci Sequence. The velocity of the pelvis served as the beginning of the series and the sequence was constructed by adding the previous two values together to the next value. In addition to identifying how well the actual velocities compared to the Fibonacci predicted

values, five coaches and one biomechanist who studies throwing, were asked to rank the throwers on the basis of best form, hardest throw and best thrower. This practical knowledge was valuable in evaluating the significance of matching or not matching the Fibonacci Sequence.

## RESULTS AND DISCUSSION

Fitness of the prediction was determined using several methods. The first process was through a regression analysis, which yielded an R2 value of 0.994 (Figure 1). Secondly, Bland Altman plots were constructed and all scores fell within the 95% confidence interval. Moreover, the root mean squared error was also calculated and are presented in Table 1.

**Figure 1.** The regression of the predicted to actual velocities of the proximal to distal sequence.

	Pelvis	Upper Arm	Forearm	Hand
RMSE	NA	0.703	2.019	2.657

**Table 1.** The root mean squared error measures for each segment. The pelvis values are not available because the pelvis for the actual and predicted were identical.

The results of the analysis indicate that the Fibonacci Sequence can act as a predictor of the actual velocities of the proximal to distal sequence of the overhand throw. While the computations

demonstrated strong numerical similarities, some differences in numerical values did exist and should be addressed. Specifically, a participant, whose velocities varied the most from the predicted velocities, is considered to be a utility player. As such, she is required to adapt her throwing mechanics based on her position on the field. For example, her throwing motion while playing third base, may be different than when playing second base, or even catching. Therefore, future research should consider capturing data from players while on the field, in different playing positions. For a practical opinion, five coaches and one biomechanist who studies throwing were consulted on which participant had the best form, had the hardest throw and was the best thrower. Not surprisingly, each person consulted had a different rubric upon which they based their opinion. However, all but one indicated that they thought that the person whose actual velocities matched the predicted velocities the closest had the hardest throw (this was not proven by the release velocity). Further, when animations of the person that most closely matched the predicted velocities and the person who least matched the predicted velocities were compared in animation form, all coaches/scientist chose the thrower with the velocities that best match the predicted values.

## CONCLUSIONS

This project has indicated that the Fibonacci Sequence can predict the segmental velocities of experienced throwers that follow the proximal to distal sequence. Further research is needed to determine if this sequence can be used to identify level of performance or even predisposition to injuries.

# ULNAR COLLATERAL LIGAMENT PROPERTIES IN BASEBALL PITCHERS THROUGHOUT A SINGLE COLLEGIATE SEASON

<sup>1</sup> Christopher Curran, <sup>1</sup> Patrick Rider, <sup>1</sup> Anthony Kulas, <sup>1</sup> Zachary Domire

<sup>1</sup> East Carolina University, Greenville, NC, USA

email: curran@students.ecu.edu

web: <https://www.ecu.edu/cs-hhp/exss/biomechlab.cfm>

## INTRODUCTION

Approximately 50% of baseball pitchers will have shoulder or elbow pain in the course of a single season [1]. Perhaps the most serious injury for a baseball pitcher is a full tear of the ulnar collateral ligament (UCL) in their throwing arm. The UCL is the primary stabilizer of the medial elbow and is critical to its stability in overhead throwing motions such as baseball pitching [2]. The prevalence of UCL reconstruction, or “Tommy John” surgery, has dramatically increased in the last 20 years in both youth and professional athletes [3].

UCL length and thickness, and the ulnohumeral (U-H) gap have been shown to change in the throwing arms of baseball pitchers compared to their non-throwing arms [4]. Research has shown significant increases in UCL thickness and UCL substance heterogeneity from pre- to post-season in a sample of high school pitchers [5]. However, it has not yet been reported if these changes are consistent in collegiate baseball, which has a much greater work load than high school pitchers.

The primary purpose of this study was to examine changes in UCL structural properties over the course of a collegiate baseball season. A secondary purpose of this study was to examine bilateral differences in UCL structural properties from pre-season to post-season in collegiate baseball pitchers.

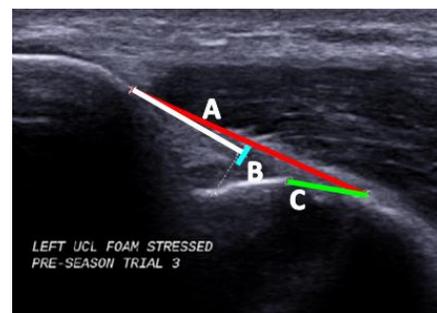

## METHODS

UCL structural properties were measured using ultrasound imaging for 10 healthy NCAA Division I collegiate baseball pitchers ( $19.0 \pm 1.3$  yrs). After signing informed consent, bilateral imaging was performed during a pre-season imaging session for both throwing and non-throwing arms. Unilateral imaging was performed bi-weekly throughout the

baseball season to track the structural properties of the UCL in the participants’ throwing arms. At the conclusion of the participants’ regular season, bilateral imaging was again performed to measure post-season structural properties. All imaging data were collected using the Aixplorer ultrasound system (SuperSonic Imagine, Aix-en-Provence, France).

Imaging was performed with participants laying supine, stabilized in  $30^\circ$  of elbow flexion using an adjustable-width arm position splint. Only the upper arm was supported by the splint, allowing for frontal plane movement at the elbow. The joint was loaded by placing a 1-kg weight in the participants’ hand.

UCL length and thickness, and U-H gap space were measured and recorded for each participant (Fig. 1). UCL length was measured from the ligament’s origin on the medial epicondyle of the humerus to its insertion on the ulnar tubercle. UCL thickness was measured as the width of the ligament at 50% of its length. U-H gap space was measured as the distance from the most distal-medial aspect of the trochlea of the humerus to the most proximal-medial aspect of the ulna. U-H gap space was also measured with the forearm supported, and the difference between conditions was termed U-H Gapping.

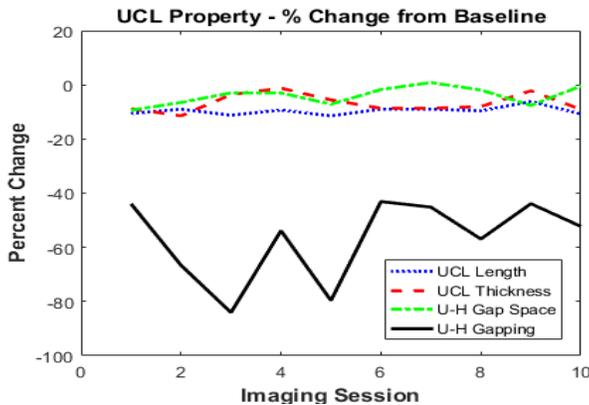

**Figure 1:** B-mode ultrasound image. A) UCL length, B) UCL thickness, C) U-H gap space.

Measurements for each property were taken as the mean value from three trials during each imaging

session. Changes in UCL properties throughout the season were reported as percent change from the initial imaging session. Time by Arm 2x2 ANOVAs were performed to examine differences in the structural properties from pre-season to post-season.

## RESULTS AND DISCUSSION

One participant did not to complete the study following the pre-season imaging. Percent change results for each outcome measure are displayed in Figure 2. Bilateral measurements for Pre- and Post-Season imaging sessions are shown in Table 1.

**Figure 2:** Percent change in UCL Structural Measurements of the throwing arm.

There was a main effect for throwing vs non-throwing arm for UCL Thickness, and for Pre- vs Post-Season for UCL Length and UCL Thickness. There were no interaction effects for any of the structural properties. Additionally, there were no trends seen in the structural properties throughout the course of the baseball season.

The decreases in U-H gap space and U-H Gapping in the participants' throwing arms during Post-Season imaging may have been a result of the elevated

throwing load or possible increased joint inflammation, preventing full the medial joint from fully expanding. The large decrease in U-H Gapping shown throughout the season may be indicative of a change in medial joint laxity during periods of elevated loading, and thus may be a useful metric for evaluating injury risk in pitchers. Additionally, fluctuations in these measurements throughout the season may be a result of time from last pitching performance, as we were unable to control for that variable in this study.

## CONCLUSIONS

U-H Gapping may be a good measure for evaluating injury risk, however it showed high variability in the present data. This may be a result of changes in different elbow structures, such as activation in the elbow flexor muscles. This suggests the need for additional methods of measuring UCL properties, including the ligament's material properties (such as modulus) in order to better identify injury risk in pitchers. Additionally, controlling time between an individual's last pitching appearance and the imaging may provide additional insight into the acute effect of pitching on the properties of the UCL.

# DIRECTIONAL COMPRESSION AND MUSCLE ACTIVITY IN A RETIRED WORLD CUP ALPINE SKIER

Linnea Zavala, Cory Snyder, James Becker, John Seifert

Montana State University, Bozeman, MT, USA  
email: james.becker4@montana.edu

## INTRODUCTION

Directional compression garments are designed to exert a perpendicular force on the underlying tissues to create an increased pressure gradient within the tissue [1]. Two recent studies reported that in competitive alpine skiers, directional compression results in reduced muscle activation, kinematic changes at the hip and knee, and increased fatigue resistance [2, 3]. However, it is not known whether the beneficial effects of directional compression are limited to competitive skiers, or if similar changes in muscle activation would be observed in recreational skiers who are technically proficient in using a carving technique.

The purpose of this study was to examine changes in muscle EMG patterns throughout a day of skiing for a recreational skier technically proficient in using the carving technique when skiing with and without lower body directional compression clothing. In the compression condition, we hypothesized lower EMG intensities (RMS) at the end of the day for vastus lateralis (VL), adductor longus (AL), rectus femoris (RF), gluteus medius (GMed), and gluteus maximus (GMax).

## METHODS

The subject was a 54-year-old, female, retired alpine ski racer who competed on the World Cup circuit from 1979-1990. Additionally, the subject has coached 20 plus years, bringing a unique background and technical proficiency with the carving technique to this study.

The participant skied two days, two weeks apart, first with directional compression tights (Opedix Kinetic Health Gear, Denver, CO, USA) and the second without. Snow and weather conditions were

similar between testing days. Bipolar Ag/AgCl surface EMG electrodes (Trigno, Delsys Inc, MA, USA) were placed on the right leg over the mid belly of the VL, AL, RF, GMed, and GMax muscles. Prior to placing electrodes skin at the placement site was gently abraded and cleaned with rubbing alcohol. Raw EMG signals were amplified at the source and recorded at 1500 Hz (Tringo Personal Activity Monitor, Delsys INC, MA, USA). A gyroscope (Motion Sensor, Electronic Realization, Bozeman, MT, USA) mounted to the back of the boot was used to track ski edge angle at 100 Hz.

Two measurement runs on were taken on each assessment day, one in the morning and one in the afternoon. A course of 12 turns around brush gates, set with 10 m between gates was used for the measurements. Between measurement runs the participant skied their choice of runs throughout the ski area. On the second testing day, this exact sequence of ski area runs was replicated.

Gyroscope data was used to determine turn times by finding the midpoints between maximum and minimum edge angles. For each turn, average root mean squared (RMS) amplitudes from the EMG were found by filtering with a band-pass and then using a 125 ms window with a 62.5 ms overlap. A 2x2 repeated measures ANOVA was used to compare morning and afternoon turn times and RMS for the compression and non-compression conditions (significance level of 0.05).

## RESULTS AND DISCUSSION

No difference in turn times was found for either compression or time of day conditions. RF demonstrated a main effect of condition ( $F = 72.633$ ,  $p < 0.0001$ ) with average RMS values

being lower in the compression condition than the non-compression condition (Table 1). GMed also demonstrated a main effect of condition ( $F = 23.582$ ,  $p < 0.005$ ) with average RMS values being lower in the compression condition than the non-compression condition (Table 1). For all other muscles there were no effects of condition, time of day, or time of day by condition interactions. A ski peak edge angle difference of 4.6% was also observed between the compression (61°) and non-compression (64°) conditions, although these results were not statistically analyzed.

A decrease in muscle activation for skiers in compression garments was previously observed [2,3]. Our findings are consistent with these results for RF and GMed. GMed activity is part of the steering phase of the carving technique and a lower average RMS value in this muscle may be directly related to the decrease in edge angle. In the compression condition we observed a strong decrease in RMS for RF muscle and not for VL. Previous studies have shown a decrease mean frequency in VL and RF as associated with skiing fatigue [4]. Thus, we would expect to see some change in VL activity with fatigue.

A decrease in RMS under a compression condition is not unique to directional compression garments. In 2016, Wang et al. reported a decrease in EMG amplitude in a compression condition for isokinetic measurements of quadriceps muscles under various movement speeds [5]. However, as the purpose of directional compression is to target specific muscles, directional compression in the garment used appears to target RF and GMed, which are

applicable to skiing, although other muscles like VL may be important as well. The effects of decreased RMS on fatigue throughout the day must be considered, but these results provided no detectable differences from morning to afternoon.

## CONCLUSIONS

A retired world cup skier, highly efficient in the carving technique, was observed for two full days of skiing. When wearing directional compression, a decrease in average RMS activity in rectus femoris and gluteus medius was observed. Average peak edge angle also decreased by 4.6% in the compression condition, although this value was not tested for statistical significance. No differences in turn duration or in time of day were observed. Further investigations are necessary to determine the effects that decreased muscle activity due to directional compression garments may have on skier fatigue.

## INTRODUCTION

Routine training for baseball pitchers includes throwing off of the mound as well as high effort flat-ground throws, sometimes greater than 92 m. In theory, increased throwing distance requires the throwing arm to 1) generate and withstand greater loads, 2) generate faster arm speed, and 3) move through a greater range of motion (1). Even though long distance throws are used for conditioning and rehabilitating pitchers, few studies have been conducted examining the effects of long distance throwing and elbow stress. Fleisig et al. (1) used 3D motion analysis to compare pitching and long toss biomechanics and reported maximum distance throws produced greater elbow varus torque than shorter flat-ground and mound throws (1). In contrast, Slenker et al (2) reported no differences in throwing mechanics among all long-toss distances.

Long-toss research is limited likely because it is difficult to complete distance throws in laboratory settings. It is now possible and easier to analyze throwing arm biomechanics using the recently developed pitching sleeve, motusBASEBALL™. This wearable device measures important throwing arm biomechanics and provides researchers the ability to analyze pitchers in field settings.

The purpose of this study was to use the motusBASEBALL to test for differences among baseball pitching and four long-toss distances. Findings from this study may help to better design optimal throwing programs for baseball pitchers.

## METHODS

The participants were college baseball pitchers (n=19; age  $19 \pm 1.3$  years;  $88.3 \pm 8.4$  kg; and  $73.9 \pm 18.6$  cm). During testing, participants were

instrumented with a motusBASEBALL™ sensor and sleeve (Motus Global, Rockville Centre, NY). Participants were allowed to complete their preferred warm-up routine with warm-up throws limited to 16 m. Once the pitcher signaled readiness, five throws were completed at each distance: 27 m, 37 m, 46 m, 55 m. Then, 5 fastballs were thrown from a regulation mound to a catcher (18.3 m away). During long-toss, no instruction or constraints were given for trajectory or crow-hop footwork.

For each throw, the sensor recorded ER (°), elbow varus torque (Nm), and arm speed (°/s). Shoulder ER was measured in reference to the ground. Zero degrees means the forearm is parallel to the ground and pointing anterior. Elbow varus torque was the peak torque measured in Nm. Arm speed was identified represented the maximal rotational velocity of the forearm during the throwing motion.

Data were summarized by computing pooled means and standard deviations for all variables at each throwing distance. For each variable of interest (ER, elbow varus torque, arm speed) a 1-way repeated measures ANOVA was completed with an alpha of 0.05. Post-hoc Tukey analysis were used to determine where significant differences existed among the throws.

## RESULTS AND DISCUSSION

During long toss, pitchers appear to externally rotate their shoulder to an extreme range of motion; the range for the long tosses was approximately 159°-170°. Interestingly, the external rotation achieved appeared to increase slightly as the long toss distance increase. For the two longest throws (46 m & 55 m), the shoulder was externally rotated an additional 5-8° than the shortest throw (27 m). Comparing ER

values from mound pitching to long toss is problematic since the mound has an incline of approximately 8° from the flat ground. The sensor measures ER relative to the ground, not the trunk, and does not account for the incline. Therefore, ER was underestimated (by the slope of the mound). This likely explains why the ER achieved during mound throws was significantly less than all long toss throws. Motus is currently developing a second generation, five device system that will address this issue by comparing the player’s shoulder motion relative to the torso instead of the ground

There were no differences found in elbow varus torque between long toss throw distances as well as mound throws. Interestingly, for all conditions, the means were quite close (53-55 Nm). These findings suggest that all long toss throws generate high magnitude elbow varus torque. Further, the effort of the throw appears to be more related to the magnitude of the varus torque than the distance of the throw. Similarly, for arm speed, the ANOVA revealed no significant findings. Again, for all conditions, the means were quite close (5460-5589°/s). These findings suggest that all long tosses generate arm speed similar to the pitch. These data also suggest

that the effort of the throw determines the magnitude of the arm speed (more so than the distance of the throw).

## CONCLUSIONS

It appears overall that the magnitude of long toss throwing biomechanics are relatively similar to pitching. These findings were consistent with those previously reported by Fleisig and colleagues (1). Coaches and clinicians should be aware that long-toss throws appear to be strenuous on the throwing arm (similar to the baseball pitch). This should be considered when using long-toss programs for practice and rehabilitation.

## INTRODUCTION

The biomechanics of the lower extremities are a key component in the efficiency of the pitching motion to deliver an effective, yet safe, high-velocity pitch. However, researchers have focused primarily on the kinematics and kinetics of the upper extremity to reduce the risk of injury in throwing athletes. Few studies focus on quantifying lower extremity pitching biomechanics. However, significant shoulder and knee injuries have begun to be diagnosed in younger, adolescent athletes [2]. Kinematic and kinetic variables related to lower extremity movements could provide important information when trying to understand injury mechanisms in the upper extremity in pitchers.

One important skill for high-velocity pitchers is the ability to drive the body over a stabilized stride leg. The landing leg serves as a pivot to transform the forward and downward vertical motions of the trunk into rotational motions of the trunk and arm segments that ultimately generate ball velocity. Studies have shown that greater momentum can be generated by hip extension and abduction and knee extension of the pivot foot, thus improving the quality of the high-velocity pitch [3].

The purpose of this study was to investigate the relationships between the lower limb kinematics and kinetics of adolescent baseball pitchers compared to more skilled pitchers.

## METHODS

Fourteen youth baseball pitchers (age: 11.6±1.3 years, height: 1.59±0.12 m, mass: 48.5±13.4 kg, velocity: 56.6±6.9 mph, 11 right-handed/3 left-handed) were recruited for this study. All testing occurred in an indoor research lab equipped with a custom pitcher's mound with two embedded force

plates; one under the itching rubber and one under the landing area. Reflective markers and marker clusters were attached to each pitcher's upper and lower extremity body segments. Kinematic data were recorded with a 14-camera motion capture system at 250 Hz. Ground reaction forces acting on the drive (rear) and stride (front) leg were sampled at 1000 Hz, and a radar gun was used to record velocity.

Each pitcher threw 15 maximal effort fastballs toward a hanging strike zone 46 ft from the pitching rubber. The fastest strike thrown for each pitcher was chosen for analysis. The variables analyzed were ground reaction forces (GRF) of the stride leg; angular velocity and orientation of the pelvis; and joint kinematics and kinetics of the hip, knee, and ankle joints of the stride leg.

All variables were measured from the instant of stride foot contact (SFC) with the force plate until ball release (BR). The hip, knee, and ankle internal rotation moments were calculated with an inverse dynamics procedure. All joint moments were normalized, and means and standard deviations of these variables were compared to other studies that observed similar kinematics of adolescent and collegiate pitchers [3,4].

## RESULTS AND DISCUSSION

The subject pool for this study was younger than the typical adolescent, high school, or collegiate subject pools of previous studies. Many of the kinematic variables were significantly lower than those described in the literature, likely due to differences in size, development, experience, and muscle strength. However, comparing the ankle plantarflexion (PF) and dorsiflexion (DF) angles and pelvic orientation at SFC and knee flexion/extension angle and moment at BR, the

averages collected in this study fell within the standard deviation of comparable values collected in similar studies (Table 1) [3,4].

The comparisons of the measurements of this study to the literature shed insight into the effects of lower extremity biomechanics on the other aspects of baseball pitching in adolescents. One such correlation is the open foot angle observed at SFC. Open foot placement can cause the pelvis to rotate too soon, which is reflected in the pelvic orientation values. From the current study, the average PF/DF angle of 9.2° was less compared to literature PF/DF value of 17.8° and 13.3°, indicating that these subjects adopted a more open foot placement. Improper foot mechanics and pelvic orientation can produce additional anterior shoulder force and medial elbow force beyond the usual forces applied during the pitching motion [5].

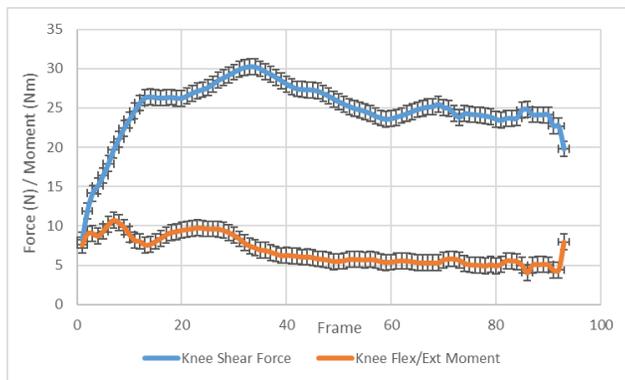

Figure 1. Mean knee shear force and flexion/extension moment on the stride leg during the pitching motion (n=14 subjects).

The moment at the knee and the hip joint angle of the stride leg in collegiate pitchers helps to drive and rotate the knee of the lead leg to accelerate the body forward [3]. The joint kinetics measured in this study were less than those observed in collegiate pitchers, and the assumed conclusion is

that these observed differences are attributed to muscular activities around the hip and knee [3]. While the average moment at the knee is relatively stable due to the moment at the hip, the knee of the lead leg does undergo extensive amounts of shear force. From SFC to BR, the knee shear force reached a maximum value of 30.3 N, which is almost 9% of the average body weight of an 11 y/o boy (Fig. 1) [4]. Forces of this magnitude with high moments and velocity can lead to injury, especially in adolescent knees with little stability. In addition, collegiate pitchers have shown a greater ability than their younger counterparts to generate the momentum of the lower limbs to increase energy of trunk rotation and arm motion [6].

## CONCLUSIONS

In an increasingly competitive environment, implementing current, consistent evidence to identify known risk factors is a key step in decreasing injury risk of adolescent baseball pitchers. Further research should expand upon unsafe or hazardous pitching mechanics and the effectiveness of pitching protocols short- and long-term on safe, effective pitching techniques for adolescent pitchers.

email: bs07343@georgiasouthern.edu

## INTRODUCTION

Postural instability is a cardinal sign of a sport-related concussion (SRC) and is commonly assessed by quiet upright static stance [1-4]. However, this type of postural assessment lacks a dual-task component that is found during sport activity. Research involving dual-task postural performance may be more sensitive to deficits in athletic populations [3]. However, additional research is needed to determine if certain types of sport-like postural tasks that include a dual-task are sensitive enough to measure postural instability post-SRC.

The purpose of this study was to examine the effect of a SRC on postural stability using quiet upright static stance and a sport-like dual-task within 24-48 hours post-injury when compared to matched controls.

## METHODS

Twenty-eight NCAA Division I athletes (male: 15, female: 13, age  $19 \pm 1$  years) diagnosed with a sport-related concussion (SRC) and 28 matched controls (NON) (male: 15, female: 13, age  $18 \pm 1$  years) participated in this study. The CONC group was diagnosed with a concussion by the team physician and evaluated within 48 hours post-concussion. The NON group was matched to the

CONC group based on gender and sport, with no prior history (within 6 months) of concussion or neurological issues. All participants completed three eyes open (EO), eyes closed (EC), and sport-like dual-task (SDT) trials. Both the EO and EC tasks consisted of 30 seconds of quiet upright stance, while the SDT was performed over a 62 second interval using the Wii Fit Soccer Heading Game. During the SDT, participants had to control an onscreen avatar while standing on a Wii Balance Board (WBB). The participant shifted their weight to head soccer balls, while avoiding similarly shaped, sized, and colored objects. All participants stood on top of (via the WBB) a single force platform (1000 Hz, AMTI, Model OR-6, Watertown, MA.). Raw kinetic data was exported into MATLAB (MATLAB 2010, MathWorks, Inc., Natick, MA) and further analyzed. Mean Root Mean Square excursions (RMS), Peak Excursion Velocity (PEV) in the anteroposterior (AP) and mediolateral (ML) were calculated per postural condition and exported into SPSS (IBM Inc., version 23, Chicago, IL) for further analysis. Four MANOVAs were run comparing mean differences between groups, with follow up t-tests.

## RESULTS AND DISCUSSION

The results revealed in the EC AP condition, SRC athletes had significantly greater PEV ( $p=0.038$ ) when compared to matched controls (Table 1). In the EC ML condition, athletes had significantly greater RMS ( $p=0.031$ ) than the matched controls. In the SDT AP condition, the results revealed that the CONC athletes had significantly greater PEV ( $p=0.003$ ) and RMS ( $p<0.001$ ) (Table 1). In the SDT ML condition, the CONC athletes had significantly lower PEV ( $p=0.002$ ) and RMS ( $p<0.001$ ) than the NON athletes (Table 1). These findings indicate that postural instability is only present during quiet upright static stance in eyes closed conditions in the current sample. However, during the SDT greater sway magnitude and increased PEV was noted in the AP direction while a reduced sway magnitude and reduced PEV was observed in the ML direction. This could indicate that CONC attempted to adopt a more conservative approach to complete the SDT in the ML direction, while simultaneously being unable to control postural sway in the AP direction. As such, sport-like postural assessments may be more sensitive to postural instability post-SRC due to the increased cognitive load imposed by the SDT. In conclusion, these results suggest that both quiet upright static

stance and SDT can detect postural instability post-SRC.

## INTRODUCTION

Anterior cruciate ligament (ACL) injuries account for 45% of all injuries resulting in 10 or more days of lost participation for athletes, they are also associated with long term health consequences and large financial costs because of surgery [1], [2]. Some risk factors of non-contact ACL injuries include a rapid valgus collapse of the knee joint while near full extension coupled with internal rotation of the tibia, faulty neuromuscular patterns, and anatomical predispositions [3]. The majority of these injuries are seen with dynamic sports movements such as cutting [4].

Limb dominance and sex have also been suggested to play a role in ACL injury risk. The dominant limb is categorized as the limb used for the horizontal movement of the bodies center of mass (i.e., propulsion), whereas the non-dominant limb is used for the vertical movement of the bodies center of mass (i.e., posture and support). Patterns between limb dominance and sex were discovered in an epidemiology study that showed males were more likely to injury their dominant limb ACL (74.1% of the time) while females injured their non-dominant limb ACL more often (68% of the time)[5].

While sex related differences have been reported between the risk of injury more research is needed on the biomechanics of cutting on the dominant and non-dominant limbs to better understand ACL injury risk related to sex and limb differences.

## METHODS

Kinematic and kinetic data was recorded on 9 male and 7 female physically active subjects (age:  $21.06 \pm 2.02$  years; mass:  $75.13 \pm 11.91$  kg; height:  $1.76 \pm .079$  m) with a history of participation in a sport

involving unanticipated cutting. Subjects were excluded if they had any previous ACL injuries, current lower extremity injuries or pain, or neurological or physiological problems that would prevent them from running and cutting. The cutting tasks were captured using a 12 camera Vicon motion capture system (VICON Inc., Denver, CO, USA) collecting at 200 Hz and two AMTI force platforms (AMTI Inc., Watertown, MA, USA) collecting at 2000 Hz with a modified Plug-In Gait marker set. Sidestep cutting was done at a 45 degree angle to the right and left, randomized with trials of running straight or running and stopping in order to make the sidestep cutting maneuvers unanticipated. Frontal, and sagittal initial contact angles at the knee joints, as well as peak vertical ground reaction force normalized to body weight were calculated using Visual 3D software (Version 5.0, C-Motion, Germantown, MD, USA) A repeated measures analysis of variance was performed to test the differences between limb dominance and sex.

## RESULTS AND DISCUSSION

A summary of the kinetic and knee kinematic data is presented in Table 1. As expected, it was found that males had significantly larger ground reaction forces compared to females ( $p < .05$ ). Although no other significant differences were found, it is important to note a few patterns apparent in the means of the different variables. Based on limb dominance, females had smaller initial contact flexion angle on their non-dominant limb compared to their dominant limb, while males showed larger ground reaction forces and a smaller initial contact flexion angle on their dominant limb compared to their non-dominant limb. Between sexes, on the dominant limb males had greater ground reaction forces compared to females, while on the non-dominant limb Females had smaller initial contact knee flexion angles, as

well as a greater abduction angle at initial contact when compared to males.

ACL injuries are known to be multifactorial in nature meaning there is not simply one cause, rather a set of conditions which increase the likelihood of the injury occurring. Many previous researchers have suggested that during cutting when the knee angle of the plant leg is less than 40 degrees there is an increased risk of injury, in the current study subject's initial contact flexion angles put them within that increased risk range, males having an even more extended knee position on their dominant limb and females having more extension on the non-dominant limb [6]. In addition, even small degrees of knee abduction have been shown to increase injury risk, in this study females had greater abduction angles at initial contact compared to males on their non-dominant limb which could indicate females are at a greater risk of injury on that limb when compared to males.

## CONCLUSIONS

The findings of this study show preliminary patterns of differential risk between the dominant and non-dominant limb in both males and females, suggesting males may have an increased risk of ACL injury on their dominant limb while females may have an increased risk on their non-dominant limb. Coaches and athletic trainers should consider limb dominance when creating injury prevention workouts while

working with both male and female athletes because ACL injury risk may be heightened by sex as well as limb dominance. Subjects are continuing to be recruited and additional kinetic and kinematic variables are being examined to expand upon these initial findings to help us further understand the influence of limb dominance and sex on lower extremity movement patterns.

# Segment Relationships Adapt to Walking Speed Differently in Healthy Young and Elderly Adults

<sup>1</sup>Jordan J.W. Craig, <sup>1</sup>Adam Bruetsch, and <sup>1</sup>Jessie M. Huisinga

## INTRODUCTION

Walking at non-preferred gait speed alters variability of foot and trunk motion in healthy young and elderly subjects<sup>1</sup>. While it is known that movement variability of individual segments changes relative to gait speed, it is not clear how relationships between segments are maintained when changing walking speeds, and what role these relationships play in maintaining stability. For example, altered trunk movement could stabilize center of mass motion in order to compensate for altered foot movement, thus maintaining whole body stability even though motion of an individual segment is abnormal. Elderly individuals often have weakness or decreased range of motion, which could alter these segmental relationships and ultimately lead to a higher rate of falls<sup>2</sup>. Therefore, it is important to examine how relationships between trunk and foot movement adapt to challenging gait requirements (i.e. speed) in healthy elderly adults compared to the optimal gait characteristics of healthy young adults.

The aim of the current study was to determine the effects of walking at non-preferred speeds on the relationship between foot and trunk acceleration variability in healthy young and healthy elderly adults in the frontal plane. The frontal plane was examined since gait is laterally unstable, and control of movement in this plane requires active control compared to passive control in the sagittal plane<sup>3</sup>. Since lower body segment motion is mechanically tied to upper body segment motion<sup>4</sup>, we hypothesized that the relationship between trunk and foot acceleration variability will not change significantly with varying gait speed in healthy young or healthy elderly adults.

## METHODS

Twenty healthy young adults (mean 23, range 20-30 yrs.) and twenty healthy elderly adults (mean 73, range 67-85 yrs.) with no history of falls participated in this study. All subjects were free from orthopedic or neurological deficits which may affect their walking or balance. Participants walked

on a treadmill at 80%, 90%, 100%, 110%, and 120% of their self-selected preferred walking speed for 3 minutes at each speed. During all walking trials, participants wore tri-axial accelerometers (Opal, APDM, Portland, OR) on their right ankle and sternum that recorded accelerations at 128 Hz for the duration of each trial. Root mean square (RMS) and sample entropy (SaEn) were calculated for the trunk and foot acceleration time series in the frontal plane using a custom MATLAB script. The segment variability ratio was calculated as the ratio of trunk variability divided by foot variability. A 2 (group) x 5 (speed) ANOVA was performed to examine main effect of group (healthy young, healthy elderly) and walking speed (80%-120%) on the segment variability ratio for RMS and SaEn.

## RESULTS

Preferred walking speed was significantly faster in HY ( $1.25 \pm 0.13$  m/s) compared to HE ( $1.10 \pm 0.27$ ) ( $p=0.02$ ). The segment variability ratio using RMS did not exhibit a main effect of group, but there was a main effect of speed ( $F=9.19$ ,  $p<0.001$ ) where the ratio increased as speed increased (Figure 1). There was a significant speed x group interaction ( $F=5.37$ ,  $p<0.001$ ). One-way ANOVA and post-hoc Tukey's test subsequently determined HE demonstrated no main effect of speed, while HY demonstrated a significant main effect of speed ( $F=5.018$ ,  $p<0.001$ ), where the ratio at 120% preferred walking speed was significantly greater than 80% ( $p=0.002$ ), 90% ( $p=0.005$ ) and 100% ( $p=0.022$ ) of preferred walking speed. The segment variability using SaEn showed a main effect of group ( $F=5.83$ ,  $p=0.02$ ) where the ratio was higher for healthy elderly compared to healthy young adults, and also a main effect of speed ( $F=2.77$ ,  $p=0.029$ ) where the ratio decreased as speed increased.

## DISCUSSION

We hypothesized that a constant relationship between acceleration variability at the trunk and foot segment would be maintained in healthy young and healthy elderly individuals regardless of walking speed. Contrary to our hypothesis, our

results show that healthy young adults adapt to non-preferred walking speeds differently compared to healthy elderly adults, as evidenced by how the segmental ratio changes with respect to walking speed. Specifically, the results showed that healthy young adults adapt their RMS segment variability ratio relative to speed, while healthy elderly adults do not adapt. This may in part be due to the attenuation of accelerations from inferior to superior segments being altered in elderly adults compared to healthy young adults<sup>5</sup>. Previous work has shown that healthy elderly adults prioritize head stability at the cost of adopting an altered trunk coordination strategy compared to healthy younger adults<sup>5</sup>. The altered accelerations at the trunk segment in healthy elderly may lead to a change in the relationship between acceleration variability at the trunk and at the feet which is not adaptable to different gait speeds. The SaEn segment variability ratio results show that there is a main effect of speed across both groups, where the ratio decreases as speed increases. However, the main effect of group for the SaEn segment variability ratio shows that the variability structure at the trunk relative to the feet is different between the two groups. Older adults have shown similar approximate entropy values for trunk accelerations compared to young adults<sup>5</sup>, indicating that our observed differences in segment variability ratio using SaEn may stem from altered acceleration variability at the feet during walking.

RMS segmental ratio is  $<1$  in both groups, indicating that the magnitude of acceleration variability is larger at the foot compared to the trunk for all speeds. The SaEn segmental ratio is  $>1$  in both groups, indicating that accelerations at the trunk are less predictable compared to accelerations at the feet for all speeds. These results indicate that

both groups exhibit less overall motion at the trunk relative to the feet, but more irregular patterns of motion at the trunk relative to the feet across walking speeds. None of the healthy elderly adults in the current study had a history of falls, but it is possible that fall-prone elderly adults exhibit further differences in segment variability ratios compared to healthy young adults, which could be a walking characteristic tied to their instability and fall risk.

## CONCLUSIONS

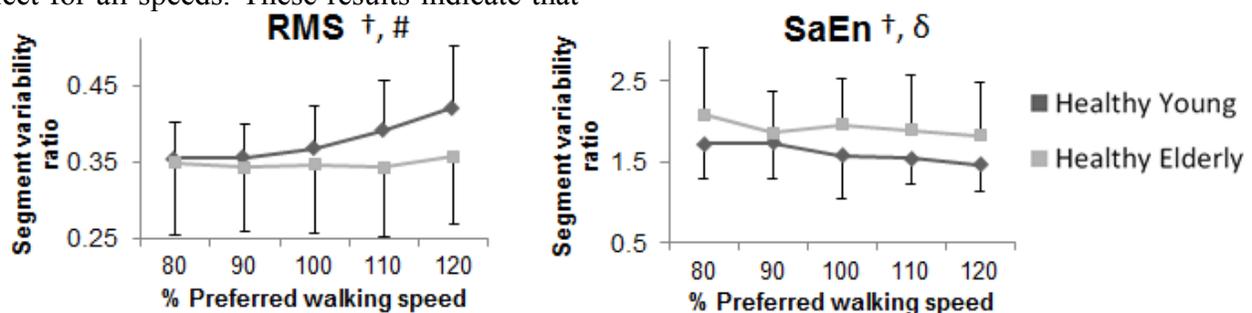

The relationship between trunk and foot motion likely plays a role in maintaining stability during gait. From our current results, it appears healthy elderly adults with no fall history do not adapt their segmental relationships to task requirements in a way similar to healthy young adults. Future studies should examine the segmental variability ratio in elderly subjects with a history of falls to determine how this measure is related to fall risk.

# KINEMATIC COMPARISON OF THREE POSTURAL LIMITS OF STABILITY TESTS IN COMMUNITY DWELLING OLDER ADULTS

Leslie Allison, Chris Wendt, Alyse Armstrong, Richard Greer, Amanda Akridge, and Samantha Wilson

Winston-Salem State University

Winston-Salem, NC, USA

Email: [wendtc@wssu.edu](mailto:wendtc@wssu.edu)

Web: <http://www.wssu.edu/school-health-sciences/departments/physical-therapy/>

## INTRODUCTION

The Functional Reach Test (FR) is assumed to be a 'low tech' postural limits of stability test that predicts fall risk, despite prior studies demonstrating that it may do neither [1,2]. No prior studies comparing the FRT with both the 'gold standard' computerized Limits of Stability® test (LOS), and the recently developed Sway Sled® test (SS), provided a kinematic analysis of how these tests are actually performed [2,3]. The purpose of this study was to compare the movement strategies used to accomplish these three tests.

## METHODS

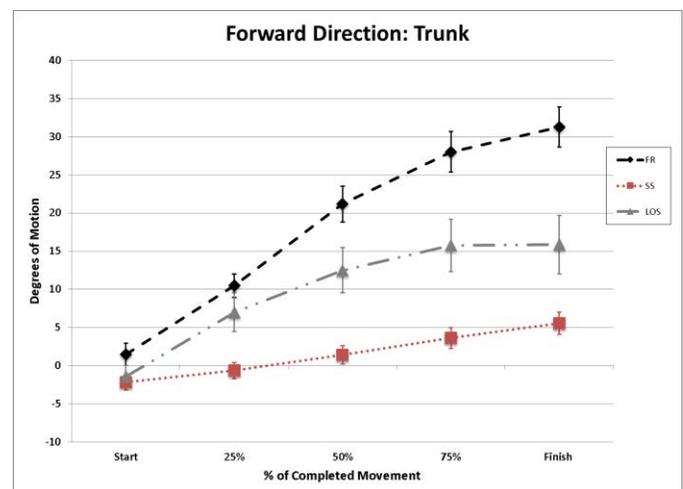

Fifteen healthy, community-dwelling older adults (mean age  $71.4 \pm 3.6$  yrs; range 65-80 yrs) were recruited to participate in the study. The majority were female (73%), white (80%), and taking less than four prescription medications (87%). No participant had a history of falls within the last 6 months.

All consented participants performed three tests (FR, LOS, SS) in one visit to the motion analysis lab. For all tests, participants adopted a standardized, height-based foot placement. Passive reflective markers captured motion at the ankle, knee, hip, pelvis, and trunk. For the FR and SS tests, after test familiarization, three trials in each direction (anterior, posterior, left, right) were performed. For the LOS, one practice test and one scored test with targets in eight directions was performed, with only anterior, posterior, left and right directions used for analysis. Five time points were identified in each completed motion, corresponding to 0% (Start), 25%, 50%, 75%, and

100% (Completion) of maximal trunk excursion (Figure 1). For each joint, a 3x5 (Test x Time) RM-MANOVA with planned, post-hoc, Bonferroni-corrected paired samples T-tests analyses were performed.

## RESULTS AND DISCUSSION

All overall multivariate tests were significant for Test, Time, and Interactions, occurring most in the forward (anterior) and backward (posterior) directions, and most at the pelvis and trunk. Post-hoc results for the Forward direction are reported here. Significant differences between tests occurred most often at the pelvis and trunk, and most as the motion progressed (50%, 75% and Completion). Significant differences were found between FR vs SS, FR vs LOS, and SS vs LOS. Differences were greatest between FR and SS, and least between SS and LOS. For example, mean differences in trunk maximal excursion were approximately 22 degrees FR vs SS, and 10 degrees SS vs LOS (see Table 1).

**Figure 1:** Mean Trunk Movement in the Forward Direction between FR, SS and LOS tests.

Restricted postural limits of stability are a risk factor for falls, and accurate measurement is important [4]. These kinematic results extend and support prior research findings indicating that the Functional Reach Test does not measure limits of stability. This may explain the limited predictive validity of the Functional Reach Test for falls.

## CONCLUSIONS

Performance of the Sway Sled® (SS) test most closely resembled the ‘inverted pendulum’ model of postural limits of stability, followed by the computerized Limits of Stability® (LOS), with the Functional Reach Test (FR) least similar. FR performance involves ‘out of phase’ backward

motion at the knee with compensatory forward motion at the trunk, versus the ‘in-phase’ forward motion of the hip, pelvis and trunk in the SS and LOS.

# EFFECT OF AN OLDER ADULT GOLF TRAINING PROGRAM ON POSTURAL CONTROL

Andrea M. Du Bois, Nicole Marcione, and George J. Salem, PhD

University of Southern California, Los Angeles, CA, USA  
email: amdubois@usc.edu, web: <http://pt.usc.edu/labs/mbrl/>

## INTRODUCTION

Aging is associated with physiological changes that impair quality of life and increase the risk for falls. A laterally directed fall is more likely to result in a hip fracture, a costly and debilitating injury [1]. Therefore, mediolateral (ML) postural control is of the utmost importance for the aging individual; however, static and dynamic ML postural control decline in older adults [2].

Multimodal exercise programs are effective in improving balance and reducing fall risk [3]. Golf is a popular physical activity that includes intermittent periods of walking equivalent to moderate to vigorous exercise intensity [4], bending over to pick up a golf ball, precise putts that challenge the static postural control of the golfer, and high velocity golf swings. The golf swing requires near maximal activation of the proximal hip musculature including the hip abductors [5], a muscle group that mechanically controls frontal plane balance. The golf swing also requires a bilateral, frontal plane weight shift, challenging dynamic postural control [6]. It is plausible that golf could be used as a therapeutic intervention to improve balance and reduce fall risk in older adults. Therefore, the purpose of this study was to assess the changes in ML postural control following a twelve week therapeutic golf intervention.

## METHODS

Two male older adults (67 y and 70 y) were recruited to participate in the study. The participants completed a 12 week comprehensive golf training program twice weekly for 90 minutes per session. The program was designed to gradually introduce the participants to golf beginning with swing training and gradually progressing to a full round of golf on a 3 par, nine hole golf course.

Before and after the golf training program, participants completed a rapid step test to assess dynamic ML postural control. Participants stood with each foot on separate force platforms (AMTI, Newton, MA; 1500 Hz). They first received a red warning light, followed by either a green or yellow light. If there was a green light, they were instructed to step as quickly as possible onto an elevated force platform (15 cm) with their right foot. If they saw a yellow light, they stepped as quickly as possible with their left foot. A total of five trials per limb were collected in a randomized order.

Temporal measures and center of pressure (COP) dynamics were analyzed for each trial. COP was filtered using a 4<sup>th</sup> order zero-lag Butterworth filter with a 5 Hz cutoff. Temporal measures included weight shift time (WT; time from initiation of movement to lift off of the stepping foot) and step time (ST: lift off to contact with the step). During the weight shift, the net ML COP range (RANGE) and the average ML COP velocity (VEL) were calculated. During the step execution, the mean displacement of the ML COP from the average COP position was calculated (MDISP).

Data was averaged across limbs and trials and presented as means and standard deviations. To represent the magnitude of the change, Cohen's *d* effect sizes were calculated for pre-post values.

## RESULTS AND DISCUSSION

Following the golf training intervention, participants were able to improve their performance on the rapid step test—WT decreased (ES 1.77;  $\Delta = -35.75$  ms). During the weight shift, RANGE (ES 8.34, Figure 1A) and VEL (ES 9.21, Figure 1B) increased. Step initiation requires a bilateral weight shift. First, an individual must shift the COP towards the stepping limb, creating an acceleration

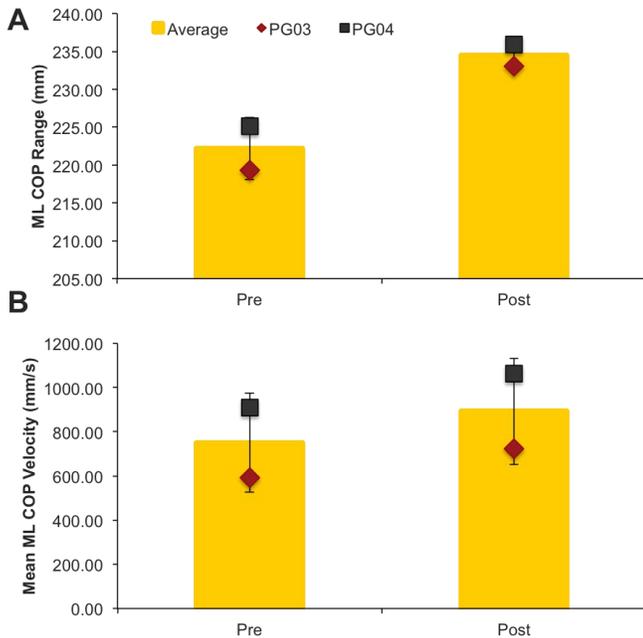

of the center of mass (COM) towards the stance limb. The individual must then rapidly shift the COP towards the stance limb to control the momentum of the COM, allowing for a safe execution of the step [7]. Not only were the participants able to more quickly shift their weight following the golf training program, but they also performed a more dynamic weight shift as demonstrated by the increased RANGE.

2). Thus, the participants not only generated a larger weight shift, but they were better able to control the momentum as demonstrated by the decreased ML COP movements during the step allowing for a more rapid execution of the step.

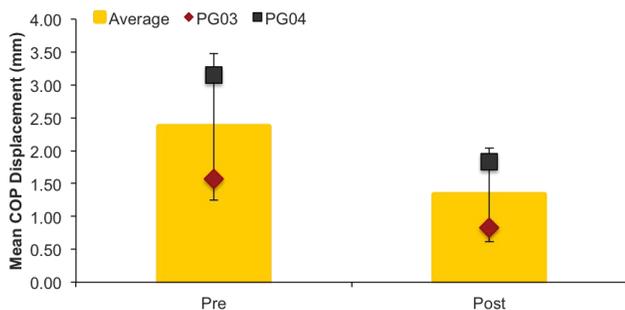

## CONCLUSIONS

Following participation in a twelve week comprehensive golf training program, the dynamic postural control of the participants improved. Participants were able to execute a rapid step more quickly following golf training. This was accomplished by a larger weight shift that accelerated the COM over the stance leg. The individual was also better able to control the momentum generated during the weight shift, allowing for a more stable and rapid step execution.

Golf is a popular recreational activity that includes multiple components including walking the golf course, bending over to pick up a ball, and dynamic golf swings. Multimodal exercise programs have been shown to be most effective in improving balance and reducing fall risk in older adults. Given this knowledge and the preliminary results of this study, it appears that golf can be utilized as an exercise intervention to improve balance and potentially reduce falls in older adults.

**Figure 1:** COP dynamics during the weight shift before (Pre) and after (Post) the golf training program. A. ML COP range B. Mean ML COP velocity.

**Figure 2:** Mean ML COP displacement before (Pre) and after (Post) the golf training program.

ST also decreased following the golf training intervention (ES 1.72;  $\Delta = -138.33$  ms). During the step execution, MDISP decreased (ES 2.55, Figure

# EFFECTS OF ELECTRICAL AND MECHANICAL STIMULATION ON FOOT SENSITIVITY IN HEALTHY ELDERLY SUBJECTS

Claudio Zippenfennig\*, Laura Niklaus, Katrin Karger, Thomas L. Milani

Chemnitz University of Technology, Department of Human Locomotion, Chemnitz, Saxony, Germany

\*email: [claudio.zippenfennig@hsw.tu-chemnitz.de](mailto:claudio.zippenfennig@hsw.tu-chemnitz.de), web: <https://www.tu-chemnitz.de/index.html.en>

## INTRODUCTION

The loss of perception due to reduced plantar sensitivity promotes falling in the elderly [1]. A phenomenon called ‘stochastic resonance’ (SR) attempts to influence sensitive receptors on the footsole with subsensory electrical [2] or mechanical [3] noise stimulation. Positive effects in relation to equilibrium could also be observed with white-noise-like (WNL) electrical stimulation applied to the lateral and medial sides of the knee joint [4]. Furthermore, only one study has investigated the effects of a subsensory noisy vibratory signal after one hour of continuous plantar stimulation [5]. Therefore, the present study investigated the effects of subsensory WNL electrical and mechanical stimulation – applied to the foot sole – on vibration perception thresholds (VPTs) of healthy elderly subjects. Moreover, lasting effects of a short intervention period with these waveforms were examined. We hypothesized that the subsensory electrical as well as mechanical stimulation leads to improvements of foot sensitivity. Lower VPTs were expected.

## METHODS

99 healthy elderly subjects (> 60yrs, 60 ♀ / 39 ♂,  $68.8 \pm 6.0$ yrs,  $165.9 \pm 19.3$ cm,  $75.1 \pm 13.0$ kg) participated in the study. All procedures were executed in accordance with the recommendations of the Declaration of Helsinki and approved by the local ethics committee. Participants were randomly assigned to one of the following groups: vibration (Vi-G), current (Cu-G), control (Co-G), or one of two placebo (PI-Gs). VPTs were measured after a five-minute intervention with either subsensory WNL mechanical (Vi-G) or electrical (Cu-G) stimulation. Co-G had a five-minute rest and both PI-Gs received a five-minute mocked mechanical (PI-Vi) or electrical (PI-Cu)

stimulation. The VPTs were estimated at two randomized anatomical locations (first Metatarsal head (MET I) and heel). All subjects performed the following procedure for each location: baseline measurement, pre measurement as a reliability test, and post measurement after treatment period. VPTs were measured using a TiraVib vibration exciter (TIRA GmbH, Model TV51075, Germany) at 30Hz. The mean of three trials was calculated and used for statistical analyses. The intervention for the Cu-G consists of a WNL electrical stimulation [4]. A two-channel stimulation current unit (Physiomed Elektromedizin AG, Germany) generated a stochastic biphasic current (frequency spectrum 10-100Hz). Electrodes were placed under the hallux and the proximal aspects of the metatarsal heads to stimulate MET I. To stimulate the heel, electrodes were placed at the Achilles tendon above the posterior edge of the calcaneus bone and under the distal area of the plantar calcaneus. Mechanical stimulation in Vi-G took place directly at the two anatomical locations via the vibration exciter. The mechanical signal was adapted to the electrical signal through a self-written Lab-View program. In both intervention groups, stimulation intensity was 90% of the individual perception threshold, which was quantified before measurement. Data was statistically analyzed using parametric and non-parametric tests for dependent samples and Bonferroni correction due to the number of accomplished tests ( $\alpha = 0.05/6 = 0.0083$ ).

## RESULTS AND DISCUSSION

Table 1 shows the results of VPTs after the described five-minute intervention for each group. Vi-G and PI-Vi showed significant increases of their VPTs at MET I or heel (Table 1). While significant changes were also found for Co-G at MET I, all other groups showed no significant differences. The performed Kruskal-Wallis-Test was only statistically significant

for the heel ( $p = 0.005$ ), which was due to the values in Vi-G (Table 1). This leads us to consider whether the five-minute intervention with sub-sensory WNL mechanical stimulation led to a deterioration in foot sensitivity. Considering the PI-Vi, this deterioration seems to have other causes than the intervention. It may be possible that methodological characteristics of the vibration exciter caused these differences. A vibrating probe (diameter 7.8mm) that protrudes 2mm through a hole in a self-constructed wooden footrest was used to measure VPTs. The five-minute intervention as well as mocked mechanical stimulation was realized in a standing position. Therefore, the major pressure on the vibrating probe which prevails in the standing position could have led to skin deformities or to adaptation process resulting in less sensitivity. These changes may influence the way the examined mechanoreceptors function. Considering the other groups, no relevant changes in foot sensitivity were observed after the respective intervention. This is particularly interesting for Cu-G, since other studies consistently demonstrated positive effects of subsensory electrical stimulation [2,4]. A major difference to other studies in the field of SR is the chosen current form. The most commonly used white noise [2,4,5] is a continuous waveform. The waveform in the present study is a frequency modulation caused by random pauses between short triangle pulses (1ms duration). The short pulses of the resulting frequency band of 10-100Hz are possibly too weak to positively stimulate sensory receptors in the foot sole.

## CONCLUSIONS

In conclusion, neither the subsensory mechanical signals nor the electrical signals used in this study had a lasting effect on plantar sensitivity in healthy elderly subjects. In addition to the methodological influences mentioned, the duration of stimulation might be too short. However, studies implementing mechanical stimulation for over an hour also do not show any lasting effects. Further studies should investigate possible lasting effects over a longer period of time (days, weeks, or months) and should use the commonly used white noise.

## INTRODUCTION

Participation in the sport of running declines sharply after the age of 45 [1]. This may be in part due to increased risk of running-related injury with age [2].

Increase in injury rates amongst older runners may be in part due to altered biomechanics. It has been reported that older runners have decreased range of motion, however the literature is equivocal [3,4]. More consistently, older runners demonstrate reduced power generation at the ankle, which is compensated for by increasing contributions of the hip [5].

The proximal shift in work seen in older runners suggests a change in coordination strategy. It has been hypothesized that disruption in the sequencing of motions associated with loading during running may contribute to injury [6]. Therefore, the purpose of this study was to compare coordination using vector coding between young and older runners.

## METHODS

Twelve young adult males (22(3) yrs, 1.80(.07) m, 78(12) kg) and 12 older males (63(3) yrs, 1.76(.06) m, 73(16) kg) who regularly ran at least 10 miles per week volunteered for this study. Runners were provided with standard neutral footwear (New Balance, Boston, MA). Gait analysis was conducted on an instrumented treadmill (Treadmetrix, Park City, UT). A 20 second trial was collected using a 5-camera motion analysis system (Qualisys, Goteborg, Sweden) at 120 Hz as participants ran at 3.35m/s.

Visual 3D motion analysis software (C-Motion, Germantown, MD) was used to process data. Hip, knee and ankle joint angles were calculated for the stance phase of gait, which was defined using kinetic data from the force plate. Motions associated with

loading response (ie showing a unimodal peak at mid-stance), were selected for analysis. These included rearfoot eversion (EV), tibial internal rotation (TIR), knee flexion (KF) and hip adduction (HAD).

Coordination was assessed using a modified vector coding technique[7]. For each frame, joint position of the distal joint was plotted on the x-axis, and joint position of the proximal joint was plotted on the y-axis. Positive values indicated positions associated with collapse (EV, TIR, KF, HAD). Coordination angle was calculated as

$$\Theta = \tan^{-1}(\Delta p_{\text{proximal}}/\Delta p_{\text{distal}})$$

Where  $\Delta p$  is the change in joint position. Using this scale, positive values indicate in phase motion (eg both joints collapsing) while negative values indicate anti-phase motion (eg. One joint collapsing while the other joint has reversed). Greater magnitude of coordination angle indicates more relative distal motion, while values closer to 0 indicate greater relative proximal motion.

Coordination angles were averaged during four phases of stance previously defined, including impact, loading, propulsion and toe-off. For each couple analyzed (EV-TIR, TIR-KF, KF-HAD, EV-HAD), a MANOVA was used to compare coordination between groups at each phase.

## RESULTS AND DISCUSSION

Coordination through stance phase in younger and older runners is depicted in Figure 1. No significant differences were observed in EV-TIR. Motion was in phase through the first half of stance, with relative TIR increasing until mid-stance. A brief period of anti-phase motion occurred before both motions

occurred in phase, with relative eversion increasing until toe-off.

Similarly, no significant differences were observed in TIR-KF coordination. Knee flexion dominated in early stance, but relative proximal motion declined until mid-stance, at which anti-phase coordination was observed. Following mid-stance relative knee motion increased, dominating propulsion and toe-off.

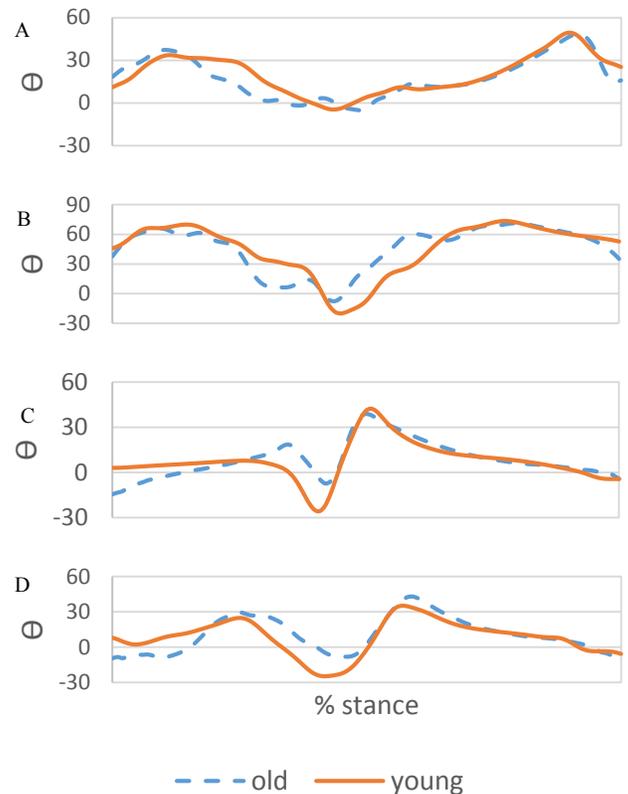

KF-HAD coordination was significantly different between young and old runners ( $p=.033$ ). Younger runners displayed KF dominated in-phase motion, while older runners had anti-phase motion, as the hip abducted while the knee flexed. Thereafter motion was KF dominated in-phase, until mid-stance when anti-phase motion occurred. During propulsion KF dominated, with relative KF decreasing until toe-off.

There was a trend towards differing EV-HAD between younger and older runners ( $p=.099$ ). Again, the young displayed eversion dominated in-phase motion, while the older demonstrated anti-phase motion. In-phase motion occurred until a period of anti-phase motion at mid-stance. Relative eversion increased during propulsion, and declined through toe-off.

## CONCLUSIONS

Older runners used different coordination strategies between the hip and knee and ankle during the impact phase of running. It appears that older runners do not allow the hip to collapse at impact, possibly to compensate for reduced ability to control the ankle. This is supported by previous work showing a proximal shift in power generation in older runners [5].

This study also found that in both groups, anti-phase motion consistently occurred at mid-stance. It has previously been hypothesized that the collapse motions should peak at mid-stance, and disruption of this synchrony may lead to injury. However younger runners actually appeared to utilize a greater degree of anti-phase motion in the transition from loading to propulsion. Thus this strategy may not be injurious, as previously thought.

# MOVEMENT VARIABILITY DURING SPLIT-BELT TREADMILL WALKING IN HEALTHY OLDER ADULTS

<sup>1</sup> Matthew J. Terza, <sup>2,3</sup> Ryan Roemmich, and <sup>1</sup> Chris J. Hass

## INTRODUCTION

The adaptability of movement patterns in the lower extremity joints is essential in achieving optimal foot placement during walking in complex real world environments. Adaptability of movement patterns is evident in the structure of joint variability from stride to stride. Novel physical constraints on the walking system may be used to challenge the walking repertoire of an individual leading to greater exploration of novel and useful dynamics changing the structure of variability.

The split-belt treadmill (SBT) provides one such opportunity to provoke the individual to explore novel movement patterns to improve the adaptability of walking. Although healthy older adults (HOA) appear to demonstrate the same spatiotemporal adaptation to the SBT as healthy young adults (HYA), it is unknown whether potential changes in the variability of movement at the joint level is similar to that of HYAs [1]. Other studies have shown different joint level walking strategies with age, therefore it is possible the HOA versus HYA would exhibit different movement strategies in response to the SBT [2]. Therefore, we sought to compare the structure of the variability of movement during split-belt treadmill walking.

Because previous SBT research has displayed similar spatiotemporal adaptations between HOA and HYA, we hypothesized that HOA would similar changes in joint variability as HYA. We further hypothesized that exposure of the SBT would elicit increased exploration in movement demonstrated by increases in the largest Lyapunov exponent (LyE) of the lower extremity joint angle trajectories over time. Additionally we hypothesized a main effect of age that would reveal the older adults as generally less predictable in their movement variability.

## METHODS

Thirteen healthy older adults (65±8 years old, 7 Males) and fourteen healthy young adults (23±4 years old, 7 Males) volunteered for this study. Individuals were fitted with retroreflective markers in accordance with the Vicon Lower Body Plug-In-Gait model. Motion capture data using an 8 camera Vicon system at 120 Hz were collected as these individuals walked in different conditions on an instrumented SBT.

Individuals walked for five minutes at their self-selected speed to familiarize them with walking on the treadmill. Then individuals walked 2 minutes with the belts tied (moving the same speed) at their fastest comfortable speed and then 2 minutes with the belts coupled at half of their fastest comfortable speed. Participants then walked in the split-belt condition with the belt under their non-dominant leg moving at their self-selected fastest comfortable speed and the belt under their dominant leg moving at half of their self-selected fastest comfortable speed for 10 minutes.

We analyzed the last 30 seconds of both of the baseline conditions and the first 30 seconds of the split-belt condition. We calculated the joint angles at the hip, knee, and ankle of each leg. Because the split-belt treadmill provides a mainly sagittal plane perturbation we analyzed exclusively the sagittal joint angle trajectories. We estimated the largest LyE of these joint angle trajectories during these condition. Higher LyE values indicate less predictable movement and greater movement exploration. To estimate LyE values the data was down-sampled to 60 Hz in accordance with recommendations for accurately estimating Lyapunov exponents in human gait data [3]. The

embedding dimension of the data set was determined to be 5 using the rate of false nearest neighbors algorithm. The time lag for each time series was determined separately using the first minimum of the average mutual information algorithm. LyE was the main outcome measure used to quantify if and to what extent the walking system was being challenged during the split-belt condition.

We exclusively compared the fast leg (the leg on the fast belt in the split-belt condition) and slow leg during split-belt walking to the same leg in the corresponding baseline speed condition (e.g. fast leg in the split-belt condition was compared to the same leg in the tied fast condition). We used a repeated measures multivariate analysis of variance MANOVA (2 x 2 x 6) age group x condition (split versus tied walking) x joint. Post hoc comparisons were made with Benjamini Hochberg corrections for multiple comparisons.

## RESULTS AND DISCUSSION

The statistical tests indicate no interaction between age and condition indicating the split-belt perturbation affects these populations in a similar manner. However, they did reveal significant main effects of age and condition. Post hoc comparisons revealed significant increases in the largest LyE at the hips and knees but not at the ankles during the split-belt condition as compared to the respective tied condition. Meaning regardless of age, this perturbation promotes greater exploration and less predictable motion from stride to stride at these

joints. To this end the SBT may have utility in aging populations as a locomotor training tool by challenging them to explore new patterns of movement in walking. Furthermore, the SBT may also expand the repertoire of adaptive movements in real world situations that involve asymmetric step foot placement. Interestingly, the post hoc pairwise comparison for the main effect of age revealed significant differences at the fast ankle and the fast hip only but in the opposite direction that we hypothesize. HOA were more predictable at these joints. This age effect result may be an indication that there is an interaction between speed and age.

Limitations of these perturbation results may be that they are specific to the speed of the belts during the split condition. Different results may be obtained at slower self-selected speeds.

## CONCLUSIONS

Complex novel walking constraints presented by the SBT may be a viable method for challenging the older adult to explore new walking dynamics, as they respond in a similar manner compared to healthy young adults.

## INTRODUCTION

We are not aware of studies of how diseases that commonly affect mobility influence older driver vehicle ingress/egress. Dufour *et. al.* investigated the effect of ingress/egress range of motion requirements on perceived discomfort [1]. Namamoto *et. al.* explored the interaction of age, stature, and vehicle design with the strength requirements for ingress and egress in passenger vehicles [2]. The goal of this study was to quantify how age, osteoarthritis (OA) and diabetic polyneuropathy (PN), muscle strength, measures of functional ability and movement strategy interact to affect vehicle ingress/egress times, because we hypothesized that longer times are associated with greater perceived discomfort ratings. We shall here only report egress times; subject variability is greater in this task [2], and we hypothesized that neither disease nor egress strategy interact with vehicle type in determining egress time.

## METHODS

We recruited elderly subjects aged between 67 and 89 years of age, 23 of whom were healthy, 12 had PN, and 12 had OA. Women comprised 48%, 17%, and 58% of each group, respectively. Subject capacities were measured at the Biomechanics Research Lab on the first visit (**Table 1**). Tests included max isometric hip abduction strength and rate of torque development (RTD), and max isometric knee extension strength. We normalized each strength measurement by subject's weight and height. Functional tests included max one legged balance times (OLB) and timed up and go test (TUG). Cognitive tests included simple reaction time (SRT), recognition reaction time (RRT) [3], Mini-Mental Status Examination (MMSE), and a paper Trails B test. Lower extremity sensory

function was scored using the Michigan Diabetic Neuropathy Score (MDNS).

**Table 1-** Capacities (SD) of participating subjects

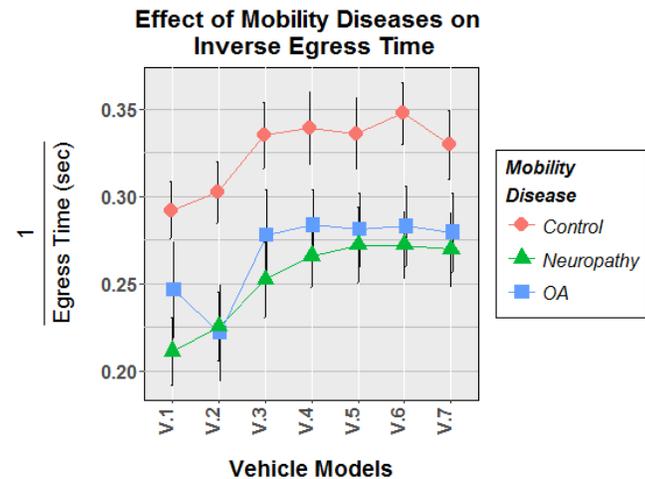

Variable	Control (n=23)	Neuropathy (n=12)	OA (n=12)
Age (yrs)	75.6(7.4)	76.8(6.5)	78.6(6.6)
Height (cm)	166.4(9.9)	177.2(7.0)	165.1(9.2)
Weight (Kg)	76.8(13.1)	99.3(15.7)	74.2(15.6)
Norm Knee Ext Torque	0.4(0.2)	0.5(0.2)	0.4(0.1)
Norm Hip ABd Torque	0.5(0.2)	0.4(0.1)	0.4(0.1)
Norm Hip ABd RTD	4.0(2.7)	3.5(2.9)	3.7(1.4)
OLB (sec)	21.6(10.7)	9.1(7.7)	6.7(7.7)
TUG (sec)	10.4(2.3)	12.1(2.1)	13.0(3.2)
MDNS	2.3(2.6)	15.1(3.9)	4.1(2.8)
SRT (msec)	165.8(24.5)	166.2(24.2)	168.2(17.7)
RRT (msec)	250.6(35.0)	239.0(35.8)	254.8(29.6)
MMSE	29.0(1.0)	29.4(0.5)	28.7(1.2)
Trails B (sec)	70.5(33.7)	95.0(49.8)	95.3(33.9)

On their second visit, subjects' ingress/egress was assessed at the Ford Motor Company Human Occupant Package Simulator (HOPS) Laboratory. Standard motion analysis techniques involving surface markers were used along with a reconfigurable setup simulating 7 different passenger vehicle models. Perceived discomfort was rated by a CP-50 scale questionnaire [4] after the subject performed both ingress and egress tasks. Egress strategy was categorized as Left Leg Out (LLO) or Both Legs Out (BLO) strategies [5]. We used linear mixed-effect modeling (LMM) for analyses and a random intercept for each subject to account for the correlation between the repeated measurements. Residuals were considered homoscedastic. R *base* package *ver. 3.3.2* and *nlme ver. 3.1* were used to run the LMM.

## RESULTS AND DISCUSSION

Egress time was not normally distributed so inverse egress time (IET), which was normally distributed, was used as the dependent variable in our analyses.

Disease showed a significant main effect on IET (**Figure 1**). Given no significant difference between the OA and PN groups, these groups were combined in the final statistical model. We also divided our vehicle models into two types based on vehicle package dimensions, with Vehicles 1 and 2 in Type I, and the other five vehicles in Type II.

**Figure 1:** The main effect of disease was significant ( $p = 0.01$ ).

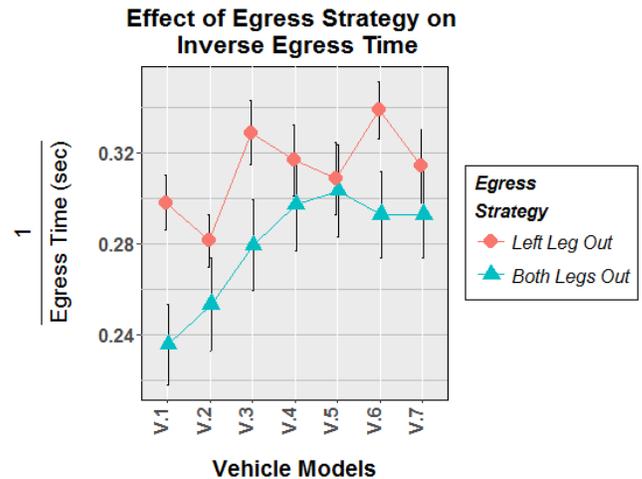

The interaction of egress strategy and vehicle model was also significant (**Figure 2**). Both functional capacity measurements showed a significant relationship with IET (**Table 2**). The final statistical model predicting IET on the basis of subject capacities, vehicle type, and egress strategies is shown at right in **Table 2**. The correlation between IET and perceived discomfort was indeed significant and equal to -0.45.

Strengths of the study include the number of subjects and use of LMM to incorporate all the data in the analyses. Limitations included the exclusion of subjects with a BMI exceeding 35 kg/m<sup>2</sup>.

## INTRODUCTION

Maintaining walking ability is critical for seniors in order to stay independent and mobile in the community. With aging, decreased walking speed is associated with reduced stride length (SL) and increased double limb support (DLS) time, and these in turn are associated with poorer health outcomes, disability, hospitalization, increased fall risk and mortality [1,2].

Functional mobility often includes activities where attention is divided. This demand to attend to multiple stimuli in the environment commonly results in detrimental changes to gait speed (GS) and spatio-temporal (ST) gait parameters [2,3]. Moreover, there is strong evidence that poor dual-task (DT) gait performance is a predictor of increased fall risk and impaired cognition [4].

In order address these age-related declines in walking capabilities it is recommended for seniors to get involved with physical activities which include training components of walking, balance, strength, and concentration [5].

Golf is a recreational activity that includes walking over hilly, uneven terrain; and various changes in body position, including high power swings and bending over to pick up a ball. Although there is evidence that golf play is associated with improved balance and walking, golf has received little attention as a *therapeutic intervention* [6]. We hypothesize that golf play is likely to improve walking capabilities and alter ST parameters of gait. The objective of the present study was to examine the influence of a 12-week golf intervention on walking and DT performance in older military veterans.

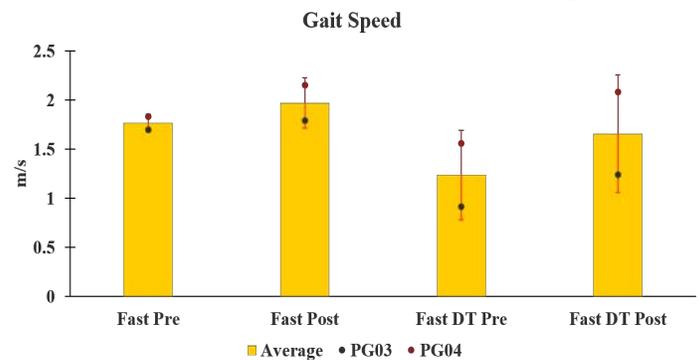

## METHODS

Fast GS, DT GS and ST gait parameters (stride length: SL and double limb support time: DLS) were measured before and after a 12-week golf intervention (2 x weekly; 90 min per session). Two male participants (74 and 67 years old) completed 5 fast gait and 5 DT gait trials while walking “as fast as possible”. For DT, participants performed a digit subtraction by 3’s task.

A standard lower extremity marker set was used to track lower extremity kinematics with a 10-camera Qualisys (Göteborg, SE) 3D motion capture system. Kinematics were collected at 60 Hz and filtered with a 4th order low-pass Butterworth filter with a 6 Hz cut off. Data was averaged across the 5 trials. Means, standard deviations, change percentage, and effect sizes (ES; Cohens’ d) are presented.

## RESULTS AND DISCUSSION

Participant PG03 attended 20/24 sessions and PG04 attended 22/24 sessions, of the 12-week golf training program. The participants’ fast GS increased by 5.3% and 17.5% (ES 1.26). DT GS increased by 29.2% and 26.1% (ES 3.75) (Fig. 1).

**Figure 1:** Mean fast gait and DT gait speed before (Pre) and after (Post) 12-week golf training intervention.

Fast DT GS was slower than fast GS for both participants at both time points. However, follow-up GS differences between fast and fast DT were not as large as at baseline. PG03 difference decreased by 25.7% and PG04 difference decreased by 34.6%. This decreased difference between pre and post time points suggests that golf training reduced the DT cost of the DT paradigm. Using the measurement of GS under a DT paradigm gives insight into the interlinked relationship between gait and cognition. The higher cognitive demand of the DT digit subtraction task may interfere with shared neural networks and act as a perturbation by disrupting gait control [4]. This study's participants' improved DT GS was accompanied by highly accurate digit subtraction scores, suggesting that the faster gait speeds were not at the cost of reduced cognitive function and that their gait control was not disrupted. Age-associated changes in step parameters include decreased SL and increased DLS time. There is robust evidence that these changes lead to impaired gait and an increase in future fall risk for older adults. Older adults may be using these types of compensatory strategies (modified gait parameters) to increase stability and avoid falls [2]. After completing a 12-week golf training program, during the fast GS, the two participants' SL increased by 44.6% and 8.0% (ES 1.20) and and DLS time decreased by 8.7% and 21.4% (ES 3.54) (Table 1). After completing a 12-week golf training program, during the fast DT GS, the two participants' SL increased by 25.4% and 32.4% (ES 2.95) and DLS time decreased by 21.0% and 43.8% (ES 5.56) (Table 2).

This study's participants had an increase in fast GS, fast DT GS, SL and a decrease in DLS time. These changes are all associated with lower risk for future falls.

## CONCLUSIONS

Both participants had improved gait parameters of fast GS, fast DT GS, SL and DLS following the completion of a 12-week golf training program. They also increased fast DT GS to a greater degree than fast GS alone. These preliminary results suggest that the physical and cognitive demands of golf (navigating the course, walking over hilly, uneven terrain, bending over, swinging, planning and strategizing) may improve gait control and lower future fall risk in older military veterans. Future expansion of this study will inform the development of golf training programs to improve everyday function and quality of life in older adults.

# MORE PUSH FROM YOUR PUSH-OFF: JOINT-LEVEL MODIFICATIONS TO MODULATE PROPULSIVE FORCES IN OLD AGE

Michael G. Browne and Jason R. Franz

University of North Carolina at Chapel Hill and North Carolina State University, Chapel Hill, NC, USA  
email: mgbrowne@email.unc.edu, web: <http://abl.bme.unc.edu>

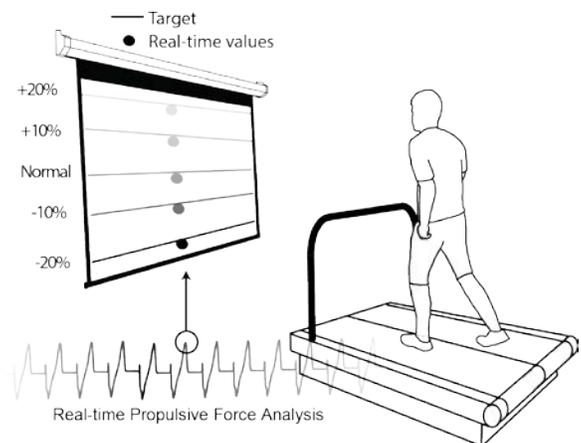

## INTRODUCTION

Propulsive forces generated during push-off (i.e., the anterior component of the ground reaction force vector;  $F_P$ ) are used to modulate walking speed. Older adults tend to walk slower than young adults. However, even prior to walking slower, older adults walk with a diminished push-off - decreased  $F_P$  accompanied by reduced ankle moment and power generation. These changes may be responsible for unfavorable and metabolically costly increases in mechanical power generated by muscles crossing the hip (i.e., a “distal to proximal redistribution”) [1]. However, despite their apparent deficit to young adults, many older adults retain the capacity to enhance  $F_P$  generation, for example to walk faster, uphill [2], or with appropriate biofeedback [3]. The joint-level modifications used by older adults to augment  $F_P$  generation in walking have yet to be fully elucidated and may be critical to informing the discriminate prescription of strategies to preserve independence in old age.

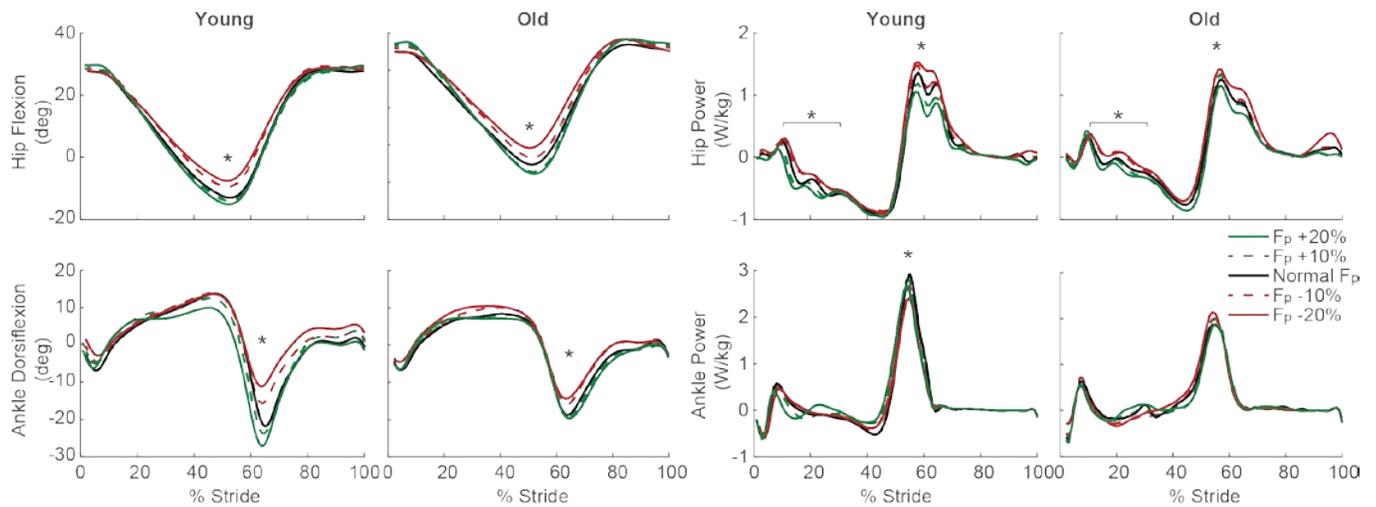

The purpose of this study was to identify age-related differences in the joint-level modifications used to modulate  $F_P$  generation during walking, an important determinant of push-off performance. We posit that there are two possibilities for older adults to enhance  $F_P$  generation during push-off. First, given the plantarflexors’ role in generating propulsion in young adults, older adults may increase ankle moment and power generation and thereby alleviate compensatory demands at the hip. Alternatively, older adults may opt to rely even more on the hip musculature for power generation, thereby exacerbating their distal to proximal redistribution. Ultimately, we seek an improved understanding of the mechanisms governing diminished push-off in old age and targets for clinical countermeasures.

## METHODS

10 healthy young adults (mean $\pm$ SD; age: 24.8 $\pm$ 5.4 years, 5 males/5 females) and 6 healthy older adults (age: 77.3 $\pm$ 4.2 years, 2 males/4 females) participated in this study. A photo cell timing system first assessed subjects’ preferred overground walking speed (Young: 1.27 $\pm$ 0.14 m/s, Old: 1.26 $\pm$ 0.16 m/s,  $p=0.45$ ). Subjects then walked normally for 60 s on a dual-belt instrumented treadmill at their preferred speed. A custom Matlab script immediately extracted the average  $F_P$  from normal walking for use in the subsequent trials. Subjects then walked at their preferred speed while watching a video monitor displaying their instantaneous  $F_P$ , updating as the average of each 2 bilateral strides (Fig. 1). Then, in 60 s trials, subjects were instructed to modify their instantaneous  $F_P$  to match target values representing normal and  $\pm 10\%$  and  $\pm 20\%$  of normal, shown as horizontal lines. For all trials, a 14-camera Motion Analysis system recorded the trajectories of 33 markers placed on subjects’ pelvis and lower extremities, from which we estimated hip, knee, and ankle joint kinematics and kinetics.

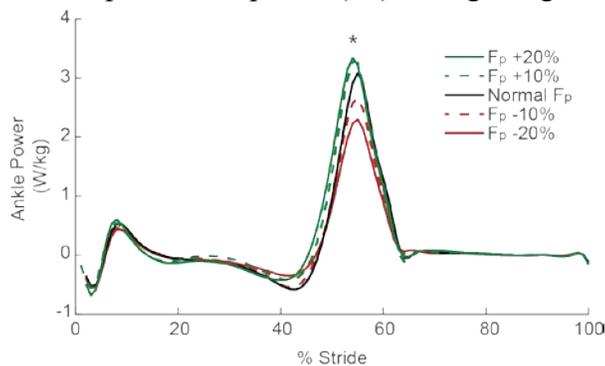

**Figure 1:** Subjects walked with visual biofeedback based on real-time propulsive force measurements.

**Figure 2:** Visual biofeedback of propulsive forces ( $F_P$ ) in both young and older adults modified ankle and hip kinematics and hip power generation with minimal change in ankle power generation. (\*Main Effect of  $F_P$ )

## RESULTS AND DISCUSSION

During normal walking, older adults exerted 12% smaller  $F_P$  than young adults and exhibited a characteristic distal to proximal redistribution (i.e., 23% less peak ankle power during push-off and 31% more hip joint positive work during stance). All subjects successfully and systematically modulated their  $F_P$  in accordance with prescribed biofeedback targets. Independent of age, walking with larger (smaller)  $F_P$  increased (decreased) peak hip extension and decreased (increased) the mechanical demands of muscles spanning the hip (Fig. 2). Interestingly, neither young nor older adults enhanced  $F_P$  generation during push-off through increases in ankle power generation. However, this is not to say that subjects could not increase ankle power. Indeed, we recently implemented visual biofeedback based on real-time inverse dynamics and revealed that at least young adults can effectively modulate peak ankle power ( $P_A$ ) through targeted  $P_A$

**Figure 3:** Modulation of push-off through direct peak ankle power biofeedback. Young adults ( $n=10$ ).

biofeedback (Fig. 3). We are exploring whether this targeted approach may more directly impact ankle moment and power generation in older adults.

## CONCLUSIONS

Our intuition and prior work led us to anticipate a reversal or an exacerbation of the distal to proximal redistribution in joint power generation when older adults increased  $F_P$  at their preferred speed. Instead, our results reveal an exciting third option: enhancing  $F_P$  via biofeedback improved peak hip extension during push-off and alleviated mechanical power demands at the hip, all without changes in ankle power. Further, older adults walked with increased  $F_P$  without increasing their total positive joint work. Thus, given the same total requisite power generation, older adults got ‘more bang for their ankle power buck’ using biofeedback - larger  $F_P$  with less hip power generation - perhaps in turn yielding faster preferred speeds and/or improved walking economy.

# LET'S FACE IT, I AM GETTING OLDER: A LONGITUDINAL STUDY OF BALANCE RECOVERY FROM FORWARD LEAN RELEASES

<sup>1,2</sup> Evelyne Carbonneau and <sup>1,2</sup> Cécile Smeesters

<sup>1</sup> Research Center on Aging, Sherbrooke, QC, Canada

<sup>2</sup> Department of Mechanical Engineering, Université de Sherbrooke, Sherbrooke, QC, Canada  
e-mail: [Cecile.Smeesters@USherbrooke.ca](mailto:Cecile.Smeesters@USherbrooke.ca), web: <http://www.usherbrooke.ca/gmecanique>

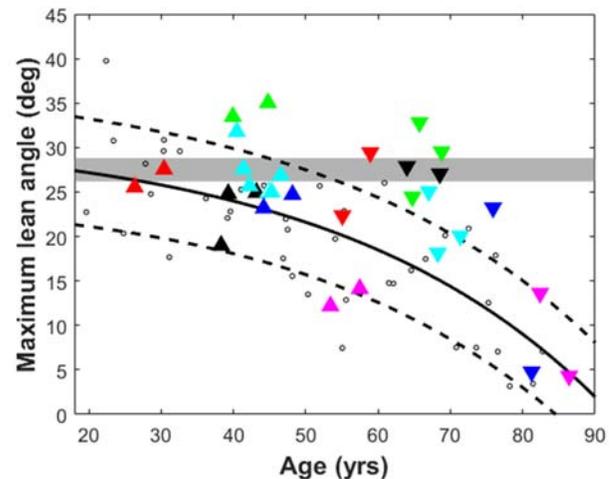

## INTRODUCTION

In a cross-sectional study of 52 participants between 19 and 86yrs, Carbonneau and Smeesters [1] showed that the ability to recover balance and avoid a fall using a single step decreased exponentially with age (Figure 1). In particular, we showed that, at the critical age of 51.0yrs, the maximum forward lean angle decreased below one standard deviation of the mean value of 18-year-olds. This decline with age was associated with longer reaction and weight transfer times, slower mean and maximum step velocities and smaller step lengths and heights, but age did not affect step time and step width. Finally, stepping (versus harness) failures increased with age at lean angles larger than maximum. The purpose of this longitudinal study was thus to validate our previous exponential regression curve [1] using a convenience sample of participants whose balance recovery from forward lean releases was repeatedly tested in our laboratory over the past 10 years.

## METHODS

Twelve healthy adults (4 women) had their balance recovery from forward lean releases tested two to six times between the ages of 26.4 and 86.4yrs. At each visit, we determined the maximum forward initial lean angle (starting at ~5deg and increasing in ~2.5deg increments) from which each participant could be suddenly released and still recover balance using a single step.

Using 4 force platforms and 2 load cells at 1000Hz, and 4 optoelectronic position sensors with 24 markers at 100Hz, the following kinematic variables were also obtained: initial lean angle; reaction, weight transfer and step times; mean and maximum step velocities; and step length, height and width at the maximum lean angles.

**Figure 1:** Mean±SD exponential regression curve (solid and dashed lines) of the maximum forward lean angle versus age for the 52 participants (black circles) from the cross-sectional study by Carbonneau and Smeesters [1]. The maximum forward lean angle versus age for the 12 participants (colored triangles) from this longitudinal study.

## RESULTS AND DISCUSSION

The maximum forward lean angle versus age points of our 12 participants followed reasonably well our previous exponential regression curve (Figure 1), except in three easily explained cases:

- Participant ▲ (black) did a lot of gardening on the eve of her first point at 38.3yrs, which decreased her maximum lean angle on that day ( $\Delta_{12}=5.8$ deg).
- Participant ▼ (red) started running a year before his second point at 58.9yrs ( $\Delta_{12}=7.1$ deg).
- Participant ▼ (green) started biking the year he retired, right after his first point at 64.7yrs ( $\Delta_{12}=7.1$ deg).

Starting at 40yrs, we started to test systematically the principal investigator of this study (participant ▲, blue) nearly every year. For the previous 10 years,

her maximum lean angle had consistently been at ~27.5deg (Figure 1, gray area), always easily recovering balance at ~25deg, but not at ~30deg and certainly not at ~32.5deg. At 40.5yrs, she obtained an exceptional 31.8deg maximum lean angle (Table 1), after returning from a sabbatical in the Canadian Rockies where she biked to work every day. By 41.4yrs, she was back at 27.6deg. However, let's face it, she is getting older. Indeed, starting at 42yrs, she was no longer able to recover balance at ~27.5deg, especially not during those long winter months. The only exception was her latest test at 46.6yrs, where she just managed 26.9deg late in the summer after biking to work every chance her hectic schedule would permit in an attempt to return to ~27.5deg.

There are not enough data points yet to draw significant trends, but her decline with age appears to be associated with longer weight transfer times and smaller step heights (Table 1). Moreover, as we often see with middle-aged and older adults, the number of protocol infractions her vigilant staff had to ask her to correct has definitely increased:

- Prior to lean release, her eyes were looking at the floor, rather than straight ahead, and her body was not kept in a straight line, her trunk having a smaller initial lean angle than her legs.
- She often attempted to anticipate lean release, obviously starting to react prior to lean release.
- Her heel strikes were definitely less stable at the maximum lean angle.
- At lean angles larger than her maximum, while she used to have only harness failures, stepping failures now often accompanied harness failures. In fact, she knew as soon as the first step was completed that she had failed and, although she could will herself to use only a single step, taking

a second step was more comfortable than falling into the harness. This confirms what we have suspected for several years, as we get older, we are able to respect the single step instruction but are just unwilling to do so [2].

## CONCLUSIONS

This longitudinal study has validated the exponential regression curve obtained in our previous cross-sectional study [1]. Furthermore, it has shown that the ability to recover balance and avoid a fall can be decreased by strenuous work but, more importantly, can also be improved with exercise. Similarly, it has given the principal investigator of this study some interesting insight into why protocol infractions increase with age. Finally, a recent 12-month prospective falls evaluation [3] showed that the maximum forward lean angle significantly predicted a future fall in community-dwelling older adults (65-90yrs). Lean releases could thus be used to screen adults over 50yrs [1] and identify those at risk of falls, or to evaluate the effectiveness of exercise-based fall prevention programs.

email: mhernand@illinois.edu, web: <http://mfp.kch.illinois.edu>

## INTRODUCTION

To maintain balance in an upright stance, humans require a prerequisite amount of cognitive resources that increases with age. Thus, the amount of attention required by an individual to maintain a quiet stance may provide a salient marker of balance dysfunction. To further our understanding of the role of attention in the maintenance of balance, we examine the effect of cognitively demanding tasks and challenging balance conditions, such as a semi-tandem stance, on the rambling (Rm) and trembling (Tr) components of postural sway [1]. Rambling is thought to represent the equilibrium trajectory of the center of mass and is postulated to reflect supraspinal processes [1,2], while trembling represents deviations from equilibrium and may reflect spinal-peripheral processes [1,2]. Given this framework, we hypothesized that rambling would be most affected by divided attention tasks and demonstrate increased relative cerebellar frequency power (0.5-1.5 Hz), particularly in older adults. Secondly, we hypothesized that trembling would be most affected by a challenging balance condition, such as a semi-tandem stance, and demonstrate increased relative reflexive frequency power (1.5-5 Hz), particularly in older adults.

## METHODS

*Subjects.* Healthy young (mean±SD, age 21±2 years, N=20, 10 female) and healthy older adults (age 65±5 years, N=20, 10 female) were recruited from the local community.

*Protocol.* Subjects stood upright, as still as possible, during 60 sec trials in either a comfortable parallel stance with feet side by side (parallel stance), or semi-tandem stance with eyes open. In addition,

subjects were asked to perform a single task or a concurrent cognitive-demanding task in half of the trials, consisting of the backward recitation of alternating letters of the alphabet, using a pseudorandomized starting letter (dual task). Data collection was performed in a single experimental session in a laboratory setting.

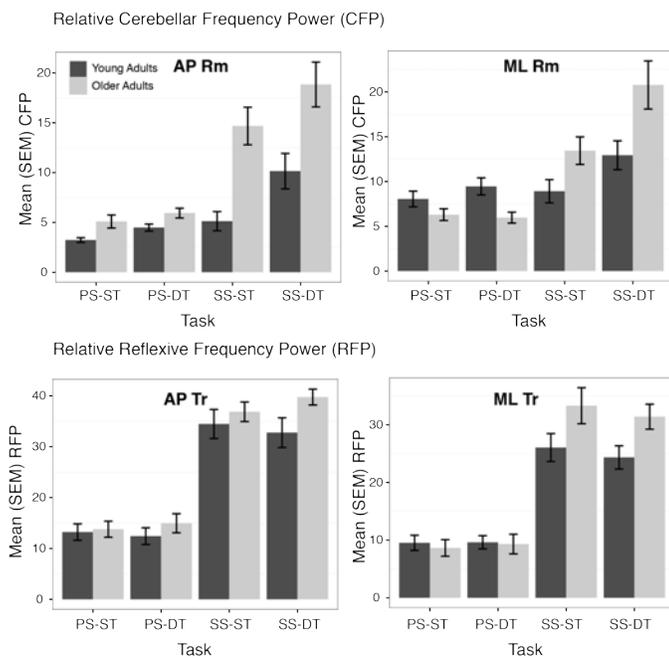

*Data Analysis.* Force plate data was collected at 100 Hz using an AMTI Accusway six-degree of freedom force plate. Raw force plate data were processed with a 4th order, zero-lag, low-pass Butterworth filter with a 10 Hz cutoff frequency. The mediolateral (ML) and anteroposterior (AP) components of the center of pressure (COP) were calculated using standard equations. Decomposition of ML and AP COP trajectories into Rm components was achieved by defining instantaneous equilibrium points when the shear force was zero and interpolating between these points using a cubic spline function [1]. Tr components were then calculated by taking the difference between the COP and Rm trajectories, as previously described by Zatsiorsky and Duarte [1]. Rm and Tr trajectories were quantified using the root mean square (RMS) and relative cerebellar and reflexive frequency power (CFP and RFP, respectively). Trials where participants lost balance were eliminated from subsequent statistical analysis. Linear mixed effects models were used to examine the effects of age, stance, and task on outcome measures using R.  $P < 0.05$  was considered statistically significant.

## RESULTS AND DISCUSSION

During split stance conditions, in comparison to parallel stance, all participants swayed with larger amplitudes, as demonstrated by increased ML and AP Rm and Tm RMS ( $p < .001$ ). Older adults, when

successful in maintaining balance, demonstrated decreased AP Rm and ML Tm RMS ( $p < .005$ ) and a significant cohort x stance interaction in AP Rm and ML Tm RMS ( $p < .05$ ), partly consistent with prior results [3]. In addition, during dual task conditions in comparison to single task conditions, increased AP and ML Tm RMS were observed ( $p < .005$ ), suggestive of increased muscle co-contraction.

During dual task conditions in comparison to single task conditions, increased CFP was observed in both AP and ML Rm trajectories ( $p < .005$ ), as observed in **Fig. 1**. However, no significant task x cohort interactions were observed in CFP ( $p > .05$ ). Older adults demonstrated increased AP Rm CFP ( $p < .001$ ). During split stance vs. parallel stance conditions participants demonstrated increased ML and AP Rm CFP ( $p < .001$ ), as well as a significant cohort x stance interaction in both ML and AP Rm CFP ( $p < .001$ ).

**Figure 1:** Relative cerebellar frequency power (CFP) of AP and ML Rm and relative reflexive frequency power (RFP) of AP and ML Tr during all quiet standing tasks. PS = parallel stance, SS = semi-tandem stance, ST = single task, DT = dual task.

During split stance vs. parallel stance conditions, participants demonstrated increased RFP in both AP and ML Tr trajectories ( $p < .001$ , **Fig. 1**). Furthermore, a significant stance x cohort interaction was observed in ML Tr RFP ( $p < .005$ ), consistent with our hypothesis.

## CONCLUSIONS

We conclude that in balance and cognitively demanding tasks in healthy older adults, stiffening strategies are still employed by older adults to maintain quiet standing, as demonstrated by decreased rambling and trembling RMS. Of novelty, dual tasking led to similar increases in the relative cerebellar frequency power in both AP and ML rambling trajectories across all participants. The similarities across both young and older adults suggests the use of similar mechanisms of postural control during cognitive-demanding tasks in healthy individuals, contrary to our hypothesis that rambling would be most affected by divided attention tasks and demonstrate increased relative cerebellar frequency power (0.5-1.5 Hz), particularly in older adults. Our data is consistent with our hypothesis that trembling would be most affected by a challenging balance condition and demonstrate increased relative reflexive frequency power (1.5-5 Hz), particularly in older adults. Furthermore, it further supports the notion that trembling, in particular, may be useful to quantify changes in reflexive, or peripheral, mechanisms in aging.

## INTRODUCTION

Older adults have increased dual-task (DT) costs compared to their younger counterparts, especially when it comes to demanding tasks such as cell phone usage and walking. In an experimental setting using virtual reality (VR), older adults took longer than younger adults to initiate crossing a busy street with traffic; this time difference was compounded during a cell phone conversation, suggesting impairments in the cognitive planning process [1]. When older adults walk and talk at the same time, gait decrements increase. The changes in gait can be measured and used as an indicator of dual-task costs incurred while walking and talking [2]. These costs may help to predict an individual's fall risk, which is important as falls are a common cause of injury among older adults and can lead to morbidity, mortality and an increased possibility of future falls [3].

To our knowledge, no such study has been done comparing walking and talking between a VR and a non-virtual reality (NVR) environment. Thus, the purpose of this study was to compare spatial and temporal gait variables of healthy older adults while walking and talking in different environments and conditions. It was hypothesized that older adults would show significant differences while walking and talking compared to walking only. Additionally, the influence of a VR environment would significantly influence their gait compared to a NVR environment.

## METHODS

Fifteen subjects,  $70.9 \pm 4.7$  years old (40%M/60%F) all right-handed, living independently in the community and free of any disorders that may

interfere with gait or cognition consented to participate in this study. Subjects completed three sessions, all approximately one week apart. During the baseline session, subjects completed three different conversations (in person (IP), on a cell phone (OP), and hands-free (HF)) while seated. Randomization occurred for the subjects to walk on a treadmill in a VR or NVR environment for the other two sessions while talking IP, OP, and in a HF conversation for 10 minutes each. Conversation topics were predetermined and randomized for every subject. A single-task, ten-minute walking only (WK) trial was recorded in each of the last two visits.

In the DT conditions, gait data was collected (100 Hz; Vicon, Oxford, United Kingdom) while subjects walked on a self-paced treadmill (Bertec Corp., Columbus, OH). The self-paced treadmill adjusts to the subject's speed as they walk. Step time, stride time, step length, stride length, step width, stance time, swing time, and double stance time were quantified through custom MATLAB programs (MathWorks Inc, Natick, Mass). Gait variables were compared between environments (VR and NVR) and conditions (IP, OP, HF, WK) using paired samples t-tests. Data was analyzed using IBM SPSS Statistics for Windows (Version 22.0).

## RESULTS AND DISCUSSION

Our hypotheses were partially supported. All conditions were compared but only significant conditions are shown (Table 1). There were no significant differences in any of the gait variables between VR and NVR environments across any DT conditions. However, there were significant differences between WK in VR vs. WK in NVR for

the following gait variables: stance time, swing time, and step width. Furthermore, several other variables came close to significance. Lack of significance could be due to the small sample size, leading to lack of power to detect the differences.

In the VR environment only, significant differences emerged between both OP vs. IP and OP vs. WK. All the gait variables measured, except for step width, were significantly different between the OP and WK conditions. All temporal variables in the OP vs. IP condition were significant (Table 1). No differences were found between any of the other dual-task talking and walking conditions.

Existing literature supports these findings in that older adults change their gait to deal with an additional task like having a cell phone conversation while walking [1,2]. The fact that there were only significant differences found in the OP condition suggests that holding a cell phone is demanding additional resources and not the conversation itself. In addition, the lack of differences present in the HF condition also supports the idea that holding a cell phone is an additional motor task. Furthermore, the idea of visualizing the person you are having a conversation with while OP may impact walking, making it different than a face-to-face conversation. In addition, the optic flow present in VR may affect the sensory system like walking in real-life; stimuli are flowing past the walker with information from the environment affecting how the sensorimotor system responds. This could explain the differences found while using VR.

Overall, the lack of significant differences between conditions and environments could be explained by the nature of our adult population. These older adults were regular exercisers and performed well while walking and talking. Only the addition of holding a cell phone, as opposed to IP and HF, seemed to perturb their gait by increasing stance times and decreasing stride lengths.

## CONCLUSIONS

Significant differences were found in the gait of older adults while walking and talking on a cell phone in a virtual reality environment and a walking only task. Additionally, the presence of VR seemed to impact their gait. This may suggest that using VR could approximate daily life and be used as part of an intervention study to reduce fall risk. In the future, different VR scenes could be used to assess the differences in various real-life situations while talking on a cell phone.

## INTRODUCTION

An increase in physiological tremor and a decline in the ability to manipulate objects with the fingers are common consequences of aging. These impairments lead to several limitations in performing activities of daily living (ADLs) such as cooking, feeding, dressing etc. and can lead to dependence and institutionalization<sup>3</sup>. Tremor, both physiological and pathological, manifests itself as an inability to hold a steady force. When individuals are asked to hold a steady force, the force is not constant, but fluctuates about a mean value. These fluctuations in force can be quantified as the standard deviation (or coefficient of variation) of force and reflect the ability of that person to perform a steady contraction.

One critical condition influencing steady force production and dexterous manipulation is the frictional properties of the surface that the fingers contact. For example, force variability was found to be significantly higher when pressing isometrically against a low- vs. high-friction surface<sup>2,5</sup>. Older adults had greater impairments than young adults while pressing down with a steady force on the low-friction surface<sup>2</sup>. This study involved the static task of pressing down with a given force, thus making the normal force the only task-relevant parameter that needed to be controlled tightly. Conversely, when performing a hybrid task of pressing and moving, young healthy participants showed greater normal force variability on a high-vs low-friction surface<sup>1</sup>. In this case producing accurately directed shear forces of sufficient magnitude to enable motion is now a task-relevant parameter and precise control of shear force plays an important role during steady normal force production.

Nonetheless, most studies examining steady force control with advancing age examine static tasks<sup>2,5</sup>. However, these tasks may not best reflect performance on ADLs which involve simultaneous

control of force and motion. Thus, the purpose of this study was to compare force steadiness in healthy young and older adults as they performed static and hybrid tasks on high- and low-friction surfaces.

## METHODS

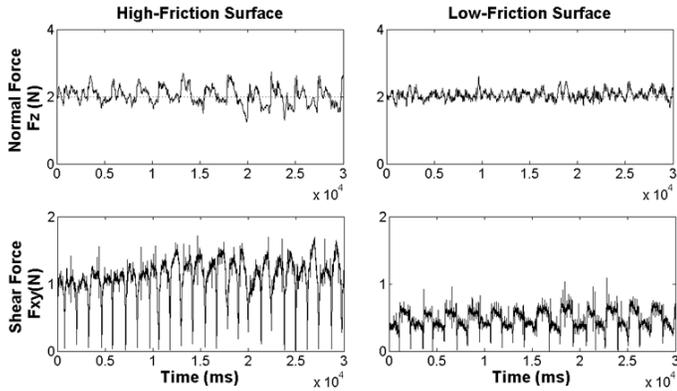

20 young (18 – 49 years) and 22 older adults (65–89 years) with no reported neuromuscular disorders or upper extremity pathologies were recruited. The iPad without a screen protector served as the high-friction surface (coefficient of friction:  $1.48 \pm 0.46$ ) and the Ionic screen protector placed on the iPad (coefficient of friction:  $0.44 \pm 0.15$ ) was the low-friction surface<sup>1</sup>. A line representing the 2 N target force was given as visual feedback on a 27-inch monitor positioned 1 m in front of the subject. Two targets were displayed as 1.5 cm circles on the iPad touch screen, and they were positioned 8 cm apart from one another. Participants performed two tasks: 1) a force matching task while pressing down statically with their index finger, and 2) a pressing and sliding task moving left/right between the two circles with the index finger pressing against the iPad screen, as previously done in<sup>1</sup>. These tasks were repeated on the low- and high-friction surface. A metronome was set at 60 beats per minute and subjects were instructed to move from one circle to the other at each beat. Each trial was 30s long.

**Data Analysis:** A custom Matlab script was used to calculate the mean and standard deviation (SD) of normal and shear forces for each condition (static/hybrid: left/right) for both low- and high-friction surfaces. SD for force was used as the measure of steadiness.

**Statistical Analysis:** Repeated measures analysis of variance (ANOVA) was performed on SD of normal and shear forces with repeated measures on age, task and friction conditions.

## RESULTS

Normal force variability (SD) was increased on the high- vs low-friction surface during the hybrid task for both the young ( $p < 0.001$ ) and older adults ( $p < 0.001$ ). Figure 1 shows representative data for older adults.

**Figure 1:** Representative data for older adults. *Top row:* Illustrates the visual feedback provided to subjects and that variability in normal force is increased on high- vs. low-friction surfaces. *Bottom row:* As expected, variability in shear force was also greater on high- vs. low-friction surfaces.

While no age effect was observed in variability during the static task ( $p = 0.284$ ), variability on the hybrid task was significantly greater in the older adults than the young adults ( $p = 0.015$ ) (Table 1).

Greater variability in shear force (SD) was observed during the hybrid force/motion tasks than the static task ( $p < 0.001$ ) and on the high-friction surface as compared to the low-friction surface ( $p < 0.001$ ) (Figure 1). The young participants had significantly greater variability in shear force as compared to the older participants during the hybrid task ( $p < 0.001$ ) (Table 1).

## DISCUSSION AND CONCLUSIONS

Older adults showed greater force variability while performing the hybrid force-matching task as compared to the static task where performance was similar between young and older adults (Table 1). This result highlights the importance of examining motor control during hybrid tasks to accentuate potential motor deficits with advancing age.

Greater variability in shear forces in young compared with older adults during the hybrid task may suggest that younger adults were more successful at maintaining a steady downward force ( $F_z$ ) by successfully exploiting variability in out-of-plane directions ( $F_{xy}$ ), consistent with the uncontrolled manifold hypothesis<sup>4</sup>. As shear forces during the hybrid task in older adults were ~34% less than those in young adults, the performance of older adults on the steadiness task may have been impaired by their relative inability to manipulate out-of-plane forces.

It is not clear what neuromuscular mechanisms lead to these changes during hybrid force/motion tasks with advancing age. Future research examining EMG and motor unit activity may allow investigators to determine the neuromuscular mechanisms that vary between young and older participants performing hybrid force-matching tasks.

email: manid@colorado.edu, web: <http://www.colorado.edu/intphys/research/nem.html>

## INTRODUCTION

Advancing age is accompanied by changes in walking performance [1, 2] and a shift in muscle activity away from ankle muscles and up to hip and knee muscles [3, 4]. Most of the information about muscle activity during walking has been obtained from studies in which older adults walked on a treadmill and the activation signals were recorded with sets of bipolar electrodes. Advances in technology, however, now make it possible to quantify activation signals from high-density surface EMG recordings while subjects walk overground.

The purpose of this study was to record the level of activation in the medial gastrocnemius and lateral soleus muscles of older adults as they walked overground at a usual speed. The activation signals were recorded with high-density grid electrodes.

## METHODS

Twenty healthy older adults (12 women,  $72 \pm 4$  yrs) were recruited to participate in up to 4 experimental visits spanning ~10 wks, each separated by at least 3 wks. From these sessions, data from 4 men ( $72 \pm 3$  yrs), acquired over 6 separate sessions, met the inclusion criteria to evaluate activation of the medial gastrocnemius and lateral soleus muscles during overground walking. Subjects were asked to walk at their “comfortable, preferred speed”.

A wearable EMG system was used to acquire high-density recordings. Two 4x8 grid electrodes (1 cm inter-electrode distance) were used: one placed over medial gastrocnemius and the other over lateral soleus. Each grid electrode had 32 detection points spread over 7 rows, and monopolar signals were recorded during the gait cycle. Foot switches were placed beneath the big toe and heel inside the shoe to identify gait events with which to denote EMG onset and offset times.

Decomposition of the high-density EMG recordings yielded 608 steps with a mean of 32 EMG channels per muscle. Those trials with poor recording quality or missing foot switch data, determined via strict Matlab algorithms, were excluded.

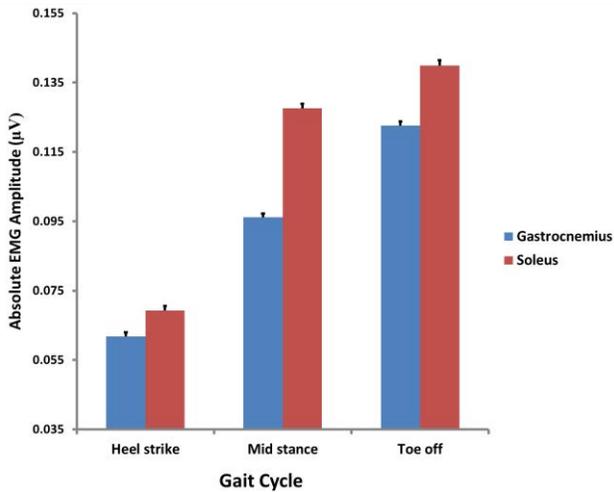

Normality tests were performed on the results. The Friedman test for non-parametric data was used to examine EMG amplitude and Wilcoxon Signed Rank test was implemented as a post hoc test with adjusted P-values.

## RESULTS

The mean EMG amplitude and standard deviation for the medial gastrocnemius was  $0.06 \pm 0.00$   $\mu$ V at heel strike,  $0.10 \pm 0.00$   $\mu$ V at mid stance, and  $0.12 \pm 0.00$   $\mu$ V at toe off ( $p < 0.0001$ ). The mean EMG amplitude for the lateral soleus was  $0.07 \pm 0.00$   $\mu$ V at heel strike,  $0.13 \pm 0.00$   $\mu$ V at mid stance, and  $0.14 \pm 0.00$   $\mu$ V at toe off ( $p < 0.0001$ ) (Figure 1). The effect sizes for comparisons between muscles at each time point ranged from -0.510 to -0.602 for medial gastrocnemius and from -0.242 to -0.604 for lateral soleus. Absolute EMG amplitude for lateral soleus was greater than that for medial gastrocnemius at all time points ( $p < 0.0001$ ).

Spatial and temporal information provided by the high-density surface electrodes showed distinct differences in activation between the two muscles, indicating greater muscle activation for lateral soleus.

The amplitude maps show that muscle activation changed during the gait cycle, and that soleus sustained activation levels through to toe off (Figure 2).

**Figure 1.** Absolute EMG amplitude (mean ± SE) for medial gastrocnemius (MG) and lateral soleus (LS) at heel strike (HS), mid stance (MS), and toe off (TO).

## DISCUSSION

The recordings obtained with high-density grid electrodes provide information about the absolute levels of muscle activation during overground walking. As a result of this technology, it is possible to compare absolute levels of EMG activity across time and muscles. The results show that muscle activation was greater for lateral soleus and was greatest at toe off for both muscles, but was also present during heel strike, likely due to coactivation of the dorsiflexor muscles, as often exhibited by older adults [5].

This technology can provide insight on the distribution of absolute muscle activity within and between leg muscles during overground walking and other mobility tasks. The approach can be used to provide more quantitative information about differences in muscle activation across conditions.

## CONCLUSION

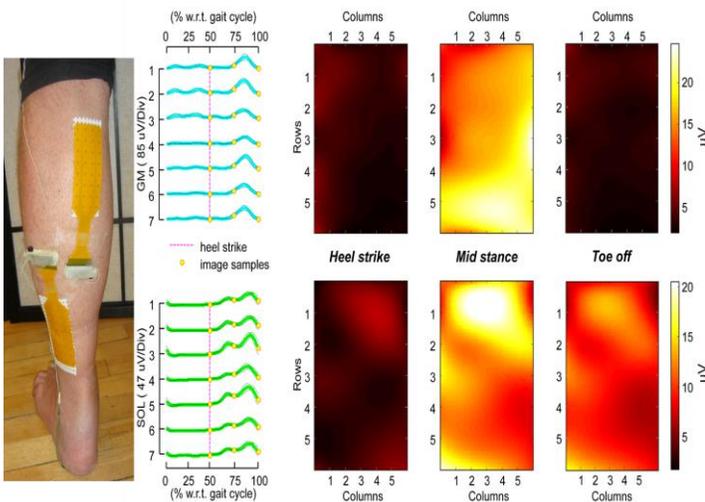

High-density grid electrodes placed on the skin over the triceps surae indicate that the greatest muscle activation occurred at toe off. Compared with medial gastrocnemius, soleus exhibited greater absolute levels of muscle activation during the three phases of the gait cycle.

## INTRODUCTION

Hip dislocation occurs in between 2% and 11% of total hip arthroplasty patients (THA) [1]. Posterior dislocations occur primarily with internal rotation and flexion of the hip while anterior dislocations occur primarily with external rotation and extension in the hip [2]. Despite the link between hip movement and dislocation, surprisingly little information exists in the literature that details the 3D kinematics of the hip during multiple common activities of daily living. Therefore, doctors are not always able to answer confidently when their patients ask about returning to particular activities following surgery. Additionally, little is known about how these specific hip movement strategies change with age. Therefore, the purpose of this study is to (1) develop normative 3D hip kinematic data for people as they perform common activities of daily living, and (2) determine how hip movement strategies change with age by comparing a group of healthy younger individuals to that of a healthy older group of individuals.

## METHODS

Twenty-three subjects (14 younger aged 19-33 years; 9 older aged 51-68 years; see Table 1 for details) were enrolled in this study.

*Table 1: Subject Demographics*

Group	Avg. Height ± Stdev (cm)	Avg. Weight ± Stdev (kg)	Avg. BMI ± Stdev (kg/m <sup>2</sup> )	Avg. Age ± Stdev (years)	Female:Male
Younger	176.96 (±10.9)	75.16 (±10.0)	24.09 (±3.3)	23.14 (±3.9)	7:7
Older	172.17 (±8.3)	81.97 (±13.5)	27.59 (±3.8)	60.78 (±6.4)	5:4
All	175.08 (±10.0)	77.82 (±11.7)	25.46 (±3.8)	37.87 (±19.4)	12:11

Motion capture was completed with a 14 camera system (Vicon Vantage) using the point cluster marker set developed by Andriacchi et al [3]. A total of 56 activities were performed, 7 of which have been selected for this initial study. The activities of interest for this study include: picking up an object while standing; standing from a chair at a normalized height; standing up from a chair lower than normalized height; standing from a soft and low chair (sofa); tying a shoe on the right foot (on a raised bar) while the left foot is planted on the ground; and ascending and descending stairs.

The analysis was performed using Nexus (Vicon) and custom Matlab scripts to calculate and extract peak 3D hip kinematics. Normalized data tables that displayed the peak angles for each motion were produced for both the younger and older groups. Comparisons between left hip kinematics were made between the younger and older groups using unpaired t-tests ( $\alpha < 0.05$ ) after the data was found to be normally distributed. The left hip was selected because it served as the stance leg while a person tied their elevated right shoe.

## RESULTS

The normative 3D hip kinematic results for each activity for both the younger and older groups of participants are shown below (Table 2). The greatest flexion angles were seen in the ball pick up and shoe tying activities. Abduction was greatest in ball pick up and the stair ascent / descent activities. The greatest internal rotation was seen in the ball pick up, sofa sit to stand, and stair descent activities.

Table 2: Activity Summary

ACTIVITY	Flexion		Abduction		Internal Rot	
	Younger (Stdev)	Older (Stdev)	Younger (Stdev)	Older (Stdev)	Younger (Stdev)	Older (Stdev)
Picking Up: Front to Side	107.4 (±7.3)	108.7 (±8.7)	20.9 (±7.9)	20.4 (±5.9)	20.6 (±6.3)	22.2 (±2.8)
Normalized Chair: Standing Up	89.7 (±9.6)	82.5 (±18.3)	11.0 (±4.1)	7.8 (±3.0)	13.7 (±5.5)	12.4 (±4.7)
Low Chair: Standing Up	94.0 (±13.6)	89.8 (±16.0)	10.3 (±3.8)	9.6 (±2.8)	15.0 (±5.6)	13.2 (±4.6)
Sofa: Standing Up	98.0 (±11.1)	95.0 (±17.7)	13.9 (±4.8)	10.6 (±4.8)	19.6 (±7.4)	15.9 (±6.0)
Stairs: Ascending	68.5 (±3.6)	72.3 (±5.4)	16.7 (±4.2)	17.0 (±3.0)	19.0 (±4.2)	17.9 (±2.1)
Stairs: Descending	46.2 (±5.4)	51.3 (±4.9)	19.2 (±4.1)	18.9 (±1.9)	19.5 (±4.9)	21.9 (±3.9)
Tying Shoe	29.0 (±8.0)	34.2 (±8.1)	8.0 (±3.0)	8.9 (±3.5)	8.1 (±2.6)	11.2 (±3.6)

The effects of age and motion were also analyzed. There was a significant difference in how older and younger subjects performed activities that required a single leg stance position. Older subjects had a significantly greater amount of hip flexion than their younger cohorts for both tying their shoes (+5.2°, p=0.006) and for descending stairs (+5.1°, p=0.02). Although not significant, the older group also had a higher amount of internal rotation while tying their shoes. There was also a significant difference between younger and older subjects for hip flexion when the three sit-to-stand activities were grouped together (-5° in the older group, p=0.009). There were no significant differences at the hip for how young and old subjects performed the picking up activity.

## DISCUSSION

The ball pick up activities employed the greatest range of motion which could put THA patients at risk for dislocation. The pivot and rotation movement is especially risky for patients who have undergone a posterior approach THA since the movement requires a substantial amount of flexion and internal rotation. All of the sit to stand activities also employ a fairly high level of flexion and internal rotation as well, especially when the seat is low to the ground and soft. These activities place the hip at a position near the peak ROM of the hip, close to where the person is at risk of soft and hard tissue impingement. [4]. This able bodied normative hip kinematic data table (and future ones to follow for the additional unreported activities) is necessary to identify

potentially risky activities for patients who have a total hip replacement. Future studies will be performed to identify how these motions are altered in a THA patient population, but this healthy normative data will serve as comparison data and provide doctors and therapists with more information that they can use to instruct post-op care.

Initial comparisons for how age influences hip movement during activities of daily living was also performed using this normative data table and initial differences were identified. For example, the results indicate that older individuals significantly increase their hip flexion while descending stairs. This increased flexion in the older group during stair decent was most likely to ensure that their heel cleared the edge of the step, possibly out of a greater fear of falling. This is speculation, but further analysis will analyze the full body kinematic profiles for both groups during all of the 56 activities to determine how movement profiles change with age. Some of the initial findings, such as the decreased flexion in the older group during sit-to-stand activities might actually indicate a lower risk of hip dislocation in older patients should these trends continue with THA patients. Once the influence of age on hip kinematics is identified, post-surgery instruction and therapy can be more targeted to the individual patient.

The work presented in this study is a critical first step towards a better understanding of how the hip moves during common activities of daily living and how those movements change with age. This data will serve as a foundation for safely collecting similar data with THA patients and for improving the instructions doctors and physical therapists provide their patients post THA.

# INDIVIDUALS WITH KNEE OSTEOARTHRITIS SHOW ASYMMETRY IN PEDALING MECHANICS

Harsh H. Buddhadev, Daniel L. Crisafulli, David N. Suprak, and Jun G. San Juan

Western Washington University, Bellingham, WA, USA

email: harsh.buddhadev@wwu.edu, web: <http://wp.wwu.edu/biomechanicslab/>

## INTRODUCTION

Cycling is a widely prescribed form of physical activity for individuals with knee osteoarthritis (OA) as it is shown to alleviate knee pain, stiffness, and improve walking speed. Despite the known therapeutic benefits of cycling, no research has examined pedaling mechanics bilaterally in individuals with knee OA.

When pedaling on a stationary ergometer, a person with knee OA can maintain a fixed pedaling intensity, by reducing the power output of the affected leg while simultaneously increasing the power output of the healthy limb because the pedals are connected by a common crank. Such inter-limb compensation of power output may reduce the efficacy and limit the improvements achieved during the rehabilitation process.

Similarly, individuals with anterior cruciate ligament (ACL) deficiency, have also been prescribed with cycling therapeutically, demonstrate significant asymmetry in pedaling mechanics. Under submaximal cycling conditions, the uninjured limb increased its output by 44-50% to compensate for the reduced effort by the ACL deficient leg [1]. However, it is not known whether individuals with knee OA also demonstrate inter-limb asymmetry in pedaling mechanics. Our purpose was to test the hypothesis that individuals with knee OA demonstrate asymmetry in pedaling mechanics.

## METHODS

Twelve individuals with knee OA ( $67.3 \pm 7.6$  years; 6 females and 6 males) and 12 age- and sex-matched healthy controls ( $66.1 \pm 7.3$  years) participated in the study. Local orthopedic surgeons confirmed and diagnosed the grade of radiographic evidence of knee

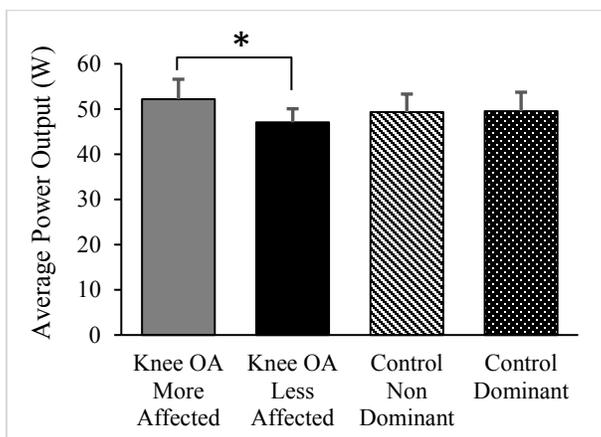

OA for each side utilizing Kellgren-Lawrence (KS) scale for participants with knee OA. The majority (8/12) of these individuals had bilateral OA, with one side more affected than the other (KS scale grade: More affected side =  $3.0 \pm 0.9$ ; less affected side =  $2.4 \pm 1.1$ ). Limb dominance for participants in the control group was determined by asking which leg they preferred to kick a ball.

Each participant completed a single 1-hour testing session. Following a bicycle set-up procedure that standardized the cycling posture on a Velotron bicycle ergometer, participants completed a 5-minute warm-up ride at 50 W at self-selected cadence. They then completed 2 minutes of pedaling at 100W-60 rpm as crank position, bilateral pedal orientation, and bilateral pedal anterior-posterior and normal pedal reaction forces were sampled synchronously at 250 Hz using a Sensix I-crankset force pedal system. Patients with knee OA confirmed that they were pain free for a week prior to the testing day and the experimental cycling condition was comfortable and did not cause knee pain or discomfort.

The crank position, pedal orientation, and pedal force data were low pass filtered at 4 Hz. The pedal forces were transposed to the crank coordinate system using pedal force, crank position, and pedal orientation data. Effective crank torque on each side was computed as a product of the component of pedal force perpendicular to the crank and length of crank arm. For a given crank cycle, the crank power on each side was computed as a product of average effective crank torque and pedaling cadence. The crank power was then averaged over 60 crank cycles. One-way ANOVA was used to examine the effects of limb-condition (e.g. knee OA- more and less affected leg, control-dominant and non-dominant leg) on average crank power. Significant differences were considered at  $p < 0.05$ .

## RESULTS

Net crank power (i.e. sum of crank power on both sides) and cadence data measured showed that both groups complied with the experimental condition (Knee OA:  $99.3 \pm 3.9$  W and  $60.3 \pm 0.5$  rpm; Control group:  $98.6 \pm 2.4$  W and  $60.2 \pm 0.4$  rpm). As expected, individuals in the control group did not show differences in power generated between their dominant and non-dominant limbs. However, individuals with knee OA demonstrated significant asymmetry in power output between their more and less affected lower extremity. Contrary to our expectations, the more affected leg yielded 11% more power (5.1 W;  $p=0.026$ ) compared to the less affected leg (Figure 1).

**Figure 1:** Effect of knee OA on average crank power during submaximal cycling at 100 W at 60 rpm. Individuals with knee OA applied more power with their more affected leg compared to their less affected leg ( $*p=0.026$ ). Mean  $\pm$  1 SD

## DISCUSSION

Our data indicates a small but significant asymmetry in crank power output, with the more affected leg yielding more power than the less affected leg. These findings contradict our hypothesis which was based on the logical assumption that grade of knee OA damage is related to function in these individuals. These findings are in agreement with those of Phan et al. [2] and Raynauld et al. [3], who did not find a correlation between function, assessed using Western Ontario and McMaster Universities

Osteoarthritis Index, and KS scores of individuals with knee OA.

Our results suggest that our patients with knee OA favored the more damaged leg rather than avoiding it. During physical therapy, the knee pain of patients with OA is alleviated and they are rehabilitated to gradually increase the use of the more affected leg and overcome compensatory limb avoidance strategies. All our patients had undergone physical therapy for their rehabilitation and they were pain free for at least one week prior to the testing session. Moreover, most of them ( $n=10$ ) were also physically active and engaged in at least 200 minutes of regular moderate intensity physical activity per week. Seven of these individuals also cycled more than 60 minutes on a weekly basis. We speculate that our physically active patients may have become accustomed to favoring the more affected leg during comfortable pain free cycling and thus had greater power output from the more affected compared to the less affected leg.

Excessive asymmetry in power output between the lower extremities can be detrimental to rehabilitation process and joint health of patients with knee OA. Thus, from a therapeutic perspective, our results of asymmetry in power output emphasize the need for monitoring symmetry of effort between legs for individuals with knee OA during cycling. Future studies should examine how inter-limb symmetry in power output during cycling changes through the physical rehabilitation process.

## CONCLUSIONS

Individuals with bilateral knee OA demonstrate asymmetry in crank power output. They apply more power with their more affected compared to their less affected leg.

# Strength of Arthroscopic Knot Tied with Compromised Suture: Effect of Defect Location

## INTRODUCTION

Suture anchors and sutures are commonly used in arthroscopic orthopaedic procedures. With recent advances in high-strength sutures, the risk of breaking an undamaged suture is relatively low. However, the risk increases substantially if the suture becomes frayed or nicked during arthroscopic procedure, such as being entrapped and pinched by suture-passing instruments. Previously studies have reported the simulation of suture abrasion against its anchor and how it affects its pullout strength in sutures with different materials [1,2]. Similar studies have been conducted with laparoscopic surgeries, where suture damaged by laparoscopic grasping forceps and needle holders [3] or robotic manipulation [4] were shown to have significantly reduced its tensile strength. What is unknown is whether incorporating the instrument-damaged spot of the suture within a suture knot would provide some shielding effect against the weakening strength.

The purpose of this study was to evaluate the effect of defect location on mechanical strength of the suture knot, by incorporating the compromised spot of the suture into the knot, or positioning inside the suture loop, or outside the suture loop.

## METHODS

Three trained orthopaedic surgeons prepared a total of 105 suture knot samples for the study. All knots were tied with No. 2 multi-strand, long chain ultra-high molecular weight polyethylene (UHMWPE) core with a braided jacket of polyester and UHMWPE (FiberWire by Arthrex, Naples, Florida). Stainless steel s-hooks (working load limit: 55lbs) were used to tie the knots. Four study groups were

formed: 1) Control (n=24), where the knots were tied with non-damaged sutures, 2) Knot (n=25), where the damaged spot was incorporated within the knot, 3) Loop (n=29), where the damaged spot was placed inside the suture loop of the knot, and 4) Out (n=27), where the damaged spot was left outside of the suture knot and loop (Fig.1).

To create the damage, suture samples from the three later groups were first placed in a scorpion suture passer (Arthrex, Naples, Florida) along with a spare suture to simulate the entrapment scenario. A controlled abrasion defect was then inflicted in the suture sample by operating the suture passer. Once visual inspection confirmed the defect, a quadruple Duncan sliding knot was tied around the s-hook with the nicked spot placed in its group designated position.

All suture knot samples were tested on a servo hydraulic load frame (Model 809, MTS Systems Corp. Eden Prairie, MN). The s-hook with suture knots tied around it was linked to an I-bolt that was mounted to the crosshead of the MTS system through a hydraulic grip. The two free ends of the suture were wrapped around to a 1-inch diameter steel bar which could rotate freely about its shaft to reduce the friction force on the suture. The suture was then pressed down and secured to the actuator (Fig.2). The fixation point of the suture was marked with permanent ink to verify that no slippage occurred during the test. The exposed suture length was kept at 5 inches for all samples. A 5 N preload was applied to the sample to pretension the specimen and provide a common starting point. The suture sample was loaded to failure at a rate of 1 mm/s. Force and displacement data were collected at 100Hz. Suture failure load was defined as the peak force before its first sudden drop on a force-

displacement plot. Suture breaking point of each sample was noted after the experiment. Comparison of the damaged groups against the non-damaged control was performed using Kruskal-Wallis test and post-hoc nonparametric comparisons with control using Dunn method for joint ranking. All statistical analysis was performed using JMP 12 (SAS, Cary, NC), and with statistical significant level set at 0.05.

**Figure 1:** Illustration of three defect locations: Loop, Knot, and Out.

**Figure 2:** Experimental setup

## RESULTS

Good agreement among the three evaluators were found in mean suture strength of each study group, where deviations of individual mean from group mean was less than  $\pm 5\%$ . The data were then pooled together to evaluate the effect of defect location.

As expected, the non-damaged Control group had the highest tensile strength, with a mean of  $278.1 \pm 32.5$  N. The Knot group, with the defect incorporated within the knot, came second, at  $264.5 \pm 37.9$  N, which was 4.9% lower than Control. The Out group, with defect left outside of the knot

and suture loop, was 11.0% than the control, at  $247.6 \pm 36.0$  N. The weakest group was Loop, with defect located inside the suture loop, at  $236.0 \pm 62.7$  or 15.1% less than the control. Both the Loop group and Out group were significantly weaker than Control ( $p < 0.017$ ,  $p < 0.015$ ). The difference between the Knot and Control was not statistically significant.

All but four of the 24 sutures in Control broke off at the knot, while the four failed inside the suture loop. Majority of the Knot group sutures failed at the knot, while five out of 25 failed inside the suture loop. In Loop and Out groups, approximately half of the sutures broke at the defect spot, while the others failed at the knot.

## DISCUSSION

Results from this study show that incorporating the defect into the knot has the least impact on the strength of the suture knot. The worst choice is to leave the defect inside the suture loop, a 15% reduction in the strength. Limitations of the study include: 1) experiments were conducted without an environmental chamber to mimic in vivo condition these suture knots are applied to. 2) The study design did not include cyclic loading of the samples before load-to-failure test. It is possible that additional dynamic creep may occur in the suture with cyclic loading, and impact the maximum force.

The strength of arthroscopic suture knot plays essential role for the integrity of tissue repairs. Accidental minor damage to the suture does occur during the procedure. Our findings suggest that incorporating the defect within the suture knot is the best option to minimize the effect.

## INTRODUCTION

The lateral malleolus is important in maintaining a congruent and stable ankle joint. Weber B lateral malleolus fractures, caused by supination and external rotation of the ankle, are the most common type of fracture of the fibula [1]. Controversy still exists regarding surgical necessity of Weber B fractures in cases where the lateral malleolus is fractured and displaced without clinically significant talar shift or medial ankle disruption. Furthermore, the results of current cadaveric biomechanical research reproducing Weber B fractures has yielded conflicting conclusions with regards to its influence upon tibiotalar contact [2-4]. The purpose of this study was to measure the contact areas and peak pressures between the tibial plafond and the talar dome in a cadaveric model with serial displacement of the distal fibula in two isolated Weber B fracture patterns (a transverse fibular fracture and short oblique fibular fracture). Our test hypothesis was that serial displacement of the distal fibula with an intact deltoid ligament complex in this Weber B fracture model would induce no significant changes in contact areas or peak pressures.

## METHODS

12 fresh (6 matched pairs) ankle cadaveric specimens with no prior history of trauma or pre-test laxity were collected from a tissue bank. Skin and subcutaneous tissue were removed from mid-tibia to the hindfoot. The extensor tendons were removed to provide access to the ankle joint. Ankle ligaments, including the deltoid complex, were meticulously maintained. The proximal tibia was potted in a PVC tube using epoxy resin and then mounted onto a Mini Bionix loading machine (MTS Inc. Eden Prairie, MN) and subjected to a 154 lbs

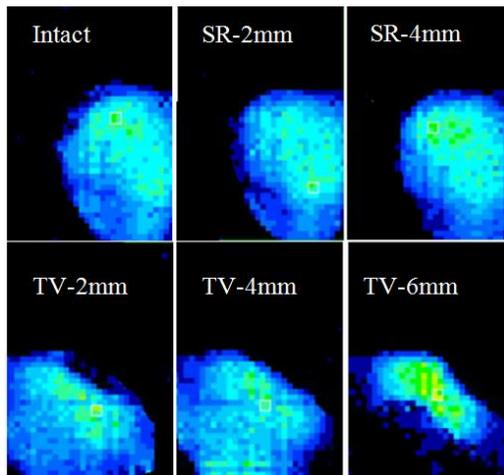

(70kg) axial compressive load (Fig. 1). A Tekscan pressure sensor (model 5033, Tekscan Inc., South Boston, MA) was placed in the ankle joint to monitor the pressure distribution and contact area. Each specimen was first tested at baseline prior to simulated fracture. With a sensor in place, the ankle was subjected to a static, axial load at neutral position, 5 and 10 degrees dorsiflexion, and 5, 10, 15, and 20 degrees plantarflexion using an angled platform. One ankle was randomly selected from each pair to simulate a transverse Weber B fracture with lateral displacement conditions of 2, 4, and 6mm of the distal fibula. A spiral oblique Weber B fracture was simulated on the contralateral ankle with two coupled displacement conditions of the distal fibula (2mm lateral translation and 5 degrees external rotation, then 4mm lateral translation and 10 degrees external rotation). These specimens were then subjected to the same static, axial load and positions as intact specimens for comparative analysis. ANOVA testing was used to compare the peak pressures and contact areas among intact specimens, transverse fracture specimens (TV) and spiral fracture specimens (SR). In statistical analysis a two-sided significance level of 0.05 was selected.

**Figure 1:** Biomechanical testing set-up on Mini Biomix loading machine.

## RESULTS AND DISCUSSION

It was found that at the neutral position (0 degree), intact specimens had similar shape of contact area and pressure distribution with the SR specimens, but not the TV specimens (Fig. 2). The average contact area of the intact specimens (376 mm<sup>2</sup>) was slightly smaller than those of SR specimens (386 mm<sup>2</sup> at 2mm translation and 386 mm<sup>2</sup> at 4mm translation) but not significant (Table 1). TV specimens had larger contact areas (420, 417 and 370 mm<sup>2</sup> at 2, 4, and 6mm translation), but not significant as well. On the contrary, the average peak pressure of the intact specimens (5.7MPa) was slightly higher than SR (5.5 and 5.4MPa at 2, and 4mm translation) and TV specimens (5.3, 5.3 and 5.4MPa at 2, 4, and 6mm translation), but again none of these values were significant. Specimens at other positions (dorsiflexion or plantarflexion) showed a similar trend. In general, more flexion indicated smaller contact areas and higher peak contact pressure, but not significant as well.

**Figure 2:** Pressure distribution of specimen #3 at neutral position. SR: spiral; TV: transverse.

The results revealed that isolated Weber B fractures (both transverse and spiral oblique models) without clinically significant talar shift or medial ankle disruption does not significantly change the contact area and peak pressures of the tibiotalar articulation. This study supported the conclusions of Clarke et al that isolated Weber B fractures may not require

surgery based on axial load cadaveric observations [3].

**Table 1.** Mean contact areas (cm<sup>2</sup>) and peak pressures. SR: spiral; TV: transverse; Df: dorsiflexion; and Pf: plantarflexion.

20Pf	6.5	6.2	6.2	7.2	6.5	5.6

## CONCLUSIONS

This study suggested that isolated Weber B fractures with the distal fibula displaced laterally up to 6mm or superolaterally up to 4mm lateral translation and 10 degrees external rotation do not cause ankle instability. Interpretation of these results suggested that without significant loss of joint congruence, there is likely no long term pathogenesis of osteoarthritis and pain in this fracture model, therefore mitigating the need for surgery.

## INTRODUCTION

Chronic constipation (CC) and fecal incontinence (FI) are common gastrointestinal problems which affect approximately 20% of the North American population [1, 2]. Dyssynergic defecation, which causes CC, is the inability to relax the anal sphincter (AS) and puborectalis (PRM) muscle during defecation. Whereas weakness and injury in AS sometimes result in FI, both problems are typically diagnosed with anorectal manometry (ARM).

In traditional ARM, the AS closure pressure is recorded using a 4 mm diameter catheter with 4 orthogonal pressure sensors. Recently, high resolution systems with many more pressure sensors have become available, but they are expensive, require dedicated space and trained staff at tertiary care medical centers. Many patients go undiagnosed because of limited access to tertiary care centers.

We designed and fabricated a low-cost, disposable, point of service, instrumented glove [3] for community gastroenterologists to assess AS and PRM function during a rectal exam. Termed “Digital Manometry” (DM) it records AS and intrarectal pressures as well as EMG data from the AS and PRM muscles. DM provides similar information to ARM at nearly 3 orders of magnitude lower equipment cost.

## METHODS

The goal of this study was to test anorectal function in 3 healthy young subjects using DM and compare the results with ARM. The DM device consists a disposable instrumented glove (Fig. 1), wrist mounted signal conditioning unit, a data acquisition unit and a laptop.

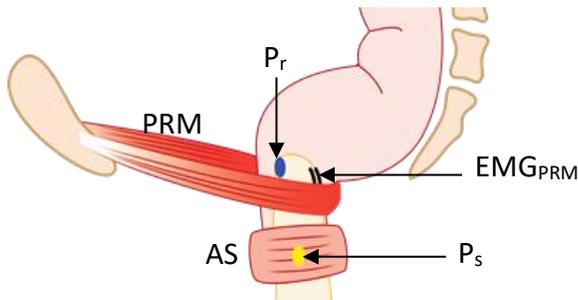

**Figure 1:** DM disposable instrumented glove

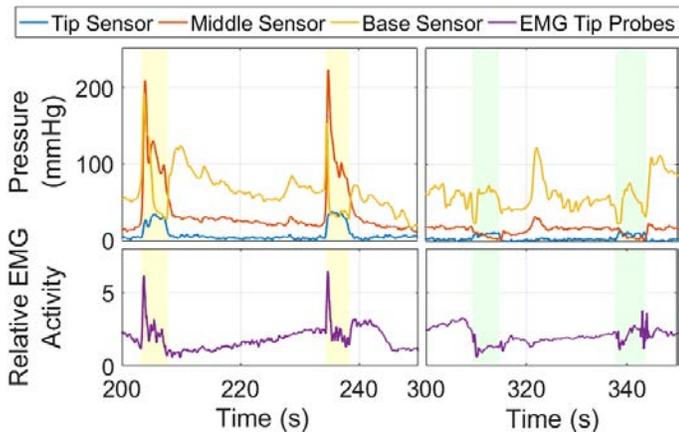

Three MEMs pressure sensors were mounted and wirebonded on a custom designed flexible printed circuit board (FPCB). After encapsulating connections by rigid adhesives, each sensor was covered by a thin layer of silicone rubber to ensure a smooth finish. The FPCB was then wrapped around a glove index digit such that pressure sensors are located on the tip of the distal phalanx, the medial aspect of the middle phalanx and the PIP joint, respectively. The FPCB has two sets of gold plated electrodes on the tip and the shaft of the digit to capture EMG signals from PRM and AS muscles. The entire digit was covered by a latex layer with EMG probes left exposed. Signals from the probe pass through a wrist-mounted signal conditioning unit and a data acquisition device to a laptop computer. Contraction durations in DM was recorded by a digital event marker.

During the study, resting pressures were recorded and then subjects were asked to maximally contract their AS muscle for three 5-10 seconds intervals separated with ~20 seconds rest periods. They were

then asked to simulate defecation by attempting to push out the examiner's finger (Fig. 2) at least three times (Fig. 3).

**Figure 2:** Schematic showing of the examiner's finger wearing the DM glove with its pressure transducers for measuring rectal pressure ( $P_r$ ) and AS pressure ( $P_s$ ) and PRM EMG ( $EMG_{PRM}$ )

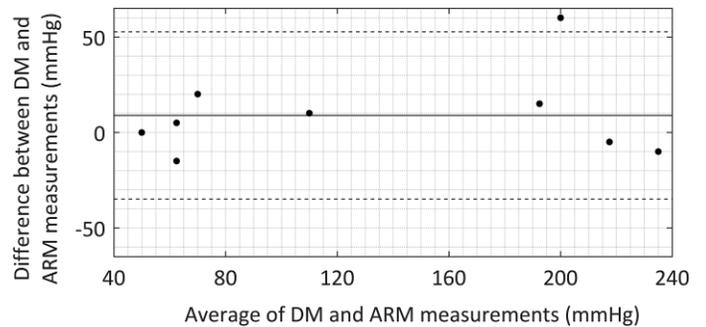

**Figure 3:** Sample AS and rectal pressures (top) and RMS  $PRM_{EMG}$  (bottom) in maximum squeeze (yellow highlights) and simulated defecation (green highlights) from one trial in one subject.

## RESULTS AND DISCUSSION

Sample results may be seen in Fig. 3. When a Bland-Altman [4] analysis was used to study the differences between DM and ARM the mean difference was found to be 9 (mmHg) and limits of agreement  $\pm 44$  mmHg (95%). The slope of the linear regression line between DM and ARM was 0.9. The physical difference between the examiner's finger diameter using DM (i.e., 22 mm) and ARM catheter diameter (i.e., 4 mm) did not lead to a systematic difference in recorded AS pressures as demonstrated by the 9

mmHg difference between ARM and DM results. The one outlier in Fig. 4 could be due to an ARM pressure reading elevated by contact stress or the DM AS pressure sensor being positioned away from the location of maximum AS closure pressure - a change of just one centimeter along the AS can cause a 30% decrease in measured AS pressure [5]. The mean (SD) resting rectal pressure values measured using DM were 29 (13) mmHg.

**Figure 4:** Bland-Altman plot showing the limits of agreement (dashed lines) between DM and ARM measurements of AS pressures.

## CONCLUSIONS

DM gave promising measurements of AS pressures at a fraction of the cost of ARM, and via additional pressure and EMG measures an assessment of anorectal functionality not provided by ARM.

## INTRODUCTION

Bone sarcomas are the fourth most common cancer in individuals under 25 years [1]. Osteosarcoma, the most common subtype of bone sarcomas in this population, is commonly observed in the growing metaphyseal regions of the femur. Limb salvage surgery (LSS) is the standard of care for osteosarcoma in the lower extremities. This complex procedure often involves removal of the tumor and reconstruction of the bone with an implantable metal and polyethylene endoprosthesis. Although LSS has greatly reduced the number of amputations in this population, the procedure is associated with more long-term complications than standard joint arthroplasty. Over time, endoprostheses fail due to aseptic loosening, polyethylene wear, and/or mechanical device fracture. These failure mechanisms indicate that the mechanical loads sustained by the bone-implant construct influence implant survivorship. At present, there is no validated standard method for objective functional outcome measurements following LSS, and only a few studies have reported gait analysis data in this population. These reports have identified two distinct, abnormal sagittal plane knee kinematic patterns during gait: fixed extension (FEx) knee and fixed flexion (FFI) knee. The FEx knee pattern is identified by persistent hyperextension of the affected knee during loading response. The FFI knee pattern consists of a constant knee flexion angle on the affected side during mid-stance (Fig. 1) [2, 3]. Our study aimed to quantify lower body gait kinematics and joint reaction forces (JRFs) of adults who have a distal femoral endoprostheses following LSS. An emphasis was placed on using advanced musculoskeletal modeling techniques to provide the first assessment of internal JRF in this population,

which we theorize can have a significant effect on longevity of the implant, and to examine differences between the FFI and FEx knee pattern groups.

**Figure 1:** Average knee flexion patterns for the fixed extension (blue) and fixed flexion (red) groups

## METHODS

Eight subjects (Age:  $36.3 \pm 18.8$  years; height:  $170.5 \pm 12.3$  cm; weight:  $71.3 \pm 15.7$  kg; 6 F, 2 M) who previously underwent LSS with a distal femoral endoprostheses gave their informed consent to participate in this IRB-approved study. None of the subjects had undergone primary or revision surgery for at least one year prior to this investigation. Three-dimensional gait analysis was performed with a 12-camera motion analysis system (MX model, Vicon Motion Systems Inc., Oxford, UK). An OpenSim gait model, Gait 2392 [4], was used as a basis for creating patient specific models. Each subject's model was altered to exclude musculature removed during the LSS. These models and the subject gait data were input into static optimization and joint reaction analysis algorithms to resolve net joint moments into individual muscle forces and calculate

the axial internal JRF at the knee. The subjects were divided into two groups based on their stance knee flexion patterns (4 FEx, 3 FFI, 1 neutral). A two-way mixed factor analysis of variance (ANOVA) was performed in JMP v12 (SAS, Cary, NC) with significance concluded when  $p < 0.05$ . Post-hoc analyses were completed using a Student's T test. Independent variables included limb, gait pattern, and a limb x gait pattern interaction. Dependent variables included peak knee flexion angle during loading response and peak knee JRF during stance phase. Statistical analyses were performed for the axial JRFs.

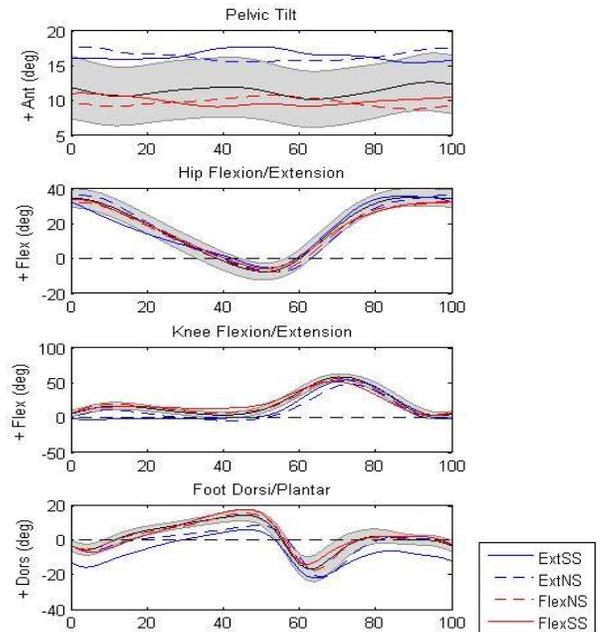

## RESULTS AND DISCUSSION

The FEx group exhibited a 37.5% higher axial JRF than the flexed group. While the surgical limb tended towards lower axial JRF, there were no statistically significant differences between surgical and non-surgical limbs. The kinematic analysis of the FEx group revealed a 605% lower peak angle on the surgical side compared to the nonsurgical side. The surgical limb of the FEx group exhibited an 854% lower peak angle than the FFI group's surgical side. Compared to the FFI group, the FEx group showed greater differences between limbs and from normal data in both kinematics and kinetics. The FEx group exhibited more gait dynamics deviations and higher joint reaction forces; putting them at higher risk of pathology or injury in the hip and ankle joints on the surgical limb and/or the contralateral limb (Fig. 2). Push-off power is greatly reduced in the FEx group, although walking speed is not significantly diminished compared to the FFI group (FEx gait speed=0.98 m/s, FFI gait speed=1.06 m/s).

## CONCLUSIONS

Our results indicated that the FEx group was more likely to experience higher axial JRFs compared to the FFI group. This observation suggests the gait pattern adopted by the FEx group may be more damaging to the implant, hence affecting its longevity. Based on the data from this study, we suspect that those patients who exhibit a FEx gait pattern may have instability resulting from weakness or muscle resection. This needs to be further explored. Post-operative quadriceps strengthening and rehabilitation is vital. A post-operative protocol

of gait analysis may be indicated to identify those who are adopting the FEx pattern. Those patients may also benefit from focused gait training as part of their regular rehabilitation protocol.

**Figure 2:** Sagittal plane kinematic results throughout the gait cycle. Solid blue line represents the fixed extension surgical limb, dashed blue line represents the fixed extension non-surgical limb, solid red line represents the fixed flexion surgical limb and the dashed red line represents the fixed flexion non-surgical limb. Solid black line and gray band represent the mean and standard deviation of a data set of 48 young adult controls from our motion analysis laboratory.

## INTRODUCTION

Transforaminal lumbar interbody fusion (TLIF)[1] has been a successful treatment to restore disk height and improve the biomechanical stability of the diseased vertebral segments. However, the placement of the fusion cage is based on the surgeon's experiences and could be affected by the surgical approach. Few studies have reported the effects of minimally invasive surgery (MIS)[2] and conventional open surgery on the cage placement. Therefore, the aim of this study was to evaluate and compare the cage positioning of MIS and open surgery. We hypothesized MIS-TLIF could improve the cage placement accuracy with respect to open TLIF.

## METHODS

We retrospectively reviewed all the MIS- and open TLIF cases between Jun, 2013 and Feb, 2015 in our hospital and selected 25 MIS-TLIF and 25 open-TLIF cases for treatment of single-level lumbar degenerative disease. No complications, like cage lipping, sinking or any other untoward effects, have been reported at the time of this study. Anteroposterior and mediolateral radiographs which were taken in routine follow-up at two weeks after surgery were retrieved for data analysis. Three reference markers of the cage were used to determine its position and orientation according to the manufacture design (Fig. 1). Radiographic bony features which have been frequently used in clinical evaluations were digitized for determination of disk dimensions, center of the interbody space, and orientation of the vertebral bodies (Fig. 1&2). The anteroposterior (AP), superoinferior (SI), and mediolateral (ML) distances from the center of the

interbody space to the center of the cage were quantified and normalized according to the vertebral body dimensions in MATLAB (The MathWorks, Natick, USA). The independent t-test was used to compare the cage positioning using MIS- and open TLIF. The significance level was set at 0.05.

## RESULTS

The averages and standard deviations of the normalized distances from the interbody center to the cage center in the MIS-TLIF group were  $-1.9\% \pm 9.4\%$ ,  $2.9\% \pm 9.9\%$ , and  $-0.5\% \pm 6.3\%$  along ML, AP, and SI directions, respectively (Table 1). Corresponding values of the open-TLIF group were  $4.9\% \pm 11.4\%$ ,  $2.6\% \pm 11.7\%$ , and  $-0.6\% \pm 7.0\%$ . Statistically significant difference ( $p = 0.027$ ) was found between MIS- and open-TLIF along ML direction. The spinal cage placement in the MIS-TLIF group is more close to the center of the interbody center along ML direction. No significant differences were reported along the other two directions. Standard deviations of the cage placement were found to be smaller in the MIS-TLIF group (Table 1).

## DISCUSSION

This study successfully quantified the spinal fusion cage position with respect to the interbody space after MIS- and open-TLIF surgery by taking the advantage of the built-in reference points of the fusion cage. The centered cage placement along ML direction is recommended in clinical reports. Our results demonstrated that the MIS-TLIF can produce a more biomechanically favorable cage placement than the open-TLIF. The cage placement precision was also found to be better in the MIS-

TLIF group. Since routine follow-up radiographs were sufficient for the evaluation, no additional radiation exposure is required. This image-based cage placement measurement would be helpful for long-term clinical follow-up for TLIF patients. Additional efforts are guaranteed to determine the accuracy and precision of this measurement.

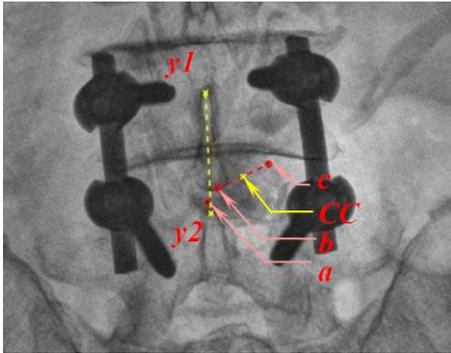

Figure 1. Point CC (Cage Center) was the center of the cage and the line (y<sub>1</sub> y<sub>2</sub>)<sup>-</sup> was the link between spinous processes of vertebrae representing vertical central line of vertebrae. The distance from (y<sub>1</sub> y<sub>2</sub>)<sup>-</sup> to CC was defined as the cage placement along the mediolateral (+/-) direction.

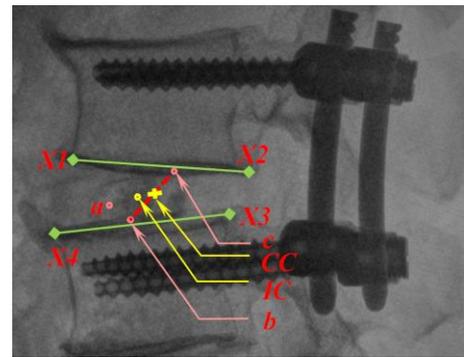

Figure 2. Point CC was the center of the cage. Point IC (Intervertebral Center) was the geometry center of the intervertebral space. The anteroposterior (+/-) and superoinferior (+/-) distances from IC to CC were quantified for evaluation of the cage placement.

# A BIOMECHANICAL COMPARISON OF SYNDESMOTIC REPAIR TECHNIQUES DURING EXTERNAL ROTATION STRESS

Jessica Goetz, Nathan Davidson, M James Rudert, Andrea Caceres, Matthew Karam, and Phinit Phisitkul

University of Iowa; Iowa City, IA, USA  
email: [jessica-goetz@uiowa.edu](mailto:jessica-goetz@uiowa.edu), web: <https://uiowa.edu/uiobl/>

## INTRODUCTION

The distal tibiofibular syndesmosis is the ligamentous junction between the tibia and fibula at the ankle. During ankle fractures or sprains, individual or all of the syndesmotic ligaments can be torn. Such injuries are often accompanied by disruption of the deltoid ligament complex medially, resulting in a highly unstable joint. It has been reported that 23%-45% of ankle fractures that are treated operatively have syndesmotic disruption that must also be operatively stabilized [1].

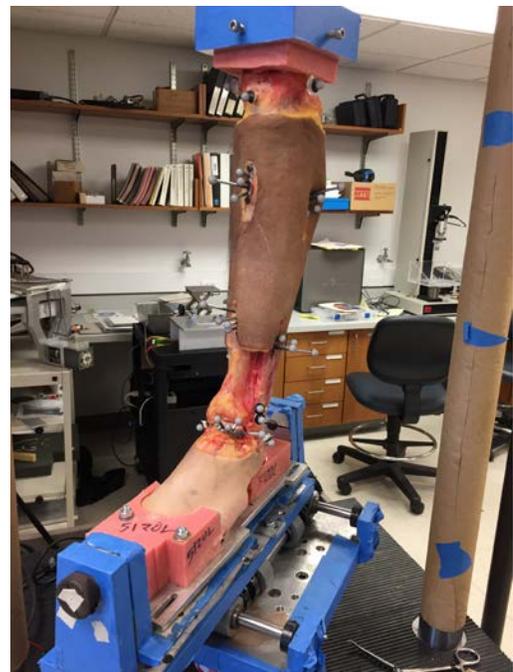

Syndesmotic injuries are most often treated surgically by rigidly fixing the fibula to the tibia using screws. However this makes a previously flexible joint completely rigid, which can induce a variety of long-term functional complications. More recently, a flexible tightrope device has begun to see more widespread application for treating these injuries. However the biomechanics of this device are still under investigation [2], often with conflicting results.

The purpose of this work was to compare the mechanical behavior of existing syndesmosis fixation techniques with techniques incorporating various augmentations to improve anatomic realism, and determine which technique would return the rotational ankle mechanics closer to those of an intact ankle.

## METHODS

Ten pairs of fresh frozen through-the-knee cadaveric lower limbs (average age 57.8 years of age, range 37-67; 8 male/2 female) were potted in polymethylmethacrylate bone cement for interfacing with a custom mechanical testing fixture mounted in a Materials Testing Machine (MTS, Eden Prairie, MN). Proximally, the fixture

consisted of a lockable rotary bearing for interfacing with the potted tibial plateau. Distally, the fixture consisted of a lockable xy stage onto which was mounted a plate rigidly immobilizing the potted toes and distal calcaneus (Figure 1). All other joints of the foot were free to move, and the proximal tibiofibular junction was left intact.

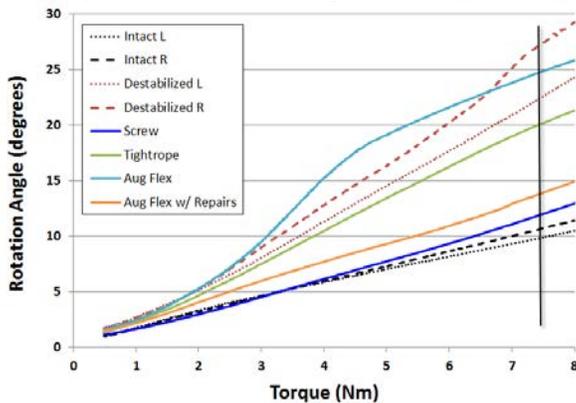

**Figure 1.** Photograph of specimen mounted in MTS for mechanical testing. Blue tape was used to mask reflections during optical marker tracking.

Clusters of reflective markers were mounted on the tibia, fibula, and talus to track bony kinematics. During testing, 750N of compressive axial load was applied to the proximal tibia while the tibia was free to move in rotation and the foot to move in the AP/ML direction. Collars on the xy stage and the rotary bearing were then locked. 100 preconditioning cycles of 5 Nm internal tibial torque (i.e. external foot rotation) were applied. Specimens were allowed to relax for 5 minutes after preconditioning. The definitive torque test

consisted of a single rotation test to 7.5 Nm of torque applied at 1 Nm/sec.

Testing was performed with all ligaments intact and again with the deltoid and syndesmotic ligament complexes completely disrupted. One leg from each pair was then randomly selected to receive “standard” fixation using a standard 4-cortex, 4.5 mm diameter screw, or a tightrope. The fixation was then exchanged and placed through the same hole. The order of fixation placed was also randomized, with 5 specimens having the screw placed before the tightrope and the other 5 having the tightrope placed before the screw. The other ankle from each pair received augmented fixation consisting of a structurally reinforced flexible syndesmosis fixation device, and that device with the addition of suture repairs of the deltoid and anterior inferior tibiofibular ligament. Again, the order of fixation was randomized with n=5 specimens receiving just the structurally reinforced flexible device first and n=5 receiving the additional ligament repair first. The repairs were then exchanged. The rotation angles at 7.5 Nm of applied torque were extracted for comparison of the stability of the different repair strategies (Figure 2).

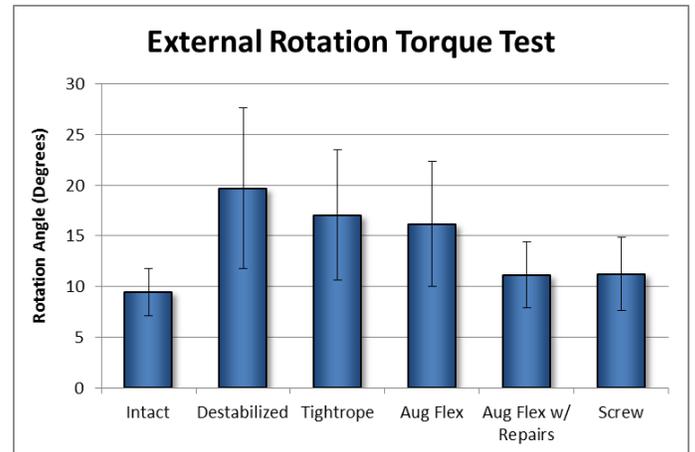

**Figure 2.** Representative torque-angle curves from a single specimen pair. The vertical line indicates 7.5 Nm where the assessment of stability was made.

## RESULTS AND DISCUSSION

Destabilizing the medial and lateral ligaments significantly increased the rotation angle under 7.5 Nm of applied external foot rotation torque. Repair with a screw returned the rotational stability to the joint to near intact levels, whereas the tightrope construct only minimally corrected rotational

instability. The structurally augmented flexible fixation device provided a slight increase in rotational stability over the tightrope device, but did not return the mechanics to intact levels. Addition of ligament repairs to the augmented flexible device successfully returned stability to near intact levels.

**Figure 3:** Average rotation angle under 7.5 Nm of torque. Error bars indicate standard deviation. n=20 for Intact and the Destabilized conditions, and n=10 for the different repair techniques.

## CONCLUSIONS

Syndesmotic repair has focused on preventing lateral translation of the fibula relative to the tibia using either screws or tightrope repairs. We have found that the tightrope alone is insufficient for restoring rotational stability despite sufficiently preventing coronal plane diastasis. Addition of structural stiffness and/or simulating the anatomic structures disrupted during injury better returned the rotational behavior of a destabilized syndesmosis to normal. This would indicate that there is a need for devices to better recreate the native anatomy.

# AN INTRA-OPERATIVE BIOMECHANICAL GUIDANCE SYSTEM FOR REDUCING ARTICULAR FRACTURES

Andrew M. Kern, Michael C. Willey, J. Lawrence Marsh, Donald D. Anderson  
Department of Orthopedics and Rehabilitation, The University of Iowa, Iowa City, IA  
email: andrew-kern@uiowa.edu, web: <http://www.uiowa.edu/uiobl/>

## INTRODUCTION

Patients sustaining intra-articular fractures (IAFs) frequently face poor outcomes. Post-traumatic osteoarthritis (PTOA) is common, partly due to elevated contact stress from residual incongruity following imprecise surgical fracture reduction.

Surgeons already strive to restore an anatomical joint surface, but intra-operative efforts face challenges related to visually judging adequacy of reduction.<sup>1</sup> To address these challenges, we have developed a biomechanical guidance system which uses established 2D-3D pose estimation methods to provide feedback about the positioning of bone fragments. In addition, since a perfectly anatomic reduction can be infeasible, contact stress analysis is used to help the surgeon decide if PTOA-inducing levels<sup>2</sup> are exceeded.

In this study, we present a prototype biomechanical guidance system and report its use in 10 surgeries performed on fractured cadaveric ankles. The accuracy of fragment alignment and contact stress analysis are also evaluated.

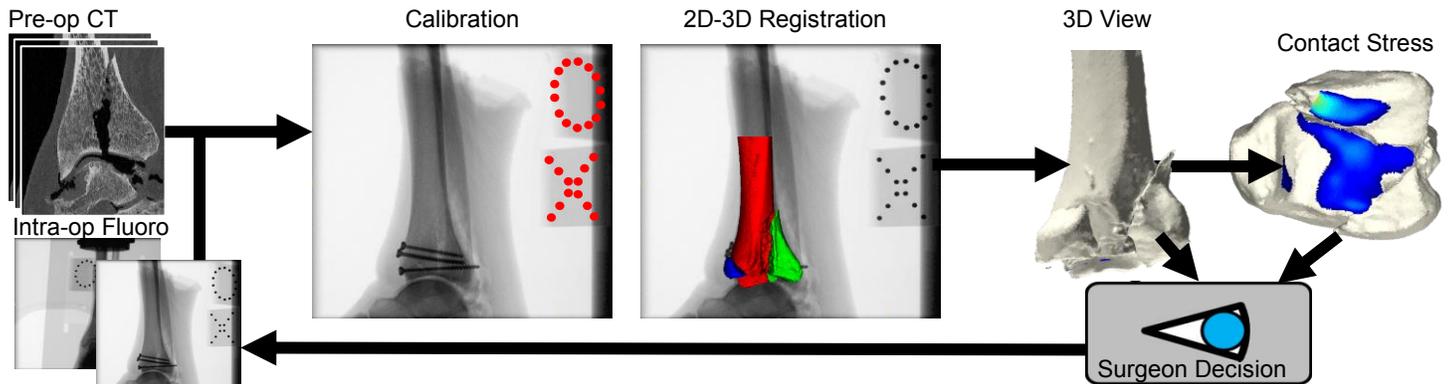

## METHODS

The biomechanical guidance system is designed to

provide accurate and useful information to the surgeon relying only upon images from a C-arm fluoroscopy unit. (Fig 1) Before surgery, individual fracture fragments are segmented from a CT scan, and 3D models of the cortical and subchondral bone surfaces are produced. The base fragment, identified as the fragment attached to the tibial diaphysis, is aligned to an anatomical coordinate system for subsequent contact stress analysis.

Intra-operatively, C-arm fluoroscopy (Siemens Cios Fusion) are first acquired, from two different views. Then the orientation of the detector is determined using a custom designed calibration object placed within the field of view. The previously segmented CT data (surfaces, as well as image intensities) are used in a 2D-3D registration algorithm to identify the pose of individual bone fragments. The 3D surface models of the articular bone fragments are displayed to the surgeon in the current state of fracture reduction.

Upon surgeon request, contact stress is computed, (assuming perfect rigid fixation) and overlaid on the 3D model. Contact stress is computed using a previously validated discrete element analysis (DEA) algorithm.<sup>3</sup> The subchondral surface of each bone is offset by 1.7 mm to simulate a uniform cartilage thickness. Contact stresses are computed in

**Figure 1.** Intra-op biomechanical guidance system. Pre-op CT and intra-op fluoro images (calibrated using custom calibration object) enable 2D-3D registration to determine pose of individual fragments. Contact stress results are computed using DEA. Surgeon uses this information to guide their progression through the operation.

a single static pose, with 1000 N axial load applied to the tibia, and 100N applied medially to simulate the stabilizing influence of the fibula.

The system was evaluated in tibial plafond fractures produced in five cadaveric ankles. The fractured ankles were reduced percutaneously, with results recorded by the guidance system. Following final reduction, a post-op CT scan was obtained to provide gold-standard geometric data for evaluation of the registration error of the guidance system. The fixation hardware was removed, and each fractured ankle was reduced a second time (i.e., 10 fracture reductions in total).

Registration accuracy of the intra-op pose data was assessed within Geomagic Studio (3D Systems) by making per-fragment comparisons to surface models of the gold standard data. Accuracy of the intra-op contact stress data was assessed by comparing contact stresses computed using the intra-op pose data to those computed using the gold standard dataset.

## RESULTS AND DISCUSSION

This prototype system was used successfully in 10 simulated surgical procedures. The system was used on average  $4.8 \pm 1.3$  times per procedure. Alignment error in 2D-3D registration is  $0.45 \pm 0.57$  mm in translation and  $2.0 \pm 2.5^\circ$  in rotation. Contact stress distributions and fracture fragment orientations produced by guidance visually compare well to gold standard results (**Fig 2**). The difference in mean and maximum contact stress for intra-op results vs. gold standard are 0.45 (7%) and 1.0 (4%) MPa, respectively.

While there was good alignment accuracy overall, there is substantial variation in alignment error, with alignment errors most commonly present when

small bone fragments are partially occluded by surgical instruments or fixation screws. Continued development of the 2D-3D alignment algorithms and additional experience with the system will likely lead to less frequent alignment failure. Regardless, the contact stress estimates did not vary substantially between intra-operative and gold standard results. This low contact stress error suggests that our guidance system produces results with sufficient accuracy for ongoing study.

## CONCLUSIONS

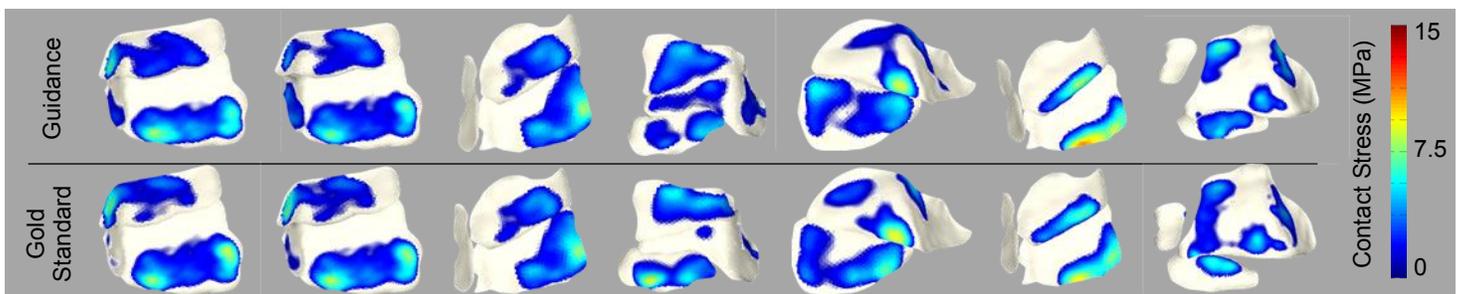

A system for providing intra-op biomechanical guidance to improve articular fracture reduction has been developed. The system was used successfully in 10 percutaneous cadaveric ankle fracture surgeries. Occasional alignment errors caused by the presence of surgical instruments notwithstanding, this study suggest that the system provides sufficient accuracy to warrant continued evaluation. Future work will involve determining the efficacy of 3D feedback in the OR for improving reduction accuracy and joint biomechanics.

# THE ANTHROPOMETRIC MODEL INFLUENCES WHOLE-BODY CENTER OF MASS CALCULATIONS IN GAIT

<sup>1</sup> Robert D. Catena, <sup>2</sup> Szu-Hua Chen, and <sup>2</sup> Li-Shan Chou

<sup>1</sup> Washington State University, Pullman, WA, USA

## INTRODUCTION

Examining the whole-body center of mass (COM) motion is one of the methods being used to quantify dynamic balance and energy expenditure during gait. One common method for estimating the COM position is to apply an anthropometric model to a marker set and calculate the weighted sum from known segmental COM positions. Several anthropometric models are available to perform such a calculation. However, to date there has been no study of how the anthropometric model affects whole-body COM calculations during gait. This information is pertinent to researchers because the choice of anthropometric model may influence gait findings and currently the trend is for a single model to consistently be used in a study.

## METHODS

We analyzed a single stride of gait data from 103 participants (age 18 to 32, 47 females, average height of 1.75m, average weight of 79.64kg, average BMI of 25.68 kg/m<sup>2</sup>). Fifty-three participants were NCAA athletes or club athletes.

Participants were asked to perform level-walking gait over a 10 m walkway at a self-selected pace. Twenty-nine retroreflective markers were taped to bony landmarks and segments slightly modified from a Helen Hays markers set. A single stride in the middle of the walkway was analyzed. A ten-camera motion capture system captured marker movement at 60 Hz. Marker data were filtered using a 4th order Butterworth filter with a cutoff frequency of 8 Hz.

A 13-segment model of the body was created in Cortex and Biosuite software (Motionanalysis Corp., Santa Rosa, CA). We compared the whole-body

COM motion in each dimension calculated from 4 different anthropometric models [1-4].

We identified the whole body COM location and velocity in each direction at the lead and trailing foot heel strikes and toe-offs. We also identified the total range of motion of the COM in each direction and the maximum velocity of the COM (vCOM) in each direction, as these are commonly used measures of balance control. A within-subject analysis of variance was conducted on each dependent variable to determine the effect of anthropometric model. Follow up pairwise comparisons were conducted using Bonferroni adjustments when appropriate with a significance level (p value) set at 0.01.

## RESULTS AND DISCUSSION

Of all models, Dempster [4] estimates the location of the center of mass highest in the body. The peak medial velocity is also slowest using the Dempster model. The vertical vCOM is highest at specific gait events using Dempster, but peak vertical velocity is only different from the Pavol model.

The Pavol model [2] does not provide much of a different estimate of COM location in the anterior-posterior or medial-lateral directions compared to other models. The vertical COM location estimated by Pavol is in between where other models estimate. The vertical peak velocity is also fastest with the Pavol model.

Plagenhoef [3] consistently estimates the location of the COM in the anterior-posterior direction during heel-strikes about 1 mm off from other anthropometric models. Medial-lateral COM position at heel-strike and total range of motion is

also off from other models. Peak medial-lateral velocity is fastest with the Plagenhoef model.

The de Leva model [1] estimates the COM lowest in the vertical direction of all models. Toe-off anterior velocity and peak anterior velocity is fastest with the de Leva model. Vertical velocity is slowest at heel-strikes using the de Leva model.

The results clearly indicate that COM motion is calculated as statistically different with the use of different anthropometric models. However, while statistically significant, the actual difference between models may not be relevant for level walking gait with respect to anterior-posterior measures of COM motion. Anterior-posterior COM differences were only calculated as being within about a millimeter of each other. COM velocities in the anterior direction were within about two centimeters per second of each model. This amount of difference between models is relatively insignificant compared to the group differences and within-subject variability typically seen in this measure.

Medial-lateral and vertical motions of the COM may be more susceptible to relevant differences between anthropometric models. Medial-lateral COM position between models was within a 1 millimeter difference, however all but the de Leva and Dempster models were statistically different from each other (Table 1). This amount of difference is more important in the medial-lateral direction compared to the anterior-posterior direction. Previous reports have found significant group differences with only a one centimeter difference in COM medial-lateral range of motion [5]. We found a 15 mm/s medial-lateral peak velocity difference between models, representing about a 10% range between models (Table 1). All models were statistically different from each other. Previous reports have found 20 mm/s difference in peak velocity could represent significant group differences [6].

Likewise, consideration should be paid toward choosing the most appropriate anthropometric model when interested in vertical COM motion, as during studies of gait energy expenditure or balance. We found that there was little relevant difference in total vertical range of motion between models, suggesting

that measures of vertical work in gait may not be affected by the anthropometric model. However, we also found that vertical velocity varies widely between anthropometric models, especially at specific events during gait. This may pose a problem for calculations that are velocity based, like kinetic energy. Appropriately identifying the vertical positioning of the COM is also important for some balance measures [6]. The vertical COM position can vary by almost 10% between anthropometric models. The use of the Dempster model may underestimate imbalance in a measure like the inclination angle, while use of the de Leva model may overestimate imbalance [7].

**Table 1.** Average ML COM movement (standard deviation) for each anthropometric model.

<b>Model</b>	<b>[1]</b>	<b>[2]</b>	<b>[3]</b>	<b>[4]</b>
<b>Range (mm)</b>	35.8 (13.7)	36.1 (13.7)	36.6 (13.8)	35.8 (13.7)
<b>Velocity (mm/s)</b>	133.0 (34.0)	130.7 (34.4)	146.0 (34.1)	125.6 (34.4)

## CONCLUSIONS

Our data can provide researchers a priori information on the model determination depending on the particular variable and how conservative they may want to be with COM comparisons between groups. These findings suggest that special consideration should be given the procedural use of an appropriate anthropometric model when medial-lateral or vertical COM motion factors into the dependent variable.

## INTRODUCTION

Since 2011, 173 per 10,000 workers in the construction industry experienced non-fatal falls to a lower level, and 40% of fatal falls in 2015 were falls from height [1]. Considering falls to a lower level accounted for 81% of all fatal falls [1], it is important to determine if occupations that require walking on a sloped surface increase fall risks to the workers.

Sloped gait has been previously studied; up and down slope [2], and cross-slope gait evaluations have been made in low angle conditions (~6 degrees) in a clinical setting [3], or with railroad ballast in an occupational setting [4]. All studies found significant changes versus level walking conditions – ground reaction force, joint moments and sagittal kinematics. While these findings are interesting, they do not replicate the steep surfaces encountered by roofers.

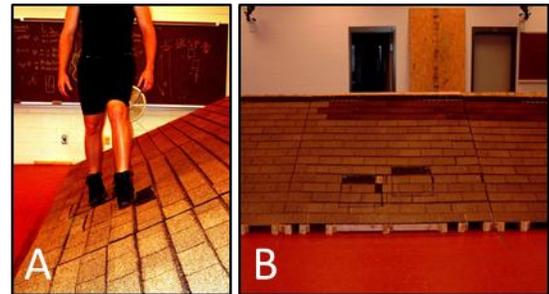

The purpose of this study is to determine how cross-slope walking on a slanted/roof surface alters the lower extremity kinematics of the upper and lower legs compared to level walking. It is hypothesized – in the sagittal plane – the up slope leg will have more flexion in the lower extremity than the level leg while the lower leg will have more extension.

## METHODS

Eleven college-aged male subjects (18.15±15 kg & 180.73±5.89 cm), who were considered inexperienced walking on sloped surfaces, participated in the study. All subjects reviewed and signed an informed consent forms and the study protocol was approved by the University of Mississippi Institutional Review Board.

Subjects completed two separate testing sessions: level surface and sloped surface walking. Due to the complexity and time requirements to install the sloped surface, the testing sessions were not randomized. The level condition consisted of a 10 meter vinyl covered walk-way. The sloped condition was a 4.43m wide x

7.32m long section of 6/12 pitch (~26°) shingled covered roof resting on the laboratory floor (Figure 1).

**Figure 1:** A) Frontal view of subject on roof segment. B) Sagittal view of 6-12 pitch roof segment.

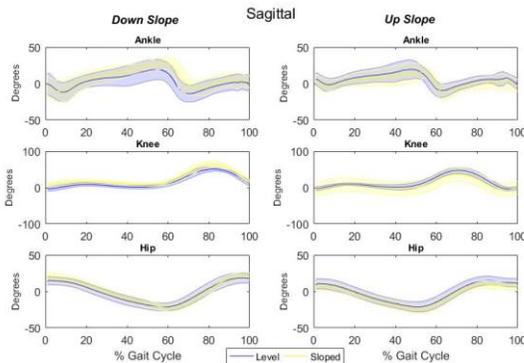

Subjects wore spandex clothes and 15 cm high work boots and were outfitted with the plug-in-gait marker set (Vicon, Inc.). The level condition required the subjects to walk across the 10 meter walk way; while the sloped condition had the subjects to traverse the sloped roof section. By traversing the roof section, one foot was higher on the slope (up) and one foot was lower on the slope (down), Figure 1A.

Ten trials from each condition were captured. Lower extremity kinematics (ankle, knee & hip) were calculated using the Plug-in-Gait pipeline in the Nexus software (Vicon). Peak angles (up-slope, down-slope, level) were compared using t-tests. Level data were separated and matched to the corresponding up-slope or down-slope leg. For example, the left leg was down-slope, thus the left down-slope leg peak angles would be compared to the left level leg peak angles. Data analysis was completed using SPSS v22 and *p*-values were set to 0.05.

## RESULTS AND DISCUSSION

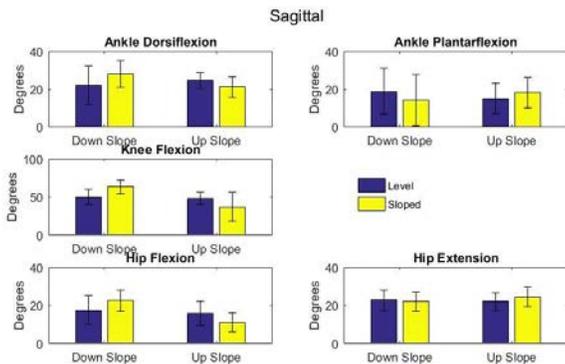

All but one (hip extension) of the lower extremity peak angles significantly changed as a result of traversing the sloped roof segment (Table 1). There was no set pattern of the change in kinematics – for

example, the downslope plantarflexion angle decreased compared to level while the upslope foot increased compared to level. Conversely, the knee flexion angle increased from level to slope in the downslope leg and decreased in the upslope leg (Figure 2 & 3; Table 1).

**Figure 2:** Time series histories of lower extremity kinematics comparing level conditions to sloped conditions.

Changes in lower extremity kinematics, posture and gait variability have all been linked to increased risk in falling. Though most of these conclusions are drawn from an elderly population [5], it should not be ignored that the changes in lower extremity kinematics experienced by individuals walking across a sloped surface could lead to the fall risks in the young and healthy.

**Figure 3:** Peaks of lower extremity kinematics comparing level conditions to sloped conditions.

**Table 1:** Peak Joint Angles and p-values of the up slope and down slope leg.

Peak Joint Angle (deg)	Down Slope			Up Slope		
	Level	Sloped	p-value	Level	Sloped	p-value
Ankle Plantarflexion	18.9 ± 12.3	13.9 ± 13.5	0.02	15.1 ± 8.0	18.3 ± 8.1	<0.001
Ankle Dorsiflexion	22.1 ± 9.9	28.1 ± 7.2	<0.001	24.5 ± 4.1	21.2 ± 5.5	<0.001
Knee Flexion	50.4 ± 9.7	63.6 ± 9.2	<0.001	48.3 ± 8.0	37.2 ± 18.85	<0.001
Hip Flexion	17.5 ± 7.6	22.6 ± 5.5	<0.001	15.78 ± 6.6	11.1 ± 5.0	<0.001
Hip Extension	22.8 ± 5.4	22.0 ± 4.9	0.28	22.2 ± 4.2	24.5 ± 5.1	<0.001

As an illustration - the increased knee flexion in the downslope leg is similar to what is observed in elderly fallers [5]. Furthermore, the reduced hip flexion in the up slope leg is comparable with a hip flexor muscle contracture.

One limitation of the current study was all subjects walked the same direction on the slope. Therefore, the right leg was always the upslope leg. Furthermore, it was not determined if this was the subjects dominant leg or not. Future studies could compare how dominant vs non-dominant legs respond as upper vs. lower leg.

### CONCLUSIONS

It is apparent that cross-slope walking presents many changes to gait kinematics that associate with increased fall risks. Long term work imposed kinematic changes may make roofers more susceptible to slips, trips and falls, once returning to a level surface. Methods to both combat these changes and educate the workforce are necessary to reduce the injury risk for this worker cohort.

# JOINT MECHANICAL POWER COMPENSATIONS WHILE WALKING WITH ANKLE RESTRICTION

Michael Christensen, Anahid Ebrahimi, Teresa Ferrara, Jill Higginson, and Steven Stanhope  
University of Delaware, Newark, DE, USA  
e-mail: mschris@udel.edu

## INTRODUCTION

During gait, individuals with an ankle impairment have restricted ankle function, quantified by reduced ankle mechanical power. These individuals develop compensatory strategies using increased proximal joint (i.e., knee, hip) mechanical power [1]. In order to study the mechanism for this inter-joint mechanical power compensation, researchers have partially restricted ankle function on unimpaired individuals using external ankle foot orthotics (AFOs). While one study reported that unilateral ankle restriction results in an increase in mechanical power at the hip [2], another found bilateral restriction leads to an increase at the knee [3]. However, these studies used AFOs which reduced ankle mechanical power by different amounts. Thus, the primary purpose of this study was to quantify the inter-joint mechanical power compensations when walking with the same amount of ankle restriction unilaterally and bilaterally.

Furthermore, joint mechanical power produced more proximally may lead to an increase in net metabolic expenditure (NME) due to a shift from the highly efficient ankle to the less efficient knee and/or hip [2]. We hypothesized this compensation in joint mechanical power will cause an increase in NME.

## METHODS

Nine healthy subjects (5F/4M,  $1.69 \pm 0.1$  m,  $34 \pm 10$  years,  $75.6 \pm 16.2$  kg) were fitted for AFOs fixed at 90 degrees between the shank and foot to resist dorsiflexion and plantarflexion. Subjects walked on an instrumented split belt treadmill at height-scaled speed of 0.8 statures/s. One 10-minute trial was collected for each of three different conditions while motion (Motion Analysis Corp., Santa Rosa, CA), force (Bertec Corp., Columbus, OH), and metabolic

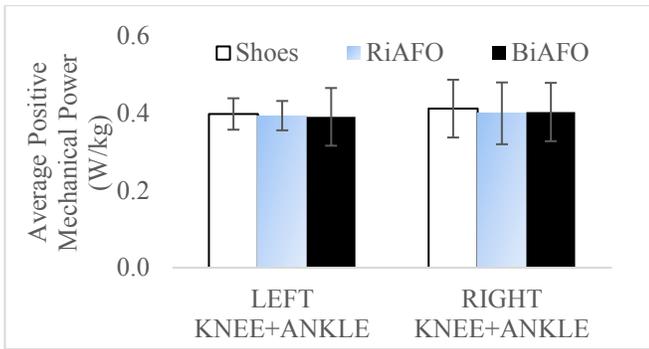

data (BD, Sydney, Australia) were collected. The subjects walked (1) with standard shoes (Shoes), (2) with an AFO on the dominant (right) limb (RiAFO), and (3) with AFOs on both limbs (BiAFO).

NME (Watts/kg) was calculated by subtracting metabolic expenditure at seated baseline prior to the start of each trial from metabolic expenditure after at least 6 minutes of walking under each condition. Average positive joint mechanical power per stride was calculated at the ankle ( $+\bar{P}_{ankle}$ ), knee ( $+\bar{P}_{knee}$ ), and hip ( $+\bar{P}_{hip}$ ) [4]. Corresponding joint metabolic cost can be estimated for the ankle (MetCost<sub>ankle</sub>), knee (MetCost<sub>knee</sub>), and hip (MetCost<sub>hip</sub>) using efficiency equations [5]. Differences in metrics between conditions were compared using several repeated measures ANOVAs with an overall  $p$  value of 0.05. All post-hoc comparisons reported have been adjusted with the Bonferroni correction using IBM SPSS (IBM Corp., Armonk, NY).

## RESULTS AND DISCUSSION

NME did not significantly change across conditions. Mechanical power and estimated metabolic cost are reported in Table 1.  $+\bar{P}_{ankle}$  and MetCost<sub>ankle</sub> both decreased significantly with unilateral (11% decrease) and bilateral (21% decrease) restriction.  $+\bar{P}_{knee}$ , and MetCost<sub>knee</sub> increased significantly on the impaired limb with unilateral (18% increase) and bilateral restriction (24% increase).  $+\bar{P}_{hip}$  and MetCost<sub>hip</sub> did not significantly change across all conditions.

Interestingly, summed  $+\bar{P}_{knee}$  and  $+\bar{P}_{ankle}$  did not significantly differ across conditions, indicating the knee compensated fully for the decrease in ankle mechanical power (Figure 1).

**Figure 1:** Summed knee and ankle average positive mechanical power ( $+\bar{P}_{knee} + +\bar{P}_{knee}$ ) for each limb.

Using the same mechanism to restrict ankle function unilaterally and bilaterally, mechanical power from the ankle was re-distributed to the knee. These findings are similar to data reported on bilateral ankle restriction previously [3]. Wutzke et al. found a primary increase in mechanical power at the hip, but this may be due to differences in the orthotic used to restrict the ankle [2]. A post hoc analysis estimated that Wutzke et al. decreased peak ankle mechanical power by 36% [2], while the present study decreased peak ankle mechanical power by 27%.

Future studies will be necessary to elucidate whether a greater level of ankle restriction will still reveal similar compensatory mechanisms for walking. Although there is a myriad of gait strategies, there appear to be certain requisites which are met. For example, David Winter found the support moment (summed ankle, knee, and hip moment) was similar across walking speeds while individual joint moments varied [6]. It will be important to investigate if total limb mechanical power is one of these requisites of gait such that small inter-joint mechanical power compensations maintain a

constant total limb mechanical power.

## CONCLUSIONS

Compensations for partial ankle restriction occurred at the ipsilateral knee during unilateral ankle restriction and at both knees during bilateral ankle restriction. Interestingly, the increase in mechanical power at the knee compensated for reduced mechanical power at the ankle such that combined ankle-knee mechanical power did not significantly differ across conditions. This re-distribution in mechanical power did not coincide with a significant change in NME.

## INTRODUCTION

Stroke affects nearly 795,000 people annually in the US, making it the leading cause of long-term disability[1]. After stroke, hemiparesis, or unilateral weakness, changes muscle activation and movement patterns and decreases walking speeds[2, 3]. Since decreased walking speeds correspond to diminished quality of life, many poststroke motor rehabilitation programs aim to increase walking speeds[4, 5].

Fast treadmill walking and functional electrical stimulation (FES) of the ankle plantar and dorsiflexor muscles have been added to a 12 week gait training program in an effort to increase walking speed [6]. In these studies, increased anterior ground reaction force (AGRF) and trailing limb angle (TLA) indicated increased walking speeds[7, 8].

To utilize active training principles [9] in gait training, we developed an adaptive, user-driven treadmill controller that adjusts the treadmill's speed to match the user's walking speed in real time. The objective of this study is to determine the relative contribution of AGRF and TLA to increased walking speed during fixed and user-driven treadmill walking. We hypothesize that similar linear relationships exist among walking speed, AGRF, and TLA for both treadmill types.

## METHODS

5 healthy adults (1M 4F, 23.2 ± 5.02 years, 1.67 ± 0.11m, 62.74 ± 10.81kg) with no history of lower limb musculoskeletal injury were recruited for this study. Kinetic and motion capture data were collected using an instrumented split-belt treadmill (Bertec Corp., OH) and an 8 camera motion capture system (Motion Analysis Corp, CA) while participants walked at their self-selected (SS) and fastest comfortable speeds on the fixed and user-driven treadmills for 1 minute each.

Visual3D (C-Motion, Inc., MD) was used to extract walking speed, average peak push-off force (AGRF), and peak TLA (Figure 1). The averages from one randomly selected limb were used for this analysis.

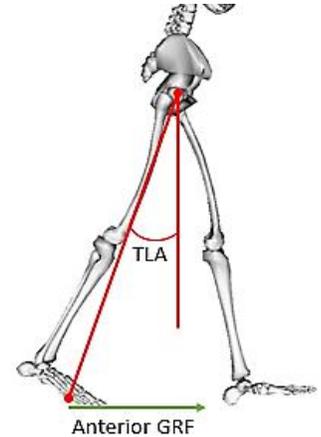

Figure 1: Definition of AGRF and TLA

Linear models were used to describe the relationships between walking speed and AGRF, walking speed and TLA, and AGRF and TLA at both the fast and SS walking speeds to determine the effect of the treadmill mode on gait mechanics.

## RESULTS

Linear models fit to walking speed, AGRF, and TLA are strong and similar at SS speeds, but at fast speeds, the relationships weaken for both treadmill modes (Figure 2, Table 1). AGRF and TLA were highly correlated at both SS and fast speeds (Table 1).

## DISCUSSION

These results show similar linear relationships among walking speed, AGRF, and TLA at the SS speeds for both treadmill types. The highly proportional relationships between SS walking speeds and both AGRF and TLA agree with findings by Hsiao and colleagues [7, 8]. However, at speeds beyond 1.75m/s, these relationships no longer hold. The relationships may change because there are multiple strategies may be used to increase walking speed. For example, one may increase their step length, cadence, or both to increase their walking speed. Despite the user's chosen speed, the relationships among walking speed, AGRF, and TLA do not change in response to the treadmill mode used.

When users walking on a fixed and user-driven treadmill were provided visual flow in a virtual reality environment, there was no significant difference in spatiotemporal parameters, and kinetic and kinematic joint variables [10]. Our results suggest that even without visual flow, our adaptive, user-driven treadmill controller allows users to employ similar strategies to reach their SS and fast walking speeds.

While this study is currently limited in the small sample size (n=5), recruitment is ongoing. The study strengths lie in the homogeneous nature of the population and the control for foot dominance. In addition, these methods control for speed by setting the fixed treadmill to the average speeds from the SS and fast trials on the user-driven treadmill. This additional step isolates the effect of the treadmill controller itself on the user's gait mechanics.

Since active training improves cognitive learning and neuromuscular rehabilitation after stroke, the user-driven treadmill presents the unique opportunity to redefine the standard of care for gait training after stroke. Future work will include spatiotemporal parameters such as cadence as well as kinetic and kinematic measures like knee flexion angle to characterize the gait mechanics used at SS and fast and fast walking speeds on the fixed and user-driven treadmill.

## INTRODUCTION

Walking is a fundamental form of human locomotion and is also a basic form of exercise. A typical walking gait consists of both stance and swing phases. During the early portion of the stance phase, the foot pronates after the instant of heel strike. This foot pronation movement helps with shock absorption and ground surface adaptation in walking. The arches under the foot play an important role in assisting with shock absorption, so the selection of proper footwear that can provide proper arch support, particularly for the medial longitudinal arch, is critical [1]. Recently, footwear manufactures have produced boots that have minimal foot support (MFS) for the foot arches. Without proper foot arch support, excessive pronation movements may change the timing and sequencing of the lower extremity joints. This alternation of the joint coordination and sequencing may potentially cause detrimental effect on foot health and lead to lower extremity injury. Therefore, the purpose of this study was to examine the movement coordination between barefoot and minimal foot support boots in walking. The results would help health practitioners to have a better understanding on how minimal foot support footwear could affect walking gait.

## METHODS

Ten college females (age  $21.3 \pm 1.2$  years) were recruited for participation in the study. Approval by the institutional ethics review board was obtained and then prior to the study participants gave written informed consent. All participants warmed up prior to the testing. Five joint reflective markers were placed on the right side of the body at the glenohumeral joint, greater trochanter, lateral epicondyle of the tibia, lateral malleolus, and base

of the fifth metatarsal. During testing, each participant walked for one minute at the speed of 1.3 m/s, a natural walking speed, on a treadmill. Participants walked both barefoot and with the minimal foot support (MFS) boots (UGG classic) with three minutes rest in between. The order of the MFS footwear and barefoot conditions was randomized to reduce the order effect. Data collection concluded in one day with a half hour in duration per participant.

A standard two-dimensional kinematic analysis was conducted with a Casio Camera (Model: EX-FH25) operated at 120 Hz in conjunction with a 650W artificial light to assist in joint marker identification. The Ariel Performance Analysis System (APAS<sup>TM</sup>) motion software was used to obtain angular velocities of the hip, knee and ankle of a gait cycle for each participant. A Butterworth filter function with a cutoff frequency of 10 Hz was applied to the data. The movement coordination pattern was defined as the timing and sequencing of joint movements, and a shared positive contribution (SPC) of proximal to distal joint and a reversed shared positive contribution (RSPC) of a distal to proximal joint based on the angular joint velocity profiles were used to assess movement coordination pattern [2-3]. A SPC or a RSPC of 0% indicates a sequential type of movement, and a SPC or a RSPC of 100% indicates a simultaneous type of movement. Paired sample *t*-tests were conducted at  $\alpha = 0.05$  between barefoot and minimal foot support footwear, and all statistical analyses were conducted with SPSS (v. 23) software.

## RESULTS AND DISCUSSION

Paired sample dependent *t*-tests were conducted on the movement coordination for the hip and knee joint angular velocities and for the knee and ankle

joint angular velocities. There was no statistical significant difference found in the positive contribution of the movement coordination for the hip and knee joint angular velocities ( $p = 0.868$ ) and for the knee and ankle angular velocities ( $p = 0.270$ ) between barefoot and minimal foot support footwear, Table 1.

From the results of this walking gait study, the hip and knee joints showed a slightly more sequential type of coordination whereas the knee and ankle joints showed a more simultaneous type of coordination. When comparing the results to a previous movement coordination study conducted by Wu et al. (2014) on running barefoot and minimalist footwear, similarly, the hip and knee joints were more sequential than the knee and ankle joints that were more simultaneous [4]. Additionally, both positive contributions of the hip and knee joints and the knee and ankle joints were higher in walking than in running. This study supports the notion that when the speed of movement is increased, the movement coordination becomes more sequential [2]. When evaluating the type of sequencing, all ten runners showed a distal to proximal sequencing in the hip and knee joints for both barefoot and minimal foot support footwear and a proximal to distal sequencing in the knee and ankle joints for both barefoot and minimal foot support footwear. These findings are similar as in the previous movement coordination study conducted on running [3]. This study indicates that walking activity, a functional kinetic chain that consists of both open and closed kinetic chains, does not follow the proximal to distal body segmental sequencing as in the open and closed kinetic chains [2,5]. The knee joint initiates the walking motion first and then follows by the ankle and hip joints. The minimal foot support footwear

does not alter the sequencing of the joint coordination pattern, and this may be because these participants already have a low pronation foot profile. Hence, wearing boots with minimal foot support footwear have minimal effect on their walking gait.

## CONCLUSIONS

The purpose of this study was to examine the movement coordination pattern between barefoot and minimal foot support footwear. Ten female participants participated in the study, and each participant walked on a treadmill in barefoot and in minimal foot support (UGG) boots. The results showed no significant change in the timing and sequencing of the walking gait when minimal foot support footwear was worn. This study further reveals the knee joint initiates the lower extremity movement in walking gait, and future studies are warranted to examine the long term effect of wearing minimal foot support footwear and to evaluate movement coordination in other functional kinetic chain activities.

## INTRODUCTION

Human gait transitions tend to reflect the optimization of gait patterns with changes in task constraints, including the speed of locomotion. As the speed of locomotion changes, adults often choose the more stable and energy efficient gait. Specifically, when walking speeds approach the preferred transition speed (PTS), stride duration variability has previously been shown to increase in adults, which subsequently stabilizes following the walk-to-run transition (WRT) [1]. However, it is unknown whether these self-optimizing tendencies during gait are also present during childhood. Therefore, this study aimed to identify whether children also use the WRT to help stabilize spatiotemporal parameters during gait.

## METHODS

Eleven healthy children (8 females, 3 males; Table 1) completed 2 sessions after written informed assent and parental consent was sought. Participants were first familiarized with the treadmill by walking and running at self-selected speeds for 15 minutes each, followed by three practice transition trials. Session 2 involved a stepped treadmill protocol that started at a self-selected walking pace and the treadmill speed increased by  $0.2 \text{ km}\cdot\text{h}^{-1}$  every 30 seconds until the participant reached a treadmill speed that was  $1.0 \text{ km}\cdot\text{h}^{-1}$  faster than the participants' PTS; the speed was then increased by  $0.5 \text{ km}\cdot\text{h}^{-1}$  until volitional exhaustion. Participants were instructed to start running at the speed that felt most comfortable. The PTS was defined as the speed at which the participant stopped transitioning between walking and running.

Three-dimensional kinematic data were collected at each speed during the stepped treadmill protocol.

Step frequency (Hz) and step length (m) for the left and right legs were calculated for 10 strides at 10 different treadmill speeds, including the participants' self-selected walking speed, five speeds prior to the PTS (i.e. PTS- $1.0 \text{ km}\cdot\text{h}^{-1}$ , PTS- $0.8 \text{ km}\cdot\text{h}^{-1}$ , PTS- $0.6 \text{ km}\cdot\text{h}^{-1}$ , PTS- $0.4 \text{ km}\cdot\text{h}^{-1}$ , PTS- $0.2 \text{ km}\cdot\text{h}^{-1}$ ), the PTS, two speeds following the PTS (i.e. PTS+ $0.2 \text{ km}\cdot\text{h}^{-1}$ , PTS+ $0.4 \text{ km}\cdot\text{h}^{-1}$ ) and a standardized running speed that was  $3.0 \text{ km}\cdot\text{h}^{-1}$  faster than the PTS (i.e. PTS+ $3.0 \text{ km}\cdot\text{h}^{-1}$ ).

**Table 1:** Participants' characteristics and preferred walking (PWS) and transition (PTS) speeds.

	Mean $\pm$ SD	Range
Age (years)	11.55 $\pm$ 0.93	10 – 13
Height (m)	1.55 $\pm$ 0.08	1.45 – 1.69
Weight (kg)	47.12 $\pm$ 10.36	32.00 – 67.86
PWS ( $\text{km}\cdot\text{h}^{-1}$ )	3.8 $\pm$ 0.5	3.0 – 4.8
PTS ( $\text{km}\cdot\text{h}^{-1}$ )	6.6 $\pm$ 0.7	4.9 – 7.7

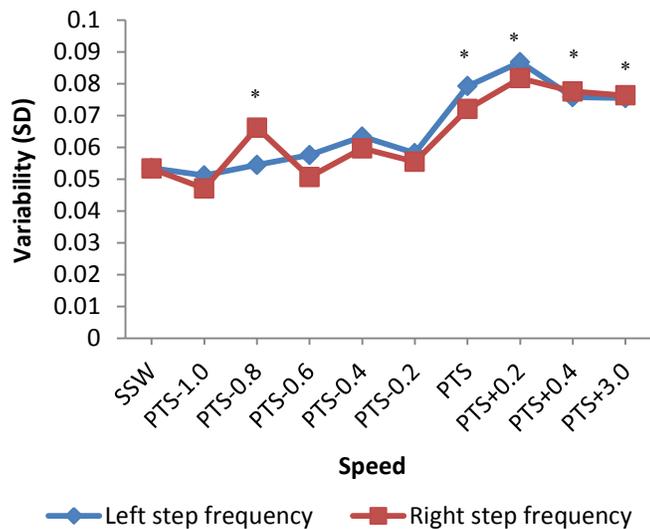

Standard deviations (SD) of the left and right step frequencies and step lengths were calculated. One-way analyses of variance with repeated measures for speed were used to analyze the effect of speed on the variability of the step frequencies and step lengths. Where significant effects of speed ( $p < 0.05$ ) were found, post-hoc least significant difference (LSD) pairwise comparisons were used to identify the specific relationships ( $p < 0.05$ ).

## RESULTS AND DISCUSSION

There were significant speed effects on the left step frequency ( $F_{(9, 90)}=3.778$ ,  $p < 0.001$ ), right step frequency ( $F_{(9, 90)}=5.534$ ,  $p < 0.001$ ), left step length ( $F_{(9, 90)}=2.459$ ,  $p=0.015$ ) and right step length ( $F_{(9, 90)}=3.952$ ,  $p < 0.001$ ).

When analyzing the walking and running speeds separately, there were generally no significant

differences in the amount of variability of the step frequencies within each mode of gait, irrespective of the speeds, with the exception of walking at PTS-0.8 km·h<sup>-1</sup>. Yet, there is a clear distinction in the variability of step frequencies between the participants' walking and running gaits (Fig. 1). Specifically, the variability of the step frequencies was significantly different between walking and running, suggesting that each mode of gait was associated with different spatiotemporal characteristics during treadmill locomotion.

**Figure 1:** Mean variability (standard deviations, SD) of the left and right step frequencies (Hz). Self-selected walking speed, SSW; Preferred transition speed, PTS. \* Significantly different than SSW for step frequency in both limbs.

Interestingly, the participants exhibited a greater amount of spatiotemporal variability following the WRT, which is in contrast to what was observed in adults [1]. Walking may have been the more stable gait pattern in children as it is the more frequently used mode of gait. Additionally, children may have more experience walking at speeds that are faster than preferred if they often walk alongside their parents or other adults, thus contributing to a more stable walking pattern.

Given that there was more spatiotemporal variability during running, the development of a mature, consistent running gait pattern may occur later in children, when compared to walking. Musculoskeletal development during childhood

could be an influencing factor, as limb length is not yet fixed. Therefore, the optimal combination of step length and step frequency may still be subject to change during this period of growth and development, hence the greater variability observed during children's gait transitions compared to adults.

Differences between the inverted pendulum mechanics of walking and the spring-mass mechanics of running may have also contributed to the differences observed between the spatiotemporal variability of walking and running. As the center of mass vaults over a somewhat fixed limb length during walking, step length variability is more limited compared to running where the use of a flight phase could increase variability. To this point, the step length variability was the greatest at the standardized running speed, whereas the self-selected walking speed elicited the least amount of step length variability.

It has been previously observed that slow running is less stable than fast walking [2], which would help explain the initial increase in the step frequency variability following the WRT and the subsequent plateau as the running speed continued to increase towards the preferred running speeds.

## CONCLUSIONS

A lack of stability in 10–13 year old children's spatiotemporal parameters following the walk-to-run transition suggests their running gait patterns may not yet be mature, which could affect their ability to optimize the efficiency and stability of their gait patterns as the speed of locomotion changes.

## INTRODUCTION

Altered trunk-pelvic motions and inter-segmental coordination in persons with unilateral lower limb amputation (ULLA) have been associated with increased risk for secondary health conditions (e.g., low back pain) [1-3]. Kinematic adaptations within these proximal segments may be a result of adopted neuromuscular strategies to account for absent sensory information and/or altered musculoskeletal tissues within the lower extremity due to trauma. In contrast, these adaptations may also indicate impaired trunk neuromuscular control, in that the neuro-musculoskeletal system cannot successfully govern kinematic variability (i.e., mechanical disturbances) and control errors in order to maintain stability. Non-linear analyses quantify the structure of variability over time using stochastic dynamics and may posit how the neuromuscular system controls the trunk in persons with varying levels of limb loss while walking. Thus, the objectives of this study are to: (1) characterize trunk local stability (as an indication of neuromuscular control) in persons with varying levels of ULLA during gait (vs. controls), and (2) evaluate the influences of concurrent cognitive challenges, as the ability to control the trunk during gait requires attentional resources, potentially further influencing trunk stability [4]. We hypothesize that persons with transfemoral ULLA will demonstrate decreased trunk local stability (greater lyapunov exponent) compared to persons with transtibial ULLA and able-bodied controls. Secondarily, persons with transfemoral ULLA will demonstrate larger decreases in local stability with increased cognitive challenge compared to transtibial ULLA and able-bodied controls.

## METHODS

Sixteen males with traumatic ULLA [8 transfemoral (TFA; mean age: 35.4 yrs) and 8 transtibial (TTA; mean age: 33.5 yrs)] and eight controls (CTR; mean age: 27.1 yrs) provided written informed consent, and all study procedures were approved by the local IRB. Participants completed a repeated measures design with three distinct conditions (in random order). For each, participants walked for 8 minutes within the Computer Assisted Rehabilitation Environment (CAREN; Motek Medical BV, Netherlands) at their self-selected speed (mean=1.1±0.2 m/s) while performing a secondary cognitive task (“easy” and “hard”) – each involving distinct attentional demands – or no (“none”) secondary task. For the “easy” task, a single object was displayed on a screen within direct line-of-sight with changing shapes. Participants were asked to press a button whenever a square appeared. For the “hard” task, two objects were displayed simultaneously, with individually changing shapes and colors. Participants were asked to press a button when both objects were either the same shape or same color.

Three-dimensional trunk positions were tracked (120Hz) using a 12-camera motion capture system (Vicon; Oxford, UK). Accelerations were derived using model-based computations in Visual3D (C-motion; Germantown, MD). Local stability of trunk movements was quantified from trunk accelerations using short-term maximum lyapunov exponents ( $\lambda$ ) [5]. Trunk ranges of motion (ROM) were also calculated in each plane as the angular deviation relative to the global coordinate system. A two-way ANOVA compared group (CTR, TTA, TFA) and task (none, easy, hard) for each plane of movement ( $p<0.05$ ). Eta squared for main effects of group are presented as an index of the power of the effect.

## RESULTS AND DISCUSSION

There were no significant interactions between the effects of levels of ULLA and task condition on trunk local stability; however, there were significant main effects of group in the mediolateral,  $F(2,62) = 20.58$ ,  $p < 0.001$ ,  $\eta^2 = 0.39$ , and axial,  $F(2,62) = 28.30$ ,  $p < 0.001$ ,  $\eta^2 = 0.47$  planes. In general, CTR demonstrated less trunk local stability ( $p < 0.001$ ) and smaller trunk ROM ( $p < 0.001$ ) compared to persons with ULLA (Figure 1). However, there were no group differences in anteroposterior plane stability ( $p = 0.34$ ). In the mediolateral and axial planes, TFA demonstrated more trunk local stability, with no differences between cognitive tasks. While the latter is contrary to prior work [6], here we used a different secondary task and a more homogenous sample with respect to age, time since amputation, and walking speed. The concomitant increases in trunk motion and local stability in the TFA group suggest these individuals may employ larger global movements proximally to account for disrupted proprioception and motor function distally. Within these increased global movements, however, this subset of TFA appear to have developed a trunk neuromuscular control strategy that is better able to accommodate increased kinematic variability within the system. This is potentially a compensatory mechanism to prevent balance impairments that can accompany trunk movements outside the base of support. Clinically, rehabilitation goals should aim to increase trunk neuromuscular control via targeted trunk rehabilitation incorporating both anticipatory feed-forward (e.g., active muscle stiffness) and reactive

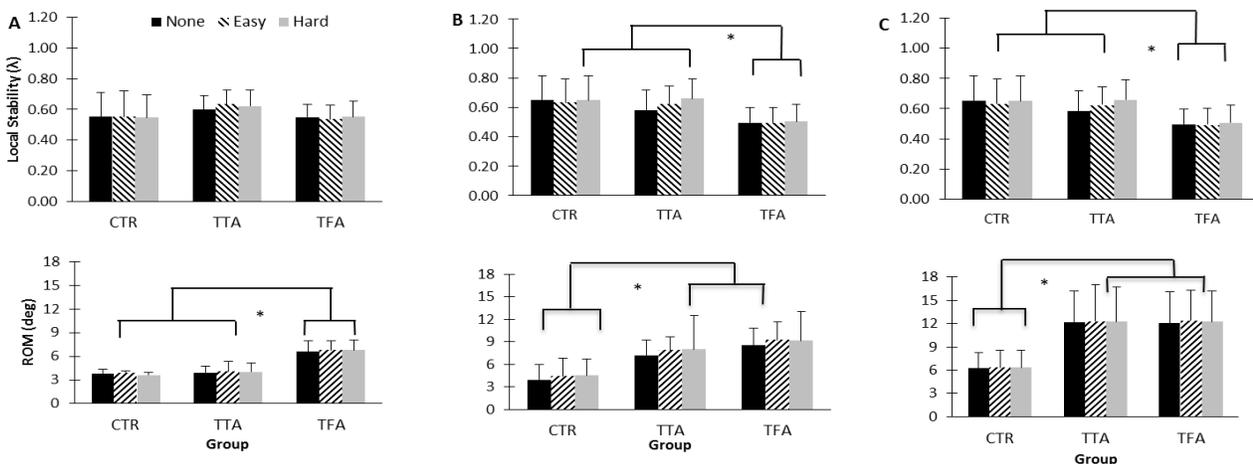

feed-back (e.g., postural adjustments through proprioceptive mechanisms), resulting in increased local stability and effective control of local mechanical disturbances.

# THE IMPACT OF ANTHROPOMETRIC CHANGES AND PHYSICAL ACTIVITY ON DYNAMIC BALANCE DURING PREGNANCY

Alexa L. Werner, Kendall M. Iverson, Christopher P. Connolly, Robert D. Catena  
Washington State University, Pullman, WA, USA  
email: [robert.catena@wsu.edu](mailto:robert.catena@wsu.edu), web: <https://labs.wsu.edu/biomechanics/>

## INTRODUCTION

Anthropometric changes and physical activity (PA) participation during pregnancy are potentially two important aspects that may influence balance changes during pregnancy [1, 2]. Understanding balance change among pregnant women is important, as falls are one of the leading mechanisms of injury during pregnancy [2] and result in negative health outcomes for both the mother and fetus. Currently there are few studies that have examined how anthropometric changes impact balance during pregnancy, and so we have a limited understanding of what mechanisms contribute to the increased fall risk of pregnant women. Most studies up to this point have focused on correlating fall risk to gestational age without examining the underlying factors that contribute to dynamic balance. Therefore, the purpose of this study was to compare gestational age, anthropometric changes, and PA during pregnancy as potential correlates to balance changes.

## METHODS

We have currently recruited and tested 33 pregnant participants, but have completed analysis of dynamic balance data for 6 pregnant women (average age of 27.75) from second trimester of pregnancy through birth. Participants were tested once a month.

Participants walked at a self-selected pace on a level treadmill for sixty seconds. Forty-eight retroreflective markers were taped to bony landmarks and segments slightly modified from an established marker set [3]. A ten-camera motion capture system captured marker movement at 100 Hz using Cortex and Biosuite software (Motionanalysis Corp., Santa Rosa, CA) and then low-pass filtered at a 6 Hz cutoff. The entire sixty-second capture was split into individual gait cycles at right heel strikes. The body center of mass (COM) was calculated

using a 13-segment anthropometric model, supported by currently in-review findings. Measures of COM motion with respect to the base of support (BOS), calculated using custom Matlab programs, were used as dependent measures of balance during each gait cycle. Along with gestational age, a range of anthropometric data were collected for all participants at each testing session [4] and used as independent variables. Measures of length were normalized by body height to derive values that could be used for comparison across subjects. Waist circumference and body mass were used to find the changes in weight distribution. To record PA, each participant wore a pedometer (Omron HJ-720ite) during normal daily activities for four days (three weekdays and one weekend day) after balance testing in our lab. We recorded the number of steps and amount of time the pedometer was worn for each day. These data were then averaged into steps/minute to represent PA.

Each independent variable was statistically analyzed using a stepwise multiple regression analysis in SPSS v23 so that the correlation of various independent variables to a balance measure could be compared. Gestational age was included among our other independent variables, as it has been often used in comparison to balance changes during pregnancy.

## RESULTS AND DISCUSSION

Table 1 contains the results of the regression equations for our independent variables.

It appears that waist circumference (as a percentage of body height) and body mass index (BMI) have the greatest correlation to most accepted dynamic balance factors such as step width and minimum distance of the center of gravity (COG) to the BOS. There is a positive correlation between center of mass (COM) medial-lateral (ML) excursion,

maximum COM ML velocity, and step width and waist size. Along with the negative correlation to minimum COG to forefoot boarder, these indicate that balance diminishes as waist circumference and BMI go up. The positive correlation to minimum COG to rear foot border indicates that balance in the posterior direction is not necessarily a concern. While the Pearson coefficient for waist size or BMI alone never exceeds 0.500, when other factors such as gestational age are added into the stepwise regression analysis the R-value can increase to as much as 0.682.

PA had essentially no correlation to balance and interestingly, very little correlation with other independent variables. This suggests that our measure of PA may not have been accurately capturing the physical abilities and/or exercise involvement of these participants. Additionally, gestational age alone had less of a correlation to balance than the correlation of waist size and BMI for the same dynamic balance measures. While the direct correlation does not indicate a strong relationship in the case of either gestational age, waist size, or BMI and dynamic balance, a combination of anthropometric factors correlate well with balance during pregnancy. Also, gestational age is only moderately correlated with anthropometry changes, so anthropometric measures add a unique indication of balance changes not captured by gestational age.

## CONCLUSIONS

Our results combine to show that certain anthropometric changes during pregnancy may be a better indicator than gestational age, or at least different indicator, of balance changes. Physical activity may still correlate with dynamic balance, but our findings from this study do not indicate this to be the case. Future investigations into this relationship will likely require more comprehensive methods of PA assessment. Future research will also examine other potential correlates to balance changes during pregnancy. The observations that COM lateral motions increase in relation to waist size and BMI seem to indicate that these factors may be part of what contributes to the increased fall risk of pregnant women.

## INTRODUCTION

In running gait, the relationship between kinematic characteristics that influence running speed are well researched. Step length (SL) and step rate (SR) are important predictors of run speed [1]. Squadrone & Gallozzi [2] found SL and SR may change when adapting to minimalist running shoes. The relationship between footstrike (FS) pattern and gait kinematics changed when runners changed to minimalist running [3] and has been shown to change during a run [4]. Much of the research performed, however, focused on the homogeneous groups of highly experienced or elite runners. While the relationship between SL, SR, and running speed is not likely to differ for a more heterogeneous population, it is not known how FS pattern may change with running speed within a more general population. Additionally, while much of the previous research classifies FS pattern based on quantitative data, practitioners such as physical therapists often qualitatively classify them. It is important to evaluate the accuracy of these observations in newly trained individuals knowing that self-reported values are not highly accurate [5].

The purpose of this study was to examine the kinematic gait characteristics of a heterogeneous population and to assess the efficacy of qualitative FS pattern assessment.

## METHODS

A heterogeneous group of 258 exercise science students (134 males, 124 females; age: 20.7±1.0 years; height: 1.74±0.11 m; weight: 74.9±8.2 kg) participated. Participants had varying levels of physical fitness and running experience. This study received university IRB approval.

Participants were educated regarding FS pattern

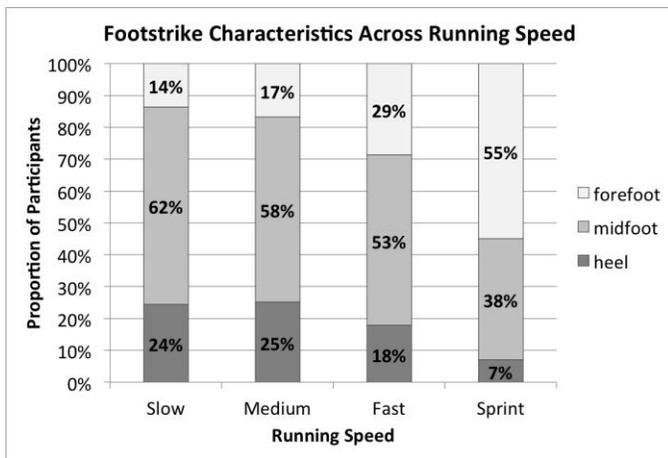

classification prior to data collection. FS pattern was determined by small group consensus and validated using video analysis by well-trained observers (Dartfish Team Pro).

Each participant completed a flying 20 m run at a self-selected slow, medium, fast, and sprint pace. Time was recorded electronically (FarmTek, Polaris) and steps were counted. Running speed (RS), SR, and relative step length (SL/HT) were calculated. A 3x4 ANOVA was run on SPSS to evaluate the three FS patterns and the four paces (alpha=0.05). A Bonferroni correction of alpha level was applied to post hoc tests.

## RESULTS AND DISCUSSION

FS analysis results are displayed in Figure 1. A greater than expected number of midfoot strikers were found at submaximal speeds. The general trend of runners adopting midfoot or forefoot FS patterns as RS increased was expected. Based on video analysis, the newly trained observers were correct for 90-92% of all FS classifications, which is much better than self-reported FS [5]. Most errors appeared to be misclassifications when the runner had FS angles close to a different classification. It is not known how errors in this real-time, subjective classification would improve with experience.

Running speed is the product of step length and step rate [1], yet SL/HT tends to level off at faster speeds. Current results follow the same trends. RS significantly increased across the self-selected paces (p=0.001), with a moderate effect size (ES=0.64), as expected. Forefoot runners were significantly faster than midfoot or heel striking runners at all paces (p=0.001), yet the ES was minute (0.07). There was also an interaction effect between the FS pattern and RS (there were several interaction effects, all with miniscule effect sizes).

**Figure 1:** FS characteristics across running speeds.

To evaluate the influence of observation accuracy, a subset of 48 subjects was statistically analyzed with the results of video classification of FS pattern. These results were similar to the larger data set. The main effect for running speed was significant (ES=0.64). There was also a significant interaction between FS and RS, but the small difference for forefoot runners no longer remained.

As expected, SL/HT was significantly greater as RS increased (ES=0.43). Forefoot strikers had significantly greater SL/HT than midfoot or heel strikers (p=0.001; ES=0.04). Similar results were found for the subset, where forefoot strikers still had greater SL/HT than midfoot or heel strikers.

Step rate also increased significantly with running speed, as expected (ES=0.51). Forefoot strikers had a significantly greater step rate than midfoot and heel strikers (p=.001, ES=0.02), and there was a significant interaction between RS and FS pattern.

**Table 1:** Footstrike and running pace kinematic characteristics. Running pace data were all significantly different for each variable. \*Significantly different footstrike pattern. †Significant interaction effect between footstrike pattern and pace.

Footstrike Pattern	Running Pace (m/s) <sup>†</sup>				SL/HT				Step Rate (Hz) <sup>†</sup>			
	Slow	Medium	Fast	Sprint	Slow	Medium	Fast	Sprint	Slow	Medium	Fast	Sprint
Heel	3.2 ±0.5	4.1 ±0.5	4.9±0.7	6.2±1.2	0.62±1.0	0.74±0.1	0.83±0.1	0.87±0.1	2.7±0.2	2.9±0.2	3.2±0.3	3.8±0.6
Midfoot	3.2±0.6	4.2±0.6	5.1±0.7	6.4±0.9	0.62±0.1	0.75±0.1	0.86±0.1	0.90±0.1	2.8±0.2	3.0±0.2	3.2±0.3	3.8±0.4
Forefoot*	3.4±0.8	4.5±0.7	5.6±0.7	7.2±0.8	0.65±0.1	0.79±0.1	0.90±0.1	0.96±0.1	2.8±0.3	3.0±0.2	3.3±0.3	4.0±0.4

As with the subset analyzed for RS, the main effect for SR and the interaction between RS and FS pattern remained across speeds, but the greater SR in the forefoot group was not present.

## CONCLUSIONS

This heterogeneous group seemed to run predominantly with heel or midfoot FS pattern at submaximal speeds and increased forefoot FS pattern as speed increased. Perhaps RS and forefoot running are influenced by the same variables; more research is needed to examine this phenomena. A few runners changed FS patterns across pace in less uniform ways, which may be due to classification error or normal variability in FS pattern [4]. We also evaluated the efficacy of qualitative assessments made by newly trained individuals to determine FS pattern. The accuracy rate reflects a degree of potential error in clinical or retail settings where evidence based decisions are determined through observational analysis.

## INTRODUCTION

Obesity remains a primary risk factor for osteoarthritis (OA) progression, as it can affect all of the tissues within the diarthrodial joint from the biological, mechanical, and structural perspectives. Although OA is often associated with an older cohort, radiographic evidence supports OA development in younger populations. Specifically, obese adolescents displayed cartilage lesions in at least one region of the knee, suggesting early damage to cartilage and increased risk for early progression of OA [1].

Previous research has cited increased sagittal [2, 3] and frontal plane [3, 4] moments in the knees of obese children during walking. With repetitive loading, these increased forces could affect both anterior-posterior and medial-lateral cartilage thickness distribution, respectively. While the increased moments at the knee joint are concerning, there has been no published research that examined whether these increased forces exist bilaterally. Yet, early asymmetries in knee joint loading have been suggested to precede the onset of symptomatic knee OA [5]. Thus, the purpose of this study was to determine the differences in kinetic symmetry between obese and non-obese children.

## METHODS

Twenty-eight adolescents (13-16 years) were classified as non-obese (N=16; age:  $14.7 \pm 1.1$ y; mass:  $54.8 \pm 8.9$ kg; height:  $1.66 \pm 0.10$ m) or obese (N=12;  $14.6 \pm 1.1$ y; mass:  $81.1 \pm 23.4$ kg; height:  $1.64 \pm 0.09$ m), based on international body mass index (BMI) cut-off points [6]. Participants were barefoot and wore tight-fitting clothing; retro-reflective markers were placed according to a previously established protocol [7].

Three-dimensional biomechanics data were collected using a 12 camera motion analysis system and 4 embedded force plates. Participants were asked to walk at their self-selected pace across the 10-m walkway. Five trials were included for processing, based on the following criteria: the presence of bilateral strides, clean footprints on independent force plates, and marker drop-out of less than 20 consecutive frames.

Kinematic and kinetic data were filtered using a bi-directional, low-pass fourth-order Butterworth filter with a cut-off frequency of 6Hz and 40Hz, respectively. Knee joint moments were calculated using inverse dynamics and normalized across stance phase. Bilateral knee joint moments in the sagittal, frontal, and transverse planes were exported for further analysis. Stance phase was subdivided into: loading (1-18%), mid-stance (19-51%), terminal stance (52-84%), and pre-swing (85-101%).

Bilateral kinetic symmetry was represented by an  $R^2$  value, which was calculated between the right and left knee joint moments in the sagittal, frontal, and transverse planes. The total sum of squares (SST) and the error sum of squares (SSE) were calculated:

$$SST = \sum_{j=1}^2 \sum_{i=1}^n (M_{ij} - M_{..})^2$$
$$SSE = \sum_{j=1}^2 \sum_{i=1}^n (M_{ij} - M_{i.})^2$$

where  $M_{ij}$  is the moment at time  $i$ ,  $M_{..}$  is the mean for that moment averaged across both sides of the body and across all time points, and  $M_{i.}$  is the mean across both sides of the body at time  $i$ .  $R^2$  was calculated:

$$R^2 = 1 - \frac{SSE}{SST}$$

$R^2$  values were transformed using Fisher's Z transformation prior to statistical analysis.

Independent t-tests identified group differences in kinetic symmetry for each sub-phase. Statistical significance was set at  $p < 0.05$ .

## RESULTS AND DISCUSSION

Table 1 provides  $R^2$  values for sub-phases that presented significant group differences in kinetic symmetry. Compared to non-obese children, the obese group exhibited significantly greater asymmetry in the sagittal plane knee joint moments during loading and mid-stance sub-phases. Additionally, the obese group presented significantly greater asymmetry in the frontal plane knee joint moments during mid-stance and pre-swing.

**Table 1:** Non-transformed  $R^2$  values for sagittal and frontal plane knee joint symmetry in obese and non-obese children.

	Non-obese (N=16)	Obese (N=12)
<b>Loading</b>		
<i>Sagittal</i>	0.95 ± 0.03*	0.87 ± 0.10
<i>Frontal</i>	0.86 ± 0.18	0.68 ± 0.35
<b>Mid-Stance</b>		
<i>Sagittal</i>	0.88 ± 0.17*	0.71 ± 0.30
<i>Frontal</i>	0.58 ± 0.35*	0.26 ± 0.30
<b>Pre-Swing</b>		
<i>Sagittal</i>	0.74 ± 0.20	0.61 ± 0.29
<i>Frontal</i>	0.82 ± 0.17*	0.61 ± 0.30

\* $p < 0.05$

The majority of group differences occurred in the sub-phases associated with deceleration and weight transfer. Although data were not collected on limb dominance, it would seem that the obese children adapt different strategies when transferring their weight across dominant and non-dominant limbs. The asymmetry in sagittal plane knee joint moments is most consistent during weight acceptance and transfer of the center of mass over the stable foot. Knee flexor moments have a stronger influence early in OA progression and given the timing of the asymmetric over-loading seen in this study, asymmetry in sagittal plane knee joint moments could potentially increase risk of early OA progression in obese adolescents.

The role of altered joint loading in OA progression has been considered in pathological cohorts (i.e. patients with ACL deficiency/injury [8], hip OA [5]), but has not been investigated in otherwise healthy obese individuals. Interestingly, it is suggested that changes in dynamic joint loading at the knee not only precedes onset of symptomatic knee OA, but also appears early in the disease course of hip OA [5]. Because asymmetric joint loading is prevalent at younger ages, the disease course for both knee and hip OA could be established well before an obese individual reaches typically recognized at-risk age ranges. Indeed, radiographic evidence has shown a high incidence of cartilage lesions in the knee joints of obese children with an average age of 14 years [1].

## CONCLUSIONS

Obese children have increased kinetic asymmetry in the sagittal and frontal plane knee joint moments during important sub-phases of stance. The altered joint loading, specifically in the sagittal plane during weight acceptance and transfer, could make obese adolescents highly susceptible to early onset of both hip and knee OA. These risks should be considered when prescribing weight-bearing exercise as part of a weight management program.

# DETECTION OF GAIT PATTERN DIFFERENCES USING FAST FOURIER TRANSFORM ANALYSIS

<sup>1</sup> Anthony Vessicchio and <sup>1</sup> Kristin D. Morgan

<sup>1</sup> University of Connecticut, CT, USA

## INTRODUCTION

In the United States, an estimated 35 out of 100,000 people suffer an anterior cruciate ligament (ACL) injury each year [1]. Previous studies have analyzed how gait patterns in individuals post ACL reconstruction differ from healthy controls [2-6]. However, these studies have focused on discrete, time domain variables; such as peak knee angle, knee extension moment, and knee excursion. Despite advancements in research and ACL injury prevention programs, ACL injury rates have increased [7]. This indicates that additional information not apparent in the time domain could provide valuable insight into alterations in knee gait patterns in post ACL reconstruction individuals.

Past studies have shown that frequency domain information can be clinically relevant when analyzing gait patterns [8-10]. Both Giakas et al. (1997) and Stergiou et al. (2002) successfully used frequency domain analyses to differentiate between healthy controls and individuals with scoliosis and elderly individuals, respectively, when the time domain variables failed to do so. This study used fast Fourier Transform (FFT) to compare differences in knee gait pattern between healthy and post ACLR individuals. Unlike past studies that focused on the frequency component of FFT alone, and this study focuses on amplitude and phase as well. We hypothesized that the amplitude, frequency, and phase components will be able to detect changes in gait patterns between healthy individuals and individuals post ACLR.

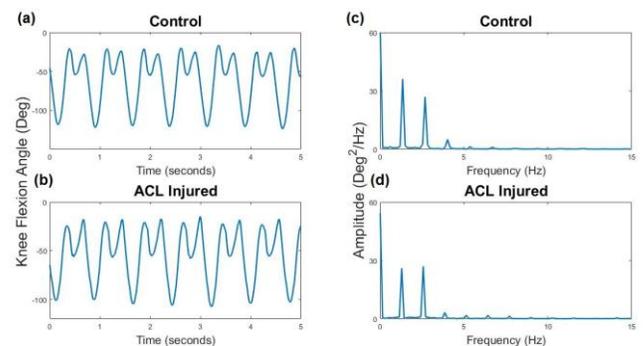

## METHODS

Sixteen control (height  $1.7\pm 0.1\text{m}$ ; mass  $66.7\pm 13.5\text{kg}$ ; age  $20.88\pm 3.9\text{yrs}$ ) and 16 post ACL reconstruction (height  $1.7\pm 0.1\text{m}$ ; mass  $68.83\pm 10.5\text{kg}$ ; age  $19.4\pm 5.1\text{yrs}$ ) participants performed a running protocol and ran at a self-selected speed (control  $2.7\pm 0.4\text{ m/s}$ ; ACLR  $2.7\pm 0.3$

$\text{m/s}$ ) on an instrumented treadmill (Bertec Corp, Columbus, Ohio). Control participants were injury free and ACLR participants were cleared for sports.

Sagittal plane knee kinematics were extracted from processed marker data. The sagittal knee joint time domain data was converted to a frequency domain representation using FFT. The FFT converts a time domain signal into the frequency domain by representing the signal as a series of sinusoids [11]. After being converted to the frequency domain, power and phase spectrums were generated for each signal using a custom MATLAB code (The MathWorks Inc., Natick, MA).

The power spectrum revealed that the majority of the signal energy was contained in the two dominant sinusoids (Fig. 1). Dominant meaning the sinusoids with the largest amplitude excluding the peak at 0 Hz. The amplitude, frequency, and phase components for those two sinusoids for the control left and right limbs and the ACLR individuals injured and non-injured limbs were analyzed. A one-way ANOVA and Bonferroni post hoc analyses were used to determine if between limb amplitude, frequency and phase means were significantly different ( $\alpha=0.05$ ).

**Figure 1.** Sagittal plane knee kinematics for a (a) control left limb and (b) ACLR injured limb during running. Comparison of power spectrums for the (c) control left and (d) ACLR injured limb.

## RESULTS AND DISCUSSION

The amplitude, frequency, and phase components of the frequency domain all showed significant differences between the control and ACLR limbs. There were significant differences in the frequency and phase components between the ACLR injured and non-injured limbs (Table 1). The second sinusoid of the ACL injured limb group showed a lower amplitude, higher frequency, and lower phase component when compared to the other groups. The first sinusoid of the ACL non-injured limb showed a significantly lower amplitude than the control limbs.

The results presented show that alterations in sagittal plane knee kinematics post ACL reconstruction can be detected from the frequency content of the signal. The amplitude, frequency, and phase components provide a novel way to detect gait pattern abnormalities associated with ACLR. These components may lead to a better understanding of the underlying mechanics involved in gait pattern changes after ACLR. The significant differences between the ACL injured and non-injured limbs support the expected asymmetry between limbs after ACLR [12]. The changes in frequency components may be due to a coping mechanism of the healthy limb present after ACLR.

## CONCLUSIONS

Valuable information can be extracted from sagittal plane knee joint kinematic data by transforming the time domain data into the frequency domain. As hypothesized, variables in the frequency domain such as amplitude, frequency, and phase can be used

to differentiate between healthy controls and subjects who have undergone ACL reconstruction.

Future work will be done to investigate the clinical relevance of these variables. Understanding the underlying mechanics associated with each frequency component may lead to improved ACL injury prevention and rehabilitation programs. Although all of the variables did not present significant differences between groups, the trends in the data lend the need for further investigation. Additional work will be done to analyze these variables in the frontal and transverse planes.

## INTRODUCTION

Healthy young adults' preferred walking speed, step length, and width minimizes metabolic cost of transport [1, 2]. However, a person's preferred movement may simultaneously satisfy underlying objectives beyond energy efficiency. When forced to, we can choose to walk with many step lengths and widths. Examining the choice between distinct non-preferred stepping patterns, which have different biomechanical (e.g. joint torques) and energetic consequences, can provide insight into the relevant objectives. For example, if a person's only objective is energy efficiency, then equally desirable stepping patterns should have the same metabolic costs.

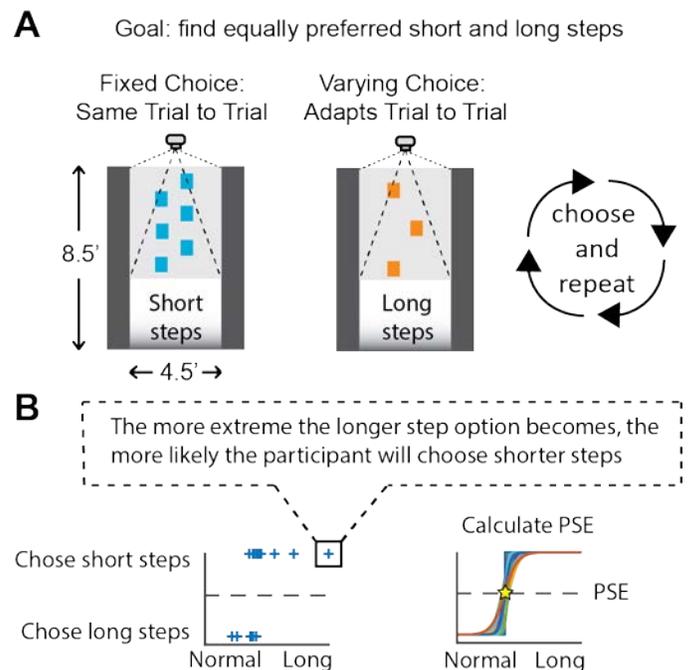

The goals of this study were to:

- 1) Develop a method to find equally preferable step length-width patterns.
- 2) Test if metabolic cost explains a person's step length-width preferences outside of their normal preferred pattern.

## METHODS

Four healthy young adults (Age:  $27.3 \pm 3.6$ , Gender: 3M) walked on an oversized treadmill at a constant speed (2.7mph), while a projector displayed stepping targets to control step length and step width (Fig. 1A). We defined step length-width patterns as "equally preferred" if there was a 50% chance the participant chose one pattern over another, also known as the point of subjective equality (PSE). To find equally preferred short, long, and wide steps, we used a two-alternative forced-choice paradigm (2AFC). During each trial, participants walked with two different step length-width patterns for 10 seconds: one that remained fixed every trial (fixed choice), and one that was updated based on previous trials (varying choice). The participant chose the step

length-width pattern they preferred most and, as a consequence, walked another 10 seconds with that step length-width pattern. An adaptive staircase algorithm determined the varying step length-width choice for the next trial so the following choice provided more information during later analysis. We chose two fixed "shorter than normal" stepping patterns and then found the equally preferred longer and wider steps by bootstrapping the participant's choices, fitting a logistic function, and calculating the point at which there was a 50% chance of choosing one stepping pattern over another (Fig. 1B). This way we can measure the set of equally preferred movements.

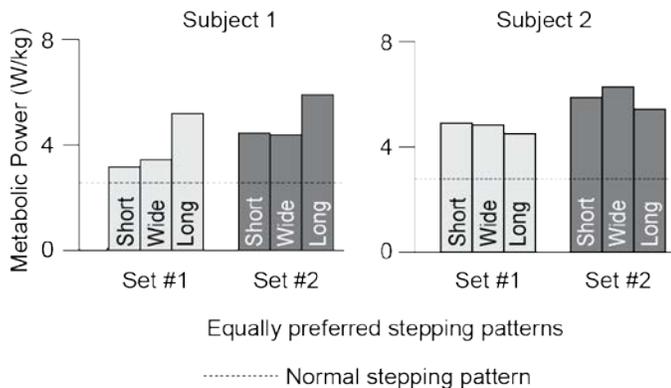

**Figure 1:** A) Example of finding equally preferred shorter and longer steps. B) Calculating equally preferred longer steps, or the point of subjective equality (PSE). A blue cross represents a participant's decision.

Participants then walked for 6 minutes with each equally preferred step length-width pattern to calculate metabolic power using open-circuit respirometry (K4b<sup>2</sup>, COSMED, USA).

## RESULTS AND DISCUSSION

We found equally preferred step length-width preferences using 2AFC. We found that 30 decision trials were sufficient to find step length-width preferences. Ten seconds was a sufficient amount of time to experience each stepping pattern and make a decision, and preferences did not change when participants were given additional time. We also found that step length-width preferences could vary significantly across participants.

Our preliminary results (n = 4) suggest that healthy young adults do not always choose the most energy efficient step length-width pattern (Fig. 2). Three out of the four participants chose longer steps over shorter steps at an increased energetic cost. One participant chose shorter steps over longer steps at an increased energetic cost.

**Figure 2:** Metabolic cost for equally preferred step length-width patterns, outside of a person's normal pattern.

## CONCLUSIONS

We used 2AFC to find equally preferred step length-width patterns. We found that step length-width preferences varied across healthy young adults, and **our preliminary results suggest that energy expenditure cannot fully explain why a person chooses one stepping pattern over another.** In fact, we found a systematic bias towards preferring longer steps to shorter steps. There are likely other factors that influence a person's choice of step length and step width such as stability, joint torques, or comfort. Models and analyses of human locomotion should consider factors in addition to metabolic cost. Future studies can use a similar approach to examine decision making with other parameters of interest (e.g. walking speed).

## INTRODUCTION

Overweight and obese individuals often use compensatory mechanisms to perform activities of daily living (ADLs), such as descending stair walking [1,2], which may contribute to increased risk of lower extremity injury such as osteoarthritis (OA) [1&3].

Both the amount and location of adipose tissue may be a determinant of certain biomechanical adaptations. An increase in total body and thigh masses has been shown to affect the kinematics and kinetics of the knee in the frontal plane [4 - 6]. Although, the effect of individual segment mass is still relatively unknown [5], we can predict that altering the mass of a segment, such as the thigh, would affect hip and knee kinematic and kinetic variables during descending stair walking.

The exact role of body mass and body mass distribution on obesity-induced biomechanical adaptations are unclear. In an obese population, marker placement becomes difficult due to the excess soft tissue artifact resulting in inaccurate calculations of hip joint centers, which may lead to errors in biomechanical data [7]. Therefore, modeling weight gain may clarify the specific biomechanical adaptations to obesity. The purpose of this study was to compare frontal plane kinematics and kinetics during descending stair walking of an obese population to simulated weight gain (centrally or peripherally) of normal weight individuals.

## METHODS

As of this submission, 15 healthy (5 male; 10 female), normal weight (BMI: 22.3±1.8) participants (age: 23.5 ± 3.7 yrs; height: 1.7±0.1 m; mass: 63.5±11.2 kg) and 5 healthy (1 male; 4 female),

obese weight (OW) (BMI: 33.3±3.2) participants (age: 25.8 ± 5.7 yrs; height: 1.66±0.13 m; mass: 93.4±24.1 kg) have participated in the protocol. Lower extremity kinematic and kinetic, data were collected while descending the stairs. Normal weight participants were loaded with three conditions: unloaded (UL), centrally loaded (CL), and peripherally loaded (PL). For the loaded conditions, participants carried external loads sufficient to increase their BMI by 5 kg/m<sup>2</sup>. For the centrally loaded condition, external load was added to a weight vest. For the peripherally loaded condition, the load was distributed to 50% in the weight vest and 25% to each thigh using specially constructed neoprene sleeves. Normal weight and obese participants descending the stairs at self-selected walking speeds for each condition speed (UL 0.975 ± 0.10 m/s, CL 0.927 ± 0.09 m/s, PL 0.906 ± 0.10 m/s & OW 0.82 ± 0.08 m/s) recorded with Brower Timing Systems, Timing Gates (Power systems LLC, Knoxville, TN). All conditions were randomized and adequate rest was given between conditions.

Retroreflective markers were placed bilaterally on bony landmarks of the trunk, pelvis and lower extremity and 3D data were collected using 10 high speed Motion Analysis Cameras (Motion Analysis Corporation, Santa Rosa, CA, USA) at a sampling rate of 200 Hz. All kinetic data were normalized to the participants' unloaded body weight. The PL condition was corrected for the added mass to the thighs. Force variables were collected using two Bertec force plates (Bertec Corp., Columbus, OH) at 1000 Hz. Joint/segment dynamics were calculated in Visual 3D (C-Motion Inc, Germantown, MD).

The experimental staircase consisted of three steps (step height 16.25 cm, tread length 27.8 cm and step width 95.75 cm) and a platform. No handrail was used but was provided for safety. For each condition

(UL, CL, PL & OW) subjects descended stairs until three valid trials were recorded. A valid trial was defined as walking down the stairs without stumbling and striking the force plate with the dominant leg.

Statistical comparisons were made by a 1-way ANOVA with  $\alpha = 0.05$  and Tukey post-test where appropriate using GraphPad Prism version 7.00 for Windows (GraphPad Software, La Jolla California USA). Data are reported as mean  $\pm$  SD.

## RESULTS AND DISCUSSION

Primary findings in this study, found that the UL was different than the loaded conditions and the obese group during descending stair walking. Specifically, the simulated weight gain and the OW group altered stance phase, step width, peak knee abduction angle, and peak hip abduction angle and abduction moment (Table 1) when compared to the UL condition. Compared to UL, stance duration was higher in CL, PL, and OW ( $p < 0.05$ ). This increase in stance time may help maintain stability and balance when during stair descent [1&2]. Compared to UL, step width was increased in PL and decreased in OW.

OW ( $2.244^\circ \pm 1.22$ ,  $p=0.028$ ) and PL ( $3.351 \pm 4.12$ ) had a significantly lower peak hip adduction angle compared to UL ( $5.336^\circ \pm 3.70$ ). Compared to UL, peak hip abduction moment increased was higher in CL, PL, and OW.

Compared to UL ( $0.055^\circ \pm 2.98$ ), peak knee abduction angle was higher in CL and OW group. No group differences were found when examining knee adduction moment. During level gait, normal weight individuals tend to walk with very little frontal plane knee movement and the knee typically stays adducted throughout stance. The observed change in knee abduction angle could explain the lack of change in knee adduction moment.

Stance phase duration, hip abduction moment, and hip adduction angle are similar between CL, PL and OW suggesting that our model of simulated obesity may mimic some of the biomechanical effects of obesity. It seems that the patterns that are used between all groups (CL, PL & OW) are very similar but there is an increased magnitude in the obese group. However, the magnitude of change in these parameters compared to UL tends to be higher in OW than CL or PL. Therefore, in order to model obesity, we would have to increase the BMI by more than  $5\text{kg/m}^2$ .

Interestingly, simulated obesity and OW elicited different responses in step width and knee abduction angle. Therefore, it is possible that mechanisms other than body mass may influence these parameters in obesity.

## CONCLUSIONS

While these are preliminary results from an ongoing study, they point in the direction suggesting that during descending stair walking weight gain may be able to be modeled. It may be possible to use an acute load to determine the biomechanical effects of weight gain and how this contributes to a chronic condition such as obesity. Further work will consider whether these effects persist in a larger sample.

## INTRODUCTION

Obesity increases risk of lower extremity injury and has been identified as a risk factor for osteoarthritis (OA) [1]. The hip and knee are weight bearing joints, where the combination of an increased load and altered biomechanics, especially in the frontal plane, during walking has been linked to the development and progression of knee OA [1-3]. Overweight and obese individuals use compensatory mechanisms during gait. Compared to their normal weight peers, obese tend to walk with a shorter step length and an increase in step width, which results in a slower self-selected speed [3]. It has been postulated that the slower walking speeds may decrease ground reaction forces and knee moments when walking [1-4].

Obesity is a multifactorial condition comprised of (among others): excess body mass, decreased relative muscle strength and power, decreased agonist recruitment, and premature fatigue. Therefore, the exact role of excess body mass and body mass distribution in obesity-induced biomechanical adaptations are unclear. The purpose of this study was to investigate the independent effects of increasing body mass centrally or peripherally on frontal plane kinematics and kinetics during gait.

## METHODS

As of this submission, 10 healthy (3 male; 7 female), normal weight (BMI:  $23.7 \pm 1.7$ ) participants (age:  $23.7 \pm 4$  years; height:  $1.69 \pm 0.13$  m; mass:  $63.8 \pm 11.6$  kg) have participated in the protocol. Lower extremity kinematic and kinetic data were collected during gait at a self-selected speed. Participants were loaded with three conditions: unloaded (UL), centrally loaded (CL), and peripherally loaded (PL). For the loaded conditions, participants carried external loads sufficient to increase their BMI by 5 kg/m<sup>2</sup>. For the CL condition, external load was

added to a weight vest. For the PL condition, the load was distributed to 50% in the weight vest and 25% to each thigh using specially constructed neoprene sleeves. Participants walked across the walk way at self-selected walking speeds for each condition speed (UL  $1.414 \pm 0.08$  m/s, CL  $1.385 \pm 0.09$  m/s & PL  $1.316 \pm 0.08$  m/s) recorded with Brower Timing Systems, Timing Gates (Power systems LLC, Knoxville, TN). All conditions were randomized and adequate rest was given between conditions. For each condition (UL, CL, PL) all subjects walked until three valid trials were recorded. A valid trial was defined as walking across the force platforms without noticeable changes in gait while striking the force plate with the dominant foot.

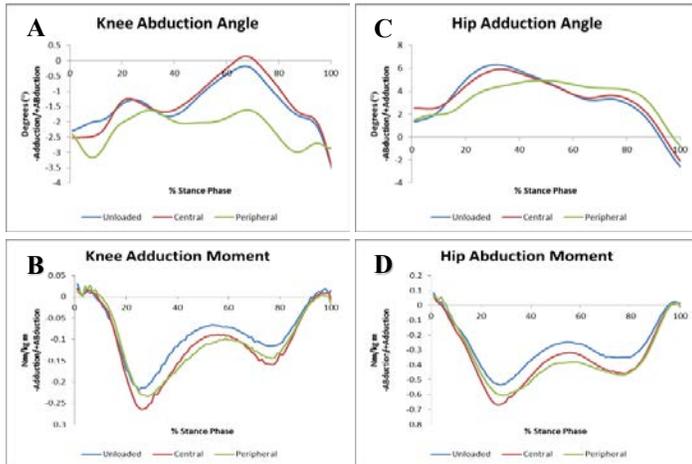

Retroreflective markers were placed bilaterally on bony landmarks of the trunk, pelvis and lower extremity and 3D data were collected using 10 high speed Motion Analysis Cameras (Motion Analysis Corporation, Santa Rosa, CA, USA) at a sampling rate of 200 Hz. All kinetic data were normalized to the participants' unloaded body weight. The PL condition was corrected for the added mass to the thighs. Force variables were collected using two Bertec force plates (Bertec Corp., Columbus, OH) at 1000 Hz. Joint/segment dynamics were calculated in Visual 3D (C-Motion Inc, Germantown, MD).

Statistical comparisons were made by repeated measures ANOVA with  $\alpha = 0.05$  and Tukey's post-test where appropriate using GraphPad Prism version 7.00 for Windows (GraphPad Software, La Jolla California USA).

## RESULTS AND DISCUSSION

External loading altered stance phase duration, step width, peak hip adduction angle, peak hip abduction moment, and peak knee adduction moment (Table 1).

Specifically, PL increased the duration of stance phase (~25%;  $p = 0.002$ ) and increased step width (0.029 m;  $p = 0.029$ ) compared to UL. The increase in step width in the PL condition produced a small decrease in peak knee abduction angle ( $p = 0.0505$ ) (Figure 1A,). With the increase in step width, most participants exhibited knee adduction throughout stance.

**Figure 1:** Stance phase ensemble curves of the knee abduction angle (A), knee adduction moment (B), hip adduction angle (C) and hip abduction moment (D) during gait N=10.

Peak knee adduction moment was higher in CL ( $0.325 \pm 0.079$  Nm/kg m) than UL ( $0.260 \pm 0.069$  Nm/kg m,  $p=0.002$ ) and PL ( $0.291 \pm 0.076$  Nm/kg m  $p = 0.025$ ). (Figure 1B). Peak knee adduction moment is the only variable that is different between loads.

PL, but not CL, also decreased peak hip adduction angle by approximately  $1.75^\circ$ , compared to UL (Figure 1C  $p=.013$ ). Furthermore, both the CL ( $0.764 \pm 0.108$  Nm/kg m,  $p = 0.005$ ), and PL ( $0.722 \pm 0.096$  Nm/kg m,  $p < 0.001$ ), increased peak hip abduction moment compared to UL ( $0.607 \pm 0.109$  Nm/kg m) (Figure 1B).

In a study comparing normal weight and obese subjects, Browning and Kram [8], found nonnormalized peak knee adduction moments were on average 20 Nm higher in obese subjects. When the joint moments were normalized to body weight McMillan et al. [6], found that during stance the obese subjects had decreased knee adduction moments by 0.04 Nm/kg m. However, these results may be due to differences in normalization methods. Finally, the decrease in moments in McMillan et al. [6], could be a result of decreased gait velocity. Gait velocity was self-selected but the differences between obese and normal weren't reported in their study.

## CONCLUSIONS

These results suggest excess body mass alters frontal plane kinematics and kinetics in a distribution-specific manner during gait. While these are preliminary results from an ongoing study, they point in the direction suggesting that body mass distribution during weight gain may affect biomechanics of the lower extremity during gait. It may be possible to use an acute load to determine the biomechanical effects of weight gain and how this contributes to a chronic condition such as obesity. Further work will consider whether these effects persist in a larger sample.

## INTRODUCTION

Knee osteoarthritis (OA) is a leading cause of disability in the elderly, and there is no curative therapy. Disease pathogenesis is not entirely understood; however, gait mechanics have been shown to play a role in medial OA development and progression. The knee adduction moment (KAM) during stance phase, a marker of knee loading, is specifically relevant for this disease. In fact, larger KAM peak during early stance ( $KAM_1$ ) and larger impulse of the KAM during total stance ( $KAM_{impulse}$ ) have been related to OA severity, pain, and loss of cartilage [1].

Therefore, there is a growing interest in gait interventions to decrease these KAM variables [2]. Recently, walking with increased step width has been reported to decrease  $KAM_1$  and  $KAM_{impulse}$ , as well as to decrease the KAM peak during late stance ( $KAM_2$ ) of walking and stair ascent in healthy subjects [3-5]. While these studies, altogether, tested for step width increases in the range of 2-19 cm, a single gait study testing several increases is missing, and the dose-response effect of step width on KAM variables is unknown.

The aim of this study was to characterize the effects of increases in step width from 8 cm to 32 cm on  $KAM_1$ ,  $KAM_2$ , and  $KAM_{impulse}$  in a group of healthy individuals.

## METHODS

Ten healthy subjects (4 female,  $24 \pm 5$  years (mean $\pm$ SD),  $21.4 \pm 1.7$  kg/m<sup>2</sup>) were tested in a gait laboratory after ethics review board approval. Their walking mechanics were monitored following a standard, validated technique using a marker-based motion capture device (Vicon, UK), force plates (Kistler, CH), and the BioMove software (USA) [6].

First, subjects performed five natural walking trials at their preferred walking speed. The normal gait characteristics of each subject, including normal step width (NSW), were calculated based on these trials. Subjects were then asked to walk across the lab while stepping on foot placement targets displayed on the floor. Using the targets, the subjects walked with step width increases of 8, 16, 24 and 32 cm from NSW while preserving their normal foot-progression angle, step length, and speed. Modification trials were recorded in random order.

The percent changes in  $KAM_1$ ,  $KAM_2$ , and  $KAM_{impulse}$  from NSW condition were calculated for each increased step width condition. Student t-tests were used to test these changes versus the null-hypothesis of no change, with  $\alpha=0.05$ . When needed, linear regressions as post-hoc analyses were performed to characterize the associations between step width increase and KAM variables.

## RESULTS AND DISCUSSION

$KAM_1$  was significantly decreased at the 16 cm increase in step width condition ( $p=0.024$ ), but not at the other increased step width conditions (Fig 1A). At all increased step width conditions, both  $KAM_2$  and  $KAM_{impulse}$  were significantly decreased compared with NSW condition (Fig 1B and 1C, respectively,  $p<0.05$ ). Post-hoc regression analyses indicated that six of the ten subjects had significant negative associations between step width increase and changes in  $KAM_1$  and  $KAM_{impulse}$  ( $R^2 > 0.8$ ;  $p<0.05$ ).

The results suggest a sort of threshold response to the decrease in  $KAM_1$  with increased step width. Indeed, while a significant decrease in  $KAM_1$  was found at 16 cm increased step width, this change was not maintained at larger step widths, potentially due to individual compensatory motions at the ankle, hip,

and trunk with such wide steps. This interpretation agrees with the larger inter-subject variations in  $KAM_1$  change at 24 and 32 cm step width increases compared to the inter-subject variations at smaller increases. In fact, while some subjects continued to display decreased  $KAM_1$  at large step width increases, others showed increased  $KAM_1$  from the NSW condition. Thus, care should be taken regarding the amplitude of step width increase in gait retraining programs to reduce  $KAM_1$ .

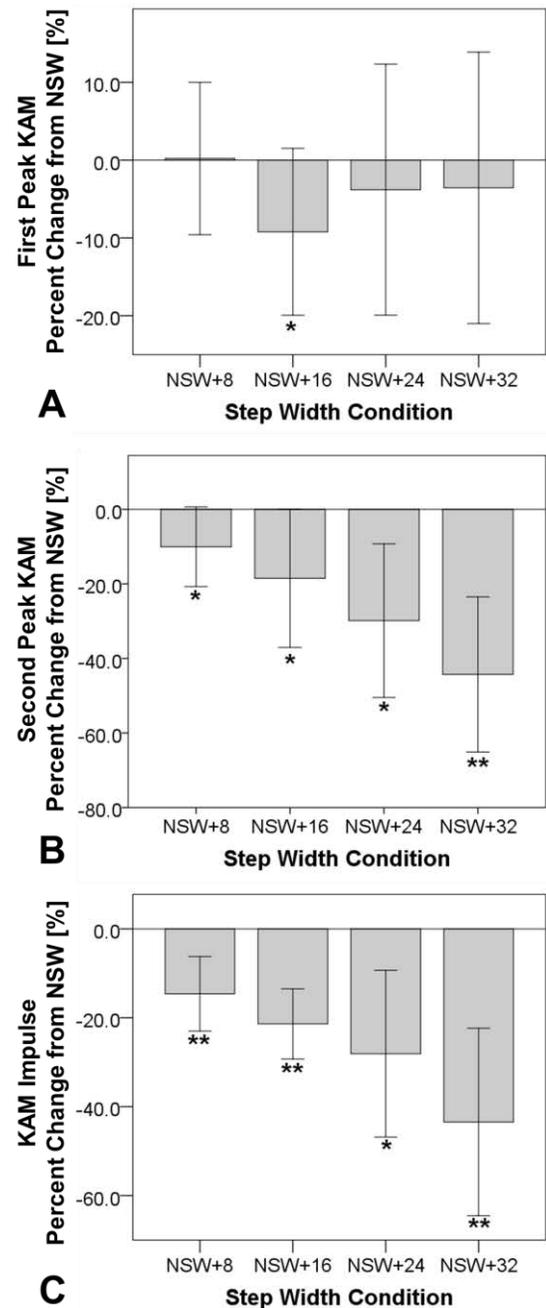

$KAM_2$  and  $KAM_{impulse}$  were observed to decrease at all increased step widths, and post-hoc regression analyses indicated that there was a linear dose-response for these  $KAM$  variables in 60% of the subjects. There was nonetheless individuality in the  $KAM_2$  and  $KAM_{impulse}$  responses as the regression results showed that  $KAM$  reductions per centimeter of increased step width ranged from 1.0%-1.9% for  $KAM_2$  and 0.9%-2.3% for  $KAM_{impulse}$ . This again supports the need for individual gait retraining programs to reduce medial knee loading ( $KAM$ ).

## CONCLUSIONS

This study highlighted a range of step width increases with consistent  $KAM_1$  reduction for healthy subjects. However, past this range,  $KAM_1$  change became subject-specific. Therefore, while this study confirmed increased step width as a possible gait modification to decrease  $KAM_1$ , this modification may be limited in the amount of  $KAM_1$  reduction it can induce. On the contrary, the decrease in  $KAM_2$  and  $KAM_{impulse}$  was generally continuous with the increase in step width. Even so, large inter-subject variation in  $KAM_2$  and  $KAM_{impulse}$  responses to step width were observed and should be considered in future gait retraining programs. Furthermore, this study was limited to a small group of healthy subjects, and it is of interest to test if these results are also present in medial knee OA patients.

email: [joshi.142@osu.edu](mailto:joshi.142@osu.edu), <http://movement.osu.edu>

## INTRODUCTION

Humans walk stably while also being energy efficient. A better understanding of the human walking controller could help us learn how these potentially opposing objectives are achieved. We perturbed able-bodied human subjects as they walked on a treadmill, and used their kinematic and ground reaction force data to determine how foot-placement and leg-force generation strategies are used to return to steady-state motion [1]. Here, we use data collected from these experiments to derive a controller for two simple models of human walking.

## METHODS

12 subjects (8 male, 4 female) walked for 10 bouts of 4 mins each on an instrumented split-belt treadmill. As they walked kinematic data from 28 markers placed on the torso and lower limbs, along with ground reaction force data from the treadmill were collected. For each individual session, perturbations were either applied in the fore-aft direction (9 subjects) or the medio-lateral direction (7 subjects), with 4 subjects participating in both types of experiments.

Perturbations were applied by humans through inelastic cords, and a load cell in series with the cords measured the magnitude of the perturbation applied. All perturbations were randomly disturbed over the walking bout, with at least 15s and at most 25s of time provided between consecutive perturbations to allow for a return to steady-state. Subjects were made to wear headphones and blinders, to prevent any anticipatory response to the perturbation. All subjects wore a safety harness connected to the ceiling.

We propose two methods for controller derivation, each applicable to a different model of the human walking controller. Both methods measure the deviation of the torso mid-stance state from its nominal value (the mean value during unperturbed walking) and use it as the error term that is being corrected.

1. Consider a biped model that uses the position of the center of pressure (CoP) and the magnitude and direction of the ground reaction force (GRF) as control variables. We can measure the time-varying response of these control variables to a known error in mid-stance torso state. This response can be broken up into many piece-wise linear functions, each mapping the mid-stance torso state into the corresponding control action.
2. Consider a biped model that uses foot-placement and push-off impulse as control variables. First, we use our experimentally collected data to determine a linear function that maps the mid-stance state deviations of human walkers in the  $n^{\text{th}}$  step to the  $n+1^{\text{th}}$  step.

$$\Delta \begin{bmatrix} X_{\text{torso}}(n+1) \\ Z_{\text{torso}}(n+1) \\ \dot{X}_{\text{torso}}(n+1) \\ \dot{Y}_{\text{torso}}(n+1) \\ \dot{Z}_{\text{torso}}(n+1) \end{bmatrix} = J_1 \cdot \Delta \begin{bmatrix} X_{\text{torso}}(n) \\ Z_{\text{torso}}(n) \\ \dot{X}_{\text{torso}}(n) \\ \dot{Y}_{\text{torso}}(n) \\ \dot{Z}_{\text{torso}}(n) \end{bmatrix}$$

For the given biped, we find a corresponding linear function that maps the deviations of torso states and control actions in the  $n^{\text{th}}$  step to the deviations of torso states  $n+1^{\text{th}}$  step.

$$\Delta \begin{bmatrix} X_{\text{torso}}(n+1) \\ Z_{\text{torso}}(n+1) \\ \dot{X}_{\text{torso}}(n+1) \\ \dot{Y}_{\text{torso}}(n+1) \\ \dot{Z}_{\text{torso}}(n+1) \end{bmatrix} = J_2 \cdot \Delta \begin{bmatrix} X_{\text{torso}}(n) \\ Z_{\text{torso}}(n) \\ \dot{X}_{\text{torso}}(n) \\ \dot{Y}_{\text{torso}}(n) \\ \dot{Z}_{\text{torso}}(n) \end{bmatrix} + J_3 \cdot \Delta \begin{bmatrix} I \\ t_{\text{step}} \end{bmatrix}$$

To derive a controller, we relate state-deviations to control-action deviations.

$$\Delta \begin{bmatrix} I \\ t_{\text{step}} \end{bmatrix} = J_4 \cdot \Delta \begin{bmatrix} X_{\text{torso}}(n) \\ Z_{\text{torso}}(n) \\ \dot{X}_{\text{torso}}(n) \\ \dot{Y}_{\text{torso}}(n) \\ \dot{Z}_{\text{torso}}(n) \end{bmatrix}$$

This would give us an effective state transition matrix of the form –

$$\Delta \begin{bmatrix} X_{\text{torso}}(n+1) \\ Z_{\text{torso}}(n+1) \\ \dot{X}_{\text{torso}}(n+1) \\ \dot{Y}_{\text{torso}}(n+1) \\ \dot{Z}_{\text{torso}}(n+1) \end{bmatrix} = J_2 \cdot \Delta \begin{bmatrix} X_{\text{torso}}(n) \\ Z_{\text{torso}}(n) \\ \dot{X}_{\text{torso}}(n) \\ \dot{Y}_{\text{torso}}(n) \\ \dot{Z}_{\text{torso}}(n) \end{bmatrix} + J_3 \cdot J_4 \cdot \Delta \begin{bmatrix} X_{\text{torso}}(n) \\ Z_{\text{torso}}(n) \\ \dot{X}_{\text{torso}}(n) \\ \dot{Y}_{\text{torso}}(n) \\ \dot{Z}_{\text{torso}}(n) \end{bmatrix}$$

We need to solve for  $J_4$ , such that we minimize the error between  $J_1$  for the human and the model

$$J_1^* = J_2 + J_3 \cdot J_4.$$

## RESULTS AND DISCUSSION

Figure 1 shows how we can use piece-wise linear functions to determine the effect of a 0.2 m/s change in mid-stance torso velocity on GRFs over the following stride. We see that a rightward push would lead to a corresponding leftward shift of the time varying GRF. A forward push comparatively leads to a backward shift in GRF during single support but almost no change in GRF while in double support.

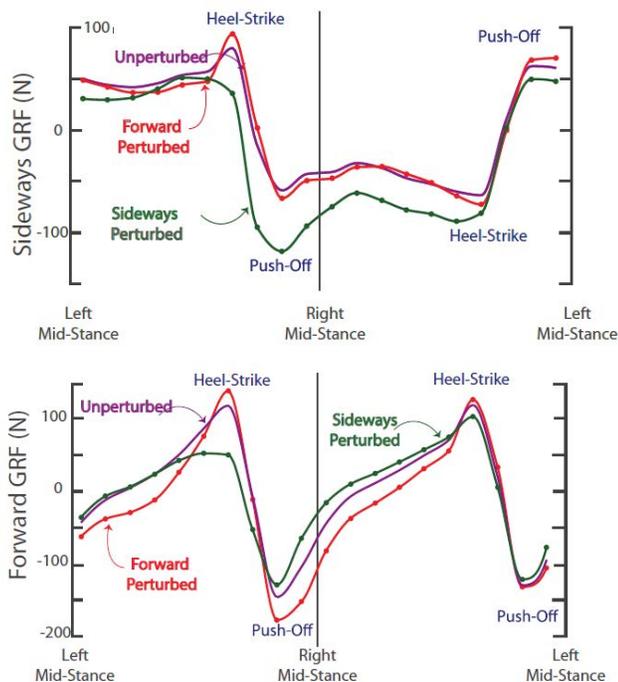

Figure 1. If a perturbation produces a 0.2 m/s deviation in mid-stance velocity in the forward (red curves) or rightward (green curve) direction sideways and forward GRFs are modulated to return to steady-state.

Figure 2 shows how the same change would affect CoP position over the following step. A rightward push causes the CoP to move far rightward and very slightly backward over the next step. An equally large forward push causes the CoP to move very slightly forward during single-stance but does not affect the sideways CoP position at all.

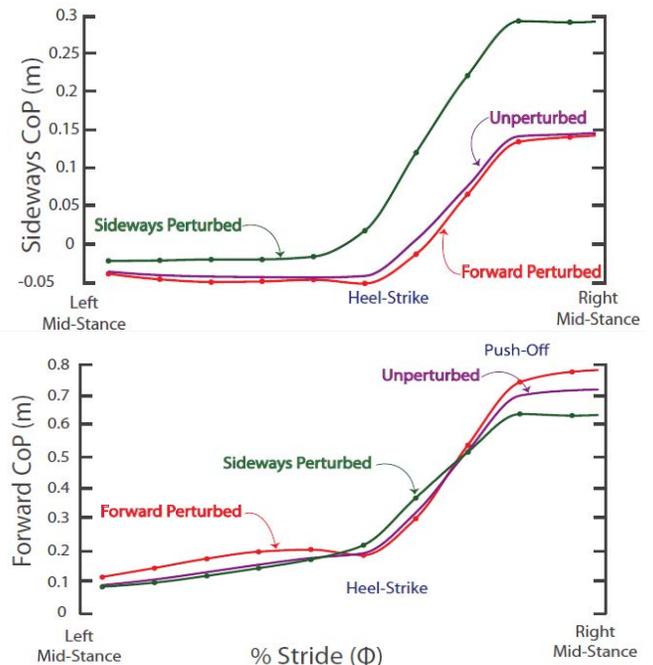

Figure 2. If a perturbation produces a 0.2 m/s deviation in mid-stance velocity in the forward (red curves) or rightward (green curve) direction CoP positions are modulated to return to steady-state.

These models show us how able-bodied humans respond to perturbations, and could be used to quantify how movement disorders impair gait or to measure the effect of rehabilitation techniques. We could also try to use these controllers to design gaits for bipedal robots, to make them more human-like.

## INTRODUCTION

Pediatric populations with gait disorders can present temporal and spatial deviations from normative gait that have severe consequences for gait function. Altered sagittal knee motion is one of the most common deviations associated with reduced gait function [1].

Visual biofeedback relies on the sensory integration of real-time visual information to modify specific motor behaviors [2]. While a variety of feedback modalities has been used to modify gait parameters [3], the use of visual feedback to modify knee flexion kinematics during pediatric gait is limited.

The purpose of this study was to investigate how pediatric participants modify their knee flexion patterns during gait using a visual kinematics feedback system (VKFS). Four modifications that increased, and that decreased maximum knee flexion during the gait cycle were tested. The study measured maximum knee flexion angle and full gait cycle error.

## METHODS

Twelve typically developing children and adolescents (6M, 6F; 11.9±2.7 yrs old) participated in the study. All research procedures were approved by the Kessler Foundation Institutional Review Board.

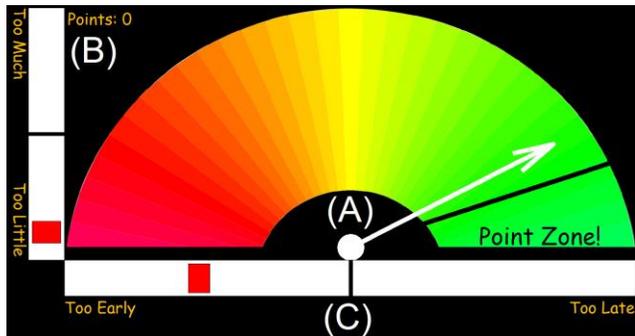

Knee flexion angle data were collected using Inertia Measurement Units (Xsens MTw, Enschede, The Netherlands) with a sampling frequency of 50Hz. Three sensors were fixed to each participant's dominant lower limb. One sensor was placed on the anterior thigh, a second sensor was placed on the posterior shank, and a third sensor was attached to the heel of the participant's shoe. To process and

integrate the data recorded by the sensors into a display for visual feedback, a VFKS was developed in MATLAB (MathWorks Inc., Natick, MA).

After calibrating the flexion angle, participants were asked to walk on the treadmill at a comfortable speed. This speed was used for the duration of each participant's testing. Participants were then asked to walk for 1 min while their natural walking knee flexion pattern was recorded ('gait analysis', GA). A reference gait cycle (RGC) was calculated by averaging 20 time normalized strides. The RGC curve between the two minima before and after maximum knee flexion was amplified and reduced by 20 and 40%, resulting in four different target gait cycles (TGC<sub>+40</sub>, TGC<sub>+20</sub>, TGC<sub>-20</sub>, TGC<sub>-40</sub>). The order of presentation of TGC was randomized, and for each TGC, participants were tested as they walked with real-time visual feedback (FB, 3 min), and with no feedback (NFB, 1 min). During FB trials, participants were asked to experiment with and adopt gait modifications in response to the visual cues displayed by the VKFS. Participants were asked to use the primary full cycle error display to score 'points', and were also provided two assistive cues on peak flexion and timing error (Fig. 1). All feedback was based on the most recent step. In NFB trials, participants were asked to try to maintain the knee flexion pattern previously learned while walking on the treadmill without feedback.

All analyzed cycles were normalized in time (0-100%, interval = 1%). The following measures were calculated for FB and NFB testing conditions by averaging data from the last 10 cycles of the trial. Mean absolute cycle error ('MACE') was calculated as the mean across cycles of the mean absolute difference between the measured angle and the TGC angle. Peak error ('PK') was calculated as the mean across cycles of the absolute error between the measured maximum angle and the maximum angle

of the TGC. Pre-exposure reference values (REF) for each of the above measures at each TGC were calculated by using the 20 RGC cycles as the measured angles.

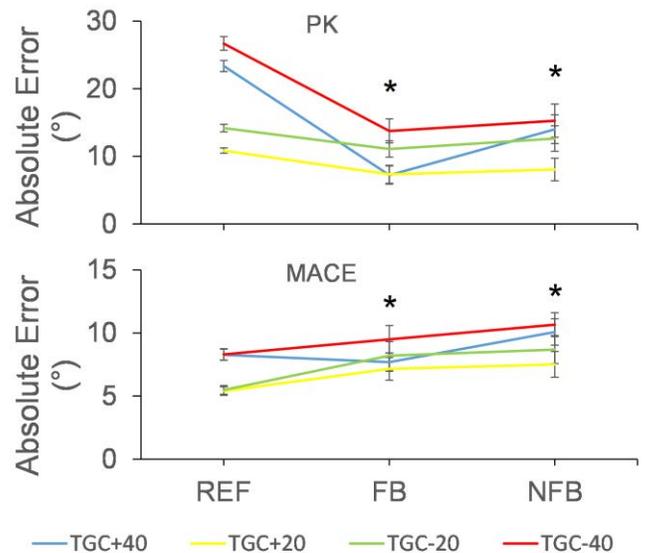

**Figure 1:** (A) The primary feedback needle moved in proportion to the sum of squared angle error across the cycle. A large error was indicated by movement of the needle to the red area, while the green area indicated a small error. A point count was incremented for each gait cycle the needle was in the 'point zone'. Secondary feedback displays indicated signed feedback on (B) magnitude and (C) timing of peak knee flexion.

For both measures and all TGCs, paired sample t-tests with a significance level of 0.05 were used to test for significant differences between REF and FB, NFB conditions.

## RESULTS AND DISCUSSION

For all TGC, PK was significantly smaller for FB than REF (Fig. 2), indicating that participants were able to use the VKFS to change maximum knee flexion in the sense indicated by the target. PK for NFB was significantly smaller than REF for TGC<sub>+40</sub> and TGC<sub>-40</sub>, indicating the ability to maintain aspects of the learned pattern after removal of feedback. However, MACE in FB and NFB was frequently higher than the respective reference measures, and in some cases these increases were significant. Increases in MACE were explained by the results of an examination of the distribution of absolute error across the cycle: decreases in the altered region (peak knee flexion) were offset by increases elsewhere. In some cases these appeared to reflect overall biasing of the gait pattern toward the change intended for peak knee flexion; for example, with TGC<sub>-40</sub>, participants often adopted a pattern with less flexion across the whole cycle. Other changes may have been compensatory motions adopted to facilitate the execution of the targeted patterns.

**Figure 2:** Absolute errors for TGCs across testing conditions. Error bars denote group standard errors. \* indicates significant differences between condition and reference for at least one TGC.

## CONCLUSIONS

Maximum knee flexion during typically developing pediatric gait was directed toward specific targets in response to the VKFS. However, overall cycle error was not reduced, indicating that by deviating maximum knee flexion from normal, other parts of the gait cycle were altered. It is possible that reduction in overall error could result from longer FB exposure times. Further work applying the current VKFS in the normalization of pathological gait patterns, rather than deviations from normal gait, might result in reductions of overall error. Additionally, the VKFS error feedback might be weighted to target a specific deviation.

## INTRODUCTION

Persons with unilateral lower extremity amputation (LEA) have altered trunk-pelvis kinematics and joint/muscle forces during walking relative to able-bodied (AB) persons [1,2]. These altered mechanics are believed to be associated with the increased prevalence of and risk for both low back pain (LBP) and falls in persons with LEA. Recent work has demonstrated that in AB walking, all joint moments in the body can contribute to net trunk dynamics, which may include complex inter-planar couplings; for example, the stance limb sagittal ankle moment can induce frontal plane trunk angular accelerations that tend to tilt the trunk ipsilaterally [3,4]. In persons with vs. without LEA, elevated ipsilateral trunk lean during prosthetic limb stance is a commonly reported deviation [1,2]. Therefore, the aim of this exploratory study was to identify the primary contributors to frontal plane angular trunk dynamics during walking of persons with LEA, in comparison to AB walking.

## METHODS

One subject with unilateral transfemoral LEA (TFA), one with unilateral transtibial LEA (TTA), and two AB controls (AB1, AB2), were retrospectively identified from records of the Biomechanics Lab at Walter Reed National Military

Medical Center. Subjects were selected such that self-selected walking velocity (SSWV) fell within +/-5%, and no participants self-reported current LBP at time of data collection (Table 1).

Subjects walked overground along a 15m walkway at SSWV, with full-body kinematics ( $f_s=120\text{Hz}$ ) and ground reaction forces ( $f_s=1200\text{Hz}$ ) respectively measured via a 27-camera motion capture system and six floor-embedded force platforms. One representative prosthetic(right) stance phase was extracted for each subject, kinematic/kinetic data were filtered at 6\25Hz, and an inverse kinematic solution was computed using Visual3D, applying the Gait2392 model definition of the OpenSim software[5]. The Residual Reduction Algorithm was used to compute a set of joint moments that best tracked experimental kinematics while also adjusting trunk center-of-mass location to reduce dynamic inconsistencies. Joint moments and kinematics were input to an induced acceleration analysis, applying a rolling-without-slipping contact constraint at each foot in place of measured forces. For each system force, mean induced angular accelerations were computed using separate positive and negative mean integrals during gait phases of interest [4]. As early stance is generally where elevated lateral lean occurs in persons with LEA, analyzed phases were limited to initial double-limb support (IDS) and early single-limb support (ESS).

**Table 1:** Demographic characteristics and self-selected walking velocity (SSWV) for the able-bodied (AB), transtibial (TTA), and transfemoral (TFA) participants.

	Gender	Age (yr)	Stature (cm)	Mass (kg)	Time Since Amp. (yr)	Prosthetic Componentry	SSWV (m/s, Fr)
TTA	Male	34	177	93	1.29	Renegade <sup>®</sup> (Freedom Innovations)	1.24 (0.17)
TFA	Male	23	174	70	1.25	Ceterus <sup>™</sup> , Power Knee <sup>™</sup> (Ossur)	1.22 (0.17)
AB1	Male	27	176	76	-	-	1.32 (0.20)
AB2	Male	27	172	81	-	-	1.42 (0.23)

## RESULTS AND DISCUSSION

Simulations were successfully generated for each subject, with quality verified against suggested standards [5]. Comparing simulated trunk kinematics (Fig. 1, left) mean trunk lean during ESS was greatest in TTA (5.0°) followed by TFA (3.6°), and AB1\AB2 (0.5° \ 0.1°).

During both IDS and ESS, inter-planar coupling was observed across all subjects. Sagittal ankle and hip moments induced notable contributions to net frontal trunk accelerations throughout stance - in agreement with prior work in AB subjects [3,4]. Contributions from the frontal lumbar moment differed between subjects (Fig 1, right): for TTA a prosthetic(right)-tending acceleration was induced, while for AB1, AB2, and TFA accelerations were intact(left)-tending, although considerably larger in TFA. Comparing AB1 and AB2, AB2 had a larger contribution from stance(right)-side knee Flx\Ext during IDS relative to AB1, while AB1 instead had a larger contribution from trailing(left)-side hip Ab\Ad. This suggests that able-bodied persons may apply notably different underlying mechanics to compose similar net frontal plane trunk accelerations. To facilitate comparison of LEA subjects with AB, the following reasoning was applied; a moment that contributes elevated prosthetic-tending, or reduced intact-tending, acceleration to the cumulative net over IDS (relative to AB1 and AB2), has potential to be associated with subsequent, elevated trunk lateral lean towards

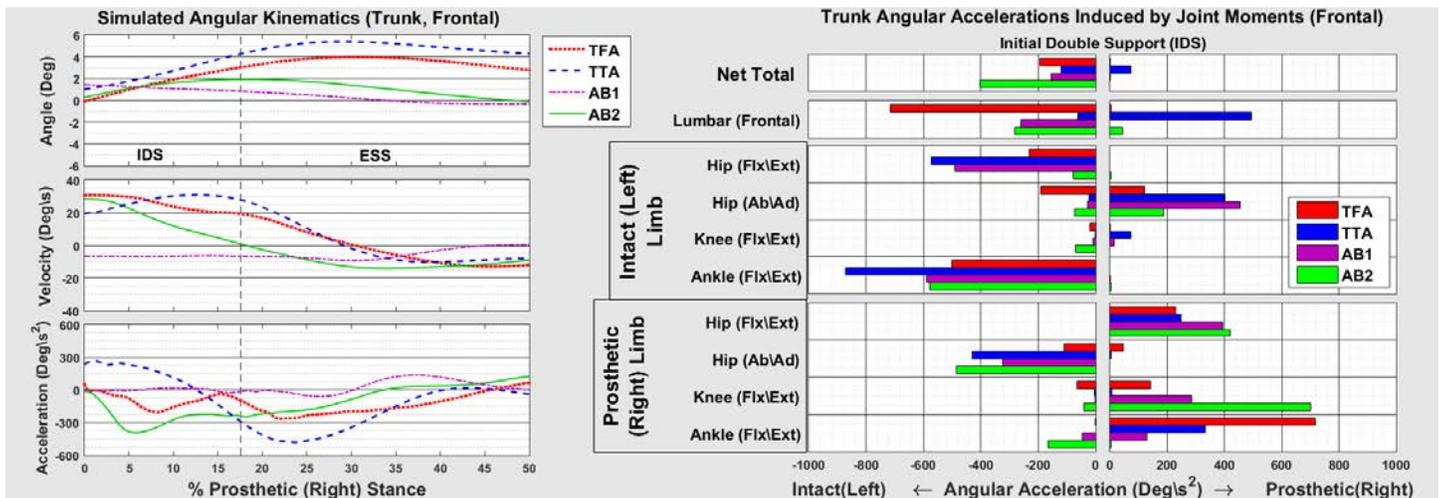

the prosthesis in later stance. For TFA, this highlighted prosthetic-side ankle Flx\Ext and prosthetic-side hip Ab\Ad. In contrast for TTA, this highlighted lumbar frontal moment, followed by prosthetic-side knee Flx\Ext, and prosthetic-side ankle Flx\Ext. The prosthetic ankle contribution was elevated in both TTA and TFA, suggesting adjustment of prosthetic ankle componentry, or distally-targeted gait re-training, may warrant investigation as means to affect elevated lateral trunk lean in LEA patients. However, these simulation-based observations require empirical validation prior to clinical translation.

## CONCLUSIONS

This exploratory study highlights that frontal plane trunk dynamics during level walking in persons with LEA and no LBP are composed of a whole-body balance of system forces, wherein distal prosthetic ankle function may play a role. A larger cross-sectional analysis is needed to ascertain if features observed in these case subjects are characteristic of the broader LEA population, and also if those with versus without LBP differ.

# Asymmetrical Limb Loading Affects Spatial and Temporal Gait Parameters Differently in Comparison to Split-belt Adaptation

Lauren Bowman, Troy Rand, M.S., Allison Hoover, Mukul Mukherjee, Ph.D.

The University of Nebraska at Omaha, Omaha, NE, USA

Email: [lbowman@unomaha.edu](mailto:lbowman@unomaha.edu); web: [unonbcf@unomaha.edu](http://unonbcf@unomaha.edu)

## INTRODUCTION

Aging and pathology, such as strokes, can result in asymmetrical walking patterns. Asymmetries may be prominent in the spatial domain (e.g. step length) or the temporal domain (e.g. step time) independently or in conjunction. It is not yet well understood how to target these domains while rehabilitating an asymmetrical walking pattern.

Asymmetrical walking patterns can be induced in healthy individuals through several different tasks including unilateral limb loading and split-belt adaptation. However, these two methods induce asymmetrical walking patterns through different mechanisms. While unilateral limb loading is an external weight added to a limb, it is perceived as one limb being heavier than the other, i.e., an internal perception. In contrast, the split-belt task exhibits an external change to the body because the environment itself is manipulated due to the two belts of the treadmill moving at different speeds. Determining how spatial and temporal components of gait are effected due to limb loading versus split-belt adaptation may give important insight into developing rehabilitation programs for those with asymmetric sensorimotor abnormalities.

Virtual reality (VR) has been shown to effect cadence, temporal walking patterns, and muscle activation during unilateral limb loading<sup>1</sup> while improving adaptability of spatiotemporal characteristics during split-belt adaptation.<sup>2</sup> However, it is not clear how VR effects spatial and temporal symmetry during asymmetrical walking during unilateral limb loading and split-belt adaptation.

The purpose of this study was to determine if spatial and temporal gait symmetries were different between walking with a unilateral limb load versus split-belt adaptation. Additionally, we wanted to determine if

walking in a VR environment had any effect on these differences.

## METHODS

Thirty two young healthy volunteers participated in this study (age  $23 \pm 2.7$  years, mass  $73.6 \pm 13.3$  kg, height  $173.0 \pm 8.6$  cm). All subjects were free of any musculoskeletal or neurological impairments that may have affected their gait or locomotor adaptation. The protocol was approved by the institutional review board of the University of Nebraska Medical Center.

Subjects were exposed to one of two asymmetrical gait patterns: unilateral limb loading or split-belt. Sixteen subjects performed unilateral limb loading and were equipped with an ankle weight weighing approximately 5% of their body weight on their left ankle (Figure 1). They performed four treadmill trials at their preferred walking speed: familiarization, baseline, limb loading, and washout (load removed). Half of these subjects (8) were exposed to VR while half were not (control group).

A second group of sixteen subjects walked on a split-belt treadmill and performed ten treadmill trials at their preferred, fast, or slow walking speed as well as split belt trials with one belt moving at their fast walking speed and the other at their slow walking speed (Figure 1). Half of these subjects were exposed to VR while half were not.

To compare interlimb coordination, the symmetry index (SI) was calculated for step length and step time for all subjects.

$$SI \text{ for Split - belt} = \frac{\text{fast} - \text{slow}}{\text{fast} + \text{slow}}$$

$$SI \text{ for Limb Loading} = \frac{\text{loaded} - \text{unloaded}}{\text{loaded} + \text{unloaded}}$$

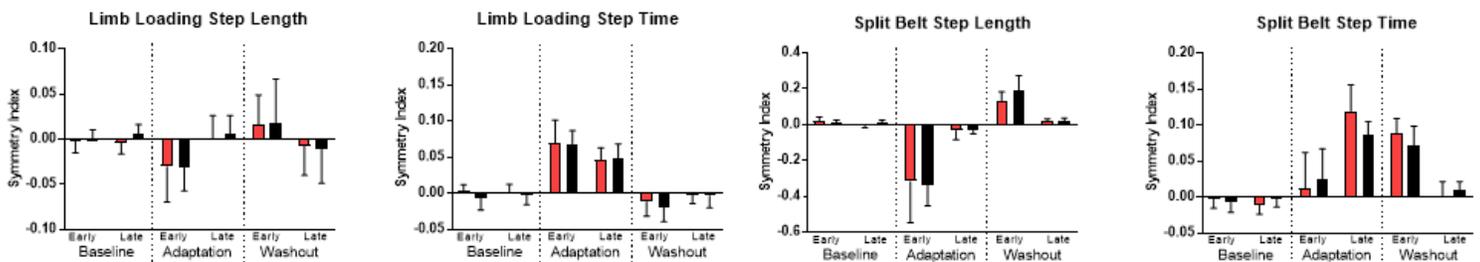

Figure 1. The left picture shows unilateral limb loading with the ankle weight fixed to the left ankle. The picture on the right shows a subject doing the split-belt task.

A 3-way mixed model ANOVA was run to compare the task (unilateral limb loading versus split-belt) and vision (virtual reality versus non-virtual reality) for fixed effects and time (baseline, early and late adaptation, early and late washout) for repeated effects.

## RESULTS AND DISCUSSION

*Step length symmetry (Figure 2):* There was a main effect of task [ $F=7.860, p<0.009$ ], and time [ $F=32.142, p<0.0001$ ] but not for vision. There was only a significant interaction for time across task [ $F=19.007, p<0.0001$ ].

*Step time symmetry (Figure 2):* There was a main effect of task [ $F=19.255, p<0.0001$ ], and time [ $F=151.679, p<0.0001$ ] but not for vision. There was a significant interaction for time across task [ $F=76.720, p<0.0001$ ] and time across task across vision [ $F=3.337, p=0.025$ ] and a borderline interaction for time across vision [ $F=2.649, p=0.057$ ].

**Figure 2:** Symmetry index for step length and step time for the limb loading task (left side) and split belt task (right side) task. Red bars indicate gait adaptation in VR. The limb loading step length scale is one-fifth the scale of split belt step length for clarity.

## CONCLUSIONS

- 1) Adaptive changes were demonstrated for both limb loading and split-belt adaptation that impacted the temporal gait patterns more than the spatial.<sup>3</sup>
- 2) VR that is known to affect gait patterns also shows differential effects based on type of task and the type of gait variable being studied.
- 3) Asymmetry induced by loading a limb is different from how it is induced by support surface velocity manipulations. This internal versus external induction of asymmetric gait patterns results in different mechanisms of gait coordination.
- 4) Future directions of research would include how internal versus external asymmetry impacts gait variability and how it is impacted by aging.

# THE EFFECTS OF GAIT SPEED ON FOOT ROCKERS

Paige Agnew, Francesca Boylan, Kate Emma, Heidi Mickunas, Ayana Phillips, Deborah King

Ithaca College, Ithaca, NY, USA

email: [dking@ithaca.edu](mailto:dking@ithaca.edu), web: <http://www.ithaca.edu/hshp/depts/ess/>

## INTRODUCTION

Locomotion is a foundational component for daily living. Legged locomotion can be broken down into two gait patterns, walking and running [1]. The hip, knee, and ankle joints have different roles depending on the phase of walking & running and must work together to produce and absorb forces to allow efficient movement through the stance phase. In walking, this is accomplished by three rockers: the heel rocker, the ankle rocker, and the forefoot rocker. While the role and movement patterns of ankle and foot have been studied extensively in running, little research has framed foot and ankle motion in running in context of the heel, ankle, and forefoot rockers even though at slow running speeds, 80 to 90% of shod runners' heel strike and exhibit all three rockers [2]. Thus, the purpose of this study is to determine the effect of gait speed on the presence and timing of foot rockers across both walking and running speeds.

## METHODS

Twenty-six healthy college aged students (age (y): 20.4, height (cm): 161.2, mass (kg): 70.1), who give their written informed consent and volunteered to participate. Following a warm-up, subjects completed one-minute walking and running trials at 4 walking speeds and 4 running speeds: 1.16 m/s, 1.46 m/s, 1.65 m/s, 1.92 m/s, 2.24 m/s, 2.68 m/s, 3.13 m/s, 3.58 m/s on a treadmill. One minute of rest at 1.3 m/s was provided between trials.

Nineteen reflective markers placed on key anatomical landmarks were used to create an eight-segment model using a modified Plug-in-Gait marker set (Vicon, Centennial, CO). Motion capture data (Vicon Nexus) was collected at 120 Hz for the last 20 seconds of each trial.

Ten strides of data for each speed were analyzed. Visual 3D was used to calculate the start and stop off the heel, ankle, and forefoot rockers based on guidelines of Bober, et al. [3]. Each rocker was then expressed as a percent of the stance phase. Stride rate and stride length were also calculated. Descriptive statistics were calculated in SPSS for the foot rocker variables. One-way repeated measures ANOVA were used to determine significant differences in the timing of the foot rockers across the treadmill speeds. Post hoc comparison were performed on significant main effects. Alpha = 0.05.

## RESULTS AND DISCUSSION

To date, data has been analyzed for 10 subjects and preliminary statistical analyzes have been performed on these 10 subjects.

Descriptive characteristics of the 5 variables are provide din Table 1. As expected, stride rates (and correspondingly stride lengths) were significantly different across speeds ( $F = 6.86$ ,  $p = .001$ ). Specifically stride rates increased over the first 3 walking speeds (1.16 m/s, 1.46 m/s, 1.65 m/s,  $p < 0.05$  for all). Not all subjects were able to walk at the fastest walking speed, which was near the walk to run transition, introducing large variability in the stride rate and stride length at that speed. None of the running speed stride rates were significantly different from each other.

There was not a main effect for percent of stance in the heel rocker ( $F = 1.051$ ,  $p = .475$ ), ankle rocker ( $F = .51$ ,  $p = .803$ ), or forefoot rocker ( $F = .857$ ,  $p = .605$ ) across speeds. Close examination of the data shows large standard deviations indicating great variability in the time spent in each rocker within each gait speed. Despite this variability, there does appear to be a consistent non-significant drop of time in the heel rocker to decrease across speed.

Once the data from the additional subjects are processed, it will be interesting to see if this drop is statistically significant. There does not appear to be a consistent pattern in the time spent in the ankle or forefoot rockers expressed as a percent of stance.

The data, however, clearly indicate that regardless of speed, there is overlap in the rockers during the gait cycle. Traditionally, the rockers are taught as the heel rocker occurring from heel strike to foot flat, followed by the ankle rocker - representing the tibia rotating forward over the foot - occurring from foot flat to heel off, and then the forefoot rocker - representing motion at the metatarsophalangeal joint - occurring from heel off to toe-off. Our data suggest that the ankle rocker starts prior to foot flat and can continue past heel off. Individual subject analysis also revealed that for some subjects at some running speeds ankle dorsiflexion begins prior to initial contact.

Since the rockers are thought to be pivotal in gait efficiency helping to minimize the motion of the center of mass [4], understanding how they interact at different speeds is valuable for evaluating and planning treatments for gait abnormalities as well as for prosthetic design.

Currently, with only 10 of the 26 subjects analyzed it is premature to conclude that gait speed does not affect the timing of the foot rockers. However, the initial analysis clearly reveals that the foot rockers are not purely sequential at the tested gait speeds. It

is anticipated that data from this study can be used to develop normative values of the timing of the rockers during gait and across speeds and to improve our understanding of the coordinated motion of the foot and ankle towards efficient walking and running.

## CONCLUSIONS

The heel ankle and forefoot rockers do not occur sequential across the gait speeds tested in this study. Speed did not have a statistically significant affect on the time spent in each rocker as a percent of stance.

# TO WALK OR TO RUN? METABOLIC COST IS NOT THE ANSWER

Erik Summerside, Rodger Kram, & Alaa Ahmed

Department of Integrative Physiology, University of Colorado Boulder, Boulder, CO USA

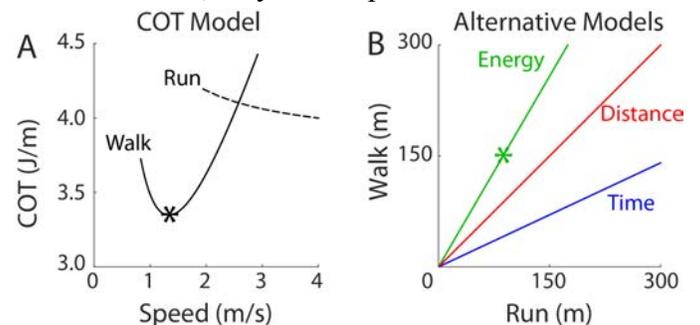

email: [erik.summerside@colorado.edu](mailto:erik.summerside@colorado.edu)

## INTRODUCTION

Minimization of metabolic cost explains several fundamental observations in locomotion such as preferred step width and length [1,2]. These preferred kinematics during walking seem to minimize the metabolic energy required per unit distance, a metric commonly referred to as cost of transport (COT). Plotting COT as a function of walking speed yields a U-shaped curve (Figure 1A). Interestingly, humans exhibit preferred walking speeds that correspond to the minimum of the COT curve [3]. One difficulty with using COT as a model to explain the preferred walking speed is that it fails to consider two other important movement constraints: time and total distance. According to the COT model, if an individual were given the opportunity to either walk a distance, 'x', or run a distance, 'y,' they should always choose the option to walk. Alternative models based on optimal foraging theory *include* costs for time and distance [4, 5]. For example, when starlings (birds) are given the choice to either walk or fly to food, the preferred mode is best predicted based on minimizing net metabolic rate (net metabolic energy expended divided by time).

We developed a paradigm to probe how metabolic energy, distance, and time explain why humans choose to walk versus run. If decisions were only based on minimizing COT, a participant should always walk (Figure 1A). We hypothesized COT would not predict choice and that there would be situations where running was preferred over walking. Instead of COT, we considered costs that were based solely on total amount of metabolic energy expended, total time spent, and total distance. Figure 1B shows the predictions of each of these three costs (green, red and blue line, respectively). For example, the green line represents the pair of walking and running options that a person would consider equivalent (here on referred to as an indifference point, IP), if he/she only cared

about choosing the option that minimized metabolic energy. In other words, they would consider walking 150m equally preferable as running 100m (asterisk in Figure 1B). For walk distances above this line they would prefer to run, for walk distances below this line, they would prefer to walk.

**Figure 1:** A) Metabolic COT for walking (solid line) and running (dashed line) across speeds. Minimization of COT occurs when walking at  $\sim 1.3$  m/s (asterisk). B) Model predictions for indifference points that minimize energy (green), distance (red), and time (blue). An individual that minimizes energy would be indifferent between walking 150m and running 100m (asterisk).

## METHODS

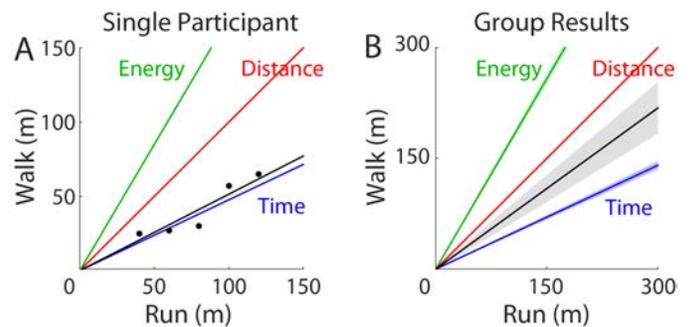

Our experiment took place in a large lighted and climate controlled indoor track facility. Participants (N=20, 12M, 8F) completed a combination of three different types of trials: walk, run, and choice trials. In walk trials, participants walked out to a designated distance and back. In run trials, they ran out to a different designated distance and back. For choice trials, they were given the freedom to repeat either the previous walk or run trial. During all trials, walking and running occurred at self-selected speeds. Participants were informed that the experiment would last two hours and that their decisions during choice trials would not affect the overall duration of the experiment (i.e. always choosing the faster option would not allow them to leave early). All trials ranged in distance between 10-250 meters and took place over 5 blocks. Each block allowed for the measurement of a single IP

which represents the relative walk and run distances where preference for one is equal to the other. Each individual block consisted of four triplets of trials (Walk/Run/Choice). The first triplet of trials in each block consisted of equal walk and run distances. Throughout a block, the run distance did not change. Walk distances were adjusted based on the participant's previous choice. If the choice was run, the walk distance was *shortened* for the next triplet. If the choice was walk, the walk distance was *lengthened*. The walk component of an IP was calculated at the end of each block by averaging the walk distances of the last walk choice and last run choice. IPs from each participant were calculated based on titrated walking distances equal to run distances of 40, 60, 80, 100, and 120m.

We calculated linear models to predict relative walk and run distances that would correspond to equal metabolic energy, distance and time (Figure 1B). Metabolism was not directly measured, but estimated using fitted equations from previously published sources [6,7]. Predictions for metabolic energy and time varied based on an individual's preferred walking and running speeds. To investigate which costs best explained gait preference, we fit a slope through the measured IPs of each participant and compared them to the slopes of each candidate cost.

## RESULTS AND DISCUSSION

All participants made some decisions to run instead of walk, suggesting they were not only minimizing COT. Figure 2A depicts IPs and fitted slope of a single representative participant that minimized time. The average fitted slope of IPs across all participants was 0.73 (0.11) (Figure 2B). This indicates that within the tested distances, running was chosen more often than walking. Average model slopes were 1.72 (0.05) for metabolic cost, 0.47 (0.02) for time, and 1 for distance. The average fitted slope across all participants was different from each of the three proposed models ( $p_{\text{met}} < 0.001$   $p_{\text{dist}} = 0.028$   $p_{\text{time}} = 0.027$ ). Total metabolic energy exclusively explained IPs for only two participants, time explained seven, and distance explained four. Seven participants could not be explained using just one model prediction.

**Figure 2:** A) Indifference points of a single participant with a slope of 0.51 (black) indicating a tendency to minimize time (blue) rather than energy (green) or distance (red). B) Average slope across all participants. Shaded region represents SEM.

We expected individuals who minimized time would move at a faster preferred speed both when walking and running, but found the slope of an individual's IP was not predictive of their preferred walking speed ( $R^2 = 0.075$ ,  $p = 0.245$ ). This suggests participants with faster walking speeds were not making their decisions in order to minimize movement time. Running speed, however, was moderately correlated with an individual's preference for running ( $R^2 = 0.359$ ,  $p = 0.005$ ) that is, faster runners were more likely to choose to run when compared to slower runners.

## CONCLUSIONS

Cost of transport alone was unsuccessful at predicting whether an individual would walk or run. Only two participants exhibited behaviors that minimized the amount of metabolic energy. Instead, most participants minimized time required to complete a trial. These results highlight the importance of considering other costs when explaining locomotion preferences.

# FRONTAL PLANE PELVIS-TRUNK COORDINATION DURING ASYMMETRIC LOAD CARRIAGE WHILE WALKING ON AN UNEVEN SURFACE

Junsig Wang and Jason C. Gillette

Iowa State University, Ames, IA, USA

## INTRODUCTION

Individuals often carry items in one hand instead of both hands during activities of daily living. Asymmetric load carriage is expected to produce a lateral shift of the center of mass and result in increased lateral trunk flexion during walking. Furthermore, carrying asymmetric loads over challenging surfaces such as uneven or irregular terrain may require further postural changes in the upper body.

To our knowledge, no studies exist that investigate pelvis-trunk coordination of asymmetric load carriage while walking on an uneven surface. Describing coordinative patterns of the pelvis-trunk may provide important measures for potential injury risk and development of low back disorders. Therefore, the purpose of this study was to investigate pelvis-trunk coordination in the frontal plane when carrying unilateral versus bilateral loads and when walking on even versus uneven surfaces. We hypothesized that: 1) pelvis-trunk coordination would be more in-phase and less variable during unilateral load carriage as compared to bilateral load carriage and 2) when walking on an uneven surface as compared to an even surface.

## METHODS

Twenty healthy young adults with an age range of 18 to 30 (16 males and 4 females; age  $25.1 \pm 4.0$  years; height  $173.4 \pm 5.2$  cm; mass  $69.9 \pm 7.4$  kg) participated in this study. Three load conditions were tested: no load, 20% body weight (BW) load on one side of the body, and 20% BW load split between both sides of the body. Two hand-held bags were filled with sealed bags of lead shot to match the two loaded conditions. After a warm-up session for one minute, the participants were instructed to walk on both even and uneven surface treadmills at their

preferred pace for 90 seconds under the three load conditions.

An eight-camera Vicon motion analysis system was used to collect three-dimensional kinematic data at a sampling rate of 160 Hz. Twenty retro-reflective markers were placed on bony landmarks. Pelvis and trunk segment angles relative to the laboratory coordinate system were calculated. Gait events were determined by changes in direction of the heel marker anterior-posterior velocity [1]. Fifteen steps were selected and analyzed during the last thirty seconds of each condition.

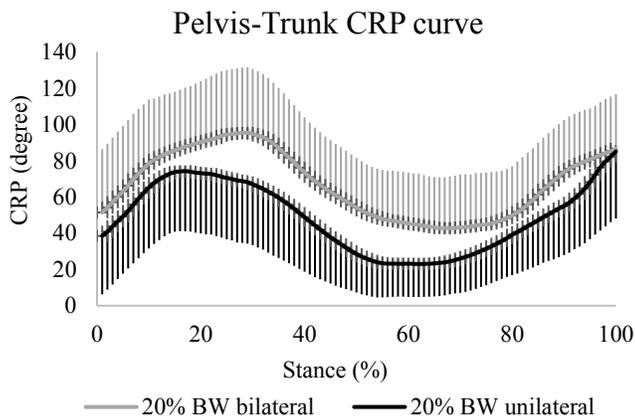

Kinematic data were low-pass filtered at 6 Hz. Pelvis and trunk ranges of motion (ROM) in the frontal plane were calculated for the stance phase. Segmental angular velocities were calculated from the segment angles utilizing the first central difference method. These data were then used to calculate phase angles from a phase plot, using the arctangent of angular velocity divided by angular displacement at each data point. Continuous relative phase (CRP) was calculated by subtracting the phase angles of the pelvis from the trunk. The CRP was evaluated for pelvis-trunk coordination. A CRP value of  $0^\circ$  indicates completely in-phase coordination, while a CRP value of  $180^\circ$  indicates completely out-of-phase coordination.

Coordination patterns were quantified utilizing mean CRP and CRP variability. Fifteen CRP curves for each participant were used to calculate a mean CRP curve and stride-to-stride variability in CRP. CRP and CRP variability were averaged over the stance phase for statistical analyses. The effect of loading conditions and the effect of different surfaces on pelvis ROM, trunk ROM, mean CRP, and CRP variability were analyzed using repeated measure ANOVA. Holm-Bonferroni post-hoc tests were performed when appropriate. The level of statistical significance for all tests was set at  $p < 0.05$ .

## RESULTS AND DISCUSSION

ANOVA indicated significant main effects of load condition on trunk ROM, mean CRP, and CRP variability (Table 1). Trunk ROM was significantly higher for the 20% BW unilateral load than the 20% BW bilateral load or no load ( $p \leq 0.013$ ). In addition, trunk ROM was significantly increased when comparing the 20% BW bilateral load to no load ( $p < 0.001$ ). Mean CRP and CRP variability were significantly lower for the 20% BW unilateral load than the 20% BW bilateral load or no load ( $p \leq 0.047$ ). CRP variability was significantly decreased when comparing the 20% BW bilateral load to no load ( $p = 0.010$ ).

ANOVA also indicated that CRP variability was significantly higher for the uneven surface than the even surface (Table 1). No interaction effects of the load and surface were found.

**Figure 1.** Mean CRP curve and CRP variability during 20% BW bilateral and unilateral loads

The present study evaluated frontal plane range of motion and pelvis-trunk coordination when carrying a unilateral versus a bilateral load and when walking on an uneven versus an even surface. Increased trunk ROM was found for the 20% BW unilateral load, while the pelvis ROM was not changed. Therefore, trunk lateral bending motions may be mainly utilized to counterbalance the laterally shifted center of mass when carrying a unilateral load.

The 20% BW unilateral load resulted in greater in-phase and less variable pelvis-trunk CRP, which is consistent with the first hypothesis (Figure 1). Given that there were no changes in pelvis ROM, it appears that changes in coordination may be driven by the trunk. Greater in-phase and less variable pelvis-trunk coordination have been reported in individuals with low back pain [2]. In addition, a lack of coordination variability has been associated with decreased flexibility and increased mechanical stress on the musculoskeletal system [3]. The second hypothesis was not supported as walking on the uneven surface resulted in no change for mean CRP and an increase in CRP variability. The uneven surface may have provided enough of a random perturbation to force the participants into a more variable coordination pattern. In summary, changes in trunk ROM, along with greater in-phase and less variable pelvis-trunk coordination may provide insight into the increased loading and stiffness of the lower back commonly associated with unilateral loads.

# Differences in Lower Body Kinetics when Walking and Walking While Holding Weapon Aim

Jennifer Neugebauer and Maria Talarico

U.S. Army Research Laboratory, Aberdeen Proving Ground, MD, USA  
email: [jennifer.neugebauer.civ@mail.mil](mailto:jennifer.neugebauer.civ@mail.mil), web: <http://www.arl.army.mil>

## INTRODUCTION

Exoskeletons and assistive devices designed for military applications should consider biomechanical differences incurred during operationally relevant movements. To date, exoskeletons have largely been developed for industrial or rehabilitative use and then applied to military applications. For military applications however, user movements may differ from those that a typical person would complete, such as walking with load and walking while shooting (shooting on the move; SM). Previous studies have identified biomechanical differences while walking with load [1] but similar findings have not been reported for a military specific task such as SM, both with and without load. During 'normal' walking, lower limb movement largely exhibits behavior similar to an inverted pendulum [2]. During SM, crouch-like movement patterns are executed to minimize weapon trace motion to improve accuracy. Biomechanical differences may dictate design considerations such as control strategies and/or actuator selection for torque input. There is a need to better understand the biomechanical differences between SM and 'normal' walking in order to account for these differences in exoskeleton design and control. The purpose of this study was to identify lower limb kinetic differences between walking and SM, both with no load and with a 22.7 kg ballistic vest.

## METHODS

Three active duty military ( $37.3 \pm 1.2$  years,  $1.758 \pm 0.092$  m,  $87.1 \pm 16.6$  kg) completed a series of walking and SM trials while carrying either no load (NL) or a 22.7 kg ballistic vest (KIT). Data were collected for 10 seconds every 30 seconds of each 2 minute trial.

Kinematic (240 Hz) and ground reaction force (GRF; 1000 Hz) data were collected simultaneously using a

12 camera motion capture system (Motion Analysis, Santa Rosa, CA) and instrumented force plate treadmill (AMTI Watertown, MA), respectively. Inter-segmental forces, moments, and powers were determined via inverse dynamics methods (Visual3D, C-Motion, Germantown, MD). All strides were averaged for each condition and subject.

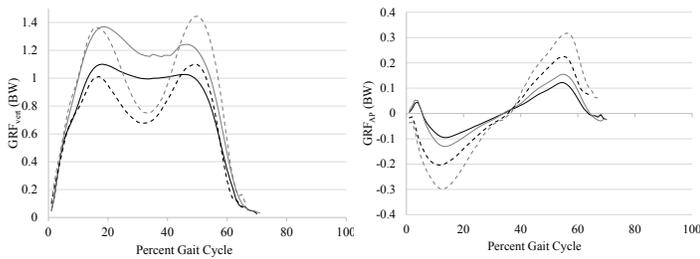

Walking and SM speeds were averaged across all trials and subjects for an overall mean. Peak vertical ( $pGRF_{vert}$ ) and anterior-posterior (AP) GRF ( $pGRF_{brake}$  and  $pGRF_{prop}$ ), vertical and AP impulse ( $Imp_{vert}$ ,  $Imp_{brake}$ ,  $Imp_{prop}$ ), and vertical loading rate ( $LR_{vert}$ ; calculated between 20 and 80% of loading) were calculated for each walk and load. All trials were normalized to a gait cycle and averaged across speed for each load (NL and KIT). Due to the small subject count, cursory statistics (R, R Foundation for Statistical Computing, Vienna, Austria) are presented to guide future studies.

## RESULTS AND DISCUSSION

Biomechanical differences were identified between walking and SM regardless of the load carried. Speed (walking:  $3.0 \pm 0.5$  mph; SM:  $2.8 \pm 0.4$  mph) did not differ between walking and SM ( $p > 0.15$ ). GRFs over the course of the gait cycle differed between SM and walking (Figure 1). For all findings, differences scaled with load (Table 1). Although  $pGRF_{vert}$  did not differ between SM and walking,  $Imp_{vert}$  was greater while  $LR_{vert}$  was lower for SM (Table 1). This relationship suggests that subjects are more slowly loading at heel contact, likely to control body center of mass motion and reduce undesired weapon motion as vertical force increases during stance. Minimizing vertical and AP weapon motion during SM is a primary goal of subjects to maintain target accuracy. This results in a crouch-like gait with increased knee and hip flexion throughout stance phase to minimize and control upper body movement. Continuous knee flexion during SM may contribute to the change in

vertical GRF profile compared to normal gait due to smaller vertical displacement of the body's center of mass. Although due to different causes, children with cerebral palsy exhibit similar hip and knee mechanics during gait as those of SM. Crouched gait reduces the ability to generate similar vertical GRF during normal gait [3], which likely influences the rate of weight acceptance and impulse.

**Figure 1:** GRF<sub>vert</sub> (left) and GRF<sub>AP</sub> (right) for SM (solid) and walking (dashed) with NL (black) and KIT (gray).

Results in the AP direction further support the differences highlighted from the vertical GRFs. Both the braking and propulsive GRFs and impulses were decreased in SM compared with walking (Figure 1).

## CONCLUSIONS

Shooting on the move and walking differ biomechanically and warrant further investigation. Although the results presented are cautionary due to the small subject numbers, the data suggests SM results in greater vertical impulse, lower loading rate, and decreased AP GRFs and impulses. Soldiers and

other tactical operators perform a variety of tasks including fundamental movements (i.e. walking) and more military-relevant movements (i.e. SM). Currently, exoskeletons are developed based on fundamental movements and assume these tasks directly translate to tactical movements. The findings from this study underscore that kinetic differences exist between walking and SM, which suggests that tactical movements may not strictly follow the same patterns as fundamental movements. Understanding biomechanical differences between tasks will provide exoskeleton developers a more comprehensive platform on which to build appropriate control systems and actuation. Future efforts should build on these results, as well as investigate differences in joint moments and powers, the effects of offset loads (larger percentage on back versus front or vice versa) and segmental loads from an exoskeleton.

# STRUCTURAL PARAMETERS OF THE FOOT AND THE BIOMECHANICS OF WALKING WITH AND WITHOUT WEDGED FOOTWEAR INSOLES

<sup>1</sup> Ryan T. Lewinson, <sup>1</sup> Ryan Madden, <sup>1</sup> Anthony Killick, <sup>1</sup> John W. Wannop, <sup>1</sup> J. Preston Wiley,  
<sup>1</sup> Victor M.Y. Lun, <sup>1</sup> Chirag Patel, <sup>1</sup> Jeremy M. LaMothe, <sup>1</sup> Darren J. Stefanyshyn

<sup>1</sup> The University of Calgary, Calgary, AB, Canada  
email: lewinson@ucalgary.ca

## INTRODUCTION

Wedged footwear is often prescribed to patients with knee osteoarthritis (OA) with the goal of reducing the peak knee adduction moment (KAM) during gait; however, these insoles do not reduce loading for all patients [1]. This has prompted the concept of personalized footwear, whereby footwear is matched to each patient to optimize biomechanical and clinical outcomes. While many researchers have attempted to identify factors that may help predict an individual's biomechanical response to wedged insoles, clinically useful predictors of knee loading and response to wedged insoles remain unknown.

It is often presumed that static foot structure is related to mechanical loads at proximal joints, making some individuals more suited to a particular type of footwear than others. While commonly considered in insole design, limited research exists to support an association between foot structure and knee joint loading or biomechanical response to wedged insoles. In this study, static structural characteristics of the foot were identified in individuals with medial knee OA and the associations between foot structure, knee joint biomechanics and biomechanical response to wedged insoles were assessed.

## METHODS

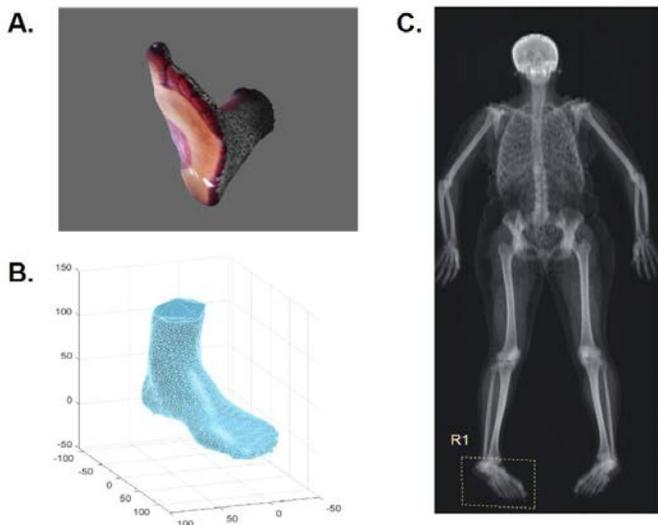

Thirty patients with medial knee OA participated in this study. The mean (SD) age, mass and height were 60.3 (8.5) years, 83.4 (21.5) kg, and 166.9 (9.5) cm, respectively and 23 were female. All patients were diagnosed clinically by a sport medicine physician and confirmed on x-ray by a radiologist. No patient had a history of joint replacement, or recent history of treatment for their knee OA, including walking aids or braces. Patients with concurrent musculoskeletal pathologies affecting the foot, ankle

or hip were excluded. OA severity of the sample was moderate (Kellgren-Lawrence grade 2.8, SD 1.3).

Patients completed a standing neutral trial as well as 5 gait analysis trials walking at 1.3 m/s in each of 3 footwear conditions: (1) their own footwear, (2) their own footwear with a 6 mm lateral wedge, and (3) their own footwear with a 6 mm medial wedge. Wedged insoles were made by 3D printer from New Balance Inc. (Boston, MA). An eight camera Motion Analysis system recorded 3D trajectories of retroreflective markers placed over each patient's most symptomatic limb at a frequency of 240 Hz, and a Kistler force platform recorded ground reaction forces at a frequency of 2400 Hz during each trial. A standard inverse dynamics approach, as described elsewhere [2], was used to calculate the KAM for each trial. The mean KAM across the 5 trials in each footwear type for each patient was used in subsequent analysis.

Whole-body dual x-ray absorptiometry (DXA) was performed on each patient, and the region distal to the medial and lateral malleoli were identified on the most symptomatic limb to determine foot mass and foot fat content. A 3D foot scanner was used to capture static barefoot foot shape for each patient. A custom Matlab script was written to analyze scans, from which foot length, foot width, arch height and hind foot angle were determined and then verified by an orthopedic surgeon (Figure 1).

Multiple linear regressions ( $\alpha=0.01$ ) were used to assess foot structure characteristics (foot mass, foot fat, foot length, foot width, arch height and hind foot angle) as predictors of KAM during walking, and the change in KAM when wearing a lateral or medial wedge insole.

**Figure 1:** (A) a 3D foot scan. (B) Reconstructed mesh used for analysis. (C) DXA used for foot mass and fat measures (designated by region labelled R1).

## RESULTS AND DISCUSSION

Foot mass, foot length and foot width were found to be collinear with other foot structure variables and so were excluded from regression analyses. Using foot fat, arch height and hind foot angle as independent variables representing foot structure, no association was found with KAM magnitude during walking ( $R^2=0.24$ ,  $p=0.060$ ). When evaluating these structural parameters in the context of KAM change in response to wedged insoles, no association was found with KAM change in lateral wedges ( $R^2=0.05$ ,  $p=0.697$ ) or medial wedges ( $R^2=0.02$ ,  $p=0.923$ ). These results were determined using raw magnitude changes in KAM, and remained similar when evaluating changes as percent changes.

Prospective studies evaluating the relationship between static foot structure and clinical disease have not been performed on patients with knee OA; however, in a population of runners, Lun et al. [3] found no relationship between arch height and running injury. The present study adds to this by suggesting that arch height, hind foot angle and foot fat content do not appear to be associated with mechanics at the knee in individuals with knee OA. In addition, while the foot is often discussed as having an influence on dynamic loading at the knee and potentially affecting response to wedged insoles,

these relationships were not identified in the present study. These results question the usefulness of static foot structure measures when prescribing insoles to patients with knee OA.

This study only assessed wedged insoles in patients with knee OA, and thus generalization of the study findings to other insole types or other populations should be done with caution. It is possible that associations between foot structure and baseline knee loading might be observed with larger sample sizes, although this would still not account for the majority of variance in baseline knee joint loading parameters, or change in knee loading with wedged insoles. Thus, other factors remain to be identified that have a larger contribution to knee loading and biomechanical response to insoles. Finally, this study did not assess whether foot structure is associated with clinical response to wedged insoles.

## CONCLUSIONS

Foot structural parameters were not found to be associated with KAM during gait and were not associated with the change in KAM induced by lateral wedge or medial wedge insoles. Taken together, these data suggest that foot structure, as defined in this study, is not associated with gait mechanics at the knee in patients with knee osteoarthritis, and demonstrate that foot structure alone cannot be used to predict biomechanical response to wedged insoles in these patients.

# LOWER EXTREMITY JOINT STIFFNESS AND WORK PERFORMED ACROSS DIFFERENT WALKING AND RUNNING SPEEDS

<sup>1,2</sup> Li Jin, <sup>1,2</sup> Michael E. Hahn

<sup>1</sup>Neuromechanics Lab, <sup>2</sup>Bowerman Sports Science Clinic, University of Oregon, Eugene, OR, USA  
email: ljin@uoregon.edu, web: <http://bssc.uoregon.edu/>

## INTRODUCTION

Walking and running are primary forms of human locomotion in daily life. Both tasks involve coordination of lower extremity joints, associated with kinematic and kinetic pattern changes. Joint stiffness and stance phase joint work are important for maintaining efficiency when locomotion task or speed changes. Previous studies have separately investigated ankle and knee joint stiffness ( $K_{ankle}$ ,  $K_{knee}$ ) in different movement conditions [1,2], and stance phase joint work ( $W_{joint}$ ) in walking and running [3], respectively. Little is known about the combination of  $K_{ankle}$ ,  $K_{knee}$ , and  $K_{hip}$  patterns, and the relationship between  $K_{joint}$  and  $W_{joint}$ .

For assistive devices, stiffness and work are key features during locomotion. Currently available assistive devices tend to be task-specific, with fixed stiffness and work parameters. The coordination of lower extremity joint stiffness and joint work when locomotion speeds change may be critical to the design of assistive devices suitable for walking and running over different speeds in patient populations. We hypothesized that  $K_{joint}$  and  $W_{joint}$  will increase when locomotion speed increased.

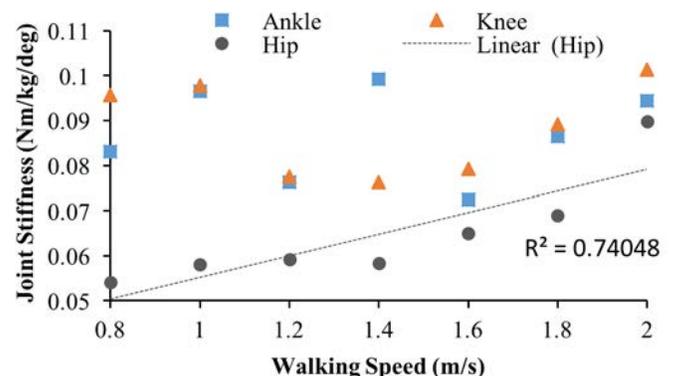

## METHODS

After providing written informed consent for this IRB-approved study, subjects were first instructed to walk on a force-instrumented treadmill (Bertec, Inc., Columbus, OH) across a range of seven speeds from 0.8 to 2.0 m/s (0.2 m/s intervals), for 90 seconds per stage. Then they were asked to run on at six speeds ranging from 1.8 to 3.8 m/s (0.4 m/s intervals), for 75 seconds per stage. Data were extracted from the middle strides of each stage.

Segmental kinematic data were collected at 120 Hz using an 8-camera motion capture system (Motion Analysis Corp., Santa Rosa, CA). Ground reaction force data were collected at 1200 Hz using the force-instrumented treadmill. Kinematic and kinetic data were filtered with a low-pass fourth-order Butterworth filter at 6 Hz and 50 Hz, respectively. Lower extremity joint angles, moments and powers were calculated using the inverse dynamics model in Visual 3D (C-Motion, Inc., Germantown, MD). Joint stiffness ( $K_{joint}$ ) was calculated as a change in joint moment ( $\Delta M_{joint}$ ) divided by joint angular displacement ( $\Delta \theta_{joint}$ ) in the braking phase of ground contact [4]. Stance phase joint positive work ( $W_{joint}^+$ ) and negative work ( $W_{joint}^-$ ) were calculated as the sum of all positive or negative joint power integrated over stance phase time [3], respectively. Statistical analysis was performed using a 2-way ANOVA (joint  $\times$  speed) in SPSS (V22.0, IBM, Armonk, NY). Bonferroni procedure was used for pairwise comparisons.

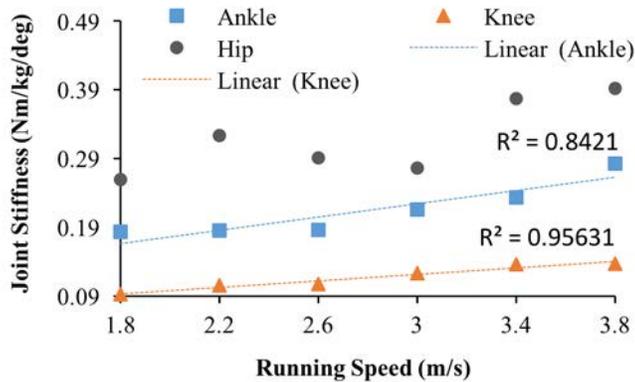

## RESULTS AND DISCUSSION

To date, six subjects ( $24 \pm 6.7$  years,  $175 \pm 10.9$  cm,  $76 \pm 11.5$  kg) have participated in this ongoing study. Initial analysis indicates that  $K_{knee}$  was

**Figure 1:**  $K_{joint}$  in different walking speeds.

significantly higher than  $K_{hip}$  across different walking speeds ( $p = 0.004$ ) (Fig. 1).  $K_{ankle}$  also tended to be higher than  $K_{hip}$  in walking (Fig. 1). In running conditions,  $K_{ankle}$  was significantly higher than  $K_{knee}$  across speeds ( $p = 0.008$ ) (Fig. 2).  $K_{knee}$  was generally lowest in running (Fig. 2).

**Figure 2:**  $K_{joint}$  in different running speeds.

In walking conditions,  $W_{ankle}^+$  tended to be higher than  $W_{knee}^+$  and  $W_{hip}^+$  across walking speeds (Table 1).  $W_{ankle}^-$  was significantly lower than  $W_{hip}^-$  ( $p < 0.0001$ ) at 2.0 m/s (Table 1).  $W_{ankle}^-$  at 1.4 m/s was significantly greater than at 2.0 m/s ( $p < 0.0001$ ) (Table 1). In running conditions,  $W_{ankle}^+$  was significantly higher than  $W_{hip}^+$  across different speeds ( $p = 0.012$ ) (Table 2).  $W_{ankle}^+$  tended to be

the highest of three different joints across running speeds (Table 2).

## CONCLUSIONS

The initial hypothesis was partially supported. Variation of  $K_{joint}$  patterns were different between walking and running.  $K_{hip}$  was positively associated with locomotion speed during walking conditions. In running conditions,  $K_{ankle}$  and  $K_{knee}$  were both positively associated with speed. As walking speed increased,  $W_{ankle}^+$  tended to increase, and  $W_{ankle}^-$  decreased.  $W_{knee}^+$  and  $W_{knee}^-$  tended to increase when walking speed increased, indicating that the knee joint is important to absorb and generate energy as speed increases. Lastly, the ankle joint is critical for producing positive work.

# STEP WIDTH DURING TREADMILL WALKING IS LONG-RANGE PERSISTENT

Simisola O. Oludare and Mark D. Grabiner

University of Illinois at Chicago, Chicago, IL USA

Email: soluda2@uic.edu, web: <http://cbr.ahslabs.uic.edu/>

## INTRODUCTION

During treadmill walking, step width has been suggested to have long range (LR) persistence [1,2,3,4] based on detrended fluctuation analysis (DFA). However, DFA does not appear to have the capacity to distinguish between short- and long-range persistence and, in addition, has been reported to falsely detect LR persistence [5,6]. However, during overground walking during eyes opened and eyes closed conditions, step width has been reported to have short range (SR) correlations based on autocorrelation analysis [7] and a modified autocorrelation analysis [8]. These analyses have an advantage of providing a direct assessment of the nature of the persistence evident in a time series.

The purpose of this study was to evaluate step width persistence using the autoregressive moving average/ autoregressive fractional integrated moving average (ARMA/ARFIMA) modeling method [5,6]. The main advantage of this method is the joint estimation of short- and long-range persistence [9]. We hypothesized that step width during locomotion will possess short term correlation structure.

## METHODS

Ten healthy young adults (23.3±1.95 years old, 64.0±16.0 kg, and 165.4±90.3 cm) walked on a microprocessor controlled treadmill for 10 minutes at 2.5 mph.

An eight camera motion capture system operating at 120 Hz tracked the motions of reflective markers placed over the shoe at the heel and 2<sup>nd</sup> metatarsal phalangeal joints (MTPJ), the acromion processes, the anterior superior iliac spines and the level of S2. The markers on the heel and 2<sup>nd</sup> MTPJ were used to construct a single rigid segment from which step width was calculated as the lateral distance between the segment centroids of subsequent foot

placements at the instant of midstance [9].

Midstance was computed as the time at which lateral trunk velocity was zero [9]. The trunk center of mass was modeled as the centroid of the segment defined from the midpoint of the line connecting the acromion processes and the pelvic markers.

Each step width time-series was modeled with 18 ARMA and ARFIMA models (nine of each). Each ARMA model was developed from two inputs, the order of the autoregressive (p) and the order of the moving average (q), which vary from 0 to 2 [5,6]. The ARFIMA models were developed from three inputs, p and q, and the fractional parameter (d). The fractional parameter was quantified from the time series and varies from positive to negative values. A positive d indicates the presence of LR persistence and a d of zero indicates SR persistence.

After the 18 models were developed, the most suitable for the time series was determined using the AIC [5, 6]. The AIC is a goodness of fit statistic that determines the best model as that which accounts for most of the data with the fewest parameters [5, 6]. The AIC values for each model (for each time series) were transformed into a weight that indicated the probability for the i-th model to be the best model given the data and the set of candidate models. These weights were used to determine whether the time series was best described by an ARMA or an ARFIMA model using the following criteria: 1) the best model (i.e. the model with the highest weight) should account for at least 90% of the set of time series (n=10) and if the model is an ARFIMA model, d should be significantly different from 0; and 2) the sum of weights of the nine models should be at least 0.90 for the given time series. If the time series is best described by an ARFIMA model it has LR persistence. To determine if the parameter d was different from 0 we used one-sample t-test against zero (p=0.05).

## RESULTS AND DISCUSSION

Based on the ARMA/ARFIMA modeling, step width time series possess LR persistence. Thus, our hypothesis was rejected. The model which best characterized the step width time series was ARFIMA with higher order autoregressive and moving average parameters,  $p = 1$  or  $2$  and  $q = 1$  or  $2$ , respectively. This indicates that an important aspect of the step width time series can be captured by short term autoregressive and moving average terms [11].

Additionally, a visual examination of a time series generated by ARMA and ARFIMA models also supports this conclusion (Figure 1). Compared to the step width (blue) and the ARFIMA (red) time series, the ARMA (black) time series resembles white noise, a short range persistent process [12].

The maximum weight for each step width time series was for an ARIFMA model and the fractional parameters,  $d$ , were significantly different from 0 ( $p < 0.001$ ) (Table 1). However, only six out of the eleven step width time series had a sum ARIFMA weight greater than 0.90. The average sum of the weights of these six time series was 0.9978, and the average sum of the weights for all ten series was 0.8908.

Table 1. Results from ARMA/ARFIMA and DFA

N	10
ARFIMA as best model	10/10
ARFIMA mean AIC weights	0.89
D (mean±std)	0.25±0.12

Although

this analysis provides evidence that step width demonstrates LR persistence, it does not directly shed any light on possible mechanical or neurological mechanisms underlying LR persistence. However, given that step width has anatomical and physiological constraints, it is possible that during locomotion step width is regulated only when it approaches its limits. This control strategy could result in a LR persistence process which is driven by the superimposition of many SR processes [11,13], thereby providing an explanation for why the autocorrelation analyses

[7,8] and DFA [1,2,3,4] present contradictory results.

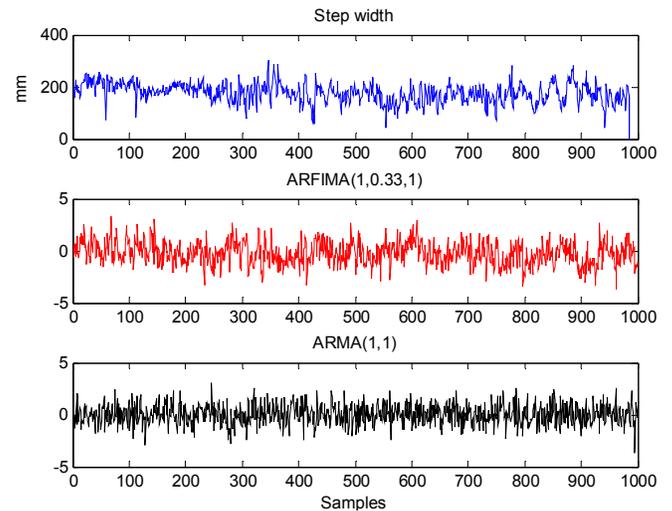

Figure 1. (Blue) Sample Step width time series with average fractional parameter,  $d = 0.33$  (Red) ARFIMA simulation with  $p = 1$ ,  $q = 1$  and  $d = 0.33$  (Black) ARMA simulation with  $p = 1$ ,  $q = 1$

## CONCLUSIONS

The ARMA/ARFIMA analysis indicates that step width during treadmill walking has LR persistence which is consistent with interpretations from DFA. Given the established biomechanical and physiological importance of step width, further study seems warranted to establish how and why persistence is manifested and its potential clinical utility.

## INTRODUCTION

Human walking has been studied extensively under approximately steady-state conditions, for example, when subjects walk on a treadmill whose belt moves at a fixed speed. In everyday life, acceleration and deceleration, obstacle negotiation, disturbance rejection, and turning are all examples of behaviors that require modulation of walking speed, which is driven by transient changes in muscle activations [1], [2], [3]. However, even during steady-state walking, the nervous system is continually modulating muscle activations based on sensory information to ensure stability, as evidenced by small continual changes in walking speed and other kinematic variables.

Weak continuous sensory and mechanical perturbations can be used to identify properties of this neural feedback control of steady-state walking [4], [5], based on a local limit-cycle approximation of human gait. Responses to perturbations are characterized in time domain using phase-dependent impulse response functions ( $\phi$ IRFs). A  $\phi$ IRF describes the response to a small brief perturbation (an impulse) applied at any phase of the gait cycle and, by extension, the response to any small perturbation. In this study, we applied this approach to characterize the effects of continually varying treadmill speed on kinematic variables.

## METHODS

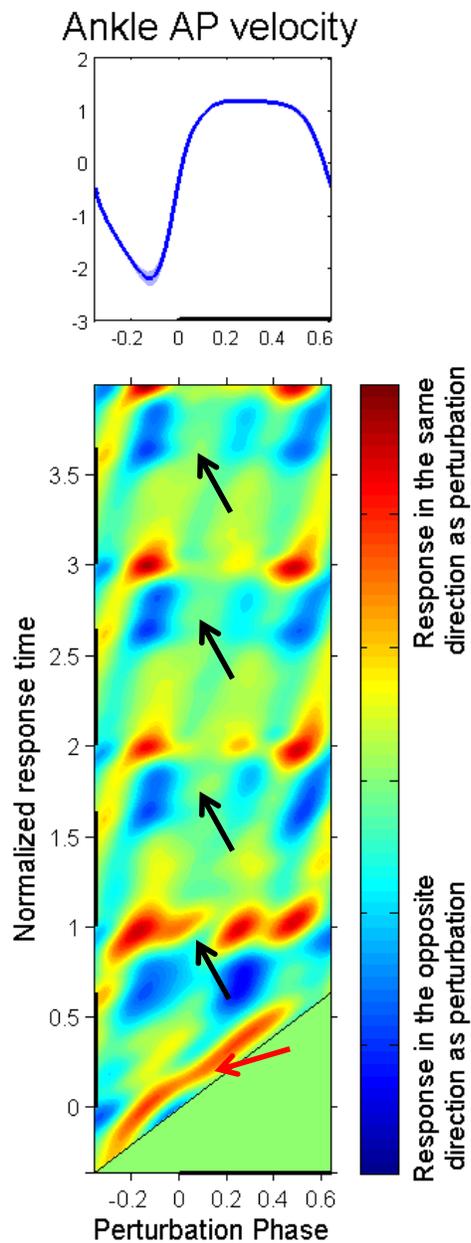

The experiment design has been previously described in detail [6]. Twelve subjects walked on an instrumented treadmill (Forcelink, Culemborg, Netherlands) at three different speeds of 0.8, 1.2 and 1.6  $\text{ms}^{-1}$ . Forty seven reflective markers were attached to different anatomical landmarks and the

kinematics were captured using a ten camera motion capture system (Motion Analysis, Santa Rosa, CA, USA). Each trial was ten minutes starting with one minute of normal walking, followed by eight minutes of perturbation, and ending with one minute of normal walking. The perturbation was designed by generating filtered white noise as an acceleration signal in MATLAB (The MathWorks, Inc., Natick, MA, USA) which was then integrated to derive a velocity signal. This signal was commanded to the treadmill using D-Flow software (Motek Medical, Amsterdam, Netherlands).

To approximate walking as a linear time periodic system [7], we replace the time with estimated phase of the gait cycle as the independent variable. Heel-strike times were used to derive a piecewise-linear causal estimate of phase, which was then filtered to obtain a continuous approximation. We then characterized kinematic responses to the perturbation signal (i.e., speed of the belt) in the frequency domain using harmonic transfer functions [4]. An HTF has a “mode” for each integer  $k$  with its own gain and phase functions. The  $k$ -th mode describes the mapping from frequency  $f$  to frequency  $f + kf_0$  where  $f_0$  is the gait frequency. To make it easier to interpret kinematic responses, we converted HTFs to the  $\phi$ IRFs described above. A correction was made for the method used to estimate phase, so that to first order in perturbation size, the resulting  $\phi$ IRFs did not depend on the estimation method [5].

## RESULTS AND DISCUSSION

Figure 1 shows the  $\phi$ IRF between the belt speed and the velocity of right ankle. As we can see in the figure, there is an increase in the velocity immediately after the onset of perturbation (the red

**Figure 1:** *Top:* Mean waveform of the right ankle anteroposterior (AP) velocity across all cycles during the trial. The shaded area shows 95% confidence intervals and the black bar on the horizontal axis marks the stance phase of the cycle. *Bottom:* the  $\phi$ IRF between the belt speed and the ankle velocity for four cycles after perturbation onset calculated from modes  $k$  with  $|k| \leq 3$ . Black bars on each axis mark the stance phase. The color red in the spectrum represents a change in the response in the same direction as the change in perturbation and blue represents changes in the opposite direction. The diagonal line is the onset of perturbation.

area along diagonal marked by the red arrow). Since the input is the speed of the treadmill, we expect to see an impulse in the foot velocity as a response to an impulse in the belt speed. This transient change in velocity is only observed in the first cycle after perturbation and fades away in the following cycles. Another important feature of the observed response is the phase resetting [8], an initial increase in the speed, followed by an immediate decrease, repeated throughout the subsequent cycles (indicated by black arrows in the figure).

The use of  $\phi$ IRFs provides a complete picture of kinematic responses to small perturbations. However, as the size of perturbations increases,  $\phi$ IRFs can be affected by second-order effects, which we are currently investigating by varying perturbation size. We are also measuring electromyographic (EMG) responses, to determine the role of neural feedback in responding to changes in treadmill speed. Longer term, future studies can apply this method to investigate transient responses in geriatric or neurological populations, using kinematic and EMG measures to better understand the neural control mechanisms used to ensure stable walking.

# STATISTICAL EVALUATION OF WALKING VELOCITY AND KNEE ADDUCTION MOMENT: ALLOMETRIC SCALING

<sup>1</sup> Samantha Andrews, <sup>1</sup>Elizabeth Parke, <sup>1</sup> Cris Stickley

<sup>1</sup> University of Hawaii, Honolulu, HI, USA  
email: sandrews@hawaii.edu

## INTRODUCTION

Knee adduction moment (KAM) is commonly evaluated in biomechanical research, specifically during the assessment of lower extremity overuse injuries and knee osteoarthritis [1]. However, walking velocity of the pathological group and controls is often different. Previous research has attempted to control for walking velocity differences by implementing a specific walking velocity [2], resulting in one or both groups walking at a non-preferred velocity. This approach, however, is based on the assumption that the relationship between KAM and walking velocity is linear, which has not been previously established. The use of allometric scaling has previously been suggested to control for walking velocity [3] but has not yet been evaluated in young, healthy individuals. Therefore, this study evaluated (1) the relationship between walking velocity and KAM and (2) the effectiveness of allometric scaling of KAM to remove the influence of body mass and walking velocity.

## METHODS

A one time gait assessment was conducted on 63 (Males = 31) healthy, young individuals with a mean height of 170.7 cm (range, 150-186 cm), a mean body mass of 75.7 kg (range, 53-126 kg) and a mean age of 25 years (range, 18-38 years). Patients were asked to walk at a self-selected pace, then at 25% faster and slower than self-selected, while 17 Vicon motion capture cameras (Vicon, Inc., Centennial, CO) collected data from 27 retroreflective markers placed on the lower extremities and trunk. Kinetic data, from one force plate (Advanced Mechanical Technology Incorporated, Boston, MA), were collected at 960

Hz and time synchronized with the kinematic data, collected at 240 Hz.

Log-multilinear regression was used to develop gender specific allometric exponents from only the self-selected velocity data for body mass (BM) and walking velocity (WV) in order to remove the influence of these variables on KAM [4]. Pearson product-moment correlations were performed for raw, ratio and allometrically scaled KAM to evaluate the effectiveness of each scaling procedure.

## RESULTS AND DISCUSSION

The correlation for males between WV and raw KAM (Nm) and between BM and raw KAM were  $r=0.343$  ( $p=0.059$ ) and  $r=0.383$  ( $p=0.033$ ), respectively. For females, the correlation between WV and raw KAM and between BM and raw KAM were  $r=0.255$  ( $p=0.160$ ) and  $r=0.489$  ( $p=0.005$ ), respectively. The correlation for males between WV and ratio-scaled KAM (Nm/kg) and between BM and ratio-scaled KAM were  $r=0.503$  ( $p=0.004$ ) and  $r=-0.124$  ( $p=0.507$ ), respectively. For females, the correlation between WV and ratio-scaled KAM and between BM and ratio-scaled KAM were  $r=0.387$  ( $p=0.029$ ) and  $r=-0.247$  ( $p=0.173$ ), respectively. Raw KAM was allometrically scaled for BM and WV using the following equation:

$$\text{RAW KAM}/((\text{BM}^{\text{exp}})*(\text{WV}^{\text{exp}}))$$

The male exponents for BM and WV were 1.020 and 1.275, respectively. The female exponents for BM and WV were 0.770 and 0.740, respectively. These exponents were used to allometrically scale KAM at each walking velocity condition. The correlations between allometrically scaled KAM and scaling variables at each walking velocity are presented in Table 1.

## CONCLUSIONS

Although ratio scaling for BM was able to remove its effect on KAM, a strong correlation between KAM and WV remained during self-selected walking trials. When allometric scaling was applied, the effect of BM and WV on KAM was completely removed, as indicated by the lack of significant correlation. Successfully removing will allow for better comparison between groups in which WV disparities are present.

When the derived exponents from self-selected velocity were applied to the fast and slow velocity data, allometric scaling was unable to completely remove the effect of WV from KAM. If the relationship between WV and KAM was linear, the application of allometric scaling should have yielded similar results as those produced when applied to self-selected data. However, 10% of the variance in KAM was still attributable to WV, suggesting that walking biomechanics do not change linearly with changes in walking velocity. The lack of linear relationship between KAM and WV is an important distinction, especially when evaluating results from previous research in which walking velocity was prescribed within the methodology.

The results of the current study suggest that the application of allometric scaling is effective in removing the effect of BM and WV from KAM when KAM was evaluated at self-selected walking velocity. However, when applied to fast and slow velocities, allometric scaling by exponents derived from self-selected velocities was unsuccessful. These results indicate the lack of a true linear relationship between walking velocity and KAM, suggesting that the use of prescribed walking velocity could significantly affect biomechanical variables during research. Subjects should complete gait trials at self-selected velocities and allometric scaling should be used to remove the effect of WV, allowing for more accurate comparisons between groups.

# GAIT INITIATION MECHANISMS IN UNILATERAL TRANSTIBIAL AMPUTEES

<sup>1</sup>Mary Roberts and <sup>2</sup>François Prince

<sup>1</sup>Département de kinésiologie, Université de Montréal, Montréal, Québec, Canada

<sup>2</sup>Département de chirurgie, Faculté de médecine, Université de Montréal, Montréal, Québec, Canada  
email: mary.roberts@umontreal.ca

## INTRODUCTION

In the United States, it is estimated that over 1.6 million people are living with an amputation, the most common being the unilateral transtibial amputation and trends indicate that this number is increasing due to dysvascular disease [1].

Walking is the most common form of locomotion and the ability to walk is an indicator of overall health as it dictates autonomy. Of particular interest is the transient process from quiet standing to steady-state walking velocity (SSWV), namely gait initiation.

Although gait initiation in the healthy adult has been well described, few studies have been carried out in the transtibial amputee (TTA) population [2,3]. Moreover, no studies have yet investigated gait initiation in the dysvascular TTA population.

Thus, the purpose of the current study is to compare the biomechanical gait initiation mechanisms of dysvascular TTA to those of healthy controls

## METHODS

Ten participants (7M:3F;  $59.1 \pm 17.3$  years old) with a unilateral dysvascular TTA were recruited via the Institut de Réadaptation Gingras-Lindsay de Montréal. TTA participants were successful prosthetic walkers without aid. Ten healthy controls (8M:2F;  $57.6 \pm 16.4$  years old) were also recruited to participate in this study.

Testing was carried out on a walkway equipped with 3 embedded AMTI (Advanced Medical Technology Inc., MA) force platforms surrounded by an 8 camera OptiTrack motion analysis system (NaturalPoint Inc., OR). From quiet standing, with both feet on side by side force plates, participants

were asked to initiate gait with their right leg and then their left leg. The third force plate was in front of the two others in order to record kinetic data of the first step. A total of 5 trials per side were recorded. Kinetic and kinematic data were both collected at 100 Hz.

Data analysis was carried out using Motive software (NaturalPoint Inc., OR) and a created MatLab program (The MathWorks Inc., MA). Statistics were carried out using SPSS (IBM Corp., NY) with a level of significance set at  $P \leq 0.05$ .

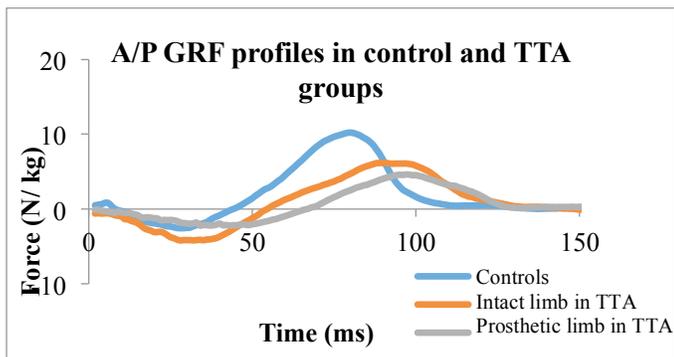

## RESULTS AND DISCUSSION

The mean SSWV attained by controls was  $1.30 \pm 0.23$  m/s and  $1.07 \pm 0.22$  m/s in the TTA group, regardless of the leading limb. This difference was found to be significant. It took an average of 3 steps for controls to reach SSWV and an average of 4 steps for TTA, regardless of leading limb. A large variability (range from 2-7 steps) was observed in the TTA group with regards to the number of steps to reach SSWV. These results corroborate prior findings with regards to a reduced SSWV in a TTA group [4].

The percentage of SSWV reached during the first step was found to be  $74.1 \pm 8.65\%$ , regardless of leading limb in controls and  $72.4 \pm 5.23\%$  of SSWV was achieved during the first step when TTA initiated gait with their intact limb and  $78.6 \pm 6.56\%$  with their prosthetic limb. The difference between the intact and prosthetic limb was found to be significant. The findings as to the percentage of SSWV reached during the first step in controls corroborate prior findings[5]. It is important to note that all TTA participants preferred to initiate gait with their prosthetic limb: in doing so, the intact limb was loaded in order to allow the prosthetic limb to swing forward. TTA are better able to

balance and stabilize on their intact limb, as sensory information is available beneath the foot. Because SSWV was found to be the same regardless of leading limb in the TTA group, the contribution to SSWV produced by each limb is therefore different and it appears as though there is compensation by the intact limb.

The average anterior-posterior ground reaction forces (A/P GRF) recorded beneath the first step are plotted in Figure 1. The reduced SSWV achieved in the TTA group is clearly outlined by the increased braking and reduced propulsion seen below in Fig. 1 with regards to the A/P GRF between both groups. Step time was greater as observed below in Fig. 1 and confirmed by step time when measured from kinematic data (results not shown here).

**Figure 1:** A/P GRF profiles of the first step during gait initiation. Force normalized to participant body weight.

As well, the loading rate of the first step vertical GRF were calculated: the loading rate was found to be  $26.1 \pm 5.13$  N/s/kg in controls and  $23.3 \pm 6.69$  N/s/kg and  $17.56 \pm 2.29$  N/s/kg in the intact and prosthetic limb, respectively in TTA. The difference between the intact and prosthetic limb was found to be significant. These results clearly demonstrate a preference for limb loading in the intact limb. This is confirmed by the lower percentage of body weight placed on the prosthetic limb versus the intact limb (results not shown here).

The range of motion (ROM) in the sagittal plane of the hip, knee and ankle, for both limbs, in both conditions are outlined in Table 1. Because the ankle joint is missing in the prosthetic limb, a significant reduction of ROM is observed. Therefore, solely passive energy storage and return is observed within the material of the prosthesis [4].

Because the plantarflexion moment created during push-off is known to be a powerful generator in walking, this reduction of ROM is yet another mechanism leading to reduced SSWV [6]. Also of interest is the reduced ROM at the knee in both the intact and moreover, the prosthetic limb in TTA's. Because of the increased radius of gyration created by a reduced knee flexion during swing phase, the swing time of the limb forward is greater shown by the reduced SSWV (results not shown here). This is further exacerbated in the prosthetic limb.

**Table 1:** ROM of the hip, knee, ankle in sagittal plane.

	Controls	Intact limb	Prosthetic limb
Ankle	$32.2 \pm 6.77^\circ$	$36.5 \pm 14.62^\circ$	$21.8 \pm 12.02^\circ$
Knee	$65.2 \pm 6.33^\circ$	$60.2 \pm 15.78^\circ$	$55.7 \pm 12.99^\circ$
Hip	$50.6 \pm 8.14^\circ$	$46.5 \pm 9.20^\circ$	$47.8 \pm 16.29^\circ$

## CONCLUSIONS

The underlying gait initiation mechanisms employed by dysvascular TTA are different than that of healthy controls, even so in the intact limb. The intact limb contributes a greater extent in achieving SSWV, although the SSWV remains reduced. The implications of understanding daily tasks, such as gait initiation, are paramount to improving rehabilitation, care and quality of life in the growing population of dysvascular TTA individuals. Further studies should aim at understanding the power profiles during gait initiation in such a population.

# DO KINETIC DIFFERENCES EXIST DURING CURB ASCENT IN PERSONS WITH ERTL AND NON-ERTL TRANSTIBIAL AMPUTATIONS?

## INTRODUCTION

Negotiation of uneven surfaces is especially difficult for those with lower extremity amputations. Relative to age-matched, non-amputees, persons with transtibial amputation (TTA) have an increased risk of falling and fear of falling [1]. Further, persons with TTA report curb negotiation is more challenging than negotiating stairs even though they are encountered with the same frequency [2, 3].

It is also unknown if amputation technique influences an amputee's ability to negotiate a curb. Traditionally, the tibia and fibula are not joined during a TTA (Non-Ertl). However, a transtibial osteomyoplastic amputation (Ertl) uses a "bone bridge" to connect the tibia and fibula sealing the medullary canal. The Ertl technique has been suggested to improve the overall physiology of the residual limb and promote greater distal load-bearing of the residual limb [4, 5].

Therefore, the purpose of this study was to determine if functional ability to negotiate a curb is different between Ertl and Non-Ertl groups. Since it has been suggested the Ertl amputation has an increased capability to bear loads on the distal end of the residual limb, it was hypothesized that those with Ertl amputations would have capacity to store energy at the ankle that can be used in total limb work. Further, the Ertl affected limb would produce greater joint work at the knee, and hip while ascending a curb compared to Non-Ertls.

## METHODS

Two groups of transtibial amputees were recruited: Non-Ertl (n = 7; 88.3 ± 16.0 kg, 1.78 ± 0.08 m; 55 ± 5 years) and Ertl (n = 5; 79.8 ± 15.5 kg, 1.79 ± 0.08 m; 55 ± 8 years). Inclusion criteria included: amputation resulting from trauma, no concomitant musculoskeletal injuries, neurological, or visual

impairments. All participants were physically active at least 3 days per week. Motion data (100Hz) and ground reaction forces (2000 Hz) were collected as participants ascended a 16 cm curb (VICON, UK) (Fig. 1). Participants approached the curb at a walk (~3 m) and ascended the curb at their self-selected walking velocity. **GROUND** and **CURB** steps were analyzed separately.

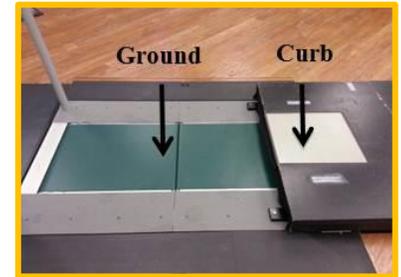

Figure 1. Image of the curb design.

Lower extremity net joint work for the unaffected and affected limbs were calculated. Positive and negative work at each joint were summed to determine the net joint work performed at the hip, knee, and ankle. Total limb joint work was computed as the sum of the net joint work at each joint.

A t-test was used to determine differences in walking speed between groups. A single factor MANOVA ( $\alpha = .05$ ; SAS 9.4, Cary, NC) was used to identify differences in work between groups and limbs.

## RESULTS and DISCUSSION

Both groups walked at similar speeds (1.28 ± 0.20 m/s Ertl vs. 1.28 ± 0.19 m/s Non-Ertl) and all participants were able to perform curb ascent with each limb as the lead limb onto the CURB.

**GROUND Step Results:** Net ankle joint work was significantly larger ( $p < .05$ ) in the unaffected limb of both groups compared with the respective affected limb (Fig. 2). Net work at the knee and hip was not significantly different across limbs. Total limb work was significantly larger ( $p < .05$ ) in both of the unaffected limbs compared to both of the affected limbs (Fig. 2).

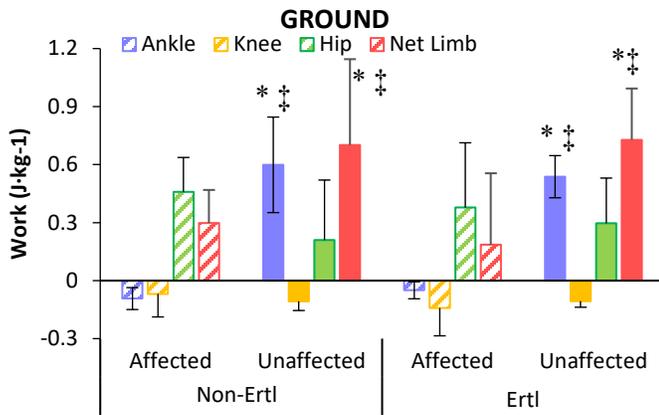

Figure 2. Work for the ankle, knee, hip, and limb for the GROUND step. \*Significantly different from Ertl affected limb; †Significantly different from Non-Ertl affected limb.

**CURB Step Results:** Net work at the ankle was significantly ( $p < .05$ ) smaller for both affected limbs compared to both unaffected limbs (Fig. 3). The Non-Ertl affected limb had significantly greater negative net knee work than both the unaffected limbs ( $p < .05$ ). The Ertl affected limb also produced significantly ( $p = .042$ ) more negative net knee work than the Non-Ertl unaffected limb, but not the Ertl unaffected limb. The Ertl affected limb differed further from the Non-Ertl unaffected limb by producing significantly ( $p = .016$ ) more positive net work at the hip.

Total limb work showed the Non-Ertl affected limb produced significantly ( $p < .05$ ) less work compared to each of the unaffected limbs (Fig. 3). However, no significant differences were found between the Ertl affected limb and each unaffected limb. The contrast of total limb work between the Non-Ertl affected limb and Ertl affected limb approached significance

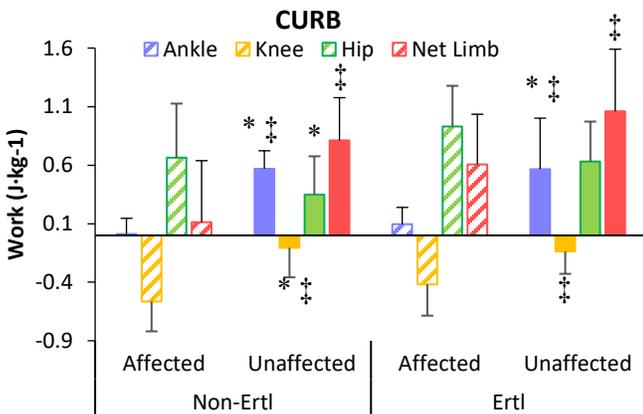

Figure 3. Net joint work for entire limb for the CURB step. \*Significantly different from Ertl affected limb; †Significantly different from Non-Ertl affected limb.

( $p = .0845$ ) suggesting that the Ertl limb overall was performing more net joint work than the Non-Ertl limb.

Results from the CURB step suggest that the unaffected limbs produced a large amount of net work at the ankle. In contrast, the Ertl affected limb produced more net hip work and very little net ankle work. The amount of work produced by the Ertl affected limb at the hip was significantly larger than the Non-Ertl unaffected limb. The inter-limb differences suggest that the affected limbs, regardless of amputation type, adopt more of a hip strategy than a knee strategy (used by the unaffected limb).

Overall, the main finding on the GROUND was that the affected limb of both groups produced significantly less work than the unaffected limb, which was most attributable to the limited amount of ankle work for the affected limb. These results are similar to those reported by Barnett et al. [6] during a similar curb negotiation task in persons with TTA.

Socket type or prosthetic foot type was not controlled which may have affected the way in which the affected limb was used. Importantly, there was no unique socket design in the Ertl group to promote distal residual limb load bearing.

## CONCLUSION

Comparisons between functional outcomes of the Ertl and Non-Ertl groups suggest the Ertl affected limb may behave differently than the Non-Ertl limb by producing more net limb work on the CURB step than the Non-Ertl affected limb, primarily at the hip. This supports our hypothesis that the Ertl limb would produce greater work while negotiating a curb compared to the Non-Ertl affected limb, but this outcome is specific to mechanics on the curb step itself.

# GAIT STABILITY IN PEOPLE WITH UNILATERAL TRANSTIBIAL AMPUTATION ACROSS WALKING SPEEDS

Ryan D. Wedge, Andrew K. LaPrè, Frank C. Sup, and Brian R. Umberger  
University of Massachusetts, Amherst, MA, USA

email: [umberger@kin.umass.edu](mailto:umberger@kin.umass.edu), web: [www.umass.edu/locomotion](http://www.umass.edu/locomotion), [www.ecs.umass.edu/mie/mrrl](http://www.ecs.umass.edu/mie/mrrl)

## INTRODUCTION

People with lower limb amputation of all levels have an increased incidence of falls [1]. There is considerable interest in how gait stability is regulated in people with lower limb amputation and how this is related to fall risk. People with unilateral transtibial (TT) amputation exhibit many inter-limb asymmetries when walking [2], such as in step length and step time, and these asymmetries may be related to gait stability. It has been shown that step length asymmetry, with a shorter step on the intact side (i.e., a forward step with the intact limb), may enhance gait stability for walking at the preferred speed [3], but the effects across speeds are presently unknown. A better understanding of the inter-relationships among gait stability, asymmetries and walking speed in people with unilateral TT amputation will help inform interventions to reduce the incidence of falls.

The margin of stability [4] is a global (i.e., whole body) measure of gait stability that should be closely related to the risk of falling. Specifically, the backwards MoS (BW MoS) at initial foot contact can reveal the strategies people use to avoid a backwards fall when transitioning onto the lead limb. The BW MoS was previously shown to be greater for the intact limb in people with unilateral TT amputation when walking at preferred speed [3], presumably to compensate for reduced push-off by the prosthetic ankle. Since the mechanisms of maintaining gait stability are of interest across walking speeds, the purpose of this study was to evaluate BW MoS between limbs over a range of speeds in people with unilateral TT amputation.

## METHODS

Data were collected for seven subjects, five with a left-side TT amputation and two with a right-side TT amputation. Four subjects had a shuttle lock

connecting the sleeve and socket, two had a vacuum socket, one was end-bearing, and all seven had a standard pylon and a split toe flex-foot. Subject characteristics are listed in Table 1.

BW MoS at initial foot contact was calculated based on the extrapolated position of the center of mass (CoM) relative to the forward margin of the base of support [3,4]. Kinematic data were captured using a high-speed motion capture system as subject walked overground along a 15 m walkway. CoM horizontal position was determined from markers on the right and left anterior superior iliac spines and posterior superior iliac spines, and then numerically differentiated to determine CoM velocity (vCOM). The forward margin of the base of support was calculated from a marker located on the lateral heel.

BW MoS was determined at initial foot contact for both limbs (prosthetic and intact) for three trials at each of three speeds (preferred and  $\pm 20\%$  of preferred). Dependent variables were tested for differences using 2 (limb)  $\times$  3 (speed) MANOVAs followed by post-hoc tests using the false discovery rate procedure. Due to the preliminary and exploratory nature of the study, significance was evaluated at  $\alpha = 0.10$ .

**Table 1:** Subject demographics: means  $\pm$  SD

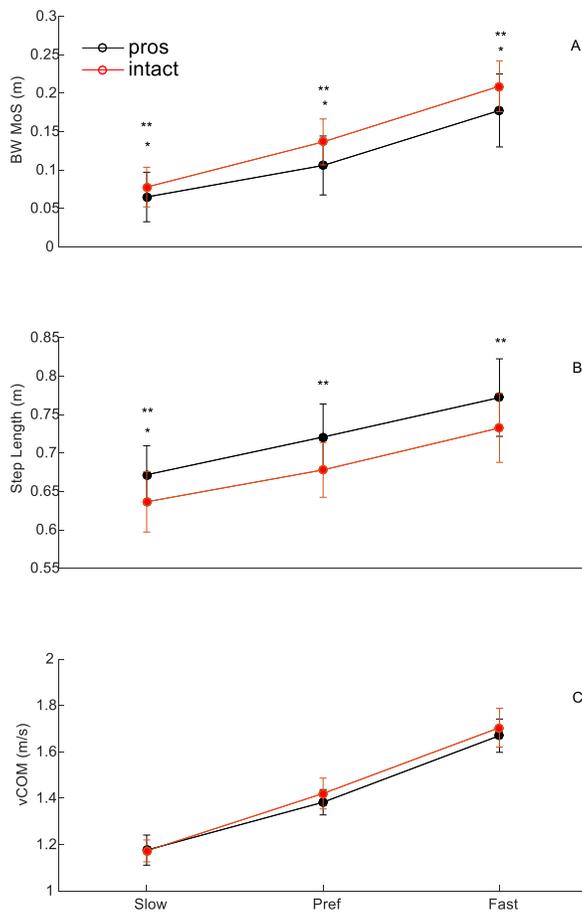

Mass (kg)	74.3 $\pm$ 15.0
Height (m)	1.78 $\pm$ 0.09
Slow speed (-20%) (m/s)	1.05 $\pm$ 0.04
Preferred speed (m/s)	1.27 $\pm$ 0.04
Fast speed (+20%) (m/s)	1.55 $\pm$ 0.07

## RESULTS AND DISCUSSION

BW MoS was greater at all speeds for the intact compared to the prosthetic side (Fig. 1A), similar to previous findings at preferred speed [3]. There was a significant effect of speed ( $p < 0.001$ ) and a significant effect of limb ( $p = 0.039$ ) for BW MoS

with no speed-by-limb interaction ( $p = 0.765$ ). Pairwise comparisons showed significant differences in BW MoS between limbs at each speed with moderate to large effect sizes (ES) (slow:  $p=0.092$ ,  $ES=0.44$ ; preferred:  $p=0.022$ ,  $ES=0.90$ ; and fast:  $p=0.052$ ,  $ES=0.78$ ).

There was a significant effect of speed ( $p < 0.001$ ) and a significant effect of limb ( $p = 0.008$ ) for step length with no speed-by-limb interaction ( $p = 0.976$ ). Pairwise comparisons showed significant differences in step length between limbs at the slow speed and large ES for all speeds (slow:  $p=0.030$ ,  $ES=0.91$ ; preferred:  $p=0.103$ ,  $ES=1.09$ ; and fast:  $p=0.126$ ,  $ES=0.84$ ).

**Figure 1:** BW MoS (A), step length (B), and vCoM (C) for both limbs across speeds. The \* symbol denotes a significant difference between limbs; \*\* denotes a moderate or large effect size.

There was a significant effect of speed ( $p < 0.001$ ) but no significant effect of limb ( $p = 0.302$ ) for

vCoM and no speed-by-limb interaction ( $p = 0.698$ ). All possible pairwise comparisons for speed effects for BW MoS, step length and vCoM were significant (all  $p$ -values  $< 0.01$ ) as was expected given the wide range of speeds (Table 1).

The subjects demonstrated a greater BW MoS on the intact side at initial foot contact across speeds, as had been shown at preferred speed [3]. The greater BW MoS for steps on the intact side was achieved primarily through a shorter step length, rather than a greater vCOM. Due to limitations of a prosthetic limb, subjects may more easily regulate gait stability via step length asymmetry rather than by a greater vCOM, which would require generating more hip work on the prosthetic side and potentially raise metabolic energy expenditure.

This was a preliminary study with a small sample size. Nevertheless, the results were consistent with clear trends and suggest expanding the sample size and testing a greater range of walking conditions.

## CONCLUSIONS

People with unilateral TT amputation achieve greater BW MoS at initial contact on the intact side versus the prosthetic side across walking speeds primarily by utilizing a shorter step length on the intact side, rather than by increasing vCOM. This provides further evidence that gait asymmetries may be functional adaptations that in the case of step length enhance gait stability.

## INTRODUCTION

The spring-loaded inverted pendulum model of human gait represents the limb as a massless strut with the mass concentrated at one end and the joints represented as springs of varying stiffness. [1] This model helps explain the pattern observed during healthy walking where the knee and ankle yield very little. In that context, the spring is relatively stiff and the center of mass (COM) moves upward from heelstrike to midstance, followed by a downward movement from midstance to toe-off. The resulting vertical ground reaction force (VGRF) reflects the acceleration and deceleration of the COM and produces waveforms that include two maxima separated by a local minimum. [2-5] VGRF shape varies with leg spring behaviors and COM acceleration, and it may reflect changes in joint motion, joint function, and health. [6-9]

Musculoskeletal (MSK) health is vital for successful participation in activities of daily life, yet worldwide variation in limb function, especially in the face of changing work roles and dietary patterns globally, remains understudied. Madagascar is experiencing a growing burden of chronic, non-communicable diseases, including MSK conditions. [10] However, no assessments of limb mechanics in a habitually unshod, agrarian sample are available. We used a Fourier analysis of the VGRF to explore limb function in this population.

## METHODS

VGRF data were collected from a sample of habitually unshod persons in the northeastern, rural

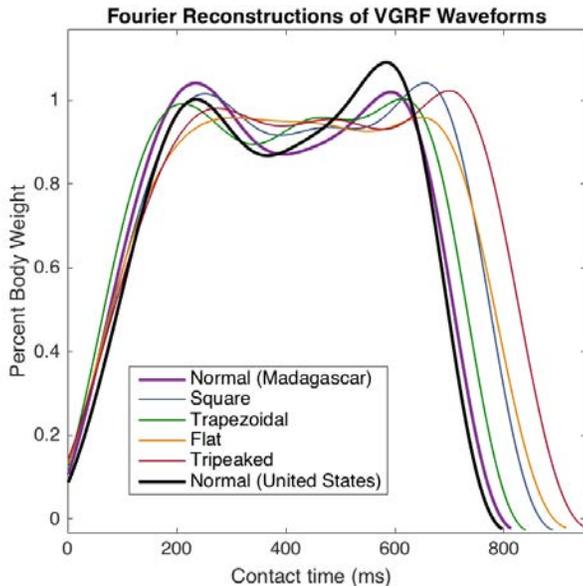

SAVA region of Madagascar (n=40; 50% female, mean age  $\pm$  SD = 43.7 $\pm$ 15.8) as well as a sample of habitually shod persons in the U.S. (n=19, 63% female, 53% White, mean age  $\pm$  SD = 31.2 $\pm$ 15.1) using a portable, biaxial force platform (PASCO PS-2142, PASCO Scientific, Roseville, CA). The PASCO force platform measured static forces within 0.1% of known weights (6 kg and 88.5 kg). Participants walked at self-selected speeds across force platforms embedded in the ground or a runway. A total of 400 and 211 valid steps were collected in Madagascar and the U.S., respectively.

To characterize and compare the shape of waveforms within and across populations, normalized VGRF data were filtered using a fourth-order low-pass Butterworth filter with a cutoff frequency of 10 Hz and zero-padded to twice the length of the vector. An eight-term Fourier model with period  $\omega = \pi / \text{contact time (CT)}$  was fitted to the waveforms using MATLAB (MathWorks, Inc., Natick, MA). ANOVA and Tukey's tests were performed to analyze the differences in waveform shape detected by Fourier coefficients within the Malagasy sample and between the Malagasy and U.S. samples.

## RESULTS AND DISCUSSION

In the Malagasy sample, five distinct VGRF waveforms were produced: a characteristic two-peaked waveform ("normal;" n=181), peaks shifted towards the early and late phases of stance in the waveform ("square;" n=74), a flat, plateau-like shape at one maximum and a sinusoidal curve at the other ("trapezoidal;" n=49), a flat curve resembling

that produced during compliant walking (“flat;” n=28), and a curve with  $\geq 3$  distinct peaks oscillating at 100% body weight (“tripeaked;” n=67). Nine coefficients (cosine  $a_{3,4,6,8}$ ; sine  $b_{1,3,5,6,7}$ ) were statistically significantly ( $p < 0.0001$ ) different between the five waveform patterns in the Malagasy sample.

**Figure 1:** Fourier reconstruction of VGRF waveforms. Normal steps in Malagasy and U.S. samples have comparable CT. The other waveforms have significantly longer CT ( $f = 24.09$ ,  $p \ll 0.001$ ).

No statistically significant differences exist in the Fourier coefficients between the normal waveforms in the Malagasy and U.S. at  $\alpha = 0.001$ ; one coefficient ( $a_7$ ) is statistically significant at  $\alpha = 0.05$ .

The gait patterns seen in the Malagasy sample are consistent with those reported as pathological gait patterns in a Western sample and recorded for patients with osteoarthritis. [11, 12] The waveforms in this sample, as seen in Western samples of persons with osteoarthritis, had longer weight receiving phases and CT. [13] Persons in occupations that demand increased physicality often experience MSK pathologies; carrying increased loads or non-standard postures contribute to the burden of MSK disorders, a pattern of labor that may be reflected in these waveforms. [14, 15]

## CONCLUSIONS

Fourier analysis of the VGRF is able to distinguish different gait patterns within a habitually unshod population in rural Madagascar, and it did not detect statistically significant differences in Normal walking VGRFs between agrarian and urban populations. This method identified atypical and potentially pathological patterns that may represent poor lower limb mechanics and joint health. This analysis provides insight into the relationships between cultural and occupational factors and joint mechanics, highlighting the importance of MSK function in a global health context.

# COMPARISONS OF THE VARIABILITY OF ACCELERATIONS BETWEEN LEFT AND RIGHT FOOT IN HUMAN WALKING

Sakdapong Chavanaves, Stephen J. Piazza and Robert B. Eckhardt

The Pennsylvania State University, University Park, PA, USA  
email: pingsakdapong@gmail.com

## INTRODUCTION

Walking, which has been called the most common human activity, features a repetitive sequence of movements with coordination between the left and right limbs to propel the body forward while maintaining stability. The results of several studies have indicated that while there is a considerable degree of symmetry between the left and right limbs in healthy walking gait, there also is evidence of asymmetry in healthy gait [1]. Such asymmetry usually is considered to be a common characteristic of pathological gait such as seen in Parkinson's disease, Huntington's disease, amyotrophic lateral sclerosis and stroke.

While many attempts have been made to research gait symmetry in both healthy and pathological gait, most studies quantified gait symmetry using only spatial-temporal gait variables and joint kinematics and kinetics. Very little is known about symmetry in measures of gait variability, despite indications that gait variability assessment is useful for distinguishing between fall-prone and healthy individuals [2]. The aim of this study was to compare the variability of readings from accelerometers affixed to the left and right feet under various walking conditions.

## METHODS

Seventeen healthy individuals (13 male and 4 female) aged  $26 \pm 6$  years participated in this study. All procedures were approved by the Institutional Review Board of The Pennsylvania State University. Each participant completed two experimental sessions on different days. The participants performed 5-minute walking trials at their preferred walking speed for each of 4 different conditions: treadmill walking (TM), overground

walking on a 2 m x 10 m rectangular path (OG), overground clockwise and counter-clockwise walking along a 1.5 m radius circular path (CW and CCW). In the first session, the participant completed two trials for each condition in random order. In the second session, the participant repeated the same procedure but completed only one trial for each condition in random order.

Participants were provided shoes and a waist belt that were fitted with tri-axial accelerometers (G-Link; LORD Microstrain). The accelerometers measured three-dimensional linear accelerations (not corrected for acceleration due to gravity) at 128 Hz with a maximum lag of  $\pm 100 \mu\text{s}$  between accelerometers.

The first 25 strides of each trial were excluded from analysis to remove transients. Heel strikes were identified as the maximum accelerations (in the axis perpendicular to the plane of the top surface of the shoes) of shoe accelerometers. 150 strides from each trial were used for the analysis.

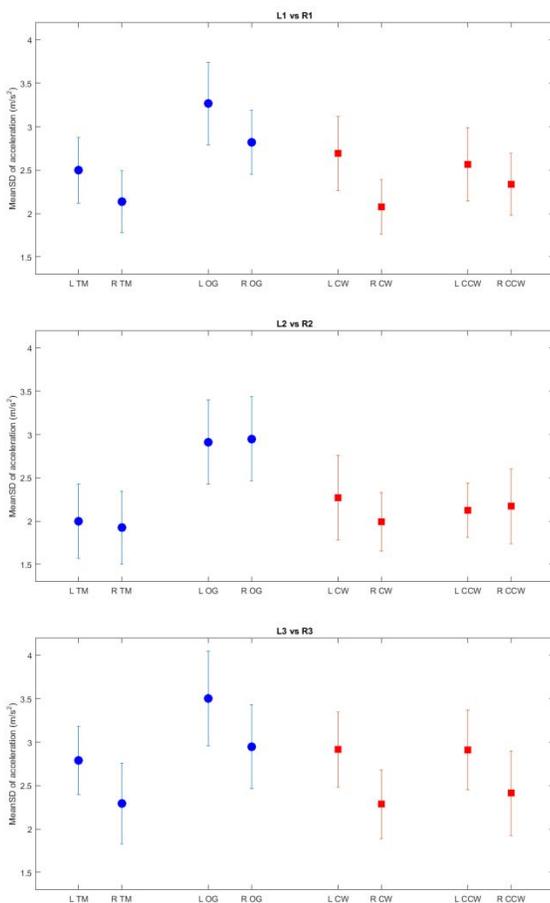

Each of the acceleration time series along the three orthogonal axes of each accelerometer was separated into time-normalized strides of 101 data points (0%-100% of gait cycle) using a shape-preserving piecewise cubic Hermite interpolation. Variability at each 1% of the gait cycle was determined as the standard deviation of the acceleration from 150 strides. MeanSD-acc was computed as the average standard deviation calculated over the entire gait cycle (the standard deviation at 0% was excluded since it represents the same gait event as at 100%).

We performed two separate 2 x 2 repeated-measures ANOVAs to compare MeanSD-acc between (1) left and right foot x TM and OG and (2) inside and

outside foot x CW and CCW. Bonferroni correction was used to reduce Type 1 error yielding  $\alpha = 0.05/18 = 0.003$  for this study.

## RESULTS AND DISCUSSION

There were significant main effects of (1) TM vs. OG walking condition in all 3 directions, (2) left vs. right foot in the anterior-posterior and the vertical directions (3) inside vs. outside foot in all 3 directions. There were significant interactions between CW vs. CCW walking condition and inside vs. outside foot in all 3 directions.

**Figure 1:** MeanSD-acc of L1 vs. R1 (anterior-posterior), L2 vs. R2 (medial-lateral) and L3 vs. R3 (vertical) for four different walking conditions. Each error bar represents  $\pm$  one standard deviation.

Our results showed that MeanSD-acc was larger for the left foot compared to the right foot, except in the medial-lateral direction, in all walking conditions. While results regarding the symmetry of kinematic

and kinetic gait variables are not conclusive [1], we have found that gait asymmetry is apparent in the variability of foot-mounted accelerometer readings. Measurements of upper limb motions have revealed that the dominant-side limb system is specialized for controlling limb trajectory dynamics, while the non-dominant-side limb system is specialized for controlling limb position and stabilization [3]. If similar specialization applies to foot motion, we might expect more consistent foot acceleration trajectories in the dominant foot. Although we did not determine the handedness or the footedness of our participants, previous research indicated that most people are right-limb dominant [4]. If we assume that the majority of our participants are right limb dominant, our results would support the possibility that the smaller MeanSD-acc for the right foot resulted from more consistent control of the right leg dynamics. In addition, it is possible that the lateralization of the foot trajectory control is direction specific, as we observed no difference between left and right foot variability in the medial-lateral direction.

## CONCLUSIONS

The variability of left-foot acceleration is larger compared to that of the right foot, except in the medial-lateral direction, across all the walking conditions tested. This difference may be an indication of both gait asymmetry and motor lateralization. Our results suggest that future studies should not assume the symmetry of gait variability measurements between left and right limbs and that gait variability should be assessed separately for each limb during walking.

# PRELIMINARY EVIDENCE THAT FOOT MECHANICAL ENERGY DURING WALKING IS DISSIPATED AS HEAT

<sup>1</sup> Jeffrey M. Patterson, <sup>1</sup> Nikolaos Papachatzis, <sup>1</sup> Kota Z. Takahashi

<sup>1</sup> University of Nebraska at Omaha, Omaha, NE, USA  
Email: [jmpatterson@unomaha.edu](mailto:jmpatterson@unomaha.edu), web: [cobre.unomaha.edu](http://cobre.unomaha.edu)

## INTRODUCTION

The human foot contains elastic structures (e.g., plantar fascia) that can store and return mechanical energy [1]. Such structures are thought to play a role in reducing the metabolic energy demands during locomotion [2]. Yet, when accounting for all structures within the foot (e.g., muscles, tendons, and soft tissue deformation), the human foot appears to perform net negative work during walking [3]. It is currently unclear how the body utilizes this net negative work; specifically, whether this energy is used to supplement the body's movement.

There are several possibilities regarding the destination of the foot's net negative work. One possibility is that the foot's energy is transferred proximally through multi-articular muscles (e.g., flexor digitorum or hallucis longus); yet, only a small portion of the foot's energy appears to be transferred through these muscles [4]. Other possibilities may be that the foot's energy dissipates in the form of sound or heat. In fact, walking can induce increases in foot temperature [5], and thus heat transfer may be a plausible outcome for the foot's net negative work.

The purpose of this study was to investigate the link between foot mechanics and temperature regulation. We aimed to increase foot's net negative work by adding mass to the body during walking. We hypothesized that the magnitude of the foot's net negative work would correlate with increased foot temperature during walking with added mass.

## METHODS

One subject (age = 33 yrs, height = 1.74 m, mass = 67.2 kg) completed barefoot walking trials over-ground and on a treadmill, both with and without added body mass. Added mass conditions included 15% body mass and 30% body mass added via a vest

that distributed the mass equally around the core. The order of the three sessions (0, 15%, and 30% added mass) was randomized.

First, baseline temperature recordings were taken at three different sites on the plantar surface of the foot (heel pad, 1<sup>st</sup> and 5<sup>th</sup> metatarsal heads), dorsal surface at the 1<sup>st</sup> metatarsal head, shank (~50% distance between knee and ankle joints), and thigh (~50% distance between hip and knee joints). Then the subject walked over a force plate targeted at 1.25 m/s. After the foot returned to baseline temperature, the subject walked on a treadmill for 10 minutes. Foot, shank, and thigh temperature were recorded after the treadmill trial.

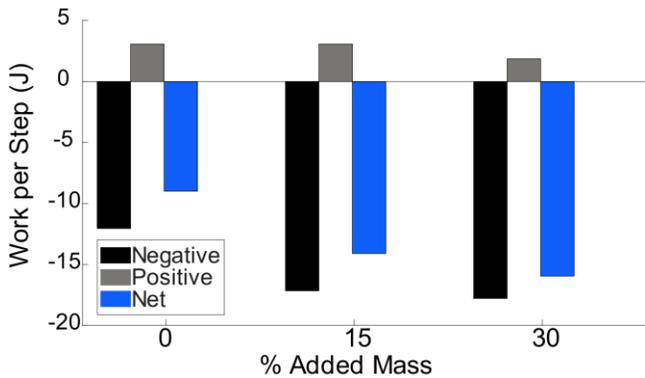

The mechanical power of the foot during the over-ground trials was quantified using a unified deformable segment analysis [6], by modeling all structures distal to the calcaneus as a deforming body [3]. Positive and negative work were quantified by integrating the power with respect to time. The net work was compared with the changes in temperature.

## RESULTS AND DISCUSSION

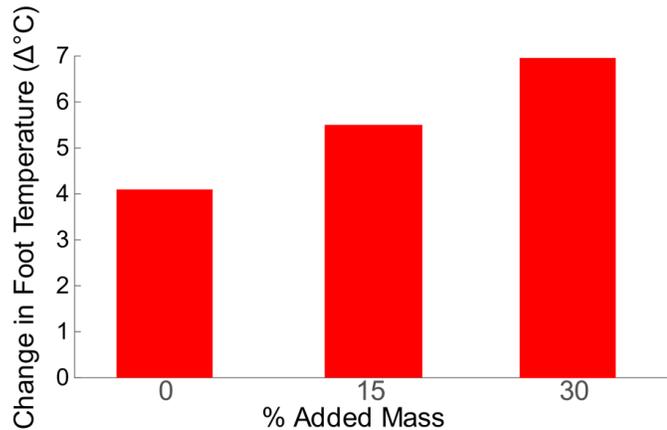

When the subject walked with added mass, the magnitude of the foot's positive work remained relatively similar. However, the magnitude of negative work increased, and thus the magnitude of net negative work increased; most notably between the 0% and 15% added mass conditions (Figure 1).

After 10 minutes of treadmill walking without added mass, temperatures increased at all sites (Table 1). Temperature increased most notably at the foot, with smaller changes occurring at the shank and thigh. Specifically, the greatest temperature changes occurred at the plantar surface (under the 1<sup>st</sup> and 5<sup>th</sup> metatarsal heads and the heel pad). Walking with added mass magnified this temperature increase,

again most notably at the plantar surface, and most drastically at 30% added mass (Figure 2).

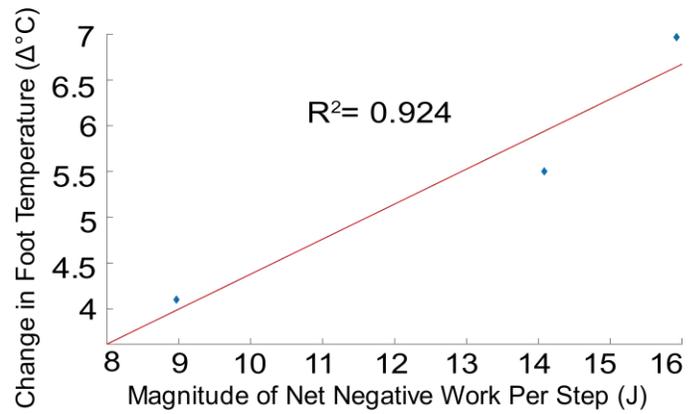

**Figure 1.** With added mass, there was an increase in foot negative work (black), small change in positive work (grey), and an increase in magnitude of net negative work (blue).

**Figure 2.** During 10 minutes of treadmill walking, the average temperature of the plantar surface increased with added mass.

As the magnitude of foot net negative work increased with added mass, the average temperature of the plantar surface also increased (Figure 3).

**Figure 3.** The magnitude of net negative worked per step (during over-ground walking) was positively correlated with an increase in average temperature of the plantar surface (during 10 minutes of treadmill walking).

## CONCLUSIONS

These preliminary results support our overall hypothesis that net negative work at the foot may be dissipated as heat. Currently, our analyses cannot parse out the exact source of heat production, such as shear force [5], soft tissue deformation, or muscle force generation. Determining such contributions is expected to give new insights into the mechanism of impaired temperature regulation, such as in patients with diabetes who are prone to ulcer formation in the foot [7].

# CHARACTERIZING AMBULATORY TENDENCIES FOR LOWER LIMB AMPUTEES

Jay Kim, Audra Davidson, and Deanna H. Gates

University of Michigan, Ann Arbor, MI, USA  
email: jaywoo@umich.edu, web: <http://rehab-biomech-lab.kines.umich.edu/>

## INTRODUCTION

Clinical prescription of prosthetic devices relies heavily on qualitative judgment of a patient's functional ability. The Medicare Functional Classification Level (MFCL) index assigns K-levels based on a patient's mobility and level of community ambulation. Because of its subjective nature, it is unclear if K-levels can accurately describe a patient's mobility across different environments [1,2], or how the potential for ambulation relates to community reintegration. Therefore, it is imperative to move toward a quantitative evaluation scheme.

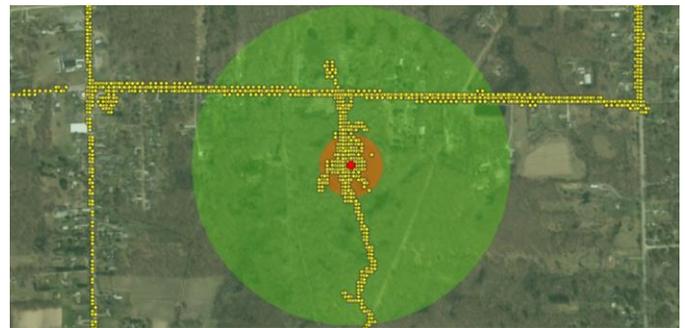

Many previous studies have used accelerometers to quantify patient walking tendencies, and a few have also utilized Global Positioning System (GPS) devices to measure patient activity in daily life [3]. This study combined the two methods of measurement to provide a quantitative representation of ambulation tendencies with corresponding contextual information i.e., location. The goal of this study was to create a more comprehensive description of a patient's ambulatory profile. These endeavors will develop a better understanding of how best to address the nuanced needs of the diverse amputee population.

## METHODS

Six lower limb amputees ( $49 \pm 18$  years old, 5 male / 1 female) participated in this study (Table 1). Participants wore two accelerometers (ActiGraph, Pensacola, Florida, USA) for seven days. The accelerometers were placed on top of the foot and on the lateral side of the ankle of the affected side. Participants were also given a GPS-enabled smart phone with a location tracking application (Ethica, Saskatoon, Canada).

A modified Theeven cut point [4] was used to detect walking bouts from the accelerometer data. This method accommodates the sedentary nature of the participant demographic. Step counts, average bout durations, and number of bouts per day were derived from accelerometer data.

To quantify community integration, GPS data was used to calculate the amount of time spent at home, near the home, and away from home. Location buffers (Fig 1) of 100 meter and 500 meter radii were created around the home address. Because data was not sampled at a constant rate, data points were linearly interpolated to total 60,480 samples per week (equivalent to 0.1 Hz sampling rate).

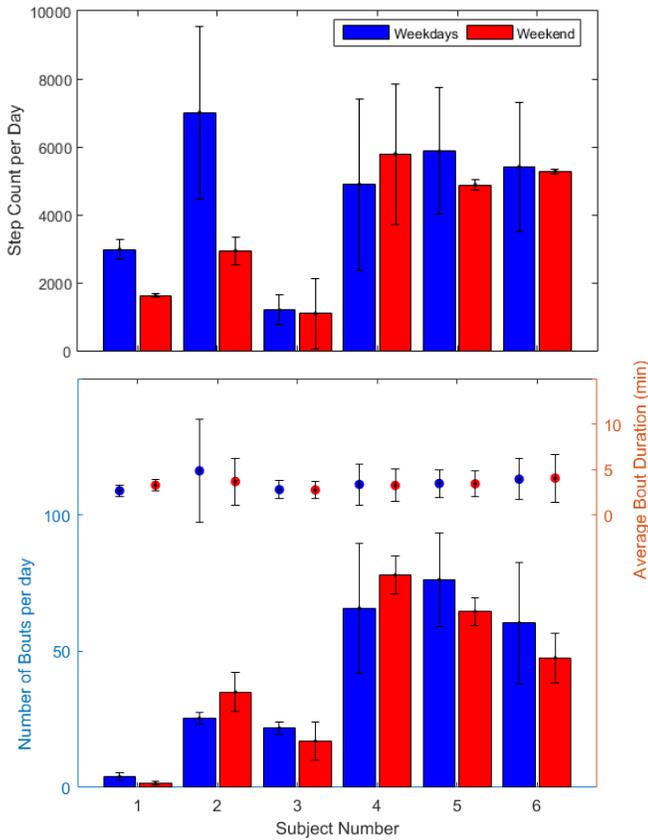

**Figure 1:** GPS points (yellow), participant's home (red), 100m buffer (orange), 500m buffer (green)

## RESULTS AND DISCUSSION

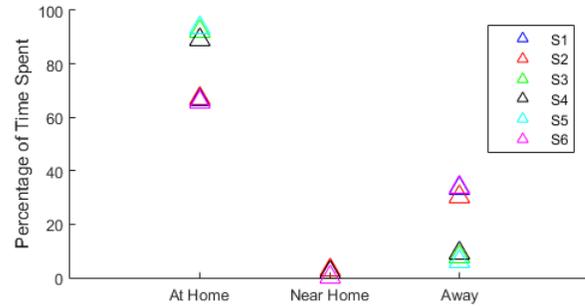

Overall, participants were more active during the week compared to the weekends, which could be attributed to workplace-related activities during the week. While step counts and number of bouts showed higher between-subject variation, average bout duration showed low variability (Fig 2).

Previous studies have used location buffers around the home and pre-determined "community" areas to observe step counts across different areas [4]. Observing the amount of time spent in the buffers of varying radii is a simpler and quicker method that

yields comparable insight into the participant's activity profile and level of engagement in the community. Participants spent the majority of their time at home but also a significant amount of time away from home, which suggests moderate community engagement (Fig 3).

**Figure 2:** Step count per day (top), average bout duration (middle), number of bouts per day (bottom), for all participants

**Figure 3:** Percentage of Time Spent at Home, Near the Home, and Away from Home

Future studies should explore an increased variety of observation parameters to develop a set of characteristics, each uniquely informative. With a more comprehensive participant profile, similarity algorithms could be used to more objectively distinguish participants' ambulatory tendencies.

## INTRODUCTION

Whole-body angular momentum is tightly regulated during walking [1] as it is important for maintaining dynamic balance. Decomposition of angular momentum in the three anatomical planes has been used to show differences in task requirements. Upward slope and stair walking require greater frontal range of angular momentum compared to level-ground [2, 3], while the sit-to-stand movement requires greater sagittal angular momentum to successfully complete the task [4]. Turning is another task that presents a greater biomechanical challenge compared to straight-line walking as it requires redirection of the center of mass and asymmetric force generation. Importantly, 34.5% of the steps taken in a given day are turning steps [5]. Therefore, the purpose of this study was to assess whole-body and segmental angular momentum during a 90° right-hand turn compared to straight-line walking.

## METHODS

Six healthy individuals participated in this study. Data in this abstract includes only five of these participants (2F/3M, 25.6±3.4 yrs, 1.73±0.11 m, 76.5±15.4 kg) as they all utilized a similar turning strategy. All participants performed two tasks: straight-line walking and 90° turning at a self-selected speed. Five straight-line walking and five right-hand turns were collected. Turn initiation and termination were defined using pelvic rotation threshold of 5° and 85°. The turn was defined as the heel strike prior to initiation to the heel strike after termination (Fig.1).

55 reflective markers were used to track full body kinematics at 120 Hz using a 20-camera motion capture system (Motion Analysis, Santa Rosa, CA). Kinematics were then low-pass filtered using a 4<sup>th</sup>-order Butterworth filter with a cutoff frequency of 6

Hz. A nine-segment model was created based on segment definitions established by ISB [9].

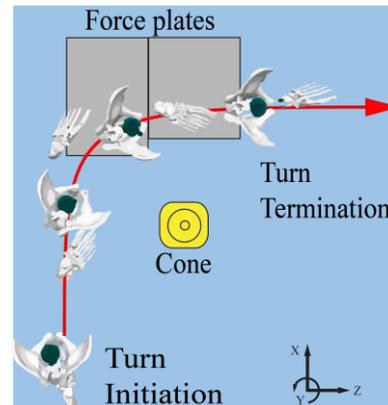

Fig 1. Steps taken during a 90° right-hand turn around a cone.

Segmental angular momenta and whole-body angular momentum were computed about the COM in the three anatomical planes during the middle step of the turn (LHS-LHS) (Fig 1). Whole-body angular momentum was computed as the summation of the segment angular momenta. A rotation matrix was then created based on the center of mass (COM) path trajectory and used to rotate the angular momentum vector from the lab reference frame to the COM reference frame. This calculation ensured that values were interpreted in the body's directions of motion. The peak-peak range of angular momentum in each anatomical plane was then computed for each limb (e.g. sum of thigh, shank and foot segments), torso, and head segments. Paired t-tests were then used to identify differences in whole-body and segmental angular momenta between straight-line walking and turning. Additionally, Cohen's d was used to quantify effect size due to the small sample size.

## RESULTS AND DISCUSSION

The range of whole-body angular momentum did not differ between straight-line walking and turning ( $p = 0.105$ ; Table 1). Differences in segmental ranges of angular momenta were observed in at

least two planes for all four segments analyzed. The right leg angular momentum was greater during turning for the frontal plane ( $p < 0.001$ ,  $d = -3.1$ ), while it was reduced in the sagittal ( $p < 0.001$ ,  $d = 1.31$ ) and transverse planes ( $p < 0.001$ ,  $d = 2.6$ ). The head segment angular momentum was greater in all planes during turning ( $p = 0.012$ ,  $|d| = 0.84$ ). Angular momentum of the left leg was greater during turning in the frontal ( $p < 0.001$ ,  $d > -3.93$ ) and transverse planes ( $p < 0.001$ ,  $d = -1.33$ ) (Fig 2). Throughout the left gait cycle of a turn the right leg generated negative frontal plane angular momentum during the swing phase, counteracting the momentum of the left leg in stance phase. Additionally, the torso range of angular momentum was also greater during turning in the frontal ( $p < 0.001$ ,  $d = -0.81$ ) and transverse planes ( $p = 0.02$ ,  $d = -0.81$ ) most likely used to rotate the body in the direction of turning.

## CONCLUSIONS

Segmental angular momenta can vary dramatically depending on the task. Turning required greater range of angular momentum for all segments compared to straight-line walking, while whole-body angular momentum remained similar during both tasks. Future work will investigate compensation strategies for maintaining dynamic balance during turning in impaired populations.

# EFFECTS OF WIDE STEP WIDTH ON STAIR ASCENT KNEE KINETICS IN OBESE PARTICIPANTS

<sup>1</sup> Derek Yocum, <sup>1</sup> Joshua T. Weinhandl, <sup>1</sup> Jeffrey T. Fairbrother, <sup>1</sup> Songning Zhang

<sup>1</sup> Department of Kinesiology, Recreation and Sport Studies, University of Tennessee, Knoxville, TN, USA  
email: [dyocum@vols.utk.edu](mailto:dyocum@vols.utk.edu), web: [web.utk.edu/~sals/resources/biomechanics\\_laboratory.html](http://web.utk.edu/~sals/resources/biomechanics_laboratory.html)

## INTRODUCTION

The obese population is 6.8 times more likely to develop knee osteoarthritis (OA) [3]. Medial compartment knee OA is associated with an increased internal knee abduction moment during level walking. Obese participants display an increase in non-normalized peak knee extension moments and knee abduction moments, compared to healthy-weight individuals [2].

Stair ascent studies have found that healthy-weight participants exhibit greater normalized peak knee extension moments and decreased knee abduction moments [6], compared to level walking.

A wider step-width (SW) has been shown to reduce the peak knee extension moment and knee abduction moment during level walking, and stair ascent [1, 4, 7]. However, this has not been studied in an obese population. The purpose of this study was to determine the effects of increased SW on knee biomechanics during stair ascent of obese and healthy-weight participants.

## METHODS

Fourteen healthy-weight (age: 21.6±0.5 years, height: 1.7±0.1 m, mass: 66.3±9.3 kg, BMI 22.5±1.9 kg/m<sup>2</sup>) and ten obese (age: 25.7±5.8 years, height: 1.7±0.1 m, mass: 100.6±12.6 kg, BMI 32.8±2.7 kg/m<sup>2</sup>) participants were recruited to participate in the study. All participants were between 18 and 40 years old. Obese participants had a BMI between 30.0 and 39.9 kg/m<sup>2</sup>, while healthy weight participants were between 18.0 and 24.9 kg/m<sup>2</sup>.

A 12-camera motion analysis system (240 Hz, Vicon Motion Analysis Inc., UK) was used to obtain the three-dimensional kinematics during the test.

Reflective anatomical and tracking markers were placed on both sides of feet, ankles, legs, knees, thighs, and hips. Each participant performed five successful trials of stair ascent in each of two test conditions, preferred and wide SW. SW was defined as the mediolateral distance between the center of masses of both feet during midstance. The wide SW was set as twice the participant's preferred SW, which has been shown to significantly reduce loading-response knee abduction moment [4, 5]. SW was calculated using the second and third steps. A speed range, average speeds ±5%, was used to monitor the speed of movement trials.

A low-pass 4<sup>th</sup> order Butterworth filter at a cutoff of 8 Hz for kinematic and joint moment calculations, and at 50 Hz for GRF calculations. A 2 x 2 (Group x SW) mixed design analysis of variance (ANOVA) was performed to analyze selected variables (22.0 IBM SPSS, Chicago, IL). An *a priori* alpha level was set to 0.05 for all statistical tests.

## RESULTS AND DISCUSSION

A wider SW reduced loading-response peak vertical GRF (p=0.045, Table 1). The obese group demonstrated significantly larger loading-response and push-off peak vertical GRFs (both p<0.001).

Significant Group x SW interactions were observed for both loading-response and push-off peak medial GRFs (all p<0.001, Table 1). This interaction indicated that the obese group increased to greater extents. The post hoc comparisons showed that the obese group had greater mean loading-response peak medial GRF during both preferred (p=0.008) and wide (p=0.001) SW compared to the healthy-weight group. Additionally, the obese group demonstrated greater mean push-off peak GRFs for preferred (p=0.033) and wide (p=0.001) SW (Table 1).

Obese participants had significantly larger loading-response peak knee extension moments ( $p < 0.001$ ). The interaction approached significance for the loading-response peak knee abduction moment ( $p = 0.051$ ) (Table 1). Post-hoc comparisons revealed that only obese participants experienced a decrease in knee abduction moment when SW was increased ( $p=0.020$ ). During push-off, an interaction ( $p=0.022$ ) was seen for peak knee adduction moment, suggesting that the wide SW increased the peak knee adduction moment for both groups, but obese participants showed a greater increase than the healthy-weight group. Post-hoc comparisons revealed that wide SW increased the push-off peak knee adduction moment in both obese ( $p=0.003$ ) and healthy-weight ( $p<0.001$ ) participants. Obese participants had greater push-off peak knee adduction moments during preferred ( $p=0.003$ ) and wide ( $p=0.030$ ) SW conditions.

This study was performed to find differences in knee biomechanics of obese and healthy-weight people during stair ascent at their own preferred and wider SW. We found that obese participants experienced higher medial and vertical GRFs, loading-response peak knee extension moments, and push-off peak knee adduction moments. A significant decrease in the loading-response knee abduction moment in the obese population indicates that a clinical modification to train obese participants to ascend

stairs with a wider SW may lower loading on the medial knee compartment.

## CONCLUSION

Further research should be performed to expose how SW effects biomechanics of the hips and ankles in obese and healthy-weight individuals. Investigation of the effects of increased SW may benefit from investigating muscle activation and joint loading patterns through modeling software such as OpenSim. Lastly, intervention studies on the efficacy of an increased SW gait modification on the obese population are merited to determine the extent in which this modification may help reduce the risk of development of knee osteoarthritis in this population.

# Central Activation Deficits of the Quadriceps Muscle in Patellar Tendinopathy

<sup>1</sup> Andrew Sprague and <sup>1</sup>Karin Grävare Silbernagel

<sup>1</sup> University of Delaware, Newark, DE, USA

email: [asprague@udel.edu](mailto:asprague@udel.edu), web: <http://www1.udel.edu/dri/tendonteam.html>

## INTRODUCTION

Patellar tendinopathy is a chronic, painful condition of the patellar tendon. It is most prevalent in athletes who participate in jumping sport, such as volleyball and basketball, where high loads are placed on the knee extensor mechanism [1]. Athletes with patellar tendinopathy demonstrate pain, reduced knee extension strength and altered kinetics and kinematics during jumping, compared to healthy controls [2, 3].

Arthrogenic muscle inhibition (AMI) is a reflexive response to joint injury, resulting in the inability to volitionally activate a muscle fully in the absence of muscle or neural tissue damage [4]. AMI of the quadriceps has been observed in patients with knee injuries such as anterior cruciate ligament rupture or reconstruction, knee osteoarthritis, and anterior knee pain [4, 5]. In these conditions, impaired quadriceps activation results in reduced knee extension torque during strength testing. Additionally, it is a contributing factor to decreased neuromuscular control, altered lower extremity kinetics and kinematics, and increased risk of injury [4]. However, AMI has not been investigated in patients with patellar tendinopathy.

The purpose of our study was to determine whether quadriceps AMI, which may contribute to altered biomechanics, is present in patients with unilateral patellar tendinopathy. We hypothesized that the symptomatic limb in patients with patellar tendinopathy would have decreased quadriceps activation compared to the contralateral, asymptomatic limb.

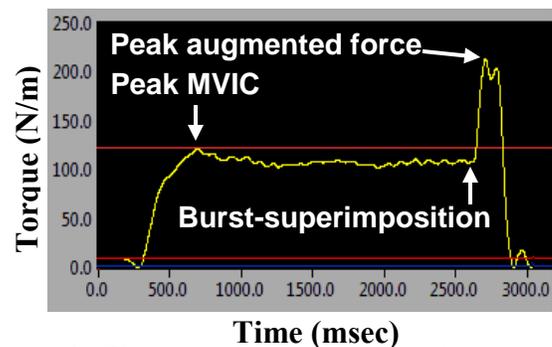

## METHODS

Four subjects (3M:1F) with symptomatic unilateral patellar tendinopathy were recruited. Participants had a mean age ( $\pm$  SD) of 26 ( $\pm$  9) years, height of

72.7 ( $\pm$  6.1) in., weight of 195.2 ( $\pm$  23.1) lbs, and symptom duration of 3.2 ( $\pm$  3.1) months.

Diagnosis of unilateral patellar tendinopathy was confirmed through clinical exam and B-mode ultrasound imaging (LOGIC *e* Ultrasound, GE Healthcare, Chicago, IL). Participants completed the Victorian Institute of Sport – Patellar (VISA-P) Questionnaire to assess symptom severity.

Knee extension peak torque and quadriceps muscle activation was assessed using a Biodex Systems 3 Dynamometer (Biodex Medical System, Shirley, NY) while performing a maximal voluntary isometric contraction (MVIC) with the burst-superimposition method [6]. Participants were seated with the hips at 90° of flexion and the knee at 60° of flexion. Self-adhesive electrodes (6 cm x 8 cm) were placed over the vastus medialis and vastus lateralis muscle bellies. After familiarization with procedures, participants performed a 3-second MVIC. During contraction, a supramaximal, 10-pulse (600  $\mu$ s, 130 V, 100 pulses per second) train of electrical stimulation was delivered to the muscle. Up to 3 trials were completed to ensure the participant had achieved maximal isometric torque prior to burst superimposition. A custom LabView program (National Instruments, Austin, TX) was used to identify the peak MVIC torque and the torque

**Figure 1.** Characteristic increase in knee extension torque production with burst-superimposition in a subject with incomplete quadriceps activation.

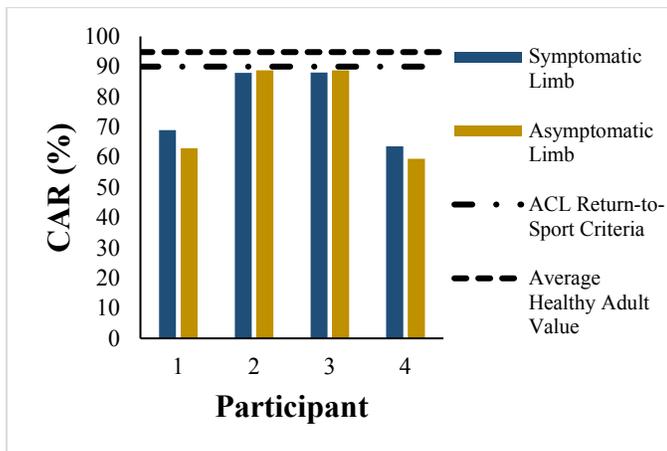

attributable to the electrical burst (Figure 1.). A central activation ratio (CAR) (MVIC torque/peak torque with burst augmentation) was calculated for comparisons.

Statistical analysis was completed using IBM SPSS Statistics 24. Due to small sample size, the Wilcoxon Signed-Rank test was used to compare limbs. The significance level was set to  $p < 0.05$ .

## RESULTS AND DISCUSSION

Participants had a mean ( $\pm$  SD) tendon thickness of 0.58 ( $\pm$  0.19) cm for the symptomatic limb and 0.47 ( $\pm$  0.21) cm for the asymptomatic limb. Their mean VISA-P score was 57 ( $\pm$  17) points.

All subjects had bilateral deficits in quadriceps activation with a mean CAR of 77.1 ( $\pm$  12.7)% for the symptomatic limb and 75.0 ( $\pm$  16.0)% for the asymptomatic limb (Figure 2). There was no statistically significant difference between CAR in the symptomatic and asymptomatic limbs ( $p > 0.05$ ). Following anterior cruciate ligament reconstruction, a cut-off score of 90% CAR has been established as criteria for return-to-sport [7]. All participants fell below this cut-off, bilaterally, and below normative values for healthy adults ( $94.8 \pm 3.6\%$ ) (Figure 2) [4].

**Figure 2.** Quadriceps central activation ratios (CAR) for the symptomatic limb and asymptomatic limb with cut-off scores for anterior cruciate ligament (ACL) return-to-sport criteria and the normative value for healthy adults.

## CONCLUSIONS

Those affected by unilateral patellar tendinopathy have bilateral reductions in quadriceps activation, which are comparable between the symptomatic and asymptomatic limbs. These values are similar to those observed in the surgical limb of patients 1-month post anterior cruciate ligament reconstruction and well below normative values for healthy adults [8]. This impairment may contribute to alterations in kinetics and kinematics during gait and sport-specific tasks. Clinicians and researchers should be aware of these deficits and how they may impact measures of strength and movement performance. Due to the cross-sectional nature of the study, we are unable to determine whether reduced CAR is a predisposing factor or adaptation to patellar tendinopathy. Prospective studies with larger sample sizes are needed to examine the relationship and how CAR deficits may influence biomechanics and functional performance.

# EFFECT OF FATIGUE AND REAL-TIME VISUAL FEEDBACK DURING DROP LANDINGS ON PATELLOFEMORAL JOINT STRESS IN HEALTHY FEMALE ADULTS

Christina Olbrantz, Jamie Bergelin, Jill Asmus, Thomas Kernozek, Drew Rutherford, Naghmeh Gheidi

University of Wisconsin-La Crosse, La Crosse, WI, USA

email: kernozek.thom@uwlax.edu

## INTRODUCTION

Patellofemoral joint stress (PFJS) may be an important factor in the development of patellofemoral pain (PFP) [1]. Fatigue has been proposed to alter lower extremity mechanics associated with PFP during landing activities [2]. Vertical ground reaction force (GRF) during landing activities may impact PFJS [1].

Our purpose was to determine how healthy females alter their PFJS using visual real-time feedback (RTF) of GRF during drop landings before and after fatigue.

## METHODS

Kinetic and kinematic data respectively, were collected using two force platforms (1800 Hz) and a 15 camera motion analysis system (180 Hz) with forty seven reflective markers. Seventeen healthy females (Age:  $22.5 \pm 1.7$  y; Height:  $188.0 \pm 6.6$  cm; Mass:  $70.8 \pm 5.9$  kg) participated. Each performed a baseline set of five drop landings from a hang bar 60 cm above the ground. After three landing trials for instruction on how the feedback worked, subjects performed an additional five drop landings with visual RTF (RTF condition) displaying their vertical GRF in body weight from a custom program using D-Flow software (Motekforce Link, Amsterdam, Netherlands). RTF displayed a sphere moving on a vertical axis during the landing where a horizontal bar marked the peak vertical GRF. During each drop landing, the numerical value of the vertical GRF from the previous trial was visually displayed for comparison. Subjects were cued to “land softly” before each drop landing to attempt to lower their peak GRF for the next trial. Following the RTF condition, subjects underwent a fatigue protocol

consisting of multiple sets of 15 jump squats. Fatigue was defined as the inability to reach 75% of maximum vertical jump height within two attempts or Borg RPE score  $\geq 17/20$ . After the fatigue protocol, the post-fatigue set of five drop landings with visual RTF was performed (Post-fatigue RTF).

The Human Body Model (HBM) (Motekforce Link, Amsterdam, Netherlands) was used to calculate muscle forces based on an 18 segment, 46 degree of freedom (DOF) musculoskeletal model. Static optimization criteria was used that estimated the muscle forces where the sum of the squared muscle activations were related to the maximum muscle strengths. The total quadriceps force (QF) was determined by summing the rectus femoris, vastus (medialis, lateralis, and intermedius) muscles from HBM. Patellofemoral joint reaction force (PFJRF) was the compressive component of the QF based on knee flexion angle. PFJS was estimated by dividing PFJRF by contact area [3]. A multivariate analysis with repeated measures ( $\alpha = .05$ ) was used to examine differences between conditions (baseline, RTF, Post-fatigue RTF). Follow-up univariate tests were completed to detect differences in each variable between conditions. Statistical calculations were completed in SPSS (IBM, Armonk, NY, USA).

## RESULTS AND DISCUSSION

Multivariate analysis indicated differences across conditions (Wilk's Lambda = .097,  $p = .01$ ). Univariate tests revealed differences for all variables across conditions (baseline, RTF, and Post-fatigue RTF) except peak quadriceps force (Table 1).

Pairwise comparisons were used to examine between testing conditions. Vertical GRF decreased

from baseline to the RTF condition (1.94 BW to 1.78 BW) ( $p = .002$ ) (Figure 1). There was a small increase in GRF to 1.81 BW from the RTF condition to the Post-fatigue RTF condition ( $p = 1.0$ ); overall, there was a 6.4% decrease in vertical GRF from baseline to the Post-fatigue RTF condition ( $p = .118$ ). Peak knee flexion angle increased from 94.0 degrees to 98.4 degrees from baseline to the RTF condition ( $p = .043$ ) and then decreased to 92.3 degrees during the Post-fatigue RTF condition ( $p < .001$ ). Maximum PFJS decreased from baseline to the RTF condition by 3.9% ( $p = .007$ ), then increased from the RTF condition to the Post-fatigue RTF condition by 3.8% ( $p = .034$ ) (Figure 2).

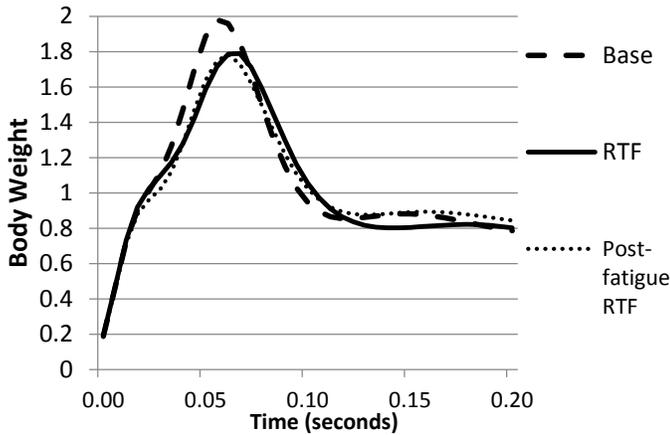

Figure 1. Peak Ground Reaction Force for each landing condition (Baseline, RTF, Post-fatigue RTF)

Patellofemoral joint stress is the interaction between knee flexion, PF contact area, and PF joint reaction

Force [2,3]. The decrease in knee flexion observed in this study during the Post-fatigue RTF condition may be related to the increase in GRF and subsequent increase in PFJS. Therefore, one should consider fatigue state when attempting to use feedback to influence performance.

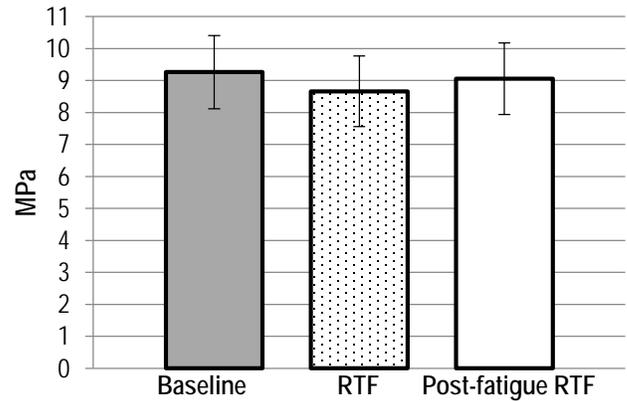

Figure 2. Peak PFJS for each landing condition (Baseline, RFT, Post-fatigue RTF)

## INTRODUCTION

Osteoarthritis (OA) of the knee is a detrimental condition for service members and is on the rise [1]. Long-term repetitive loading of the lower extremity during tasks such as walking, running and cutting have been associated with the development of OA. It is known that joint contact forces (JCFs) increase during these tasks when the individual carries additional body-borne loads (BBL). This is a pressing issue for military populations as soldiers carry loads in excess of 30% body weight while completing military relevant training and mission scenarios. How increased JCFs are distributed across the knee joint and within cartilage, and how this may impact the progression of OA, is currently unknown. However, by combining traditional motion capture methods with computational models, it is possible to simulate the cumulative effect of BBL on cartilage.

We investigate two key metrics: interstitial fluid pressure and von Mises solid extra stress. Increased fluid pressure enhances load support, shields the solid matrix, promotes low frictional coefficients and thus reduces tissue and joint wear. von Mises stress in the solid matrix is a scalar measure of distortion energy related to shear stresses. Studies indicate that shear forces play a critical role in the destructive mechanical loading that comprises chondrocyte health and initiates extracellular matrix degradation [2]. We aim to determine how mechanical properties of healthy and diseased cartilage impact the tissue's ability to dissipate forces across the joint associated with varying additional BBL.

## METHODS

Nine male military personnel (participants,  $21.1 \pm 3.8$  yrs,  $72.5 \pm 9.4$  kg,  $1.8 \pm 0.1$ m) completed two test sessions where they donned light or heavy BBL configurations. The light load (LL,  $\sim 6$  kg) was

composed of a helmet, mock weapon, boots, socks and spandex shirt and shorts. The heavy load (HL,  $\sim 40$  kg) consisted of the light load plus body armor with a fabric ammo panel attached on the anterior and a standard issue military backpack. During each test session, individual participants performed three successful run-to-stop maneuvers. These maneuvers required the participant to run down a 10 m walkway at 3.5 m/s and plant their dominant limb on a force platform embedded in the floor, immediately stopping in a low and ready position (i.e. eyes forward, weapon pointed downward at  $\sim 45^\circ$ , legs wide and slightly bent).

We developed OpenSim simulations following methods detailed in Ramsay et al. [3]. While we considered the LL negligible for modeling purposes, for the HL we distributed both a 20-kg body-borne load evenly across the torso and applied at the torso's center-of-mass (CoM) and applied a second 20-kg mass, representing the backpack, 10 cm posteriorly and 5 cm below the torso CoM. We calculated the JCF between the femur and tibia in the longitudinal axis of the tibia for all subjects and averaged them across the two conditions.

Using ABAQUS v6.13 (Simulia, Pawtucket, RI) we created a finite element model including an average femur, tibia, menisci and cartilage using geometries obtained from OpenKnee v1 [4]. We defined the femur and tibia as analytical rigids, menisci as neo-Hookean materials and cartilages as a poroelastic neo-Hookean materials. We completed meshing using the sweep mesh functions in ABAQUS with cartilages defined using C3D4P elements and menisci using C3D4 elements. We simulated varying (two) levels of cartilage health (Healthy and OA) by changing material parameters, cf. Table 1. Simulations were ramped over corresponding time

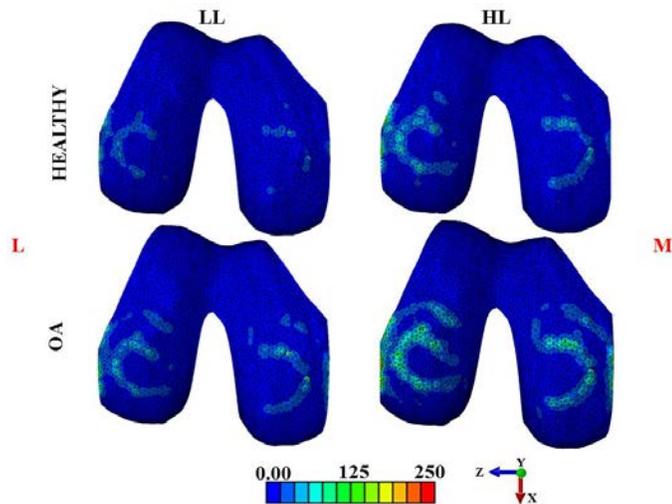

steps to the maximum JCF calculated from our corresponding OpenSim simulations for both conditions. We applied force to the proximal end of the femur, which was constrained in all degrees-of-freedom except for the axial direction. We constrained the tibia in all axes of rotation.

**Table 1.** Material properties for the FE model [5,6].

Material Properties	Healthy	OA	Menisci
	Cartilages	Cartilages	
$E$ (MPa)	0.5	0.28	28
$k$ ( $10^{-15} \cdot \frac{m^4}{N \cdot s}$ )	1	6	-
$\nu$	0.45	0.45	0.36

## RESULTS AND DISCUSSION

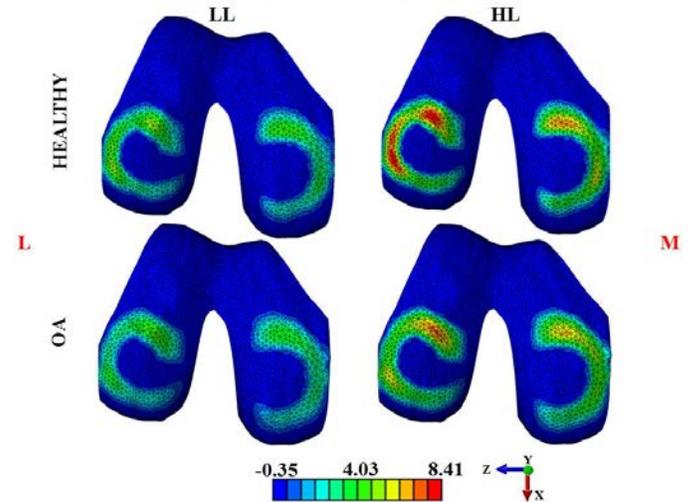

Averaged across 9 participants, the maximum JCFs were 1572.3 N and 2494.5 N for the LL and HL conditions, respectively. We applied these loads to the FE model to obtain distributions of solid von Mises stress and fluid pressure. Peak stresses were primarily distributed where cartilage had direct contact with the menisci, see Fig. 1. Stresses increased in the HL condition compared to the LL condition. The stress appears to be redistributed to the outside boundaries of the condyles in the OA tissue condition.

**Figure 1.** von Mises Stress (kPa) distribution for medial (M) and lateral (L) femoral condyles.

The largest fluid pressure (and thus load support) occurs in the healthy tissue during the HL condition, see Fig. 2. Healthy tissue has a lower permeability and thus generates higher interstitial fluid pressure under load to support increasing JCFs without

increasing shear stresses within the tissue. Increased shear forces may expedite the progression of OA.

**Figure 2.** Interstitial Pressure (mPa) distribution for medial (M) and lateral (L) femoral condyles.

In our model the primary load bearing surface appears to be the lateral condyle, while higher loads are typically expected in the medial condyle. We attribute this result to the neutral alignment of the femur with respect to the tibia and believe different results could be obtained if we included dynamic rotation of the knee in our simulations.

## CONCLUSIONS

Completing tasks with BBL will increase the amount of force to be distributed across the knee joint. Healthy cartilage provides fluid pressure load support to prevent increased shear stresses that compromise tissue health in the knee. The load carrying capacity of osteoarthritic joints is clearly comprised, resulting in greater intra-tissue stress concentrated particularly at the outside boundaries of the femoral condyles. With models like these, we intend to better understand the long-term impact of load carriage, both in healthy and osteoarthritic populations, in order to maximize the safety and longevity of soldiers, athletes and the general population.

## INTRODUCTION

With the advent of effective uniform treatment regimens and improved supportive care, the survival rate for pediatric cancers has improved dramatically over the past several decades with 80% of patients now cured of their disease [1]. Osteosarcoma (OST) is the most common malignant bony tumor of children and young adults, typically arising in the metaphyses of long bones during periods of rapid bone growth [2]. OST most commonly develops in the distal femur, proximal tibia, and proximal humerus. Standard treatment consists of chemotherapy. However, surgical resection is the mainstay of local tumor control and is necessary to ultimately achieve a cure. Several approaches to surgical resection are possible, including limb salvage procedures, amputation and rotationplasty. While surgical outcomes are generally associated with acceptable function and patient satisfaction, morbidity may include infection, gait dysfunction, chronic pain, or mechanical failure. This can lead to significant disability with a negative impact on quality of life.

Three-dimensional (3D) motion analysis is a well-established method for quantitative assessment of movement abnormalities in patients with motor impairments. However, there is limited evidence regarding gait abnormalities and associated strength deficits in young adult survivors of OST. The purpose of this study was to assess kinematic and kinetic abnormalities, as well as isokinetic strength deficits in young adult survivors of OST.

## METHODS

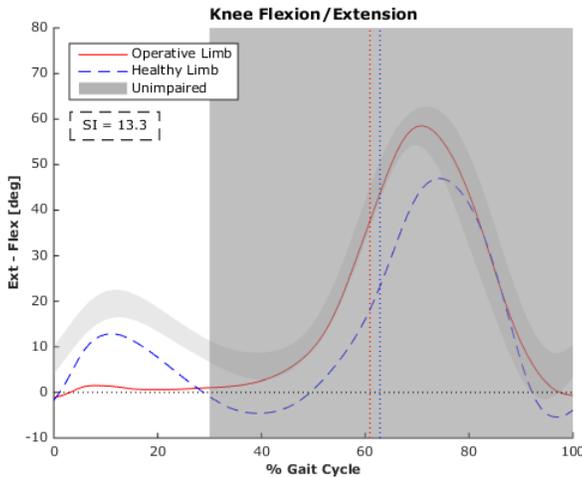

Nine young adult survivors of OST were recruited for the study (age:  $24.4 \pm 4.6$  years). Eight of the subjects previously underwent surgical intervention for tumor resection and limb salvage. Study

participation required a single visit to the Motion Analysis Lab (MAL) for testing ( $5.5 \pm 3.3$  years post initial surgery). Subjects were instrumented with 40 reflective markers on the torso and lower extremity, following a modified Helen Hayes marker set. Lower extremity kinematics and kinetics were measured during gait using a 12-camera Raptor4 system (Motion Analysis Corp.; Santa Rosa, CA) with four force plates embedded in the walkway (AMTI; Watertown, MA). Data were captured using MAC Cortex software and post-processed in Visual3D (C-Motion, Inc; Germantown, MD). For this analysis, sagittal plane knee biomechanics were assessed during the first 30% of the gait cycle for both the operative and healthy sides. Symmetry index (SI) was measured as the summed differences in joint angle (or moment) between the operative and healthy limb normalized to total range of motion; higher SI values corresponded to greater asymmetry.

Knee flexion/extension torque was measured via isokinetic strength testing using the Biodex System 4 dynamometer (Biodex Medical Systems, Inc; Shirley NY). Each participant performed a series of flexion/extension cycles at two speeds ( $60^\circ/\text{s}$  and  $180^\circ/\text{sec}$ ). The healthy side was tested first. Verbal encouragement was provided throughout testing, with the participants directed to perform the cycles at full effort and as fast as possible through the full range of motion. During each series of cycles, continuous angle position and torque data were collected from the dynamometer. Each time-series of the cycles were assessed for key angle/torque measures, and peak torque deficits were calculated as the percentage difference between the operative and healthy limbs for the quadriceps and hamstrings. Deficits were calculated as:  $1 - \frac{\text{operative peak torque}}{\text{healthy peak torque}}$

## RESULTS AND DISCUSSION

Blunted knee flexion (Figure 1) and extension demand were observed for patients with higher SI values. Strong correlation was measured between knee angle SI and quadriceps peak torque deficits at both speeds (60 °/s:  $R^2 = 0.93$ ; 180 °/sec:  $R^2 = 0.75$ ). Moderate correlation was measured between knee moment SI and quadriceps peak torque deficits at both speeds (60 °/s:  $R^2 = 0.63$ ; 180 °/sec:  $R^2 = 0.55$ ) (Figure 2).

**Figure 1:** Representative sagittal knee kinematics.

Higher SI values and strength deficits were linked to patients with femoral resections. Femoral resection required a prosthetic implant that was designed to allow  $\sim 5^\circ$  of hyperextension to unload the quadriceps during standing and single leg stance. However, some patients regained strength and symmetry

demonstrating that the implant did not automatically lock a patient into a weak leg and hyperextension pattern.

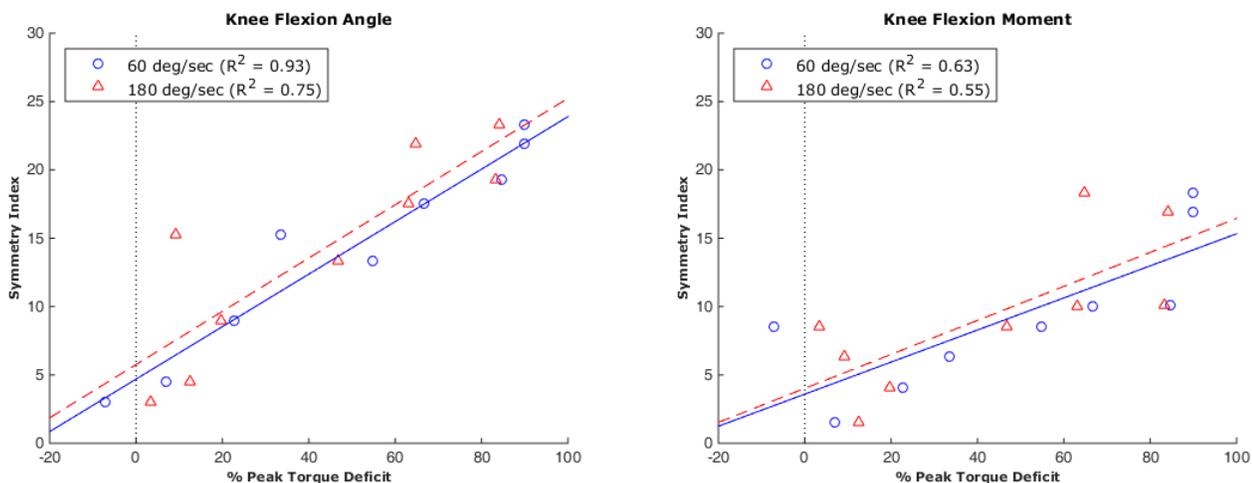

Quadriceps weakness may contribute to the lack of extensor mechanism in the operative limb for patients with greater asymmetry. The limb may have inadequate eccentric strength required to control the flexion response during weight acceptance. Focusing on strength symmetry during rehabilitation may promote improved biomechanical outcomes. A comparison cohort of unimpaired walkers demonstrated knee kinematic and moment SI values of  $5.5 \pm 2.0$  and  $4.1 \pm 2.2$ , respectively. These values corresponded to strength deficits of approximately 20%, which may serve as a quantifiable target during the rehab process.

## CONCLUSIONS

This study demonstrates a link between isokinetic asymmetry and biomechanical asymmetries in the operative and healthy limbs of young adult survivors of OST. Future studies should investigate the biomechanical response to a quadriceps strengthening program in young adult survivors of OST.

## INTRODUCTION

Total knee arthroplasty (TKA) is a popular surgical solution to patients suffering from osteoarthritis, with numbers projected to reach 3.48 million by 2030 [1]. Multi-radius (MR) and single-radius (SR) TKAs are two popular design concepts (fig 1). The femoral condyles were first hypothesized to exhibit a single radius of curvature during knee flexion. The last century of research is in agreement that the femoral condyles have a multi-radius curvature with shifting center of rotation during knee flexion [as reviewed in 2]. However, despite greater similarity to the anatomical knee joint, the MR design does not improve walking over SR designs [3].

Previous research in our laboratory found that the SR design TKA more closely replicates normal walking kinematics and kinetics than the MR design. Specifically, knees implanted with MR TKAs had decreased knee flexion and power absorption than SR during level walking [3]. However, during the stance phase of walking knee flexion angle is minimal. Therefore, we aimed to answer whether MR designs more closely replicate normal knee kinematics and kinetics during daily living tasks that require high knee flexion during the loading phase, such as stair descent. We hypothesized that MR knees would more closely replicate the stair descent kinematics and kinetics of healthy age matched controls, than SR knees.

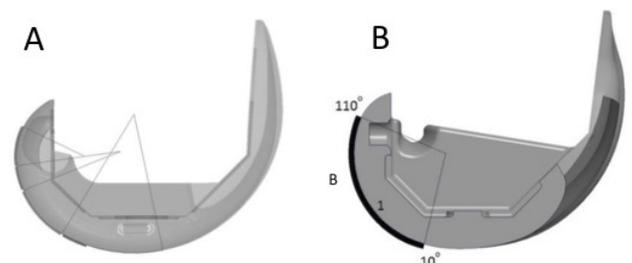

## METHODS

Three groups of subjects participated in accordance with IRB guidelines: TKA subjects with a SR (Stryker Triathlon® Total Knee Replacement System) design (n=8, m=87.4±18.53 kg.), TKA subjects with a MR (Biomet Vanguard Complete Knee System) design (n=8, m=84.3±13.63 kg.), and

age-matched healthy control subjects (n=8, m=76.4±9.22 kg.).

We collected data 1-year post-operatively using ten Eagle-4 digital IR cameras (EVaRT 5.0.4, Motion Analysis Corp., CA) at 120Hz. Subjects wore 28 reflective markers (modified Helen Hayes [4]) while walking at a self-selected pace down a staircase affixed to force platforms (AMTI, MA) sampling at 1,200Hz for at least 5 step cycles.

Orthotrak 6.2.8 (Motion Analysis Corp.) was used to calculate joint kinematic and kinetic parameters. Individual trials for each subject were averaged using the Orthotrak multi-trial processing module. Statistical comparisons of kinetic and kinematic parameters (minimum/maximum of knee angles, moments, and power) were performed with an ANOVA and Tukey's post-hoc analysis using a custom written R programming script (www.r-project.org),  $\alpha = 0.05$ .

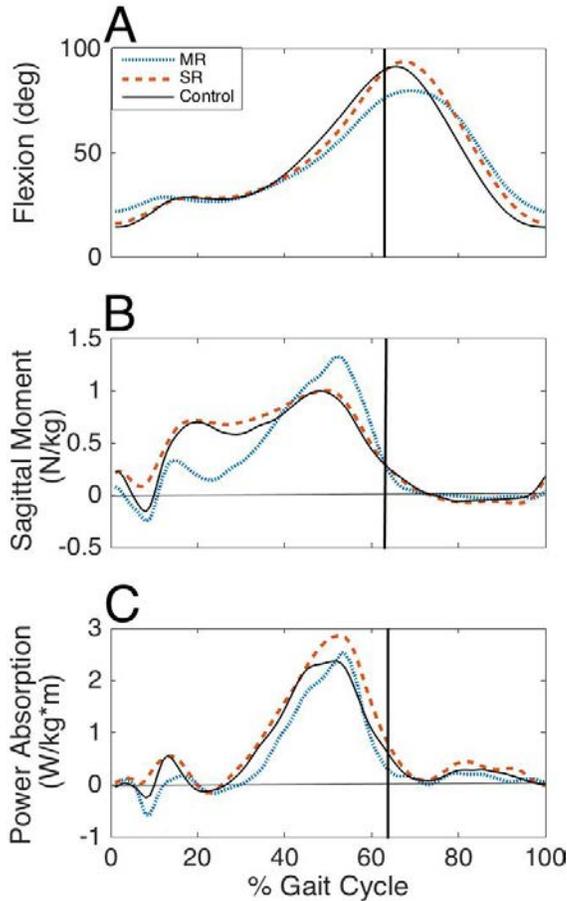

**Figure 1:** Representative multi-radius total knee design (A) and single radius design (B).

## RESULTS

For all three groups knee kinetics and kinematics are comparable to previous research on stair descent [5]. No differences were observed for peak knee abduction angle or frontal moment between the groups ( $p>0.32$ ). The minimum sagittal moment during stance for both the SR and MR knees were both significantly higher than the controls ( $p=0.02$ ,

p=0.05). The peak power absorption was significantly less for SR than MR (p=0.02), but neither was different than the controls (table 1). There were no differences in step width between groups, indicating that the groups may have similar levels of dynamic stability, i.e. neither requires a 'cautious' gait to prevent falling (p=0.62) [6].

**Figure 2:** Sagittal plane knee flexion (A), moment (B) and power (C) over one gait cycle.

**DISCUSSION**

In contrast to the previous research on level walking, we did not find any significant differences

in knee flexion or peak sagittal moment during stair descent. This may be due to the constraints of the task (i.e. the foot must be placed within the stair dimensions). Although the differences are not enough to establish significance, the MR knees exhibit decreased knee flexion and increased stance moment.

We also found that similar to level walking, peak power absorption during stance is significantly less for the MR compared to SR [3]. This can be attributed to the lower angular velocity for MR patients (fig 2). The MR knee has a reduced radius of curvature at greater knee flexion, reducing the superior-inferior distance of the tibia and femur. This may contribute to laxity of the collateral ligaments, and alter the mechanics of the knee at greater flexion angles [discussed in 3].

**CONCLUSIONS**

Both, MR and SR TKA devices were able to closely replicate normal stair descent kinetics and kinematics. The initial trends suggest that the MR knee performs differently to SR knees especially at higher flexion angles, but statistical power must be improved (via increased sample size) before stronger conclusions can be made.

## INTRODUCTION

Nearly 50% of all injuries sustained by athletes are to the lower extremities. Approximately 200,000 of these lower extremity injuries occur to the anterior cruciate ligament (ACL) each year, half of which require surgery and/or rehabilitation. Unfortunately, these patients are 15 times more likely to re-injure themselves within the first year of surgery, and only half return to their prior level of activity [1]. Much research has focused on knee mechanics and rehabilitation in patients who have undergone ACL reconstruction (ACL/R) surgery. These studies commonly exclude patients with damage to other structures of the knee. However, at least 50% of ACL-related injuries occur in conjunction with damage to the meniscus, articular cartilage, and/or other ligaments [2].

Since most patients incur injuries involving multiple structures of the knee, it is necessary to expand research and understanding of knee mechanics and muscle activation in these cases. Additionally, there may be key features in patients post ACL/R that apply to patients with complex knee injuries. For instance, it is well-known that ACL/R patients often demonstrate limb asymmetry even after they return to sport, which may be a factor associated with high re-injury rates. Altered muscle activation timing may be an underlying cause to these asymmetries [3]. Prior reports, however, are inconsistent in describing changes in muscle activation timing for patients post ACL/R, and to our knowledge, no studies have compared muscle activation timing in patients with various combinations of knee injuries.

Therefore, the purpose of this case series is to describe knee mechanics and muscle activation timing in athletes with complex knee injuries. These steps are important for guiding research that will

further examine a more diverse knee injury population and contribute to rehabilitation decisions that will help to reduce the risk of re-injury when returning to sport.

## METHODS

Knee mechanics and muscle activation timing in three individuals with different sports-related knee injuries (Age:  $20 \pm 4$  years; 2 males; Time post-surgery:  $20 \pm 6$  weeks) were assessed using three dimensional kinematics, kinetics and surface electromyography (EMG). Individuals performed five repetitions of the single leg land bilaterally from an 8" box, a task commonly used during return to sport rehabilitation testing. Kinematic and kinetic data were used to compare symmetry across subjects, and the symmetry index (SI) was defined:

$$SI = \frac{\text{Uninvolved Limb} - \text{Involved Limb}}{\text{Uninvolved Limb}} \times 100\%$$

where an increase in SI represents greater asymmetry. Data were also collected from a healthy control to provide a basis for comparison (Age: 24 years; Male).

EMG data were collected from the vastus medialis oblique (VMO) during the single leg land. Muscle activation timing during the preparatory phase of landing was evaluated as this phase has previously been identified as a critical time point for knee stabilization. The preparatory phase was defined as 100 ms prior to initial contact, defined as the time point when the foot contacted the force plate [4]. EMG data were demeaned, rectified and smoothed using a fourth order low-pass Butterworth filter with a 10 Hz cutoff frequency. A threshold of 25 times baseline activity was defined as the onset of muscle activation.

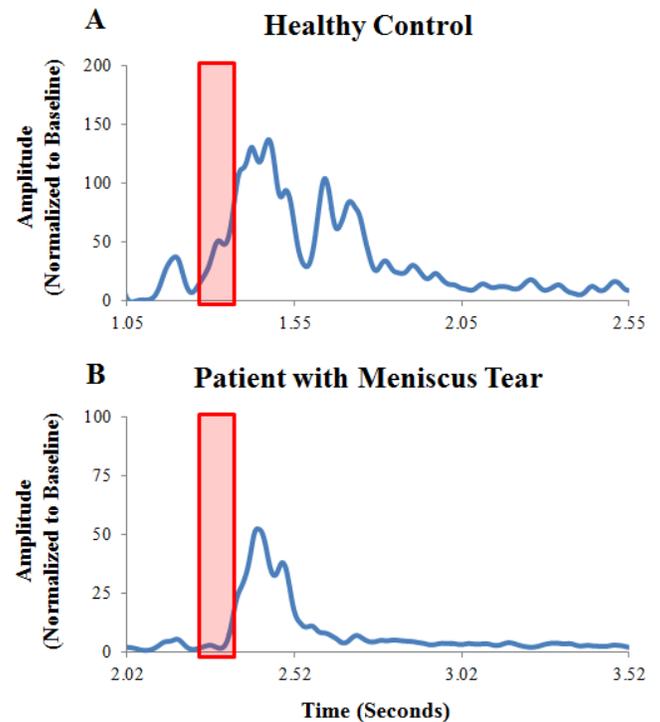

## RESULTS AND DISCUSSION

Lower limb asymmetries were evident in patients with knee injuries based on the peak internal knee extensor moment and peak knee power absorption at landing (Table 1). Specifically, the healthy control demonstrated more symmetry for the peak moment and power with an SI of 7.2% and 19.6%, respectively, contrasting from the injured subjects (average peak moment and power SI for injured subjects: 25.2% and 38.5%, respectively). Additionally, delayed muscle activation timing for the VMO was present for subjects 01 and 02 (Table 1, Fig. 1) as compared to the healthy control. More specifically, the onset of muscle activation for the healthy control occurred 40.6 ms into the preparatory phase, differing from subjects 01 and 02 who did not achieve muscle activation until after initial contact.

It has been suggested that patients post ACL/R use imbalanced force absorption strategies, resulting in decreased knee extensor moments on the involved limb [5]. Our findings align with this evidence as all three subjects displayed reduced knee extensor moments on the involved side during landing. Each subject also showed reduced peak knee power absorption at landing on the involved limb which is consistent with previously reported data on the ACL/R population, suggesting that a stiffer landing strategy is possibly being applied.

The results from the EMG data suggest that muscle activation timing is altered in patients with knee injuries. It is well-established that the quadriceps play a major role in stabilizing the ACL during landing [6]. Therefore, delayed activation of the VMO could increase the risk for re-injury, as the quadriceps may not be activating soon enough to provide the appropriate amount of stability.

In summary, the results from this case series provide insight for clinicians that treat athletes with complex knee injuries. These results suggest that

**Figure 1:** Muscle activity of the VMO for the A) left leg of the healthy control and B) involved leg of the patient with a meniscus tear. The shaded box represents the preparatory phase (100 ms) prior to initial contact.

patients who have incurred damage to multiple structures of the knee exhibit altered knee mechanics and muscle activation similar to what has previously been reported on the ACL/R population. By understanding a more diverse knee injury population, targeted rehabilitation programs can be developed to reduce the risk of re-injury in athletes who are returning to sport.

## INTRODUCTION

Total knee arthroplasty (TKA) is the most common surgical procedure to overcome end-stage osteoarthritis (OA) in the knee joint. In the US, more than 700,000 TKA surgeries are performed annually, to which 97% of those due to OA [1]. Within 10 years of the primary TKA, almost 50% of patients undergo a secondary TKA on the contralateral limb due to OA progression [2].

Individuals with end-stage knee OA exhibit asymmetric knee joint loading. This asymmetry is believed to compensate for pain and weakness in the affected limb [3]. While TKA effectively relieves knee joint pain, asymmetric kinematics/kinetics persist post-operation [4]. Post-TKA asymmetric gait patterns use greater joint loading, knee adduction moment and shorter stride length in the non-surgical limb, while showing lower knee flexion angles and shorter stance phase in the surgical limb [5]. It is thought that by shifting more load on the non-surgical limb, the chances of contralateral OA may increase [6]. However, it is difficult to assess loading in clinical settings as the needed equipment can be prohibitively expensive.

Thus, the purpose of this study was to investigate if spatial temporal measurements predict inter-limb loading asymmetry during walking in patients after TKA. We hypothesize that spatial-temporal asymmetry will be positively correlated with loading asymmetry post-TKA.

## METHODS

18 individuals after TKA participated in this study (Table 1). Data were collected using an instrumented split-belt treadmill (Bertec Corp. Columbus, OH) and an 8-camera motion capture system (Motion

Analysis Corp. Santa Rosa, CA). Kinematic data were sampled at 100 Hz and the force data were sampled at 2000 Hz. Subjects performed the 6-meter walk test to determine self-selected (SS) and fast speeds. One-minute walking trials for each speed (SS & fast) were recorded.

Table 1. Subject Information	Mean (SD)
Age	66.1 (5.8)
Mass (kg)	88.4 (19.0)
Height (m)	1.7 (0.1)
Self-Selected Speed (m/s)	1.1 (0.2)
Fast Speed (m/s)	1.4 (0.2)
Time Post-TKA (months)	11.8 (6.7)
Gender	9M/9F
Unilateral/Bilateral	8 Uni / 9 Bi
BMI	29.6 (5.3)

The kinetic and kinematic data were analyzed using Visual 3D (C-Motion Inc. Germantown, MD). Pearson correlation coefficients were calculated using SPSS Statistics (SPSS Inc, IBM Corporation). Inter-limb symmetry ratios were defined as  $S_x/\text{no}S_x$  value. Values above 100% indicate greater loading values on the surgical limb. VGRF values were normalized based on body weight (N/BW). Knee moments values were normalized on body weight multiplied by height (N/BW\*HT).

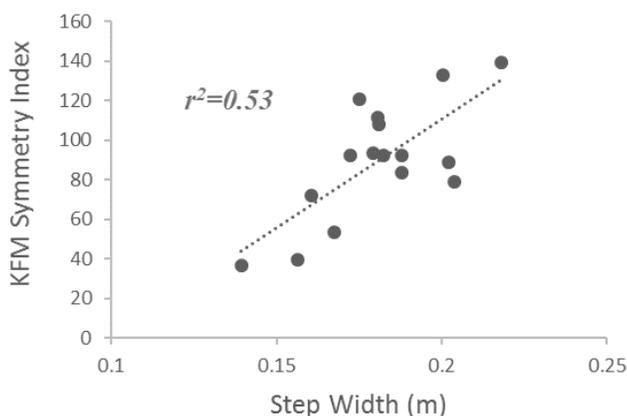

## RESULTS AND DISCUSSION

Overall, no correlation was found between spatial-temporal (stride length, step length, step time) and loading (1&2 peak VGRF, knee flexion moment, and knee adduction moment) symmetry, with the exception of stride width. Stride width symmetry showed a significant correlation with knee flexion moment symmetry ( $r^2=0.53$ ,  $P<0.001$ ) during fast walking trials (Figure 1). These results not only specify step width as an indicator of knee moment flexion asymmetry, but also suggests that there may exist an optimal range of stride width that is correlated with knee flexion moment symmetry. It

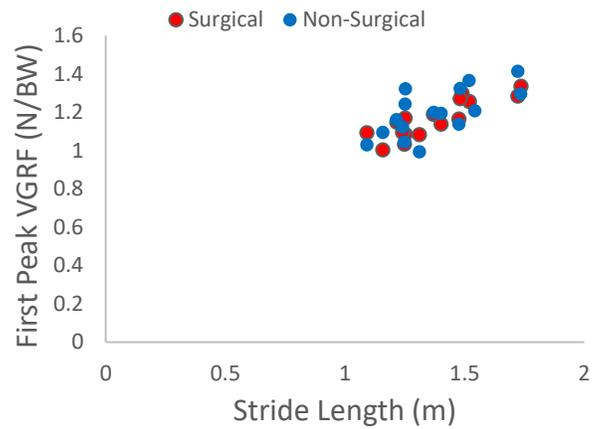

has been previously shown that a wider step width decreases the first knee adduction moment peak in healthy adults [7], but at the cost of increased knee flexion moment while no investigations have been done in post-TKA.

Subjects demonstrated inter-limb loading asymmetry post-TKA, but the direction of asymmetry varied between subjects (Table 2). Patients shifted more load on one limb, which is thought to be the cause of OA progression on the contralateral limb [6]. Within limbs, results showed correlations between stride length and 1st peak VGRF during self-selected (Sx  $r^2=0.49$ , NSx  $r^2=0.48$ ) and fast (Sx  $r^2=0.73$ , NSx  $r^2=0.46$ ) walking, but no significant correlation was recorded between symmetry indices during self-selected and fast walking. This indicates that as stride/step length increases, first peak vertical ground reaction forces increase, but these measurements do not adequately describe VGRF asymmetry post-TKA (Figure 2).

Table 2. Kinetic Symmetry Results			
	Symmetry Index	SS (1.09 m/s)	Fast (1.4 m/s)
Peak Knee Adduction Moment (N.m/BW*HT)	Average	106.64%	110.18%
	Range	48-280%	42-270%
Peak Knee Flexion Moment (N.m/BW*HT)	Average	90.01%	89.70%
	Range	16-151%	36-139%
1st Peak VGRF (N/BW)	Average	97.92%	97.77%
	Range	90-106%	82-109%
2nd Peak VGRF (N/BW)	Average	98.68%	98.05%
	Range	90-106%	87-103%

**Figure 1.** Correlation between step width and peak knee flexion moment symmetry at fast walking speed.

**Figure 2.** Correlation between stride length and 1<sup>st</sup> peak VGRF for surgical and non-surgical limbs at fast walking speed.

## CONCLUSIONS

A significant correlation between stride width and knee flexion moment symmetry index was found, though no other significant correlation between spatiotemporal and loading symmetry indices at either self-selected or fast walking speeds was recorded post-TKA. Future work should examine the mechanisms related to stride width and loading in a TKA population, as well as exploring individual step width in relation to center of mass. Dividing step width into single limb variables will allow exploration into whether asymmetric foot placement is a driving factor in loading asymmetries post-TKA. Overall, however, these findings indicate that clinically accessible methods to assess joint loading are needed to assess interlimb loading asymmetry in post-TKA patients, as simple spatiotemporal measures may not provide proper insight into loading asymmetry.

# FUNCTIONAL IMPLICATIONS OF MENSTRUAL CYCLE ON KNEE LAXITY, RATE OF FORCE DEVELOPMENT AND ELECTROMECHANICAL DELAY

David Hawkins and Amber Sorensen Van Cleave

University of California Davis, CA, USA  
email: dahawkins@ucdavis.edu, web: <http://hpl.ucdavis.edu/>

## INTRODUCTION

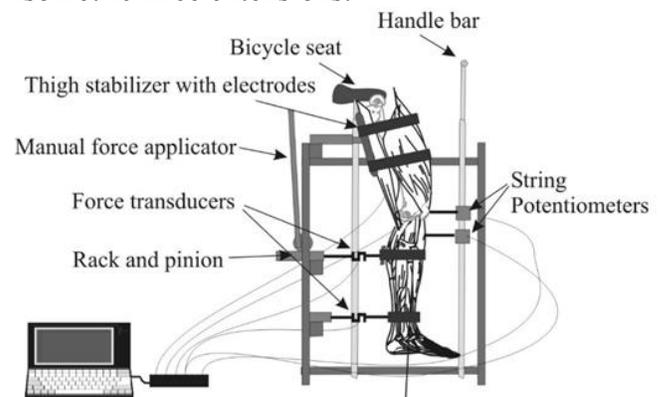

Ligament and tendon stiffness affects physical performance and injury risk. Evidence indicates that ligament/tendon stiffness can be affected by fluctuations in hormone levels in women [1], with increased estrogen concentrations associated with decreased collagen synthesis and fibroblast proliferation. Serum estradiol concentrations are typically lowest and highest just before the start of menses and ovulation, respectively [2]. Based on this evidence, it is reasonable to expect that ligament/tendon stiffness would be highest around the start of menses and lowest around ovulation. However, the functional implications of the menstrual cycle on ligament/tendon stiffness are not clear. Several studies have reported no significant effect of estrogen levels throughout the menstrual cycle on knee laxity in women [e.g., 3], while other studies reported significant associations [e.g., 4]. If there are strong functional implications, then there should be differences in functional measures of ligament/tendon stiffness between the start of menses and ovulation.

The purpose of this study was to test the hypothesis that ligament/tendon stiffness is greater at the start of menses compared to ovulation in healthy young women. To achieve this goal, 3 indirect measures of ligament/tendon stiffness; anterior knee laxity (AKL), knee extension rate of force development (RFD), and knee extension electromechanical delay (EMD), were compared between the start of menses and at ovulation over 3 months.

## METHODS

Twenty females, who ranged in age from 18 to 26 years old ( $22 \pm 2$  years, mean  $\pm$  SD) and had a regular menstrual cycle, were recruited. All protocols were approved by the University of California-Davis Institutional Review Board.

AKL, RFD and EMD were quantified using a custom knee arthrometer (CKA) (Fig 1) [5]. Subjects performed a standard 10 minute treadmill walking protocol to warm-up. They were then positioned in the CKA with their right knee secured in a 25-30 degrees flexed position. AKL tests were performed, followed by tests of maximum effort isometric knee extensions.

**Figure 1:** Custom knee arthrometer used to quantify AKL, RFD and EMD.

During the AKL test, a  $\sim 2$  second cyclic anterior force (-50 to 250 N) was applied 20 times through a force sensor (LC101-50, Omega Inc, Stamford, CT) positioned on the upper portion of the lower leg while displacement of the tibia relative to the femur was recorded using 2 string potentiometers (SP1-4, Celesco, Chatsworth, CA). Electromyography was used to monitor the activity of the quadriceps and hamstrings. AKL was quantified as the average relative tibial displacement at a 200 N force for the last 10 cycles.

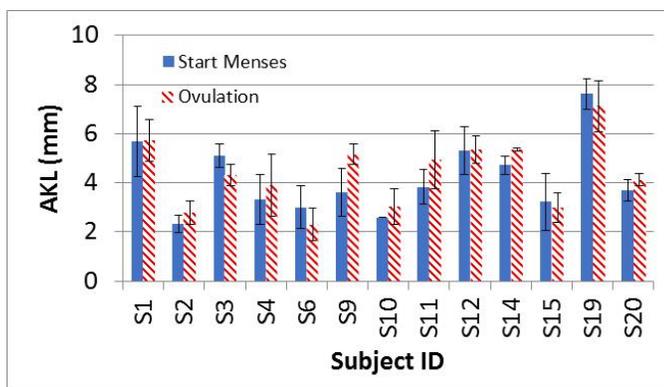

Following the knee laxity test, the strap located approximately 10 cm distal to the knee was removed and the subject performed 4 maximum effort isometric knee extension efforts with each effort separated by approximately 2 seconds. The force developed at the ankle to restrain the leg from moving was recorded along with the muscle activation. The time from the initiation of

quadriceps muscle activation to the time force was detected at the ankle (i.e. EMD), as well as the maximum slope of the force-time response (i.e. RFD) were determined. These tests were repeated for 3 months on the day of the start of menses and on the day of ovulation, determined using ovulation test strips (One Step Ovulation Test Strips, Babi, Beijing, China). A paired T-Test was used to compare the average AKL, RFD, and EMD between start of menses and at ovulation. Significance was set at  $p < 0.05$ .

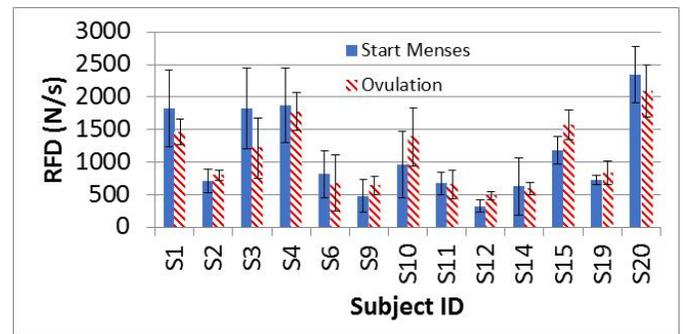

## RESULTS AND DISCUSSION

Among the 20 subjects who enrolled, 7 chose to discontinue their participation for various reasons. Data from 13 subjects were considered in the analysis.

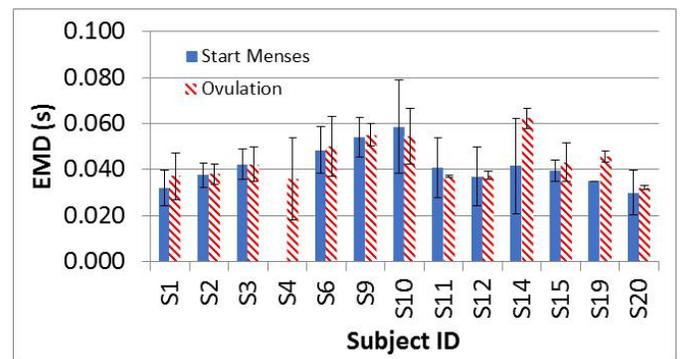

The group averages for AKL, RFD, and EMD at start of menses and at ovulation were 4.15 mm and 4.39 mm, 1107 N/s and 1093 N/s, and 0.041 s and 0.044 s, respectively. These averages are consistent with the stated hypothesis. If ligament/tendon stiffness is greater at the start of menses compared to ovulation, then AKL should be lower, RFD greater, and EMD lower at the start of menses compared to ovulation. However, AKL, RFD, and EMD responses varied between subjects (Figs 1-3), and there were no significant differences in AKL ( $p=0.23$ ), RFD ( $p=0.86$ ), and EMD ( $p=0.13$ ) between paired averages at the start of menses and at ovulation.

**Figure 1:** Average ( $\pm 1$  std dev) of anterior knee laxity (AKL) for each subject at the start of menses and at ovulation.

**Figure 2:** Average ( $\pm 1$  std dev) knee extension rate of force development (RFD) for each subject at the start of menses and at ovulation.

**Figure 3:** Average ( $\pm 1$  std dev) knee extension electromechanical delay (EMD) for each subject at the start of menses and at ovulation. EMD was not successfully recorded at menses for S4.

## CONCLUSIONS

Based on the evidence from this study, there are no generalized functional implications of menstrual cycle on ligament/tendon stiffness.

# FEA of Lateral Meniscus Posterior Root Avulsions on Tibiofemoral Contact Mechanics

<sup>1</sup>Erika Fojtik, <sup>2</sup>Andrew Geeslin, <sup>1</sup>Peter Gustafson

<sup>1</sup>Western Michigan University, Kalamazoo, MI, USA

<sup>2</sup>Borgess Orthopedics, Kalamazoo, MI, USA

Email: [erika.g.fojtik@wmich.edu](mailto:erika.g.fojtik@wmich.edu)

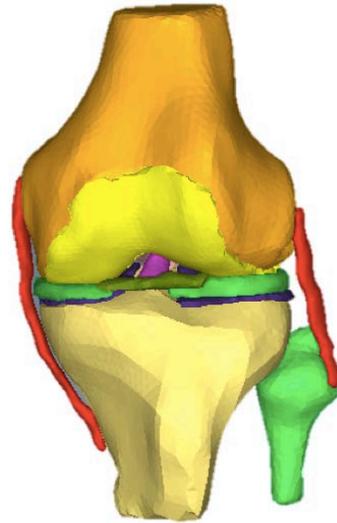

## INTRODUCTION

The effects of lateral meniscus posterior root avulsions have been studied in combination with intact meniscofemoral ligaments (MFLs) and deficient MFLs to understand the changes in contact mechanics in the knee and to determine the function of the MFLs. This study was done to validate a patient-specific finite element model (FEM) of a knee against experimental data conducted on cadaveric knees to study the effects of posterior root avulsions of the lateral meniscus.

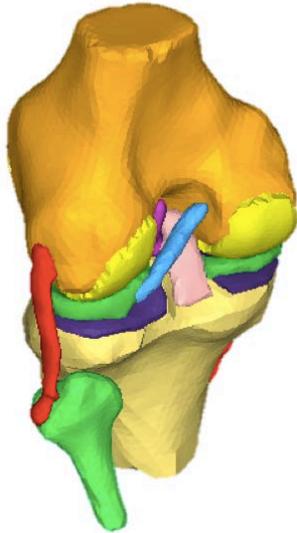

## METHODS

Magnetic resonance imaging (MRI) was used with 3D Slicer segmentation software to develop the finite element model. Anatomical structures included in the model are the anterior cruciate ligament (ACL), femoral cartilage, femur, fibula, lateral and medial collateral ligaments (LCL/MCL), medial and lateral meniscus, posterior cruciate ligament (PCL), posterior meniscofemoral ligament (pMFL), tibia, and tibial cartilage. The anterior meniscofemoral ligament (aMFL) was omitted from this study due to its lack of presence in the knee. Hypermesh software was used for mesh generation and refinement. Tetrahedral elements were globally used for the model. The model generated from

Hypermesh is shown in Figures 1 and 2 for the anterior and posterior views, respectively. From the model, the following conditions are explored: (1) intact, (2) lateral meniscus posterior root avulsion (LMPRA), and (3) deficient pMFL and LMPRA. The model of each condition maintains a fixed flexion angle of 0° under a 1000 N compressive load. Model outputs include contact pressure and distribution in the tibiofemoral contact region.

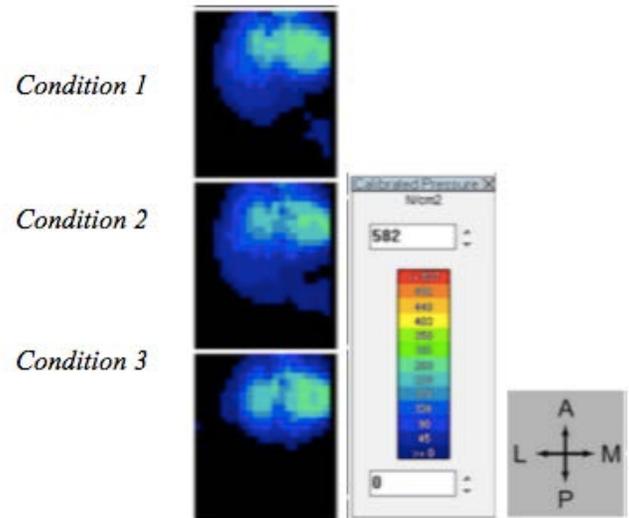

**Figure 1:** Anterior perspective of the knee model in Hypermesh.

**Figure 2:** Posterior perspective of the knee model in Hypermesh. Posterior meniscofemoral ligament (pMFL) shown in light blue.

## RESULTS AND DISCUSSION

A preliminary set of finite element analyses (FEA) will provide contact pressures and distributions across the tibiofemoral contact region to compare and validate with experimental data. The given experimental data from Geeslin et al. resulted in pressure mapping shown in Figure 3 for the three aforementioned conditions [1]. This work concluded that lateral meniscus posterior root avulsions reduce contact pressure (peak) by 6.1% in the lateral compartment [1]. The absence of the meniscofemoral ligaments, in combination with LMPRA, results in a more severe increase in contact pressure (peak) of 28.2% [1].

**Figure 3:** Contact pressure maps of the lateral compartment from experimental study done by Geeslin et al. for condition (1) intact knee, (2) LMPRA, and (3) LMPRA and pMFL deficiency. (These graphics were modified with permission from Geeslin [1].)

Development of musculoskeletal finite element models, especially those validated against laboratory experimentation, are critical to describe the biomechanics of dynamic axial loads, rotational loads, and shear stress incident upon the knee. The preliminary results are intended to provide data and insight for future validation of intact and structurally deficient knee joint models. Clinical relevance is based on providing orthopaedic surgeons with an improved knowledge of the biomechanical consequences of the available repair techniques of lateral meniscus posterior root avulsions, and thus improved capability for surgical decision making.

# **SURFACE STIFFNESS AND KNEE JOINT LOAD EFFECTS WHILE RUNNING**

Victoria A. Price, Daniel J. Kuhman, Stacey Meardon, J. C. Mizelle, Paul DeVita  
Biomechanics Laboratory, Department of Kinesiology, East Carolina University, Greenville NC

## **Introduction:**

Running shoes and surfaces have been developed to help enhance running efficiency and to alter ground impacts by changing the total surface stiffness<sup>3</sup>. Similar to a massed spring, an individual contacts the running surface, flexes their lower limb joints, and stores strain energy through the muscles, tendons, and ligaments. This stored energy is then released back to the limb and the limb joints extend and propel the individual into the next stride<sup>4</sup>. However to maintain global running mechanics, an individual will increase leg stiffness while running across a compliant ground surface and conversely decrease stiffness on harder surfaces. Increasing leg stiffness causes landing impact forces to increase<sup>2</sup> and potentially may counteract beneficial effects of impact load reduction while running on a softer surface. The knee is a determinant for reducing impact forces and changing leg stiffness<sup>2</sup>. Knowing more about knee joint forces while running on surfaces with different stiffnesses has the potential to improve injury prevention strategies.

It was our objective to determine the effect of surface stiffness on knee joint contact forces during running. We expected forces to remain consistent across different surface stiffnesses secondary to leg adjustments. Thus, our hypothesis was that knee joint loads would not be statistically different across varying levels of surface stiffness.

## **Methods:**

We recruited 17 healthy recreational heel strike runners. They provided written informed consent and ran across a 15m track at a consistent pace ( $3.46\text{m/s} \pm 5\%$ ) on 3

ground conditions (hard floor with embedded force plate and 1 and 2 layers of 1.6cm thick Shore00 65 of shock absorbing mat covering the hard surface condition). The study protocol took place over 2 days. On day 1, participants were able to practice running over the various ground conditions at the test speed, on day 2, data were collected. Five successful trials per surface condition were collected using an 8 camera motion capture system (Qualisys Tracking Manager). Kinematic and kinetic data were analyzed through V3D and Quick Basic, and knee joint tibio-femoral (TF) and patella-femoral (PF) forces were estimated through musculoskeletal modeling<sup>1</sup>. Knee joint angular stiffness was also calculated by finding the ratio of the peak torque at the knee joint, simultaneous to the knee joint angular displacement. Data were statistically compared among surface conditions with a one way ANOVA, using three levels and  $\alpha < 0.05$ .

## **Results and Discussion:**

Compressive PF and compressive TF forces were not significantly different between surface conditions supporting our hypothesis. However, knee joint angular stiffness, the rate to the vertical GRF impact peak (vGRF), maximum anteroposterior braking force, and TF shear force for both force magnitude and rate to the maximum force were found to be statistically different and decreased as the surface stiffness decreased (all  $p < 0.03$ ).

Post-hoc testing revealed that knee joint stiffness was less in the softer surface conditions compared to the stiffest condition. Rate to the vGRF impact peak,

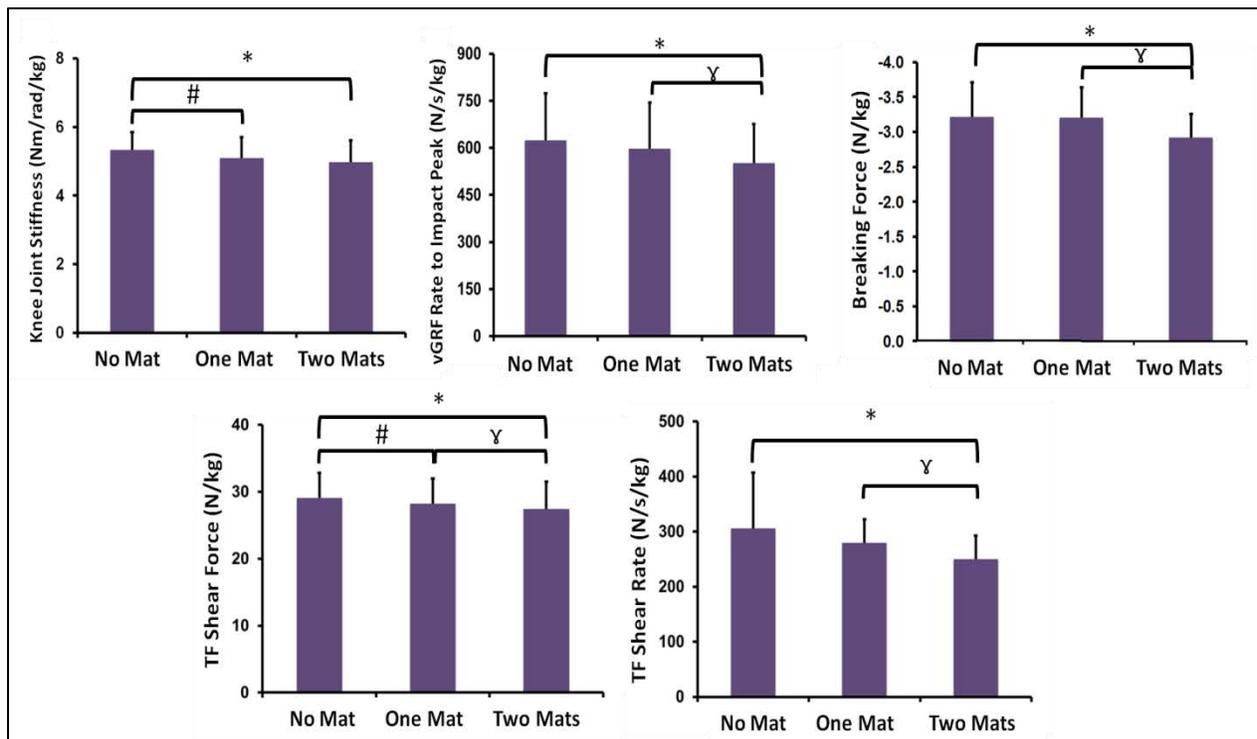

maximum anteroposterior breaking force, and the rate to the maximum TF shear force were statistically different between the softest surface stiffness and the stiffer conditions (all  $p < 0.05$ ). Maximum TF shear force post-hoc tests indicated that all stiffness conditions were statistically different from each other (Figure 1).

Our hypothesis was partially supported for knee joint compressive loads but not for the shear loads. As the participants ran across the increasingly dampened surfaces their knee joint angular stiffness decreased. This is contrary to existing literature that suggests an inverse effect between surface stiffness and leg stiffness, which is closely related to knee joint stiffness. In addition, the rate to the vGRF impact peak and the breaking force magnitude decreased with the surface

stiffness. Our data supported the idea that running across differing surface stiffnesses does not statistically alter knee joint compressive forces but can reduce knee joint shear forces. Future research should determine if this strategy is beneficial to a broader range of individuals including those with fore- and mid-foot strike patterns.

## INTRODUCTION

The quadriceps is a powerful muscle group that plays a significant role in many activities of daily living and sports. This group of muscles produces movement at both the hip and knee joint. The knee is a complex joint that must withstand a great deal of stress. The amount of stress placed on the knee puts the joint at risk of injury, dysfunctional movement, and pain.

Patellofemoral pain, also known as anterior knee pain, is one of the most frequent knee conditions seen by sports medicine providers [1]. Dysfunctional tracking of the patella is thought to be a possible cause of such knee pain. There is controversy related to whether or not weakness in the vastus medialis portion of the quadriceps muscle plays a critical role in patellar tracking. It is thought that weakness in the vastus medialis will cause the patella to track laterally.

It has been shown that asymmetric quadriceps loading leads to an alteration in the mediolateral forces [2]. The purpose of this project was to determine if reduced maximal strength of the vastus medialis will cause optimized muscle forces in a musculoskeletal model to increase laterally directed patellar forces or patellar torsion.

## METHODS

Seven young adults (3 males, age: 21.3±2.1 yr; body mass: 68.9±6.7 kg; height: 1.84±0.07 m and 4 females, age: 25.3±5.2 yr; body mass: 56.6±11.3 kg; height: 1.64±0.08 m) with no lower limb injuries and a heel toe running style volunteered to participate.

Running motion data were recorded simultaneously with ground reaction forces Kinematics at 200 Hz using 8 Vicon MX cameras (Vicon, Centennial, CO, USA) and force data at 1000 Hz (AMTI, Watertown, MA). Participants ran at 3.5 m/s with their right foot landing on the force platform.

Two models for each participant were constructed using Matlab. A rigid body model was used to estimate the joint moments using inverse dynamics and a musculoskeletal model was used to estimate length and velocity adjusted maximal dynamic muscle forces and moment arms of 44 muscles in the lower extremity [3]. Muscle forces required to produce the inverse dynamics joint moments were estimated using optimization techniques that minimized the sum of the muscle stress squared and were constrained to equal the moments found using the rigid body model. The moments used as constraints were in the sagittal plane at the ankle, knee and hip, as well as the ankle and hip moments in the frontal plane. The lower and upper bounds of the muscle forces were zero and the maximal muscle forces found using the musculoskeletal model, respectively.

The patellar tendon force was estimated using the quadriceps tendon to ligament force ratio [4]. The muscle and tendon forces acting on the patella were then summed and the medio-lateral directed force and the torsion were selected for analysis. The computer model was then altered to reduce the maximum force producing capabilities of the vastus medialis muscle. The optimization algorithm was applied to the new model and the resultant patellar forces and torsions were recalculated. Reductions of 10%, 20%, 30%, 40% and 50% of the normal vastus medialis force were examined. Peak medio-lateral forces and torsions were identified as a

present of the peak values in the original model. Paired t-tests were utilized to determine the effect of decreased vastus medialis force for each participant, with an alpha criterion of 0.05.

## RESULTS AND DISCUSSION

As expected, the reduced maximum force producing capabilities of the vastus medialis decreased its estimated muscle force. In turn, this increased the vastus lateralis muscle force in order to create enough extensor torque to produce the movement (Figure 1).

Peak patellar mediolateral forces were increased by 2.5% from the 100% condition to the 50% condition while peak patellar torsion was increased by 10.1%. Only the 50% and 60% conditions were statistically significantly different from the 100% condition in these two variables (Table 1).

It should be noted that these results are dependent on the orientation of the muscles relative to the patella. In the Arnold model, the vastus medialis, the vastus lateralis and the patellar ligament tend to pull the patella in a lateral direction. A more

complex model might be necessary to fully understand the loading of the patella. It should also be noted that this technique does not allow for alterations in the kinematics or joint moments that might occur during actual weakening of the vastus medialis muscle.

## CONCLUSIONS

The musculoskeletal model with optimization of muscle forces was able to model the effects of decreased vastus medialis strength. This resulted in small increases in laterally direct patellar forces and somewhat larger patellar torsions.

# EFFECTS OF AGE, GENDER, AND BMI ON MAXIMUM KNEE FLEXION IN SINGLE AND DUAL LEG BODYWEIGHT SQUATS

David Herlihy, Kevin O'Brien, and James P. Schmiedeler

Aerospace and Mechanical Engineering, University of Notre Dame, Notre Dame, IN, USA

email: dherlih1@nd.edu, kobrie23@nd.edu, schmiedeler.4@nd.edu

## Introduction

The bodyweight squat is often used for training and biomechanical evaluation, in part because of its similarity to many functional tasks [1]. Squat depth as measured by maximum knee flexion is a common performance metric, so squats may be categorized as partial, half, or deep/full based on that angle [2]. Being overweight, as measured by body mass index (BMI), is known to lead to reduced knee flexion in bodyweight squats [3]. The authors, however, found no literature quantifying differences in bodyweight squat depth associated with age or gender. Expanded use of motion capture systems for biomechanical analysis of large numbers of individuals performing standard motions like the bodyweight squat has enabled a dramatic increase in sample size for quantifying these differences. This work leverages such a data set to determine the effects of age, gender, and BMI on maximum knee flexion in both single and dual leg bodyweight squats.

## Methods

Data were collected from 1068 subjects who participated in biomechanical analysis activities using a markerless motion capture (120 Hz) (Organic Motion, New York, USA) and cloud-based analysis software (DARI, Kansas, USA) system through their employers or educational institutions. All subjects self reported as being healthy and gave their informed consent to have their data, including height, weight, age, and gender, shared without personal identifiers for research and development purposes prior to data collection. This study was approved by the appropriate Institutional Review Board.

The subjects were divided into four groups by age and gender: 133 older males (age range 40-77 years; mean  $\pm$  std dev:  $52 \pm 8.37$  years); 220 older females (40-72:  $51.8 \pm 7.71$  years); 407 younger males (18-24:  $20.3 \pm 1.38$ ); and 308 younger females (18-31:  $21.4 \pm 3.6$ ). Each subject was instructed to perform a dual leg bodyweight squat, a single-leg bodyweight

squat with the left leg, and a single-leg bodyweight squat with the right leg. No instructions about arm placement during the squats were given. The number of other activities each subject performed in his/her data collection session varied. The DARI software computes a large number of kinematic and kinetic quantities for each motion, but this work exclusively analyzed maximum knee flexion angle for each leg.

BMI was computed for each subject as mass in *kg* divided by the square of height in *m*. All data analysis was performed using the software R. An initial multi-factor ANOVA considering all 1068 subjects was used to determine the effects of age, gender, and BMI on maximum knee flexion angle for each of the three types of squats. Since age and gender were both found to be main effects in all three cases, subsequent multi-factor ANOVAs were performed on subject subgroups divided according to age, and single factor ANOVAs were performed on subject subgroups divided according to age and gender to quantify the effect of BMI.

## Results and Discussion

The results of the multifactor ANOVA considering just the younger group of subjects (male and female) determined that BMI was a main effect, but gender was not. As shown in Fig. 1, statistically significant differences were found between the maximum knee flexion angle in the dual leg squat and the single leg squat, but no significant differences were found between the genders for either type of squat. In contrast, the multifactor ANOVA considering just the older group (male and female) found that both gender and BMI were main effects. As shown in Fig. 2, older male subjects exhibited maximum knee flexion angles in both dual leg and single leg squats that were significantly larger than those of older female subjects. The F values from the ANOVAs for the maximum left knee flexion angle in the single-leg squat with the left leg and the dual leg squat are reported in Table 1, and similar values were found for the other angles not reported here.

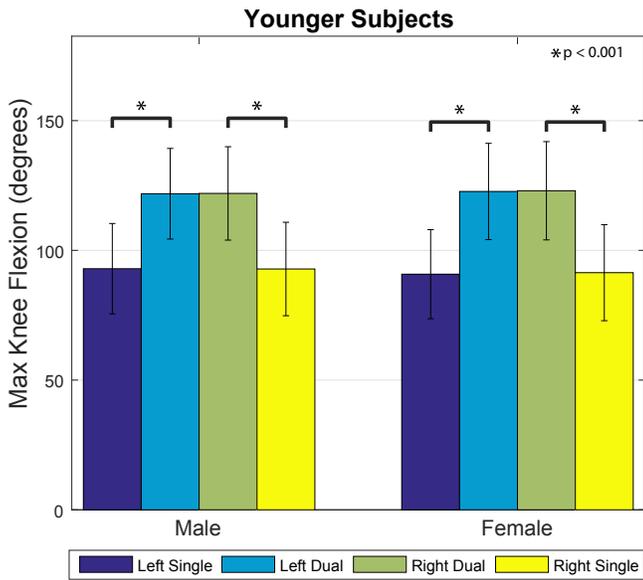

FIGURE 1. Maximum knee flexion in single and dual leg squats for younger subjects.

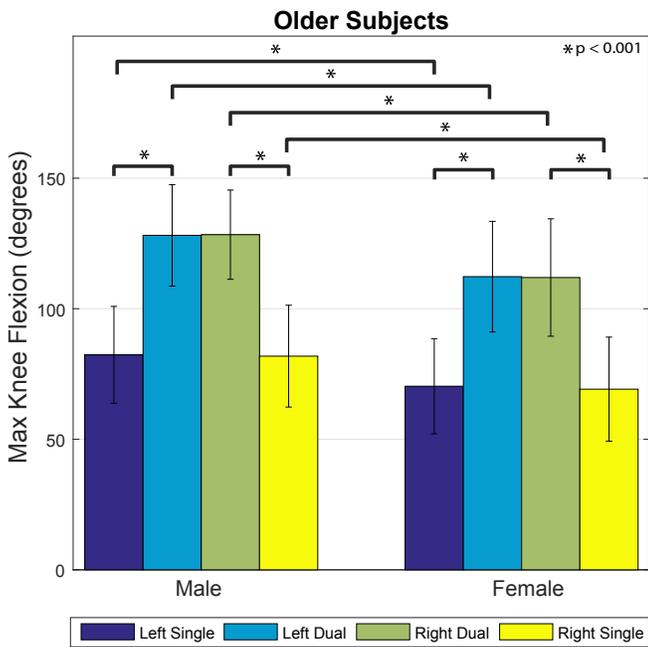

FIGURE 2. Maximum knee flexion in single and dual leg squats for older subjects.

TABLE 1. Effect of gender on maximum left knee flexion in single left leg squats and dual leg squats.

Age Group	F Value (p Value)	
	Single Left	Dual Left
Younger	2.22 (>0.1)	1.99 (>0.1)
Older	49.82 ( $\leq 0.001$ )	81.23 ( $\leq 0.001$ )

The results of the single-factor ANOVAs performed on the older male, older female, younger male, and younger female subgroups indicated that BMI was a main effect on maximum knee flexion for single leg squats in all groups. As BMI increased, the average maximum knee flexion decreased. Table 2 reports the F values for the maximum left knee flexion angle in the single leg squat with the left leg and the dual leg squat. Similar values were found for the angles not reported here. An increase in BMI had a comparatively larger negative effect on maximum knee flexion in both single and dual leg squats for the older female group than the older male group, despite both groups exhibiting a decline. Across all four groups, BMI had a much stronger effect on maximum knee flexion in single leg squats than in dual leg squats. While BMI had a significant effect on the variance of the maximum knee flexion for dual leg squats in both older subject groups, it did not have a significant effect in either younger group in the dual leg squat.

TABLE 2. Effect of BMI on maximum left knee flexion in single left leg squats and dual leg squats.

Grouping	F Value (p Value)	
	Single Left	Dual Left
Older Male	27.64 ( $\leq 0.01$ )	9.68 ( $\leq 0.01$ )
Older Female	64.89 ( $\leq 0.01$ )	18.74 ( $\leq 0.01$ )
Younger Male	61.78 ( $\leq 0.01$ )	1.03 (> .3)
Younger Female	54.43 ( $\leq 0.01$ )	3.99 (> 0.05)

## Conclusions

While younger subjects exhibited no differences in bodyweight squat performance across genders, female subjects exhibited greater degradation of bodyweight squat depth with an increase in age than did male subjects. Furthermore, the effect of BMI was on squat depth was greater for single leg squats than for dual leg squats. These data can inform rehabilitation and athletic training practice.

# FUNCTIONAL BALLISTIC MOVEMENTS IN CHILDREN WITH A HISTORY OF PONSETI CORRECTION FOR TALIPES EQUINOVARUS: PRELIMINARY RESULTS

<sup>1</sup>Patti Berg-Poppe, <sup>1</sup>Renee Burnham, <sup>1</sup>Boni Slagerman, <sup>1</sup>Mark Wilcox, <sup>1</sup>Lana Svien, and <sup>2</sup>Geoffrey Haft

<sup>1</sup>University of South Dakota, Vermillion SD, USA

<sup>2</sup>Sanford Health Systems, Sioux Falls SD, USA

email: Patti.Berg@usd.edu

## INTRODUCTION

Congenital Talipes Equinovarus (CTEV), also referred to as “clubfoot,” is a condition of unknown etiology formed in utero. At birth, an infant presents with inversion, adduction, and equinus of the joints of the foot and ankle to varying degrees.<sup>1</sup> The Ponseti method for correction of clubfoot involves serial manipulations and castings followed by a bracing regimen.<sup>1</sup> While the Ponseti method is the treatment of choice for CTEV, when compared to children born with typical feet, children undergoing the method demonstrate less power and flexibility<sup>2,3</sup> at the foot and ankle, leading to differences in the performance of complex functional activities demanding power and flexibility.

A study of ballistic performance of children post Ponseti correction has not yet been undertaken. Ballistic tasks require complex, rapid, powerful movements to achieve maximal force in a short time.<sup>4</sup> Successful completion of such tasks requires sufficient power<sup>4,5</sup> and flexibility.<sup>5</sup> The purpose of this study was to measure differences in ballistic movements in children with a history of Ponseti correction for CTEV against an age- and gender-matched control group. We hypothesized that children with a history of Ponseti correction would differ from those without CTEV in measures of ballistic movement success due to differences in body structures of the corrected foot/ankle and the elevated demands of ballistic tasks.

## METHODS

Musculoskeletal measures of the lower extremity included strength, passive range of motion (ROM), and closed-chain assessments (Table 1).

A digitized walkway was used to measure ballistic task performance, including standing broad jump, single leg hop, and triple leg hop distances traveled. The standard protocol for the Sargent jump test<sup>6</sup> was used.

## RESULTS AND DISCUSSION

Participants comprised 18 subjects, including 9 children with a history of CTEV following Ponseti correction (CTEV-G) and 9 age- and gender-matched (6 male/group) control group (CG) participants. Matched children did not differ in age (CTEV-G = 8.89±1.27 years; CG = 8.82±1.39 years) or BMI (CTEV-G = 20.2±7.23; CG = 16.25±0.78).

There were no statistically perceived between-group differences in musculoskeletal measures of strength or passive joint range of motion (Table 1). The CTEV-G demonstrated lower degrees of mean passive joint range of motion and greater variability, observed as larger standard deviations. Dorsiflexion strength was greater in CTEV-G and approached significance. A statistically significant difference in closed chain lunge test was observed, with greater degrees of motion identified in CTEV-G (Table 1).

CTEV-G subjects demonstrated poorer ballistic performance than CG subjects; however, the standing broad jump was the only ballistic test to reveal a statistically significant between-group difference (Table 1). No significant correlations were found between ballistic test performance and passive foot or ankle ROM.

## CONCLUSIONS

The CTEV-G showed greater closed kinetic chain dorsiflexion as compared to CG. The greater ROM may be due to mechanical inefficiency during the

stance phase in the gait cycle. The CTEV group may compensate more at the hip, as demonstrated in other studies.<sup>3</sup> Differences in standing broad jump performance may be due to excess DF in the closed kinetic chain of the corrected foot, thereby limiting the full advantage of the stretch reflex used in ballistic tasks. Another possible explanation is a decrease in push-off power, either due to mechanical inefficiency or compensations at the hip joint.

While children with CTEV show poorer jumping distances than matched control subjects for all ballistic tests, these differences did not meet a level of statistical significance, with the exception of the standing broad jump. Ponseti correction alters foot and ankle biomechanics successfully enough that an analysis of ballistic performance does not differentiate children with a history of Ponseti treatment for CTEV from peers unaffected by the congenital condition.

Parents seeking advice about prognosis and outcomes related to their infant's ability to keep up with peers after Ponseti correction for CTEV can be reassured that while deficits in ballistic performance may be present, these deficits are unlikely to significantly impact functional performance in general

email: Patti.Berg@usd.edu

## INTRODUCTION

Idiopathic toe-walking (ITW) is an atypical toe-toe gait pattern with the absence of heel strike and without a specifically identified etiology.<sup>1,2</sup> Few studies have been published analyzing static postural control and muscle activation patterns in children with ITW.<sup>3,4</sup> This study examined static postural control in children with ITW by measuring loading patterns and activation of muscles controlling the knee using variable sensory conditions.

The purpose of the analysis was to examine knee agonist-antagonist muscle activation to explain center of pressure (CoP) distribution trends under variable postural control conditions.

## METHODS

Surface electromyography (EMG) was applied to rectus femoris (RF) and biceps femoris (BF) to measure the percent of MVIC utilized under a matrix of the firm (Fi) or foam (Fo) surface and eyes open (EO) or eyes closed (EC) conditions for muscles controlling the knee. A ratio was calculated to represent the strength of simultaneous agonist-antagonist contraction. This value was utilized for between-group comparisons and to examine relationships with CoP data.

## RESULTS AND DISCUSSION

Ten children participated in this study. Five children comprised the ITW group (3 male and 2 female; mean age=8.73 years, range 5.92-11.08); 5 age- and gender-matched children comprised the control group (mean age=8.42 years, range 5.67-10.08).

The ITW group demonstrated consistently lower RF and BF activation under all sensory conditions (Table 1). These between-group differences in muscle activation did not meet statistical significance with the exception of BF activation under eyes-closed conditions, showing significantly greater activation of the BF in the control group (Table 1). While activation levels of RF and BF were lower in the ITW group than in the CG under all conditions, RF:BF ratios were much higher in the ITW group.

A comparison of CoP<sub>AP</sub> showed more posterior positioning in the ITW group under all conditions (Table 2); this difference met a level of statistical significance for the FoEC condition alone. As a single group (N=10), there was a negative, high, and significant correlation found between the ratio of RF:BF activation and CoP<sub>AP</sub> positioning under the conditions of FiEO, FoEO, and FoEC; the correlation approached significance under the FiEC condition (Table 3). By group, these correlations were strong for the ITW, but did not meet statistical significance; correlations were much weaker for the CG than for the ITW group (Table 3).

## CONCLUSIONS

A general trend was observed in both groups in which quadriceps activation decreased and hamstring activation increased as sensory conditions become more complex. A trend was also observed in both groups in which CoP position shifted more posteriorly as sensory conditions become more complex. Under all conditions, ITW mean CoP was more posteriorly positioned than CG CoP. The more anteriorly positioned CG showed a more balanced pairing of quadriceps and hamstring muscle activation. In contrast, the ITW group recruited a

greater balance of quadriceps activity in response to a more posteriorly positioned CoP. Because these values capture a 10-second composite timeframe, it is possible that the quadriceps were being called on during the 10-second capture to react to backward sway as the feet were required to maintain a foot-flat position in stance. The reduced levels of activation in comparison to the CG may be explained by compensatory strategies that relied more heavily on control at the ankle or hip for additional postural control.

While these findings are individual rather than group-specific, they suggest insight into the way children utilize musculature at the knee for postural control under a variety of surface and sensory conditions.

## INTRODUCTION

Foot loading can be asymmetric between the left and right sides at the onset of independent walking until up to 3-4 years of age [1]. As children mature, symmetry improves due to increased postural stability and motor control [1]. However, previous research has found that for children with unilateral clubfoot, the unaffected side is not normal and displays differences from typically developing feet [2, 3]. In addition, different treatment methods, Ponseti versus comprehensive releases, have been found to produce different outcomes in children with clubfoot (with Ponseti treatment resulting in a more favorable outcome) [4-6]. To date no study has assessed the foot asymmetry between children with unilateral clubfeet that were treated with Ponseti casting versus those treated with posterior medial release (PMR).

## METHODS

Children with unilateral clubfoot treated with Ponseti (N=40) and with PMR (N=40) were retrospectively reviewed for this study. Subjects were age and height matched, but weight was unable to be matched (Table 1). Foot pressure analysis parameters for a 10 area .prc mask [7] was analyzed using the emed® X (Novel Incorporated, Munich, Germany). The areas masks include the total foot, hallux, second toe, third-fifth toes, first metatarsal, second metatarsal, third-fifth metatarsal, medial midfoot, lateral midfoot, medial hindfoot and lateral hindfoot. Parameters analyzed included force time integral (FTI), pressure time integral (PTI), maximum force (MF), mean pressure (MP), contact time (CT), contact area (CA), peak pressure (PP), heel width (HW), forefoot width (FFW), midfoot width (MFW), foot length (FL), medial contact area (MCA) and lateral contact area (LCA).

With the areas and parameters combined there were 82 data points per foot for the final analysis.

The Asymmetry Index (ASI) was used to assess differences between the unaffected and affected side parameters. ASI is defined as

$$ASI = \left| \frac{2(X_U - X_A)}{X_U + X_A} \right| \times 100\%$$

where an ASI of 0 is perfect symmetry [8]. The  $X_U$  and  $X_A$  are the same parameter for the unaffected and the affected sides respectively. Previous research on the ASI has found that an ASI value of  $\leq 10\%$  is acceptable [8].

## RESULTS AND DISCUSSION

The weight of the Ponseti group was significantly larger than that of the PMR group; therefore FTI and MF were calculated as a percent of bodyweight before the ASI was calculated. ASI results show that out of 82 parameters the Ponseti group met  $\leq 10\%$  acceptability in 9/82 (10.9%) parameters and the PMR group met acceptability in 4/82 (4.9%) parameters (Table 2). The remaining parameters had ASI values ranging from 13-87% for the Ponseti group and 11-103% for the PMR group.

There were 20 parameters of the 10 area .prc mask that were significantly different between the Ponseti and PMR treatment groups. For all of these parameters, the Ponseti group demonstrated a lower ASI value (Table 2). Of these variables, 15 were located on the medial side of the foot print. This indicates that there is significantly less asymmetry on the medial side of the foot for the Ponseti group compared to the PMR group ( $p < 0.05$ ).

Both groups demonstrated acceptable symmetry for the total foot print for MF, FFW and FL. When assessing symmetry in masked areas of the foot, only the CT of metatarsals 3-5 reported acceptable symmetry for both groups. The Ponseti group reported acceptable symmetry for CA (total foot,

medial hindfoot, lateral hindfoot), LCA and for MP of the total foot. Previous research has shown that data from the total foot alone does not give a complete picture of the forces affecting the foot when walking [9]. Therefore, for clinicians it is more beneficial to examine pressure under specific regions of the foot instead of the total foot[10]. Results of this study show that if symmetry analysis is only conducted on the total foot print, differences between the Ponseti and PMR treatment groups are not as readily apparent. Therefore, it is recommended that symmetry analysis for children with clubfeet be assessed in specific regions of the foot.

The data in this study reports AIS ranges that exceed those previously found in typically developing children [8] (Table 3). This would indicate that even after surgery, children with unilateral clubfeet do not achieve symmetry that is equal to their able bodied peers. However, these results would support previous assertions that Ponseti treated clubfeet have more favorable outcomes [4-6], due to the Ponseti group reporting double the number of variables with acceptable symmetry and with the ASI values for the 22 variables reported in Table 2 being significantly smaller in the Ponseti group.

## CONCLUSION

The results of this study demonstrate that the Ponseti method was more successful at producing acceptable symmetry of foot pressure variables under specific regions of the foot than clubfeet treated with PMR.

## INTRODUCTION

Lower limb trauma (LLT) impairs walking stability, especially on variable terrain [1]. Additionally, prolonged activity and load carriage may also impair stability [2]. Military service members are often required to navigate varied terrain for extended periods while carrying loads. In order to maintain military readiness and potentially return to duty, wounded service members must be able to perform these tasks while maintaining stability, avoiding falls which could further injure them. The range of whole-body angular momentum (H) has been used to quantify dynamic stability in various populations and walking conditions with a greater range indicating greater instability [1,3]. We hypothesized that when walking over variable terrain under load carriage, both the frontal and sagittal plane H would: 1) increase with distance walked for both groups, 2) be greater for individuals with LLT than able-bodied controls (AB), and 3) increase with distance at a faster rate for LLT than AB.

## METHODS

Twelve individuals with LLT wearing a custom carbon fiber ankle foot orthosis (1F/11M, 31±5 years, 1.81±0.09 m, 94.8±10.6 kg) and 14 AB (3F/11M, 29±11 years, 1.76±0.10 m, 75.2±12.7 kg) completed a simulated military patrol in a virtual reality environment (Computer Assisted Rehabilitation Environment, Motekforce Link, Amsterdam, NL). Participants wore a Kevlar vest and helmet and carried a mock M4 rifle. The patrol consisted of 8 blocks, each with sections of steady-state platform positions and variable terrain at 1.4 m/s and a graded portion that increased speed and incline with each block. Participants completed as

many blocks as they were able to before quitting or being told to stop due to excessive pain or fatigue.

During the patrol, we collected full body kinematics using a 24-camera motion capture system (Vicon Motion Systems, Oxford, UK). As our measure of stability, we calculated H in the frontal and sagittal planes for each step from a 13-segment model created using Visual 3D (C-Motion Inc, Germantown, MD). The H values were normalized to Height × Body Mass × Walking Speed and averaged for each block for each participant. We focused our analysis on the more challenging variable terrain sections of each block. In order to analyze the influence of prolonged activity and LLT on walking stability, we used a linear mixed-effects model (MATLAB R2015b, The MathWorks Inc, Natick, MA):

$$H = \beta_D \cdot Distance + \beta_G \cdot Group + \beta_I \cdot (Distance \times Group) + (1|Participant)$$

Where H is the range of angular momentum in the frontal or sagittal plane, Distance is the distance walked by the end of each block, Group is coded as 0 for AB and 1 for individuals with LLT, and (1|Participant) represents a random intercept for each participant.  $\beta_D$ ,  $\beta_G$ , and  $\beta_I$  represent the coefficients for Distance, Group, and the interaction between the two, respectively. A coefficient was considered significant if  $p < 0.05$ .

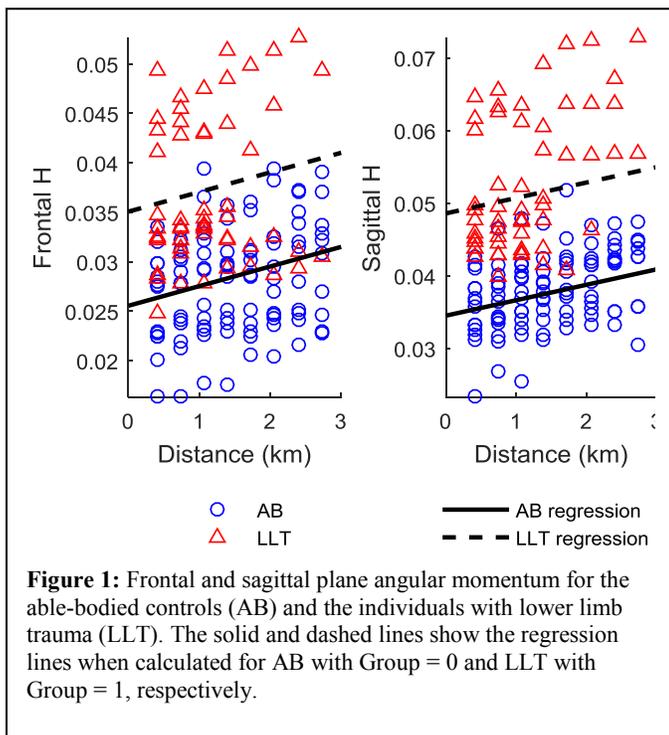

## RESULTS AND DISCUSSION

Overall, the models for both frontal and sagittal plane H had strong fits with adjusted  $R^2$  values over 0.95. Additionally, the coefficients for Distance and Group were significant for both planes, yet the interaction term was not significant (Table 1).

**Table 1:** Values for the linear mixed-effects model coefficients. The Distance coefficient indicates how angular momentum (H) changes with prolonged activity, the Group indicates the baseline difference in H between groups, and the Interaction indicates a difference in the rate at which H changes with distance between the 2 groups. **Bold** coefficients were highly significant with  $p < 0.001$ .

	Distance	Group	Interaction
	$\beta_D$	$\beta_G$	$\beta_{DG}$
Frontal	<b>0.00198</b>	<b>0.00951</b>	-0.00037
Sagittal	<b>0.00213</b>	<b>0.01407</b>	0.00010

In support of our hypothesis, the significant Group effect suggests that individuals with LLT are more unstable than AB when walking over variable terrain. Further, the significant Distance effect indicates that walking stability degrades for both groups following prolonged walking with load carriage. The rate at which walking stability deteriorates appears to be the same for both groups as shown by the lack of a significant interaction effect (Figure 1).

Besides differences in stability, the LLT group also completed fewer blocks on average. As a result, there is a chance that our model is influenced more by the few individuals with LLT that completed all 8 blocks. It is possible that if we had a greater number of participants in the LLT group complete

more blocks, we would have been able to see a difference in the rate of destabilization. Specifically, there may be a point at which stability deteriorates more rapidly in individuals with LLT which may limit task performance. However, task performance by individuals with LLT in this study was primarily limited due to endurance or pain. This means that a stability deficit was likely not the limiting factor for these patients at short distances and that pain and endurance also need to be addressed when returning to occupational tasks.

In a previous study, we found that by exposing an individual with a transfemoral amputation to increasing levels of walking surface pitch and roll oscillations, over time they were able to improve their tolerance, function, and stability [4]. This provides promise that similar interventions may be able to return wounded service members back to comparable levels as their uninjured peers.

## CONCLUSIONS

Although the individuals with LLT started out more unstable, both groups became more unstable at the same rate following prolonged walking over variable terrain. This suggests that if we are able to improve patients' baseline stability, they may be able to achieve the same level of walking stability as uninjured service members, even during long patrols.

# MOTOR STRATEGY AND LOCOMOTOR ADJUSTMENTS IN CHILDREN WITH AND WITHOUT DOWN SYNDROME WHILE NEGOTIATING STAIRS

Huaqing Liang, Xiang Ke and Jianhua Wu

Georgia State University, Atlanta, Georgia, USA. Email: hliang2@gsu.edu

## INTRODUCTION

Children with Down Syndrome (DS) often show impaired motor control and ability, and walk with a slower speed and a shorter step length compared to typically developing (TD) children [1]. When negotiating an obstacle, children with DS often stop for a longer duration in front of an obstacle before crossing it than their TD peers [2]. When crossing it, children with DS tend to choose a more conservative crawling strategy to reduce the risk of falling [3], and they display a lower toe clearance than TD children [2]. In comparison, stairs negotiation is another setting to study adaptive locomotion in children, but requires moving the center-of-mass up constantly. However, to our knowledge, few studies have been conducted to examine this paradigm in children with and without DS. The purpose of this study was to understand motor strategy and gait adaptation in children with and without DS while transitioning from level surface to stairs.

## METHODS

### *Subjects*

Fourteen children with DS (4M/10F) and fourteen age- and gender-matched TD children (4M/10F) participated in the study. Mean (SD) age of the DS group was 8.6 (1.9) years, height 1.18 (0.11) m, and mass 27.2 (10.4) kg. Mean (SD) age of the TD group was 8.2 (1.9) years, height 1.31 (0.11) m, and mass 29.4 (7.0) kg.

### *Experimental design*

An 8-camera Vicon motion capture system and the Vicon full-body PSIS model was used for data collection. Subjects walked along a 5-meter walkway, and then ascended a three-step staircase. There were three custom wooden staircases with different riser heights: 17cm (LS), 24cm (MS), or 31cm (HS). There were two loading conditions: without ankle load (no load) or with ankle load (ankle load) equaling to 2% of the body weight on each side. There were 6 conditions in total and

subjects completed 5 trials for each condition. The presentation of the conditions was randomized. Subjects were given sufficient rest between conditions.

### *Data analysis*

Motor strategies were categorized as: avoidance, crawling, or walking. If the subject did not ascend the staircase, it was an *avoidance* strategy. When the subject used all four limbs to ascend the staircase, it was a *crawling* strategy. When the subject walked up the staircase, it was a *walking* strategy. The proportion that each strategy was chosen was calculated for each subject under each condition.

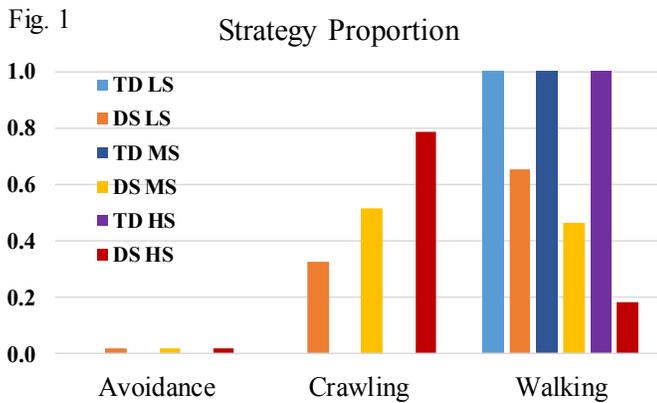

In each trial, the leading foot was defined as the first foot the subject used to ascend the staircase, and the other foot was considered as the trailing foot. The placement of these two feet (i.e., distance between the toe and the staircase) as well as stance time before ascending were calculated for both leading and trailing feet. In addition, vertical toe clearance was calculated as the vertical distance between the toe marker and the height of the stair, and it was only calculated for the trials when subjects used the *walking* strategy. The customized MATLAB program was used for data analysis.

### *Statistical analysis*

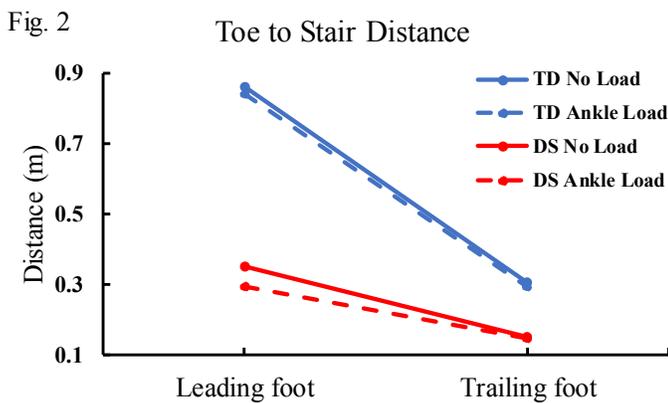

A series of 4-way (group  $\times$  stair  $\times$  load  $\times$  foot) ANOVA with repeated measures were conducted on foot placement, stance time, and toe clearance. Post-hoc pairwise comparisons with Bonforreni adjustments were conducted when appropriate. Statistical significance was set at  $\alpha = 0.05$ .

## RESULTS AND DISCUSSION

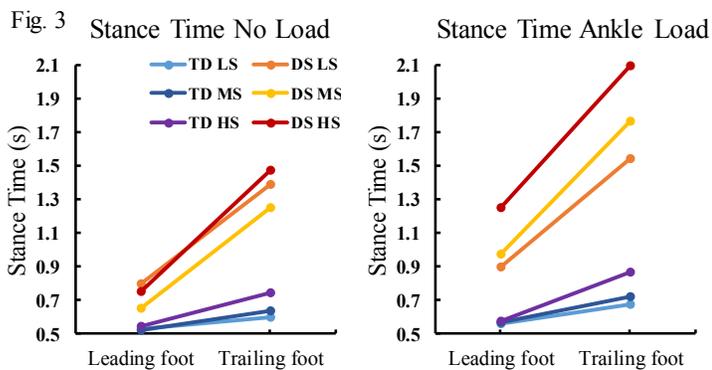

Across the two loading conditions, both groups showed a similar strategy distribution. All the TD subjects walked up the staircase in all conditions (Fig. 1). However, the DS group primarily walked up the stairs in the LS condition but crawled up in the HS condition.

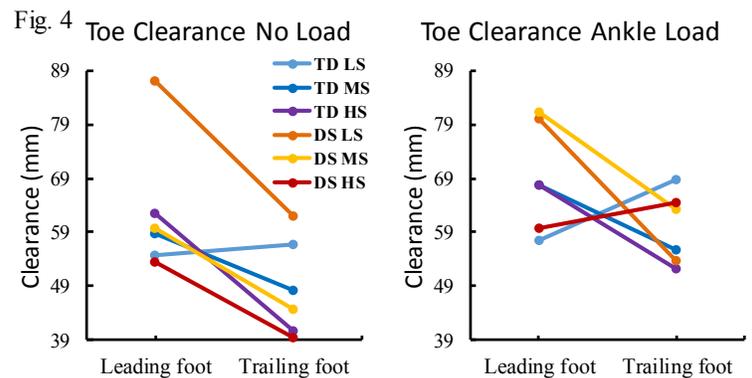

Both groups placed the leading foot further away from the staircase than the trailing foot (Fig. 2). However, the DS group placed both of their feet closer to the stairs than the TD group, and the difference between the placements of the two feet was smaller in the DS group. There was a group by foot interaction and a load by foot interaction (both  $p < 0.05$ ). No effect of stair height was found.

The DS group displayed a longer stance time before negotiating the staircase than the TD group, and both groups showed a longer stance time for the trailing foot than the leading foot (Fig. 3). There was a group

by load, a group by step, and a load by stair interaction (all  $p < 0.05$ ). Post-hoc analysis revealed that stance time was longer in the HS condition than the other two stair-height conditions only with ankle load. Weight appeared to affect only the DS group such that they had longer stance time in MS and HS conditions with ankle load compared to no load.

Both groups generally displayed a higher vertical toe clearance for the leading foot than the trailing foot (Fig. 4). There was a group by load by stair-height interaction, and a group by foot by stair-height interaction (both  $p < 0.05$ ). Without ankle load, the DS group tended to produce a higher toe clearance in the LS condition and a lower toe clearance in the HS condition when compared to the TD group. However, the addition of ankle load resulted in a similar toe clearance between the two groups across three stairs conditions.

## CONCLUSIONS

When ascending stairs, the DS group utilized a conservative *crawling* strategy more often, especially when the stairs were higher. When preparing for the ascent, the DS group placed their feet closer to the stairs, and took longer time in the stance phase than their TD peers. Additionally, the DS group did not show as good adjustments as the TD group in toe clearance when negotiating staircases. All the results suggest that the DS group had limited motor ability when adapting to stairs with different heights.

## INTRODUCTION

How individuals with cerebral palsy (CP) and other neurologic injuries recruit and coordinate their muscles to achieve tasks of daily living remains an open question. Muscle synergies provide one method to quantify coordination patterns of multiple muscles during a task [1]. Synergies are calculated from electromyography (EMG) data and identify weighted groups of muscles that are commonly activated together. Among individuals with neurologic injuries, synergies describe greater variance in EMG data compared to unimpaired individuals [2-3], suggesting "simpler" control strategies that may contribute to impaired function.

In CP, synergy complexity is reduced compared to unimpaired individuals during gait and greater reductions are associated with increased functional impairment and worse outcomes after treatment [4]. While synergy complexity provides one measure of impaired motor control, understanding which muscles are activated together in synergies may provide insight into alternative control strategies for locomotion. The aim of this study was to evaluate whether synergy coordination patterns are altered in CP and related to functional ability compared to typically-developing (TD) peers.

## METHODS

We evaluated synergies during gait for 1312 individuals with CP (age: 11.8±7.3 yr, height: 1.3±0.2 m, mass: 36.0±17.3 kg) and 76 TD controls (age: 10.8±3.6 yr, height: 1.4±0.2 m, mass: 40.6±16.4 kg). EMG data was collected over a gait cycle from five muscles: rectus femoris (RF), medial hamstrings (MH), lateral hamstrings (LH), medial gastrocnemius (MG), and anterior tibialis (AT). EMG data was high-pass filtered at 35 Hz,

rectified, low-pass filtered at 10 Hz, and normalized by the maximum value for each muscle [2].

Nonnegative matrix factorization (NNMF) was used to calculate synergies that could explain the greatest variance in EMG data for each individual. Briefly, NNMF identifies the synergy weights ( $W_{m \times n}$ ) and synergy activations ( $C_{n \times t}$ ) for a specified number of synergies ( $n$ ) that minimizes the error:

$$EMG_{m \times t} = W_{m \times n} \cdot C_{n \times t} + \text{error} \quad (1)$$

where  $m$  is the number of muscles and  $t$  is the number of time points. The total variance accounted for (tVAF) by a given number of synergies was calculated as  $1 - \frac{\text{sum of squared error}}{\text{sum of squared EMG data}}$ . K-means cluster analysis was used to identify similar synergies across all individuals. Silhouette analysis was used to identify the number of clusters that best described unique groups of synergies. The silhouette coefficient for a given number of clusters provides a measure of how tightly each cluster is grouped relative to neighboring clusters. For the number of clusters with the maximum silhouette coefficient, we compared the similarity of synergy weights as the average correlation coefficient between the CP and TD groups. Student's t-tests with a Bonferroni correction for multiple comparisons were used to compare tVAF and synergy weights between CP and TD groups.

## RESULTS AND DISCUSSION

Two and three synergies could describe on average 93 and 97% of the variance in EMG data during gait in CP, versus 89 and 96% in TD peers (**Fig. 1**,  $p < 0.001$ ). K-means analysis indicated similar synergy weights between CP and TD groups. For example, in the three-synergy solution ( $n = 3$ ), three clusters provided the most cohesive clusters of synergy

weights, indicating that there were not unique clusters for CP and TD groups.

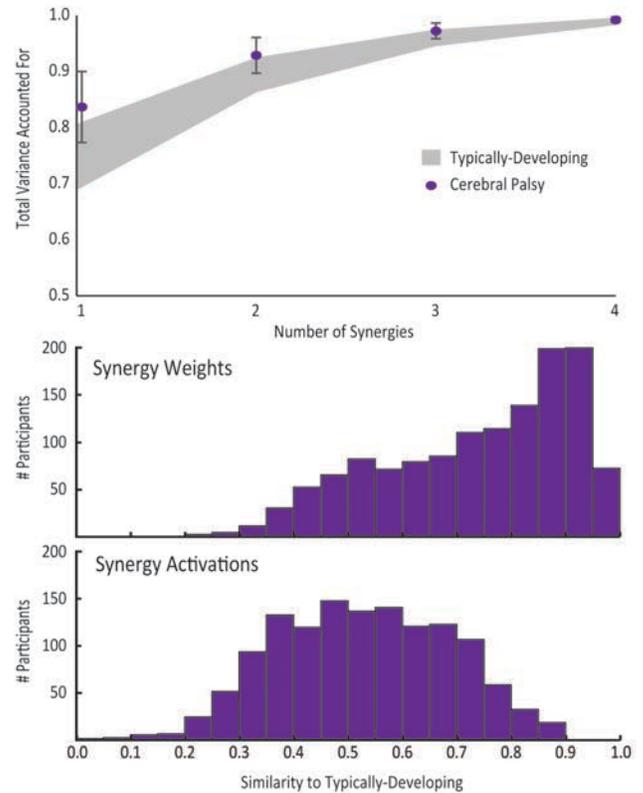

The average similarity of CP synergy weights and activations to the TD synergies were 0.74 and 0.53, respectively. The gastrocnemius showed the greatest difference in synergy weights, with increased coactivation with other muscles (**Fig. 2**). Individuals with less impairment, as measured by Gross Motor Functional Classification System (GMFCS) Level, had synergies more similar to the TD group. The average similarity of synergy weights and activations were 0.82 and 0.64 for GMFCS Level I and 0.69 and 0.47 for GMFCS Level IV.

## CONCLUSIONS

Individuals with CP did not have distinct patterns of synergy weights during gait compared to TD peers. CP synergies described greater variance in muscle activity and were related to functional impairment in CP, but overall reflect common muscle coordination patterns across diverse gait patterns.

# VALIDITY OF USING HEAD MOTION TO DETECT DUAL-TASK GAIT IMBALANCE IN ADOLESCENTS WITH CONCUSSION

Will Pitt and Li-Shan Chou

Department of Human Physiology, University of Oregon, Eugene, OR, USA  
email: [chou@uoregon.edu](mailto:chou@uoregon.edu), web: <http://choulab.uoregon.edu>

## INTRODUCTION

Return to play (RTP) criteria for concussed adolescent athletes vary considerably and are currently based on: time, resolution of subjective symptoms, and normalization of simple balance tasks [1]. Symptom surveys have been shown to normalize within one to two weeks and balance measures can return to baseline in as few as three days. With increasing evidence of long term impairment from repetitive concussive injury, it is essential to institute valid and objective RTP criteria that reliably establish full recovery and reduce risk for successive injury.

Recent investigations of concussion related gait imbalance employ a dual-task paradigm, which combines walking with concurrent cognitive test performance [2]. This line of study has revealed an inability of concussed subjects to control their whole body center of mass (WB COM) as indicated by an excessive medial-lateral (M-L) displacement, faster peak M-L velocity, and slower peak anterior-posterior (A-P) velocity. While these impairments gradually improve over time, they still exist at a significant level as long as two months post injury and, more concerning, worsen when subjects RTP inside of two months [3]. This suggests current RTP criteria may not be sensitive enough to capture lingering deficits in dynamic motor functions, and RTP prior to complete recovery could increase the risk of subsequent injury.

Analysis of the WB COM motion relies on camera-based motion capture technology and requires a whole body retroreflective marker set up. Simplification of the measurement of dual-task gait balance impairment may allow for increased clinical utility and facilitate the application of emerging low cost technologies such as accelerometry. This study

aims to determine if head COM kinematics are able to identifying dual-task gait imbalance previously identified by whole body COM kinematics.

## METHODS

Forty-four high school athletes (8F) were recruited from three local high schools. Twenty-two subjects suffered a concussion in athletics participation were tested within 72 hrs of injury. Concussion diagnosis was made by physicians or athletic trainers [1]. Concussed subjects were matched to healthy controls by sex, height, mass, age, and sport.

Subjects walked at a self-selected pace along a straight walkway under two task conditions: walking only (single-task) and walking while performing a question and answer (dual-task Q&A) battery consisting of spelling a five letter word backwards, or counting backwards by sixes or sevens. Subjects were instructed to look straight ahead at an X placed on the wall during the trial. Data collected from three trials for each condition were used for analysis.

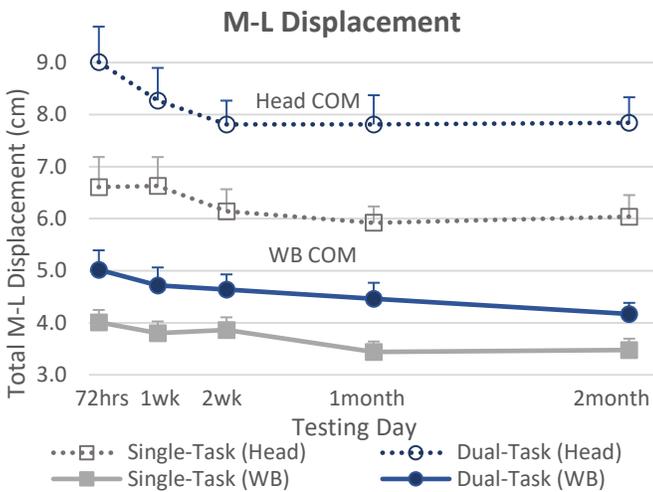

A set of 29 retro-reflective markers were placed on bony landmarks [4]. The head was tracked with five markers: one at the top of each ear, the forehead, back of the head, and on the top of the head such that the plane formed between it and the two ear markers was roughly aligned with the frontal plane. Markers were tracked with a 10-camera motion analysis system, sampling at 60Hz. Marker trajectories were filtered using a low-pass, zero-lag, second-order Butterworth filter with a cutoff frequency of 8Hz. WB COM was calculated as the sum of the weighted masses of 13 body segments. Head COM was defined as the midpoint between the two ear markers.

WB and head COM position data were normalized to one complete gait cycle (heel strike to ipsilateral heel

strike). Total M-L COM displacement was defined as its excursion along the M-L direction. Peak velocities of the COM along the M-L and A-P directions were also identified. Two-way analyses of variance were performed on head COM data for each outcome measure to determine interaction and main effects of group (concussed and control) and condition (single-task and dual-task). Statistical analyses were performed with SPSS version 24 (SPSS Inc., Chicago, IL).

## RESULTS AND DISCUSSION

Concussed subjects were tested at  $2 \pm 0.7$ ,  $8 \pm 1.7$ ,  $17 \pm 3.4$ ,  $31 \pm 4.1$ , and  $59 \pm 3.4$  days after injury. No significant differences were noted between groups for height, mass, or age. Previous statistical analysis of WB COM [2] revealed significant group by task interactions for M-L displacement and peak A-P velocity as well as main effects of group and task for peak M-L velocity.

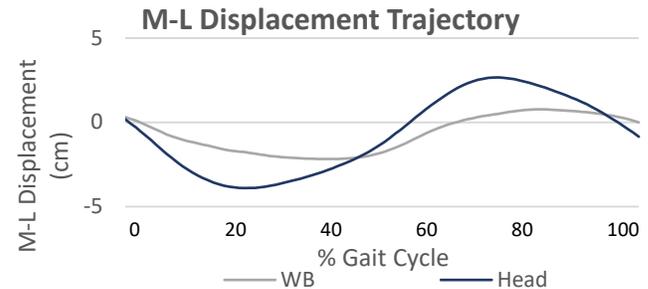

**Figure 1:** Total medial-lateral displacement (mean  $\pm$  SE) of the head and WB COM for concussed subjects during single-task and dual-task conditions

Similar analyses were performed in this study for head COM that did not detect any significant interaction effects for any of the three outcome measures. Further analysis of head peak A-P velocity revealed a significant main effects of group ( $p = .017$ ), however, in repeat analysis with average gait velocity as a covariate, the main effect was reduced to a non-significant level.

Examination of head and WB COM displacements

along the M-L direction revealed similar trajectories through the gait cycle. Head displacement magnitudes were about twice those of the WB, and head trajectory deviations occurred on average 7% sooner than WB deviations (Fig. 2). This suggests the deviation of the head contributes to WB COM M-L displacement rather than being used as a strategy for WB COM stabilization.

**Figure 2:** Representative plot of the head and WB COM trajectories along the M-L axis.

## CONCLUSIONS

Whole body gait analysis is time consuming and as of now confined to well-equipped gait analysis laboratories. The establishment of head COM kinematics as a sensitive measure of dual-task gait imbalance would facilitate study of this impairment. However, results from this study failed to establish its validity. While the profiles of the head COM data for each of the three outcome measures (Fig. 1) were similar to those of the WB COM, substantial variability in head COM measures likely contributed to the lack of significant effects. The inability to reliably control head orientation without significantly affecting natural movement patterns appears to eliminate the utility of head COM measures in detection of dual-task gait imbalance in concussed individuals.

## INTRODUCTION

Post-stroke hemiparesis is a major source of gait impairments. The kinematic characteristics in such impairments are often described with decreased walking speed and step length, asymmetric joint kinematics, and decreased paretic joint range of motion (ROM) in hip, knee, and ankle joints during gait. Especially the foot drop syndrome, a more ankle extension (plantarflexion) along the talocrural (ankle) axis during mid-swing phase, causes an occasional failure of limb advancements, and increases the trip-related fall risk and fall-related injuries [1].

The reduced ROM at paretic joint in individuals with post-stroke hemiparesis is caused by the increased resistance during passive dorsiflexion. The continuous passive motion for paretic joints helps to increase passive joint ROM by decreasing lower limb joint stiffness, and, in turn, increase gait speed [2].

Figure 1. Ankle Movement Trainer

Ankle Movement Trainer (AMT) was developed to provide 3-D isokinetic ankle movements along talocrural and subtalar axes while seated (Figure1). Ankle joint is defined along 3 orthogonal axes as International Society of Biomechanics recommended for the movement coordinate system [3]. However the subtalar joint is naturally 42 degree tilted on average in sagittal plane [4,5]. The AMT was designed to move along the tilted subtalar joint axis during inversion/eversion.

The objective of this study is that the 3-D isokinetic passive ankle movement training using AMT is effective to improve gait symmetry and walking speed for the individuals with chronic post-stroke hemiparesis. To evaluate the effectiveness of AMT ankle intervention program, we evaluate gait kinematics measured while walking on even and uneven surface, which represents real environment rather than lab environment that provides accurate effects of the developed AMT intervention program.

## METHODS

Total 15 patients with post-stroke hemiparesis (6 females, age:  $64.9 \pm 9.0$  yrs, duration:  $9.5 \pm 5.6$  yrs) were recruited for this study. This study was approved by the NRC Institutional Review Board and all participants signed written informed consent form before the study (NRC2015-03-020).

The AMT exercise program consists of total 12 sessions (four week three sessions per a week) about 30 minutes per a session. A session consists of 20 repetitions of two simple movements (20 dorsi-/plantar flexion; 20 inversion/eversion) and 40 repetitions of two constrained movements (40 Dorsi-flexed Inversion/Eversion; 40 Everted Dorsi-/Plantar flexion).

For gait trials, subjects wore a full-body safety harness. Gait performances were recorded at 100Hz while walking on 10m even and uneven surface total eight times respectively. The even surface was a flat walkway covering with industrial carpet and the uneven surface was fully scattered with wooden triangular pieces with randomized length from 5 cm to 15cm on the flat surface, which was covered with 10m x 1.5m industrial carpet. The kinematic symmetry was evaluated by comparing between paretic and non-paretic kinematics. Walking performances of Pre- and Post- AMT trainings were compared with paired-sample t-test (Significance level:  $p < 0.05$ ).

**Table 1:** Comparison between pre- and post- AMT training in joint kinematics of paretic limbs while walking on even and uneven surfaces (\* is  $p < 0.05$ )

Paretic ROM (deg) (N=15)		Pre-AMT	Post-AMT	P
Even	Hip	29.9 ± 9.7	33.5 ± 8.4	.097
	Knee	40.7 ± 11.3	42.0 ± 12.4	.692
	Ankle	17.0 ± 6.1	18.6 ± 6.1	.316
Uneven	Hip*	23.2 ± 11.4	29.0 ± 9.9	<b>.013</b>
	Knee*	29.7 ± 16.8	35.4 ± 15.3	<b>.034</b>
	Ankle*	12.4 ± 7.1	15.1 ± 7.9	<b>.034</b>

## RESULTS AND DISCUSSION

All subjects successfully participated in 12 AMT training sessions and two pre- and post-AMT training gait evaluations on even and uneven surface.

Table 1 and 2 show the joint and step kinematics while walking on even and uneven surface,

**Table 2:** Comparison between paretic and non-paretic step kinematics while walking on uneven surface and between pre- and post- AMT training (WS: walking speed, SL: step length; SW: step width, ST: step time)

		Paretic Side					Non-paretic Side				
		Pre-AMT		Post-AMT		p	Pre-AMT		Post-AMT		p
		Mean	SD	Mean	SD		Mean	SD	Mean	SD	
Even Surface	WS (cm/s)	39.0	18.9	40.4	17.8	0.440	52.6	24.0	58.1	21.5	0.100
	SL(cm)	29.8	10.8	31.9	9.2	0.059	31.4	11.2	32.9	9.9	0.375
	SW(cm)	16.7	5.2	17.1	5.0	0.390	17.6	5.1	18.0	4.6	0.509
	ST(ms)	840.3	167.5	837.2	143.5	0.866	565.9	274.4	563.3	175.9	0.967
Uneven Surface	WS (cm/s)*	<b>25.7</b>	17.0	<b>32.0</b>	17.8	<b>0.017</b>	35.9	22.6	40.4	24.6	0.101
	SL(cm)*	<b>21.4</b>	10.9	<b>24.3</b>	10.8	<b>0.009</b>	25.0	10.6	26.7	10.8	0.128
	SW (cm)	20.2	6.4	20.9	7.6	0.658	20.4	6.2	20.8	5.4	0.707
	ST(ms)	904.6	181.8	829.6	194.4	0.614	740.8	278.6	678.4	257.3	0.240

compared between Pre- and Post- AMT trainings. There was significant increase in joint ROM in hip, knee and ankle during walking on uneven surface (Table 1), and there were significant increased walking speed and step length in paretic side after the AMT training (Table 2). However, in joint ROM or step kinematics during walking on even surface between Pre- and Post- AMT trainings, there were no significant kinematic changes.

## CONCLUSIONS

Four week 3-D ankle movement training using the developed AMT is effective to increase walking speed, step length and lower limb joint kinematics while walking on uneven surface in the adults with chronic post-stroke hemiparesis.

## INTRODUCTION

As individuals with post-stroke hemiparesis typically demonstrate reduced walking velocity and spatiotemporal gait asymmetry, an important goal of rehabilitation is to improve gait pattern. The asymmetrical gait characteristics are associated with reduced weight shifting toward the paretic leg, which may be a consequence of a “learned nonuse” and can be reversed by forced use of the paretic leg. A recent study has applied the concept of constraint induced movement therapy to force use of the paretic leg and promote weight shift towards the paretic leg [1]. Visual feedback is another approach to enhance motor learning for improving weight shift ability in stroke rehabilitation [2]. Potentially, combined constraint induced movement therapy with visual feedback could have a positive impact on gait patterns in individuals with post-stroke hemiparesis.

The purpose of this study was to examine the effects of combined pelvic assistance force with visual feedback during treadmill walking on over-ground spatiotemporal gait characteristics in individuals with post-stroke hemiparesis. We hypothesized that combined pelvic assistance force with visual feedback would improve over-ground spatiotemporal gait characteristics in individuals with post-stroke hemiparesis. The addition of visual feedback would result in greater improvements when compared to pelvic assistance force only.

## METHODS

A total of 15 subjects (age =  $55.4 \pm 7.0$  years) with hemiparesis due to chronic (> 6 months) stroke participated in the study.

Subjects were asked to walk on the treadmill for 2 test sessions: (1) combined pelvic assistance force with visual feedback (COMBINED) and (2) pelvic assistance force only (PELVIC). The order of 2 test sessions was randomized. Each test session was 15 mins with a 10-min sitting break between sessions. Each test session consisted of 5 sections: 1-min baseline, 7-min training, 1-min post-training (no pelvic assistance force/visual feedback), 1-min standing break, and 5-min training. The treadmill speed of each test session was set at subjects' self-selected comfortable speed. In all sessions, subjects wore an overhead harness for safety, and could use the front handrail for safety.

A mediolateral assistance force was applied to the pelvis toward the paretic leg through a customized cable-driven robotic system to facilitate weight shift [3]. The magnitude of assistance force was set at 9% of body weight, and would be adjusted if subjects could not tolerate. The pelvis and ankle positions were recorded using 4 custom designed 3-dimensional position sensors. The recorded ankle position signals were used to trigger the assistance force applied from initial contact to mid-stance of the paretic leg. A custom-written LabVIEW program was used to collect pelvis and ankle position signals at 500 Hz as well as to command assistance force signals to the motors.

Visual feedback was provided through a computer monitor placing in front of the treadmill that displayed vertical bar graphs corresponding to the subjects' weight bearing on the paretic leg. Weight bearing was monitored with a mobile SmartStep device (Andante Medical Devices). When subjects exceeded the target weight bearing, the vertical bar would go above the horizontal line. The target

weight bearing was displayed as a horizontal line graph on the computer monitor and set was at 120% of weight bearing on the paretic leg during baseline.

Spatiotemporal gait variables were evaluated using a 10-m instrumented pressure mat (GAITRite) before and after each test session. Variables of interests included walking velocity, stance time, single leg support time, stride length and step length. Stance time and single leg support time were normalized to the whole gait cycle time (% gait cycle).

Paired-sample t-tests were used to compare: 1) before and after spatiotemporal gait variables within the COMBINED and PELVIC, and 2) change in spatiotemporal gait variables between the COMBINED and PELVIC. Change in spatiotemporal gait variables was computed as  $[(after - before)/before] * 100$ .

## RESULTS AND DISCUSSION

Overground single leg support time ( $p=0.01$ ), stride length ( $p=0.01$ ) and step length ( $p<0.01$ ) significantly improved after the COMBINED (Table 1). Overground walking velocity ( $p=0.02$ ) and step length ( $p=0.01$ ) significantly improved after the PELVIC (Table 1). However, the change in spatiotemporal gait characteristics (velocity,  $p=0.70$ ; stance time,  $p=0.17$ ; single leg support time,  $p=0.47$ ; stride length,  $p=0.30$ ; step length,  $p=0.36$ ) was not significantly different between the COMBINED and PELVIC (Table 1).

Combined pelvic assistance force with visual feedback may facilitate weight shifting toward the paretic leg during stance that might increase paretic leg loading. Increased loading enhanced activation of load-sensitive afferents, which inhibited the initiation of swing and prolonged the duration of single leg support time. Increased loading might also enhance paretic leg hip extension. With the movement of treadmill belt, paretic leg was pulled into more hip extension that resulted in a stretch of hip flexor. The stretch response may induce paretic leg stride forward thus increase the stride and step length.

## CONCLUSIONS

Combined pelvic assistance force with visual feedback improved single leg support time, stride length and step length of the paretic leg in individuals with post-stroke hemiparesis. The addition of visual feedback did not result in greater improvements when compared to pelvic assistance force only. Spatiotemporal gait characteristics after stroke can be improved by applying additional pelvic assistance force and/or visual feedback about weight bearing.

## INTRODUCTION

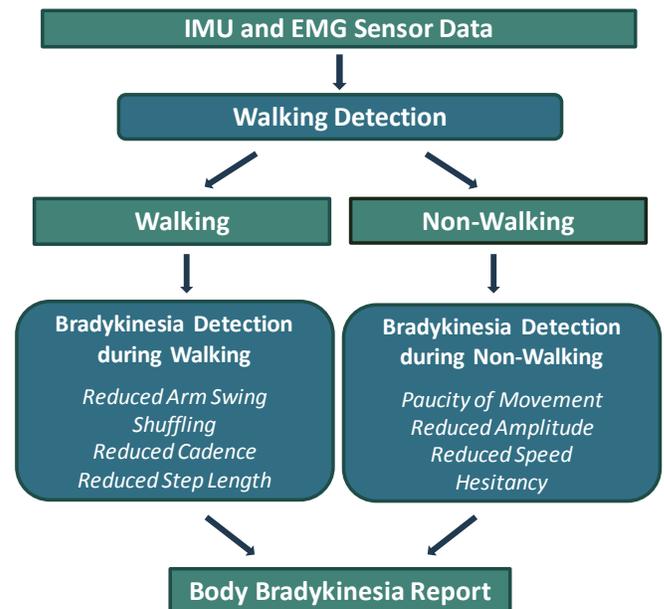

Sensor-based systems have been used to monitor the motor symptoms of Bradykinesia in Parkinson's disease (PD). But these tool have only been used during scripted activities defined by the Unified Parkinson's Disease Rating Scale (UPDRS), such as repeated finger tapping and opening and closing of the hand [1]. Such approaches lack a complete framework to monitor the full complement of motor symptoms associated with whole-body bradykinesia or track possible fluctuations in severity throughout the day resulting from wearing off [2]. Therefore, we have developed a novel approach to autonomously monitor, in real-time, the symptoms of UPDRS-defined Body Bradykinesia during unconstrained activities of daily living using body-worn sensors and machine learning algorithms.

## METHODS

Patients with mild to moderate Parkinson's disease (n=17, Hoehn & Yahr 1-3) participated in experiments designed to monitor PD motor symptoms during a 3-hour period of unconstrained activities of daily living in a home-like setting. Trigno™ IM wireless sensors (Delsys, Inc. Natick, MA) placed on the distal upper- and lower-limbs of the more symptomatic side of the body were used to record inertial measurement (IMU) and electromyographic (EMG) data. Videos of the subject were recorded and annotated by movement disorder experts to identify activity states and score Body Bradykinesia based on Item 31 of the UPDRS.

We designed a unique algorithm architecture to detect Bradykinetic motor symptoms without a-priori knowledge of movement activities being performed. Because the motor symptoms of Body

Bradykinesia may manifest differently for different activities, we designed a feedforward neural network to autonomously detect walking and non-walking (Figure 1). We tracked Body Bradykinesia separately for these activities by extracting characteristic features of motor symptoms from the recorded IMU-EMG signals. Features of bradykinesia during walking included reduced arm swing, shuffling, reduced cadence, and reduced step length. Features of bradykinesia during non-walking included paucity of movement, reduced amplitude, reduced speed, and hesitancy of movement. Dynamic Neural Network (DNN) algorithms were designed to classify the presence and severity of Body Bradykinesia based on these features. Annotations of the video provided by the clinicians served as the ground truth for assessing accuracy.

**Figure 1:** Algorithm approach for tracking Body Bradykinesia during unconstrained activities of daily living.

## RESULTS AND DISCUSSION

Our algorithms detected walking and non-walking activities with an accuracy of 99.5% and successfully identified Body Bradykinesia with overall accuracy of 94.6% (Table 1)

Type of activities	Accuracy (%)
Walking	96.7
Non-walking	93.8
Overall	94.6

## CONCLUSIONS

These results demonstrate the first successful sensor-based approach for autonomous monitoring of Body Bradykinesia during activities of daily living. By eliminating the need to perform scripted activities, our approach supports the viability of an ambulatory system that could be used in the home or community to monitor fluctuations of Body Bradykinesia. Similar algorithms are under development for

tracking the full complement of movement disorders associated with PD<sup>3</sup>. When completed, the wearable system will provide comprehensive motor outcome data needed by healthcare providers to better manage medication titration, adjust DBS settings, and establish efficacy for new interventions undergoing clinical trials.

## INTRODUCTION

Gait performance has received considerable attention in the literature across a variety of clinical populations and age groups. Gait speed is often considered one of the best clinical metrics for assessing movement [1] and is often considered a surrogate for overall morbidity and mortality.

Clinical gait assessments performed overground at a self-selected pace are common, with primary outcomes including gait velocity and spatiotemporal gait characteristics. Typically, several trials of overground gait are collected and outcome metrics are averaged across trials to improve accuracy [1].

In persons with movement disorders there is a need for gait assessments to be more comprehensive as patients often have balance difficulty and trouble with changing direction and initiating and terminating gait. The Primary Gait Screen (PGS) is a new assessment protocol which incorporates gait initiation, turning, and gait termination into the standard overground assessment using the same available space and pressure mat (Fig. 1). To break the assessment into different tasks, the user determines the software processing parameters that work best. The PGS may be a useful assessment to easily capture more comprehensive movement data in clinic in a brief period of time.

However, before the PGS assessment can be accepted we must first test if the gait velocity calculated during PGS is accurate when compared to overground walking. To date, there are no comparisons between simple overground gait assessments at a self-selected pace and the PGS. Thus, the purpose of this study was to determine if the gait velocity calculated during the PGS is an

accurate measure of gait velocity when compared to simple overground walking. Further, we altered processing parameters to determine the most accurate settings to calculate gait velocity.

We hypothesized gait velocity would be faster in the simple self-selected walking trials compared with the PGS trials. Further, we anticipated the most conservative processing of the PGS (i.e., with the greatest cropping) would most closely resemble gait velocity measured during the self-selected walking trials.

## METHODS

Overground gait was assessed in 102 adult patients diagnosed with a movement disorder (47F, 55M; age:  $67 \pm 9$  years). Patients completed a standard protocol on an 8m Zeno Walkway (ProtoKinetics, Havertown, PA) including a single 4x self-selected speed trial (4xSS) and two trials of the Primary Gait Screen, resulting in a total of 4 passes during the PGS. During the 4xSS trial, all patients started 1m before the walkway and turned 1m after the end of the walkway to account for acceleration and deceleration. Further, the first and last 0.6m of the 4xSS trials were excluded to eliminate the first and last steps on the mat for accommodation purposes.

In effort to preserve the clinical applicability of the assessments, the gait velocity data were processed using the Protokinetics PKMAS software. The PGS trials were processed 3 times using 3 different cutoff parameters (1m, 1.5m, 2m). For example, during the 1m cutoff processing, the data from the first meter and last meter of the walkway were ignored in the computation of gait velocity. During the 1.5m cutoff processing, the first and last 1.5m were ignored, resulting in a velocity calculated from the middle 5m

of the walkway. Both trials were processed independently and the resulting gait velocities from the two trials were averaged for each condition.

Paired samples t-tests were used to compare the calculated gait velocities from the PGS cutoffs to the reference group: the 4xSS trial ( $p < .05$ ).

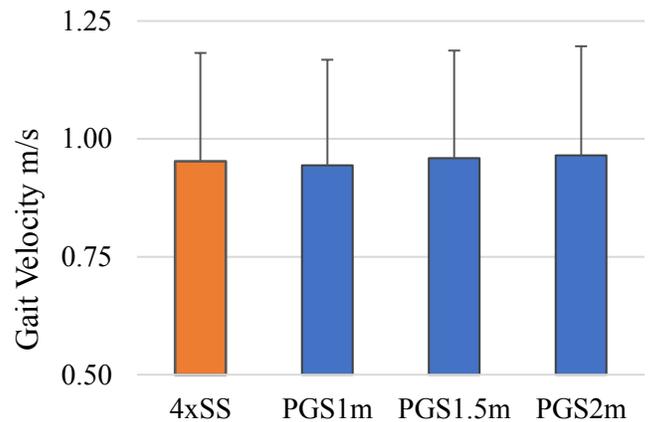

## RESULTS AND DISCUSSION

No significant differences were found in gait velocity between the 4xSS and the computed PGS gait velocities (1m:  $t(101) = 1.157, p = .250$ , Cohen's  $d = 0.037$ ; 1.5m:  $t(101) = -0.951, p = .344$ , Cohen's  $d = -0.029$ ; 2m:  $t(101) = -1.746, p = .084$ , Cohen's  $d = -0.055$ ) (Fig. 2). As evidenced by the very small effect sizes, the mean differences in gait velocity ranged from 0.007 m/s (using 1.5m cutoff) to 0.013 m/s (using 2m cutoff). These differences do not meet the minimally important difference in gait velocity in these populations [2].

These results suggest the PGS may be a useful and accurate clinical assessment of overground walking in persons with movement disorders. To broaden the application of these results, future investigations should expand upon this analysis to look at the gait initiation and gait termination portions of the PGS, in addition to the self-selected gait.

Limitations in this investigation include the diverse sample of patients with varied diagnoses, although

this sample likely represents a realistic cross-section of patients that may be seen in a clinical setting.

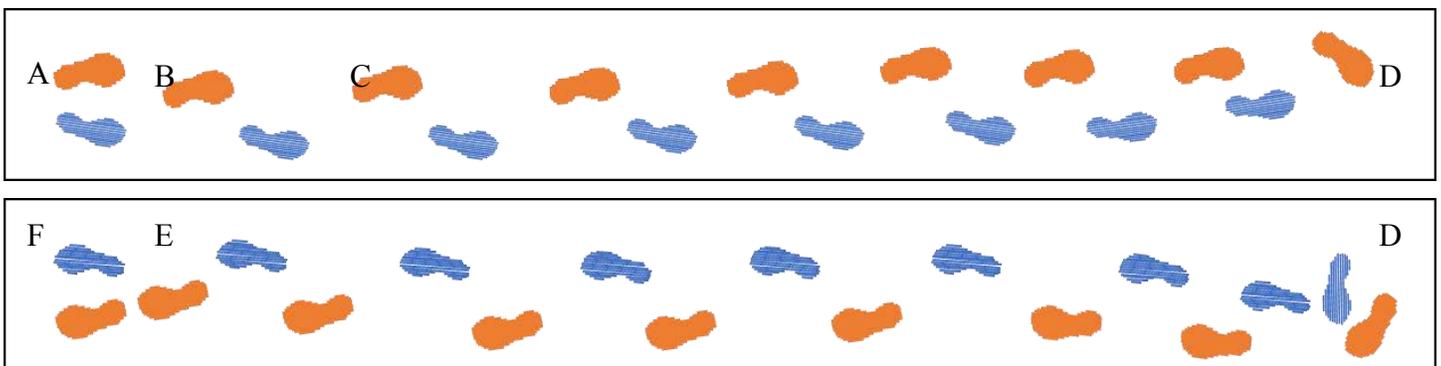

**Figure 2:** Mean and standard deviations of the computed gait velocities for the 4x Self-Selected (4xSS) and Primary Gait Screen (PGS) trials at different cutoff distances.

## CONCLUSIONS

The self-selected walking portion of the Primary Gait Screen does appear to be a good measure of gait velocity in persons with movement disorders.

## INTRODUCTION

Both Parkinson's disease (PD) and osteoarthritis (OA) demonstrate deficits in gait brought about by similar symptoms; stiff joints, slowness, inflexibility, weakness, and a need for assistive devices. Recently, a study by Jones and colleagues [1] reported that arthritis co-occurs in almost 26% of PD patients (n=341). Yet, although similarities in functional impairments exist between the two populations, little is known about the impact of OA on gait impairment in persons with PD. Furthermore, the literature is void of large-scale cohort studies that provide this information.

Understanding the impact of OA on PD is critical to determine the extra burden that OA may contribute to gait impairment in persons with PD and consequently the medical management of these patients. Thus, we sought to understand to what extent OA severity impacts functional mobility performance in patients with PD across time. To investigate this, we evaluated performance times from the Timed Up & Go (TUG) test in patients with PD and OA. Increased OA severity was hypothesized to be predictive of lower functional mobility performance.

## METHODS

We included 4,428 patients with PD from the National Parkinson's Foundation QII database with available timed up and go (TUG) and OA information at baseline and 1-2 years follow-up (9 months to 27 months after baseline) in this analysis. The data were obtained from 16 participating National Parkinson Foundation Centers of

Excellence from within the United States. All participants signed the informed consent.

All evaluations were done in the on medication state. Patients registered in the database between 2009 and 2016 were included. Demographic information of those used in the analysis can be found in table 1.

For the dependent variable, functional mobility, performance was assessed using the TUG test and patients' performance was categorized as either "High" or "Low" functional mobility. High functional mobility performance was defined as performing the TUG in 12 seconds or less [2]. During the TUG test, patients were instructed to stand up from a chair and walk forward at their comfortable speed for 3m, then turn around and walk back to the chair and sit down. The evaluation was timed in seconds from the command, 'go' until the participant made contact sitting in the chair. If the patient could not perform the task without using their hands to push off, they were allowed to perform the test while using their hands or an assistive device to push off the chair. All patients who could not perform the task without using their hands to push off were designated as "Low" functional mobility.

We added sex, age, body mass, and standardized cognition (immediate 5-word recall, verbal fluency, delayed 5-word recall) as covariates to the analysis based on their impact on gait speed and/or their potential to limit mobility [2,3]. To evaluate differences in TUG performance among OA groups we performed a logistic regression while controlling for the pre-specified covariates.

## RESULTS AND DISCUSSION

At baseline 2,538 (57.3%) patients reported no symptoms of OA, 1,047 (23.6%) reported asymptomatic/minimal OA, and 843 (19.1%) reported symptomatic OA (moderate to very severe).

Both the asymptomatic/minimal OA and symptomatic groups had significantly more patients with low functional mobility (TUG>12 seconds), both at baseline (Figure 1). Similar results hold at the 1-2 year follow-up ( $p<0.0001$ ). In addition, there were higher proportion of patients with low functional mobility at follow-up than baseline for all three OA groups, however, the differences among groups in change from baseline to follow-up were not significant ( $p=0.360$ ).

The between group difference remained statistically significant after covariate adjustment with the use of logistic regression. Specifically, at the baseline visit, the odds of having high functional mobility skill for patients with asymptomatic/minimal OA was 1.50 times (95% CI: 1.23-1.84;  $p<0.0001$ ) compared to those with Symptomatic OA; while the odds for patients without OA was 1.71 times (95% CI: 1.43-2.05;  $p<0.0001$ ) compared to those with Symptomatic OA. The between group differences were similar at 1-2 year follow-up, with odds ratio of 1.78 times (95% CI: 1.45-2.19;  $p<0.0001$ ) for those with asymptomatic/minimal OA compared to those with Symptomatic OA; and odds ratio of 1.84 times (95% CI: 1.53-2.04;  $p<0.0001$ ) for those without OA compared to those with Symptomatic OA.

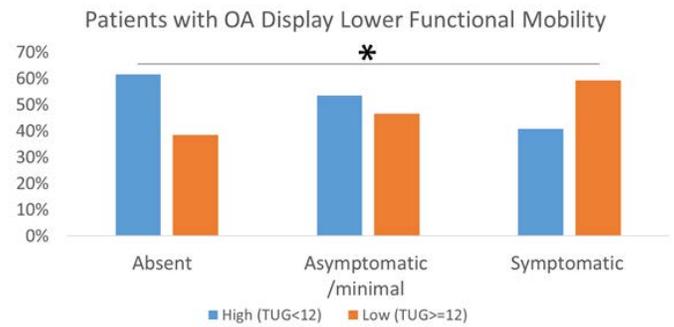

Figure 1. Percentage of patients with high and low functional mobility as measured by the TUG test.

## CONCLUSIONS

This study is one of the first to focus on understanding the influence of osteoarthritis in patients with PD and how this may affect their function and mobility. In summary, functional mobility performance was influenced by OA severity in patients with PD. Specifically, patients with PD who also have a diagnosis of OA have a 1.5-1.8 times increase in risk of displaying low functional mobility. These findings highlight the importance of recognizing the extra burden of OA on functional mobility in patients with PD.

## INTRODUCTION

Ankle osteoarthritis is a debilitating disease with patients reporting levels of impairment as high as those associated with end-stage kidney diseases, congestive heart failure, and end-stage hip arthritis [1, 2]. There are approximately 50,000 new cases of post-traumatic ankle arthritis reported each year [3]. The ability to quantitatively assess impairment and gait mechanics in clinical settings is challenging. A potential alternative is identifying spatiotemporal variables that are indicative of pathology that can be effectively assessed in the clinic.

The objective of this study was to investigate a clinically-accessible method of identifying gait asymmetries (“limp”) and other changes in patient gait associated with ankle osteoarthritis. We predicted that there would be differences in swing and stance time between affected and unaffected limbs. Sex-specific effects were also investigated to account for sex-based differences, allowing for correction of treatment disparities.

## METHODS

This is a secondary analysis of prospectively collected data on a group of 242 (110 men, 132 women) end-stage ankle OA patients. Only those subjects that have isolated unilateral involvement, no contralateral pain, and no rheumatoid arthritis diagnosis were included (Table 1).

Each subject completed at least four self-selected speed walking trials using an eight-camera motion capture system (Motion Analysis Corporation, Santa Rosa, CA; 120Hz). Heel-strike and toe-off timings were exported from Visual3D after ensuring strike patterns had been correctly identified. Four temporal variables were calculated using a custom Matlab script: stride time, swing time, stance time, and

double support time. Stride, swing, and stance time were defined as heel-strike to heel-strike, toe-off to heel-strike, and heel-strike to toe-off on a single limb, respectively. Left double support time was defined as left heel-strike to right toe-off, and right double support time was defined as right heel-strike to left toe-off. Each temporal variable was averaged across steps for a single trial and then across trials for each subject, and for each limb. Steps per trial and trials per subject both varied between subjects.

An ANCOVA comparing sex and limb (affected and unaffected) while co-varying for average walking speed was run for each variable using JMP Pro 13. All 2-way and 3-way interactions between sex, limb, and walking speed were also examined. An alpha level of 0.05 was used for all analysis.

## RESULTS AND DISCUSSION

No significant 3-way interactions were seen, but several 2-way interactions were significant. (Fig 1). Among the main effect differences, sex-specific effects were seen with men having higher stride, swing, and stance times than women (Fig 1). Limb-specific effects were also seen: swing time was higher on the affected limb and stance time was higher on the unaffected limb. The increase in swing time and decrease in stance time on the affected limb was an expected outcome and may function as a compensatory pattern due to ankle pain on the affected limb.

Effects of walking speed were seen in stride, stance, and double support times but not in swing time. Effects of walking speed on the study variables was sex-dependent for all variables and limb-dependent for all variables except for stride time.

High coefficients of variation, which ranged from 11.6% to 48%, were seen in all study variables and

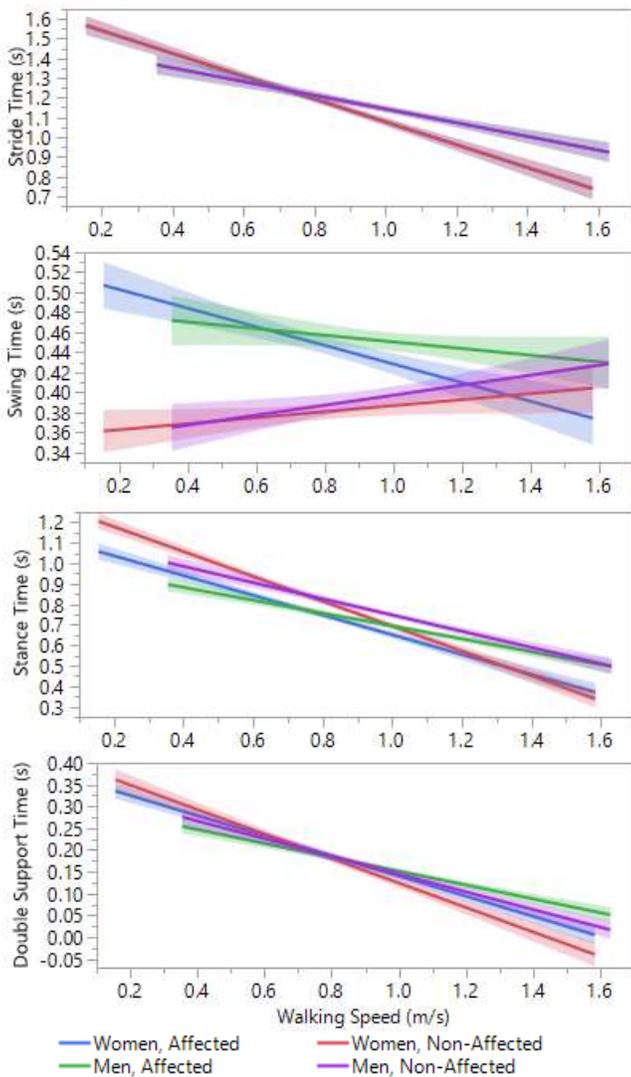

Figure 1: Stride, Swing, Stance, and Double Support Times as a function of walking speed. Results shown by sex and limb differences. \*\*Note: Time scales vary between graphs.

may have restricted significance of results. The highest coefficients of variation were seen in double support time, which also saw the fewest significant effects.

Literature examining sex-specific temporal gait differences in ankle OA patients is limited. It is unclear whether the sex-specific effects observed in this study are present in healthy populations or are a result of sex-specific pain coping compensatory

mechanisms. Similarly to our results, Valderrabano et al found that stride time was not different between limbs in pre-operative ankle osteoarthritis patients [4]. Nuesch, et al. observed no decrease in stance time as a percent of stride time [5], which disagrees with our finding of shorter stance time on the affected limb. Conversely, Shih et al observed decreased stance time and increased swing time on the affected limb, both of which agree with our results [6]. However, Shih et al also saw an increase in double support time on the affected limb, which our results did not reflect.

## CONCLUSIONS

It is possible that temporal variables, which are much easier to collect than 3D motion capture data, can be used to quantify limp and gait compensation; walking speed could play a large role in this quantification, along with limb-specific differences between swing and stance times. These results demonstrate the value of using these simpler variables to evaluate compensation. Results of this study demonstrate the complexity of this patient population and bring up intricacies in studying ankle OA gait. Future studies are needed to better understand variability within the ankle OA patient population and sex-specific differences observed in temporal parameters.

## INTRODUCTION

United Cerebral Palsy (UCP) reports that an estimated 764,000 individuals in the United States exhibit one or more symptoms of CP, and a recent multisite UCP study of school-age children found that 24.8% of these individuals use walkers [1]. It is estimated that more than 10,000 pediatric walkers are sold each year in the United States [1].

The purpose of a posterior walker is to increase the mobility of the user while maintaining stability and proper posture. Walkers enhance stability by providing both vertical and lateral support at the user's hands. However this increase in stability comes at the cost of having to pull the walker along. Children with CP typically are weaker and fatigue faster than their typically developed peers. Additionally they have been shown to do 59% more work per unit mass on average than TD children [2]. This work develops a method for quantifying the stabilizing forces and the associated increased energetic cost of walking with a pediatric posterior walker for children with CP.

## METHODS

Two children with CP, GMFCS II and IV were instructed to walk in a straight path at their self-selected comfortable walking speed using a custom instrumented posterior pediatric walker (Fig 1). A typical posterior walker was instrumented at the handles with a 6 DoF load cell (ATI) to capture all forces (1080Hz) applied through the handles. Kinematic data was collected at 120 Hz using an 8 camera motion capture system (Vicon) and the full-body Plug-in-Gait marker set in tandem with the 5-point set for the walker located at each handle end (2), load cell locations (2), and center cross bar (1).

Vertical and lateral forces applied to the handles were normalized via body mass to quantify the

stabilizing forces applied by each test subject. The anterior/posterior forces applied at the handle were used in conjunction with the 3D location of the load cells in order to calculate the mechanical work required to move the walker during typical straight walking.

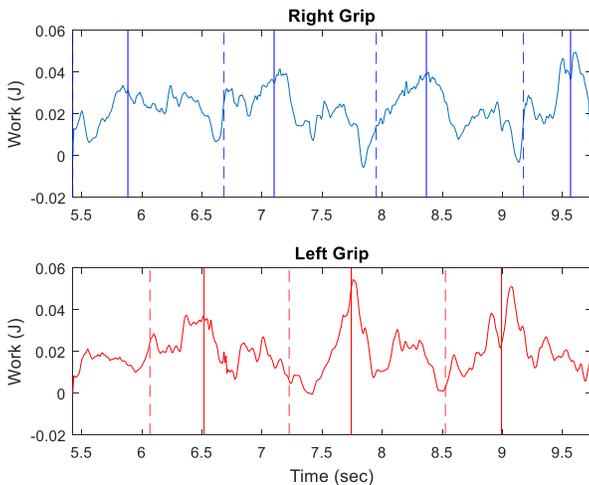

**Figure 1:** Instrumented walker with five markers (left/right grip, left/right sensor, bar) and load cells at connection from handles to walker.

For each time point force, data was subsampled to match kinematic data, and instantaneous work at each handle was calculated as the instant force multiplied by the distance traveled over each time sample. Total work was calculated as the sum of the work done at each handle over the whole trial, these data were normalized by the total linear distance traveled by the walker. Gait events were also identified in order to quantify how the work applied to the walker changed relative to the gait cycle.

## RESULTS AND DISCUSSION

The average total work to move the walker per distance travelled for subject 1 was 9.2(1.9) J/m (GMFCS II) and subject 2 was 15.9(1.9) J/m (GMFCS IV). This compares with the normalized vertical [0.369(0.050) N/kg and 1.9(0.14) N/kg] and lateral [0.0646(0.011) N/kg and 1.41(0.13) N/kg] support forces for each.

Evaluating the instantaneous work relative to gait events shows that a pattern can be seen near foot off (FO) and foot strike (FS) (Fig 2).

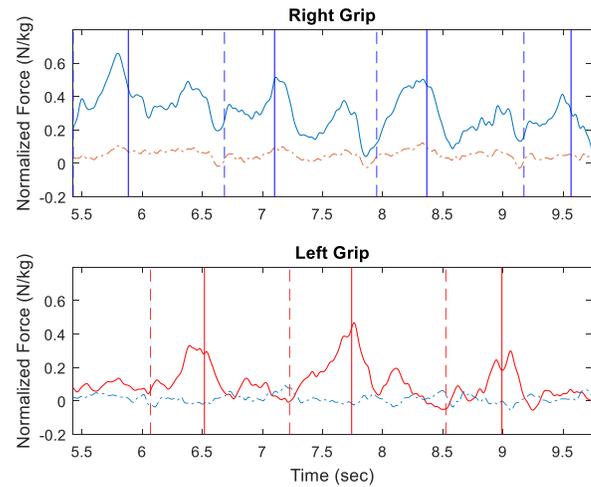

**Figure 2:** Work done on the left and right grips over one trial marked with respective FO events as dashed lines and FS events as solid lines.

Near FO events there is a relative minimum in the amount of work done on the walker, often approaching a negative value. At FS events, we see local maxima reached. These observations reveal how the user has incorporated the walker into their gait. At FO, entering into the swing phase of their gait, the user performs negative or low magnitude work, this coincides with the moment of max power generation needed by the subject during gait to start their next step and move their CoM up and over the stance leg. At FS, entering double support, the user pulled the walker forward with the maximum work observed.

The vertical and lateral forces applied to the walker at the grips reveals how the walker was used for stability and to what extent over the trials (Fig 3). The vertical force shows a similar relationship to the FO and FS events as the total work. During the swing phase between FO and FS, the vertical force increases to a local maxima revealing increasing use

for stability. After FS, the vertical force drops back down as the user is in double support and more independently stable.

**Figure 3:** Normalized vertical (solid) and lateral (dashed) force where downwards is positive, with FO and FS events marked as dashed and solid lines respectively.

## CONCLUSIONS

The two subjects tested are representative of the extreme walker users, subject one with little reliance on the walker and subject two unable to ambulate without the walker, and were chosen to bracket a typical walker user.

It has been reported that ambulatory children with CP do on average 1.03 J/kg-m of total work while walking without assistive devices [2]. For subject 1, an independent community ambulatory, with a mass of 45kg this equates to approximately 46.4 J/m. So adding the walker their work done would increase by nearly 20%, the increase would be far greater for subject 2.

With the significant increase in work required to use a walker, a child with CP may not be able to use it for long periods of time and thus decrease their overall mobility. The observed patterns in work required and vertical force indicate that a control system for a motorized walker could be designed to decrease the work applied to the walker.

# METABOLIC AND MECHANICAL DEMANDS OF SYMMETRICAL AND ASYMMETRICAL WALKING ON A SPLIT-BELT TREADMILL

Jan Stenum and Julia T. Choi

Department of Kinesiology, University of Massachusetts Amherst, Amherst, MA, USA  
email: jstenum@umass.edu, web: <http://blogs.umass.edu/jtchoi>

## INTRODUCTION

Metabolic and mechanical costs during symmetric walking can be predicted from speed, step length and step rate. How does gait asymmetry affect the energetics of walking? Walking with asymmetric speeds [1] (e.g., on a split-belt treadmill) or asymmetric step durations [2] incurs an added metabolic cost. In split-belt walking, it is not clear if the extra metabolic cost is due to greater mechanical costs, poor efficiency, or a sub-optimal stride rate. We asked whether the mechanical power performed by each leg is dependent only on the ipsilateral leg speed (and independent of contralateral leg speed). We hypothesized that greater mechanical power explains the increase in metabolic power during asymmetrical walking, independent of stride rate.

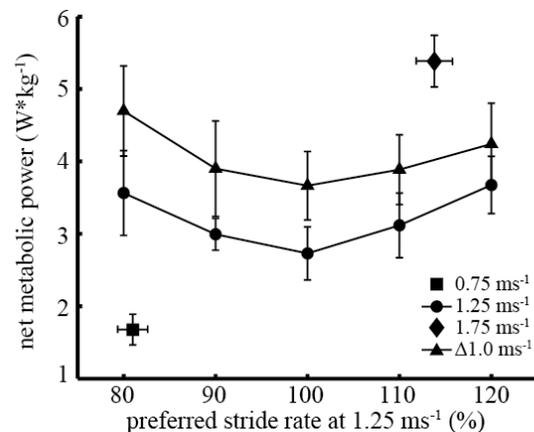

## METHODS

5 subjects participated (4 male, 1 female; age  $20.4 \pm 1.96$  years; mass  $69.8 \pm 2.7$  kg). First, subjects walked symmetrically at  $1.25 \text{ ms}^{-1}$ ,  $0.75 \text{ ms}^{-1}$  and  $1.75 \text{ ms}^{-1}$  at preferred stride rates. Then, subjects walked symmetrically at  $1.25 \text{ ms}^{-1}$  and, following a 10-minute adaptation period, asymmetrically at belt speeds of  $0.75$  and  $1.75 \text{ ms}^{-1}$  ( $\Delta 1.0 \text{ ms}^{-1}$ ) on a split-belt treadmill at 80, 90, 100, 110 and 120% of their preferred stride rate at  $1.25 \text{ ms}^{-1}$ . Each trial lasted 5 minutes. We calculated net metabolic power from expired air. We calculated the average external positive mechanical power performed on the center of mass by each leg as the dot product of each leg's ground reaction forces and the center of mass velocity (obtained by integrating net ground reaction forces) divided by stride duration. External positive mechanical work is performed during the initial part of single support and during push-off. To characterize the distribution of positive mechanical work during stance, we divided power production during single support by the total amount. Because preferred stride rates at  $0.75 \text{ ms}^{-1}$  and  $1.75 \text{ ms}^{-1}$

approximated 80% and 110% of preferred stride rate at  $1.25 \text{ ms}^{-1}$ , we compared each leg's mechanical variables for symmetrical walking at  $0.75 \text{ ms}^{-1}$  and  $1.75 \text{ ms}^{-1}$  against those of asymmetrical walking at 80% and 110%, respectively (using paired t-tests).

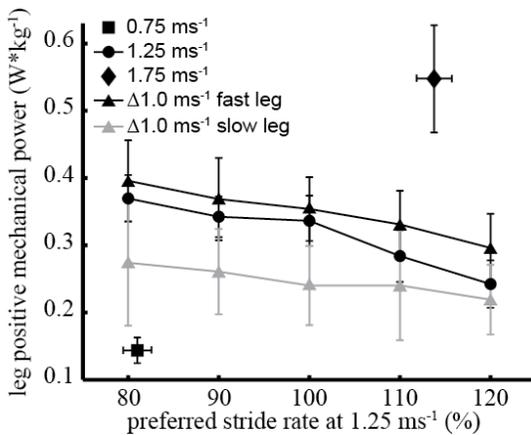

## RESULTS AND DISCUSSION

Preferred stride rates were 44.4, 54.8 and  $62.4 \text{ strides} \cdot \text{min}^{-1}$ , at  $0.75$ ,  $1.25$  and  $1.75 \text{ ms}^{-1}$ . During asymmetrical walking at  $\Delta 1.0 \text{ ms}^{-1}$ , step durations (heel strike to heel strike) from the slow to the fast leg increased (+18 to +23%) while step durations from the fast to slow leg decreased (-19 to -23%) relative to symmetric step durations.

**Figure 1:** Net metabolic power. Error bars are one standard deviation.

Net metabolic power of asymmetrical walking at  $\Delta 1.0 \text{ ms}^{-1}$  was greater than symmetrical walking at the same averaged belt speed, i.e.  $1.25 \text{ ms}^{-1}$ , at all stride rates ( $P \leq 0.018$ ) (figure 1). That is, walking in an asymmetrical environment incurs an added metabolic cost that is independent of stride rate. This is consistent with the added metabolic cost (independent of stride rate) of enforcing asymmetrical step durations with a metronome [2].

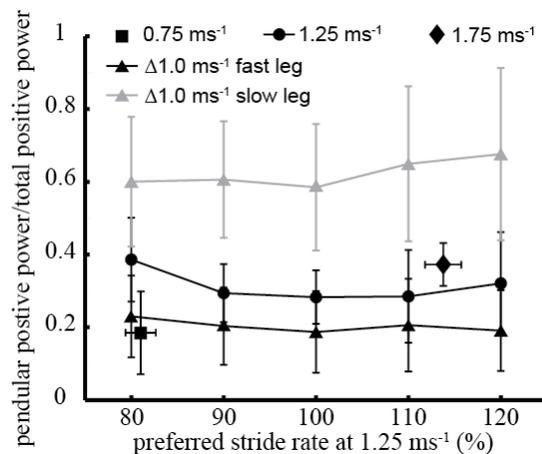

**Figure 2:** External positive mechanical power of each leg. Error bars are one standard deviation.

However, the total external positive mechanical power summed across both legs was not different between asymmetrical walking at  $\Delta 1.0 \text{ ms}^{-1}$  and symmetrical walking at  $1.25 \text{ ms}^{-1}$  (not shown) ( $P \geq 0.291$ ). This is contrary to enforcing step duration asymmetry with a metronome, which resulted in greater external positive mechanical power [2]. During asymmetrical walking at  $\Delta 1.0 \text{ ms}^{-1}$ , positive mechanical power of the fast leg was greater than the slow leg at all stride rates ( $P \leq 0.036$ ) (figure 2). The positive mechanical power of the slow leg during asymmetrical walking was greater than the positive mechanical power performed while walking symmetrically at  $0.75 \text{ ms}^{-1}$  (slow leg's belt speed) ( $P \leq 0.044$ ) even after normalizing to the longer stance duration of the slow leg in asymmetrical walking (1.00 s vs 0.92 s;  $P < 0.001$ ). The positive mechanical power of the fast leg during asymmetrical walking was less than the positive mechanical power performed while walking symmetrically at  $1.75 \text{ ms}^{-1}$  (fast leg's belt speed) ( $P \leq 0.008$ ) even after normalizing to the shorter stance duration of the fast leg in asymmetrical walking (0.54 s vs 0.60 s;  $P < 0.002$ ).

In addition to the greater positive mechanical power performed by the slow leg during asymmetrical walking at  $\Delta 1.0 \text{ ms}^{-1}$  compared to symmetrical walking at  $0.75 \text{ ms}^{-1}$ , a greater proportion of the mechanical work was performed during single support ( $P < 0.016$ ) (figure 3). Because positive external work during single support is performed by work at the hip and knee (and not the ankle), this suggests that positive mechanical work by the slow

leg during asymmetrical walking at  $\Delta 1.0 \text{ ms}^{-1}$  is performed with poor efficiency [3]. The fast leg during asymmetrical walking at  $\Delta 1.0 \text{ ms}^{-1}$  performed a smaller proportion of positive mechanical work during single support than symmetrical walking at  $1.75 \text{ ms}^{-1}$  ( $P < 0.016$ ) (figure 3) which suggests a greater efficiency.

Although joint work is not redistributed by walking speed, efficiency is greatest between 1.25 and 1.75  $\text{ms}^{-1}$  and poorest at  $0.75 \text{ ms}^{-1}$  [4]. The effect of walking speed on efficiency and the redistribution of positive work between single support and push-off during asymmetrical walking likely means that the poor efficiency of the slow leg is not fully balanced by the improvement of efficiency of the fast leg during asymmetrical walking at  $\Delta 1.0 \text{ ms}^{-1}$ .

**Figure 3:** Ratio of pendular positive power during single support to the total amount of positive power over stance of each leg. Error bars are one standard deviation.

We have shown that walking in an asymmetrical environment on a split-belt treadmill incurs an added metabolic cost that is independent of stride rate. Contrary to our hypothesis, this is not explained by greater positive mechanical power during asymmetrical walking. Rather, the redistribution of work by the slow leg could explain the increased metabolic cost.

# EFFECT OF FREQUENCY ON WHOLE BODY MOVEMENT CONTROL IN CHILDREN WITH AND WITHOUT DOWN SYNDROME DURING TWO-LEGGED HOPPING IN-PLACE

Matthew Beerse and Jianhua Wu

Georgia State University, Atlanta, GA, USA. Email: [mbeerse1@student.gsu.edu](mailto:mbeerse1@student.gsu.edu)

## INTRODUCTION

Hopping in-place generally follows a spring-mass model for adults and typically developing (TD) children [1]. Increasing hopping frequency demands increased whole-body vertical stiffness and constrained horizontal movement. Children with Down syndrome (DS) often exhibit limited movement ability due to reduced muscle strength, joint coordination, and balance control [2]. It is unknown if children with DS are able to hop outside of their preferred frequency, like their TD peers. This study aimed to assess the whole-body control strategies employed to modulate hopping frequency by children with DS compared to TD children.

## METHODS

*Participants:* Fifteen children with DS and 16 TD children were recruited for this study. Six children with DS were unable to coordinate continuous hopping and were removed from analysis. We age- and sex-matched 9 TD children corresponding to the remaining 9 children with DS. Mean age (SD) was 9.57 (1.53) years, height was 1.22 (0.10) m, body-mass was 30.58 (10.37) kg, and leg length was 0.64 (0.06) m for children with DS (3M/6F) and 9.28 (1.46) years, 1.37 (0.09) m, 32.54 (6.70), and 0.74 (0.07) m for TD children, respectively. Children with DS were shorter in height and leg length, but had similar body mass compared to TD children.

*Experimental design:* Each subject completed three trials of hopping at a self-selected pace to calculate the subject's preferred frequency. We randomly presented four frequency conditions based on their preferred frequency. A metronome led the frequency conditions which consisted of their *preferred* frequency, 20% decrease (*slow*), 20% increase (*moderate*), and 40% increase (*fast*). Two of the DS subjects could complete the *fast* condition so this condition was removed from data analysis.

*Data collection:* Kinematic data was collected using an 8-camera Vicon motion capture system sampling

at 100Hz. We attached a full-body PSIS marker set. Kinetic data was collected using an AMTI force plate sampling at 1000Hz. For each condition, subjects hopped for 20-seconds. Three trials were completed for each frequency condition.

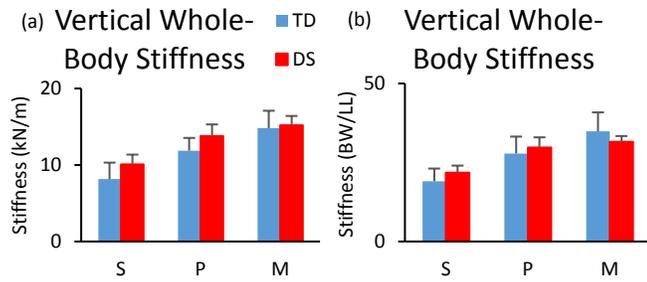

*Data analysis:* We calculated whole-body vertical stiffness as the linear regression slope of vertical ground reaction force (GRF) vs. vertical center of mass (COM) displacement over the stance phase [4]. Vertical COM displacement was calculated by double integration of COM acceleration from the vertical GRF [3]. We also normalized whole-body vertical stiffness by bodyweight (BW) and leg length (LL). For horizontal movement, COM position was estimated from marker data using segmental analysis [2]. We calculated anterior/posterior (AP) and medial/lateral (ML) COM range as the difference between the maximum and minimum positions during stance phase. We calculated AP and ML toe displacement as the difference in position of the toe marker between hops.

*Statistical analysis:* Repeated measures two-way (2 group x 3 condition) ANOVAs were conducted on each raw or log-transformed variable. Bonferroni adjusted post-hoc pairwise comparisons were completed when necessary. A significance level was set at  $\alpha=0.05$ .

## RESULTS AND DISCUSSION

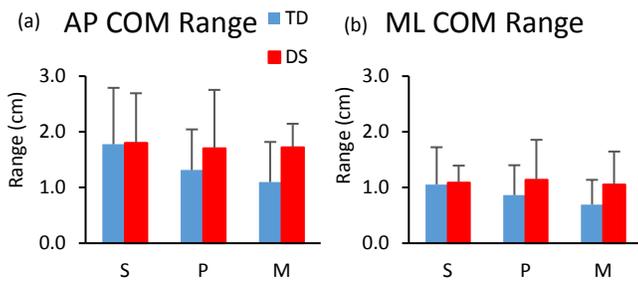

Children with DS hopped at a faster preferred frequency (2.65 Hz) compared to TD children (2.29 Hz). However, children with DS hopped with a similar whole-body vertical stiffness (no group effect for absolute and normalized stiffness). Both children with DS and TD children increased whole-body vertical stiffness when increasing hopping frequency (condition effect for absolute:  $p<0.001$ , normalized:  $p<0.001$ ) (Fig. 1). Both groups increased hopping frequency from *slow* to *preferred* and *slow* to *moderate*, but not *preferred* to *moderate*.

Fig.1

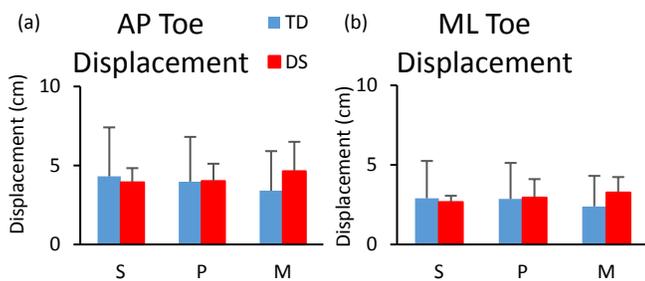

Note: S for *slow*, P for *preferred*, and M for *moderate* frequency condition.

Fig.2

Only TD children decreased AP COM range with increasing frequency (Fig. 2a; group by condition interaction:  $p=0.040$ ). From *slow* to *moderate*, TD children decreased AP COM range ( $p=0.005$ ), resulting in a comparatively greater range in children with DS at the *moderate* condition ( $p=0.012$ ). ML COM range was not different between groups and unaffected by frequency condition (Fig.2b).

Fig. 3

At the *moderate* frequency children with DS increased AP and ML toe displacement, while TD

children decreased (group by condition interaction:  $p<0.001$  for AP and  $p=0.002$  for ML) (Fig. 3a). Both groups decreased stance time with increasing hopping frequency (Table 1). TD children decreased flight time and hopping height with increasing frequency, while children with DS also decreased from *slow* to *preferred*, but increased at *moderate*.

Similar to TD children, children with DS aged 6-11 years are able to modulate their whole-body vertical stiffness and follow a spring-mass model. However, children with DS did not effectively coordinate hopping at the *moderate* frequency condition, demonstrated by hopping height and flight time. This result is similar to previous studies where children with DS, when asked to tap on a pad faster, incorrectly tapped with greater force [4]. Children with DS did not display as much balance control as TD children. TD children reduced AP COM range of motion and AP displacement between hops to increase hopping frequency. Children with DS were unable to modify AP COM range of motion and increased AP displacement between hops at the *moderate* frequency.

## CONCLUSIONS

Children with DS modulate whole-body movement similar to TD children. However, children with DS demonstrate ineffective control strategies and greater horizontal movement when required to hop at a 20% increase (*moderate*).

# BIOMECHANICAL ANALYSIS OF TIMED UP-AND-GO (TUG) TEST IN CHILDREN WITH AND WITHOUT DOWN SYNDROME

Matthew Beerse, Michael Lelko, Jianhua Wu  
Georgia State University, Atlanta, GA, USA. Email: [mbeersel@student.gsu.edu](mailto:mbeersel@student.gsu.edu)

## INTRODUCTION

The Timed Up-and-Go (TUG) test consists of multiple functional tasks of daily living [1]. Specifically, the test requires the participant to stand up from a chair, walk, turn-around, and sit down. The TUG test has been shown to be a valid tool to assess functional mobility in children with DS [1]. While children with DS take a longer time to complete the test compared to typically developing (TD) peers, it is unknown how children with DS perform at each phase of the task. The purpose of this study was to compare the biomechanical pattern of the TUG test between children with and without DS, particularly during the sit-to-stand and walk-out phase.

## METHODS

*Participants:* Fourteen children with DS (4M/10F) and 14 sex- and age-matched TD children were recruited for this study. Mean (SD) age for children with DS was 8.58 (1.91) years, height was 1.18 (0.12) m, body-mass was 27.16 (10.41) kg, and leg length was 0.62 (0.08) m, and for TD children was 8.20 (1.78) years, 1.31 (0.10) m, 29.60 (6.75) kg, 0.71 (0.07) m, respectively.

*Experimental design:* Subjects sat on a chair without side arms, feet in contact with the floor, hip and knee flexed at about 90 degrees and ankle at neutral. Subjects were instructed to stand up from a chair, walk towards a target 3m away, touch the target, turn around, walk back to the chair, and sit down. Subjects completed five trials and were reminded not to run and to walk as fast as possible in each trial.

*Data collection:* We attached a full-body PSIS marker set to the subject and collected kinematic data using an 8-camera Vicon motion capture system sampling at 100Hz.

*Data analysis:* We visually separated the trials into five phases: (1) sit-to-stand, (2) walk-out, (3) turn around, (4) walk-in, and (5) stand-to-sit. We used the criteria below to differentiate the phases across trials

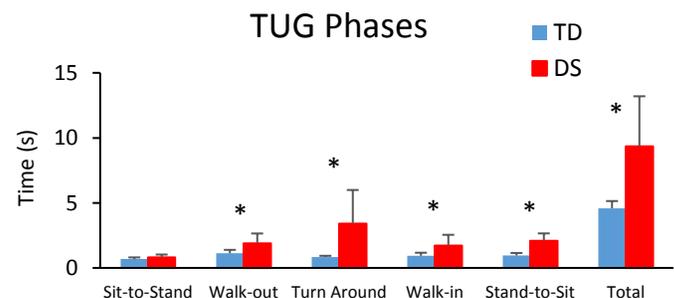

and subjects: sit-to-stand started with the initiation of forward trunk lean and ended with the end of vertical movement of the upper body; turn-around started at the beginning of pelvis rotation and ended when the pelvis orientation returned along the anterior/posterior (AP) axis; and stand-to-sit started at the beginning of pelvis rotation before lowering to the chair and ended with the end of vertical movement of the upper body. The walk-out and walk-in phases were coded as the time between sit-to-stand and turn around, and turn around to stand-to-sit, respectively.

During the sit-to-stand phase we assessed the center-of-mass (COM) excursion and its peak velocity in the AP, medial/lateral, and vertical directions. We also calculated peak extension angle and velocity of the ankle, knee, and hip in the sagittal plane over the entire phase. During the walk-out phase we calculated step length, step width, and walk speed. We normalized step length, step width, and walk speed [2], but statistical results were unaffected.

*Statistical analysis:* Independent t-tests were conducted on the TUG time, each phase duration, and each phase variable to compare the two groups. A significance level was set at  $\alpha=0.05$ .

## RESULTS AND DISCUSSION

Fig. 1

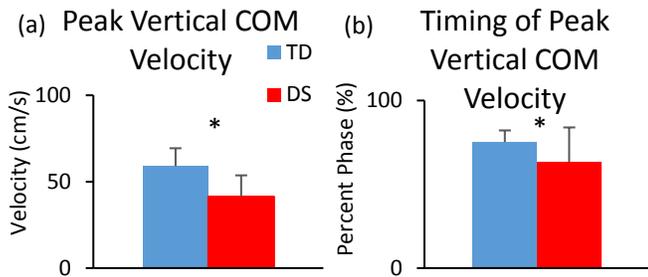

Note: \* indicates statistically significant differences.

Children with DS took longer to complete the TUG task compared to TD children ( $p<0.001$ ) (Fig. 1). On

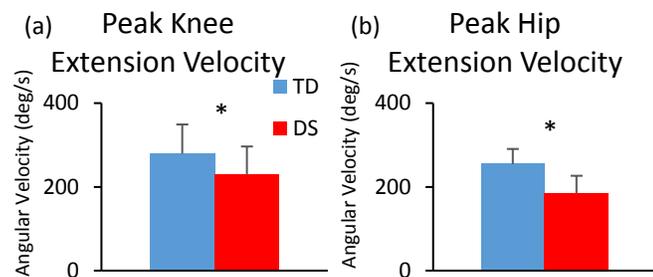

average, children with DS completed the TUG task in 9.35 seconds compared to 4.59 seconds for TD children. Broken down to the five phases, children with DS took longer for each phase except the sit-to-stand phase ( $p=0.054$ ).

Fig. 2

During sit-to-stand, both groups demonstrated similar COM excursion in each direction and peak COM velocity in AP and ML. However, in the vertical direction, the DS group showed a slower peak COM velocity ( $p=0.021$ ) and reached peak velocity earlier in the phase ( $p=0.046$ ) (Fig. 2a-b). Both groups reached similar peak ankle, knee and hip extension angles during the sit-to-stand phase. However, the DS group exhibited slower peak hip and knee extension velocities than the TD group ( $p<0.001$  and  $p=0.046$ , respectively) (Fig. 3a-b).

Fig. 3

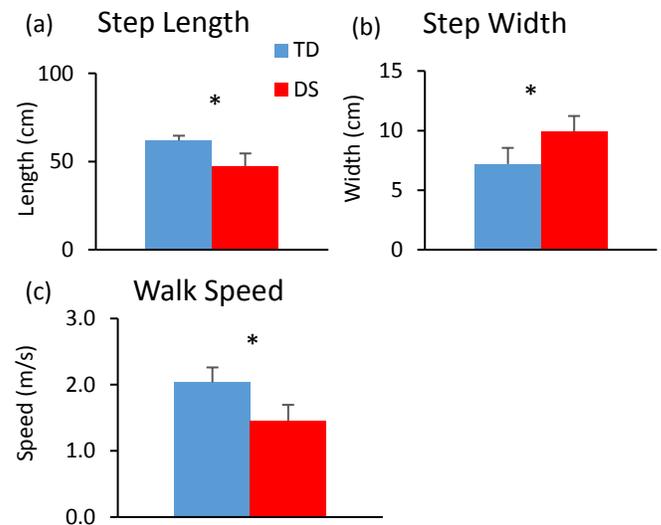

During the walk-out phase, children with DS took shorter but wider steps and walked at a slower speed. There was a group effect for step length ( $p=0.004$ ), step width ( $p=0.013$ ), and walk speed ( $p<0.001$ ) (Fig. 4a-c).

The results of TUG duration are similar to previously published data on children with DS aged 3-13 years [1]. Interestingly, when broken down to each phase, children with DS required more time across each phase, except sit-to-stand (although it approached a

significance). With a similar vertical COM excursion during sit-to-stand, TD children continued to increase vertical COM velocity and reached a greater peak later in the phase. Further, peak extension velocity of the hip and knee joints were lower in children with DS. These results may suggest that TD children may have a better ability than children with DS to transition from sit-to-stand to walking.

Fig. 4

During the walk-out phase, children with DS walked with a spatiotemporal gait pattern typically seen in children with DS at this age range [2]. However, during the TUG test children with DS did walk faster than previously reported preferred walking speeds in this group [2, 3]. Therefore the group difference may suggest a lower capacity for children with DS to modify gait pattern for a specific task, or achieve a fastest walking speed comparable to TD children.

## CONCLUSIONS

The TUG tests consists of separate tasks that assess functional mobility. Children with DS took longer to complete the test and demonstrated slower movement during the sit-to-stand and forward walking phases of the test.

# PARAMETERIZING JOINT-LEVEL VARIABILITY DURING WALKING FOR STROKE VICTIMS

Anne E. Martin and Mukul C. Talaty

Pennsylvania State University

Email: aem34@psu.edu, mxt103@psu.edu

## INTRODUCTION

Predicting how likely an individual is to fall could improve rehabilitation outcomes, thereby improving the quality of life for millions of individuals. Variability in gait temporal parameters is correlated with fall risk [1] and with clinical measures of gait impairment [2]. Since changes in temporal parameters occur due to changes in joint movements, leg joint variability may provide valuable information about fall risk. Joint variability has been parameterized for young, healthy adults walking at their self-selected speed [3] but not for other populations. Since stroke is a common cause of impaired gait, this abstract presents initial work in parameterizing joint variability for stroke victims. Specifically, it shows that joint variability can be parameterized mathematically using low-order Fourier series for both stroke victims and healthy adults.

## METHODS

Joint angle data from 7 stroke patients (average speed 0.5 m/s), 6 slow, healthy adults (average speed 0.5 m/s), and 7 young, healthy adults (average speed 1.2 m/s) walking overground at their self-selected speed were used. The data from the stroke and slow, healthy subjects were collected using a Coda CX1 (Charnwood Dynamics, Leicestershire, England) active marker motion analysis system system. The data from the young, healthy subjects were collected using a Vicon (camera model: T20S, Oxford, UK) motion capture system. For comparison, artificial joint angle data were created with known variability (filtered zero-mean random noise). A total of 34 strides from each population were used, except for the slow, healthy subject data which had 29 strides. (The young subject data were a subset of the data from [3]). Each stride was divided into stance and swing periods, and the periods were analyzed separately. The affected and contralateral sides were analyzed separately for the stroke subject data, while only the right leg was analyzed for the healthy data.

The per-subject mean motion for each joint was determined and subtracted from the total joint motion for each step (Fig. 1). This gave a time history of the joint variability. To parameterize the variability mathematically, a second-order Fourier series was fit to the stance period variability and a first-order Fourier series was fit to the swing period variability (Fig. 1). The quality of each fit was calculated using the  $R^2$ -value and the normalized root mean square error (RMSE). The normalized RMSE is the RMSE divided by the range of the variability. Pairwise t-

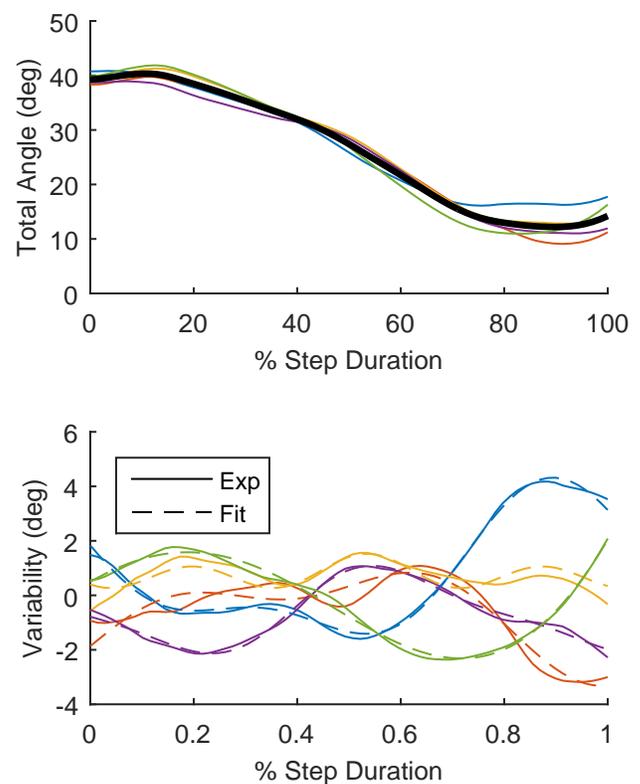

Figure 1: Top: The total (thin lines) and mean (thick line) joint angles. The pointwise difference between the mean and total angle is the variability. Bottom: The experimental variability and the best fit second-order Fourier series. The Fourier series fits the data very well. Both plots show the affected-side stance hip angles for a stroke subject.

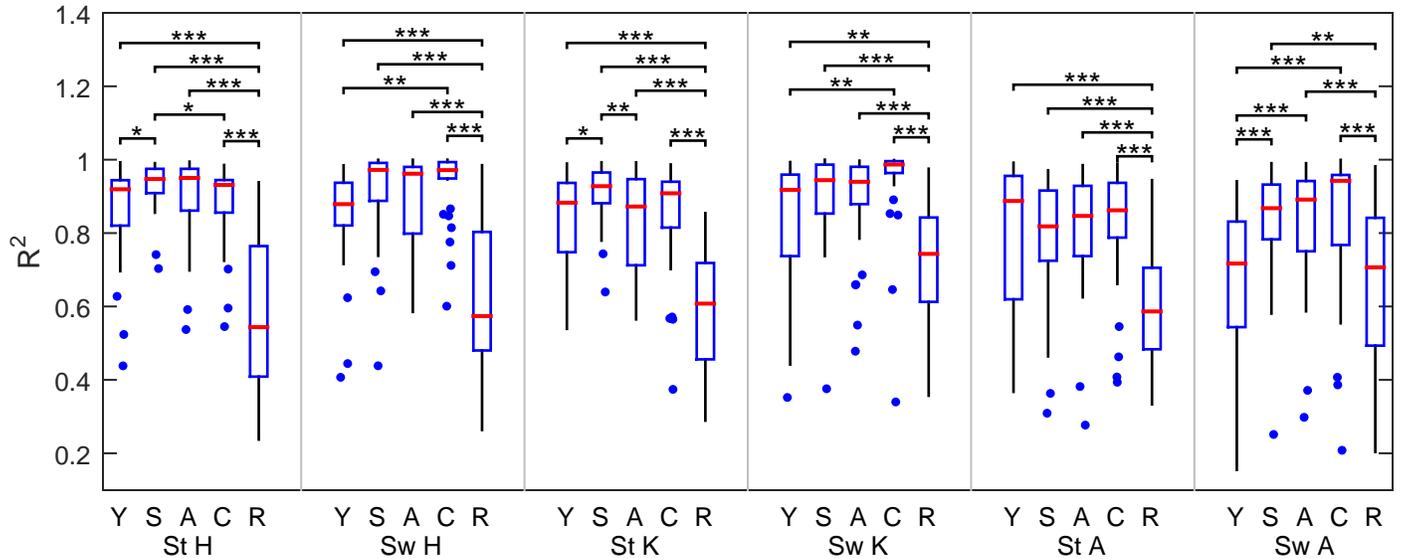

Figure 2: The  $R^2$  values for all groups (Young healthy, Slow healthy, stroke Affected side, stroke Contralateral side, aRtificial), joints (Hip, Knee, Ankle), and periods (Stance, Swing). Larger values indicate better fit. Statistically significant differences are indicated: \* = p-value < 0.05, \*\* = p-value < 0.01, \*\*\* = p-value < 0.001. Statistical significance was similar for the RMSE values. Blue dots indicate outliers.

tests using the  $R^2$ -value and the normalized RMSE were conducted between each of the five groups for each joint and period.

## RESULTS AND DISCUSSION

With the exception of the young swing ankle, low-order Fourier series fit the true experimental data significantly better than the artificial data as expected using both goodness of fit measures (Fig. 2). This provides confidence that the variability is not simply measurement noise and that similarities or differences between populations are true. The fits for the true experimental data were quite good, with  $R^2$ -values consistently above 0.8 and normalized RMSE consistently below 8% of the variability range. For all joints and periods of the stroke subjects, the goodness of fit between the affected and contralateral sides were similar. For the stance joints, the goodness of fit was similar between the young, slow, and stroke subjects. For the swing joints, the goodness of fit was slightly better for the stroke and slow subjects than for the young subjects. This indicates that a second (or first)-order Fourier series well captures the joint variability as a function of step progression in stance (or swing) joints for both healthy adults and stroke victims. This is true despite considerable dif-

ferences in mean walking speed. Further, the systems used to collect the experimental data were different, indicating that joint variability and this parameterization is robust to different data collection methods, at least some gait impairments, and walking speed.

## CONCLUSIONS

The joint variability during walking for both healthy adults and stroke victims has a remarkably similar structure and can be parameterized mathematically using the same method for both populations. Further, the accuracy of the parameterization is similar. The values that define the Fourier series may be different for each population, although this work remains to be done. The full characterization of joint variability will be included in physics-based models of human gait [4] and used to investigate fall risk.

# TORSIONAL MALALIGNMENT SYNDROME AND THE MAXIMUM INTERNAL VARUS KNEE MOMENT DURING GAIT IN INDIVIDUALS WITH DISABILITIES

<sup>1</sup> Alexandria Case, <sup>1</sup> K. Mitchell Barr, and <sup>1</sup> Amy Lenz

<sup>1</sup> Mary Free Bed Rehabilitation Hospital Grand Rapids, MI, USA

email: alexandria.case@maryfreebed.com, web: <http://www.maryfreebed.com/>

## INTRODUCTION

Torsional malalignment syndrome (TMS) is defined as the combination of two orthopedic pathologies — femoral anteversion (medial twist in femur) and external tibial torsion (lateral twist in tibia) occurring in the same limb. This creates a “wringing” effect on the knee which may contribute to common knee pathologies such as patellofemoral pain syndrome, cartilage tears, ligament sprains, ligamentous laxity and osteoarthritis [1].

We have observed in our gait analysis laboratory over the years that many patients who present with TMS demonstrate a “valgus thrust” corresponding to an abnormal internal varus knee moment. The purpose of this study is to determine the effects of TMS on maximum internal varus knee moment (MxVKM) in a disabled population. The correlation between the severity of the TMS and the magnitude of the MxVKM will also be analyzed.

We hypothesize that: (a) Patients with TMS will have an increased MxVKM compared to patients without TMS and typically developing peers and (b) For patients with TMS, there will be a moderate positive relationship between the degree of TMS and the magnitude of MxVKM.

## METHODS

This was a retrospective matched comparative correlational design. A comparison of the MxVKM was made among patients with TMS, patients without TMS (nTMS) and typically developing (TD) individuals. The TMS group was made up of 91 limbs from patient ages 4-60 of any diagnosis drawn from the Mary Free Bed Rehabilitation Hospital’s Motion Analysis Center for routine clinical gait analysis between 1994 and 2016.

Limbs were included in the TMS group if they had the following combination of physical exam measurements: a transmalleolar axis >25 degrees external and a difference between hip internal and

external rotation passive range of motion (IR-ER)  $\geq 30$  degrees [2, 3]. In the event that a patient met these criteria on multiple study dates, only the most recent study data was utilized. Any limb which met the criteria was included. (Some patients presented with bilateral, and some with unilateral TMS.) Patients were excluded from the study if the data was collected while the patient was using an assistive device given the interference with the validity of moment data collected. Additionally, patients presenting with an inconsistent gait pattern not definable by a single representative gait cycle were excluded from the study. The non-TMS and normative groups were matched to those patients whose limbs were in the TMS group on the basis of age and gender. The non-TMS group was also matched to the TMS sample based on diagnosis where possible.

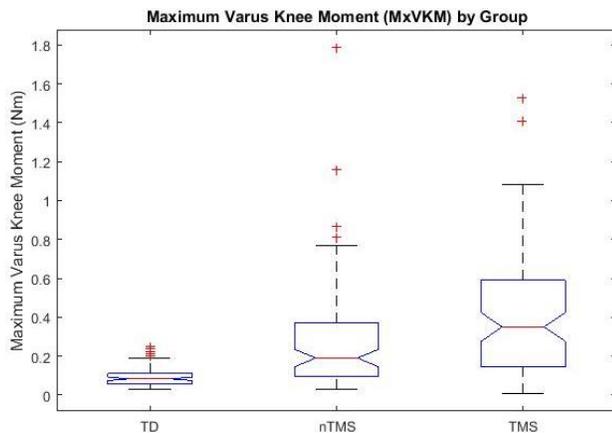

The magnitude of counter torsion in patients with TMS was defined using a novel measure we termed the “Torsional Malalignment Syndrome Angle” (TMSA), defined as the sum of the difference between hip internal and external rotation passive range of motion and the degree of external tibial torsion (ETT):  $TMSA = Hip\ IR-ER + TMA$ .

A Lilliefors test was conducted and indicated that the data did not fit a normal distribution. Therefore, a Kruskal-Wallis test and post-hoc Mann-Whitney U-tests were conducted, with an alpha level of  $p < 0.05$  used to establish significance. A Spearman correlation was done to determine the correlation, if any, between the TMSA and the MxVKM of the patients with TMS.

## RESULTS AND DISCUSSION

A Kruskal-Wallis test determined the differences between the MxVKM of the three groups to be statistically significant ( $p = 0.000$ ). Mann-Whitney U-tests between individual groups found statistical significance between all groups; TMS/nTMS, TMS/TD, nTMS/TD ( $p = 0.0013, 0.0000, \text{ and } 0.0000$ ,

respectively). The TMS group median MxVKM was 0.350 Nm ( $\bar{x} = 0.395 \pm 0.31$  Nm, 4.2 times greater than normal; range = 1.524 Nm). The nTMS group median MxVKM was 0.190 Nm ( $\bar{x} = 0.266 \pm 0.26$  Nm; range = 1.763 Nm), 2.3 times greater than normal. The TD group median MxVKM was 0.083 ( $\bar{x} = 0.091 \pm 0.08$  Nm; range = 0.222 Nm). These are represented in (Fig. 1).

**Figure 1:** Maximum Varus Knee Moment (MxVKM) by Group. The median is indicated by a red horizontal band in each plot, with interquartile ranges annotated with blue bands on each plot. Outliers in each group are noted with red “+” signs.

A Spearman rank correlation coefficient of 0.222 showed a weak correlation between our novel measurement of TMS severity (TMSA) and the magnitude of the maximum varus moment. This highlights the multifactorial nature of an abnormal varus knee moment pattern and the high degree of variability in the sample.

In normal gait, the ground reaction force (GRF) in the frontal plane scarcely ever crosses lateral of the knee joint center, yielding a largely internal valgus knee moment. However, as demonstrated in this study, in disabled patients, the GRF often remains lateral to the knee, leading to an internal varus knee moment. This is believed to occur for a variety of reasons including lower extremity weakness, motor control deficits, excessive lateral trunk sway, midfoot collapse, genu valgus deformity and/or long bone torsion.

Abnormal internal varus knee moments have been found to be associated with ETT in patients with spina bifida (SB) [4]. Surgical correction of ETT in patients with SB via a tibial internal rotation

osteotomy has been found to lead to significant improvement in the varus knee moment postoperatively [5].

In TMS, the tendency for the ground reaction force to pass lateral to the knee joint is believed to be compounded over ETT alone. This is because, in addition to ETT which can cause the weight bearing surface of the foot to be positioned lateral of the weight bearing axis (WBA), femoral anteversion causes the knee joint to be positioned medial of the WBA. This can increase the perpendicular distance of the ground reaction force laterally with respect to the knee joint center and explains, we believe, why the MxVKM was significantly higher in our patients with TMS. The subsequent internal varus knee moment leads to increased compressive forces in the lateral knee compartment and increased distractive forces at the medial knee. In addition, there is a tendency for pathological lateral patellar tracking.

Given the findings of this study, we believe that future research should focus on whether TMS compounds the abnormal effect that ETT alone creates on the varus knee moment. This is clinically significant as it may indicate that treatment of the femur by external rotation osteotomy is necessary in addition to the tibial internal rotation osteotomy to optimize surgical outcomes.

## CONCLUSIONS

Disabled patients have a significantly higher MxVKM than do their non-disabled peers. Those patients with TMS have a significantly higher MxVKM than do matched peers without TMS. Using our novel measure for TMS severity, there is only a weak relationship between the severity of TMS and MxVKM. Further investigation into this relationship may be warranted.

## INTRODUCTION

The framework of muscle synergies may be useful to evaluate muscle recruitment and coordination in the clinic [1]. In individuals with cerebral palsy (CP), prior research has shown that the dynamic motor control index during walking (walk-DMC) decreases with functional impairment and may be associated with post-treatment outcomes [2, 3]. In evaluating over 400 individuals from one clinical center, prior work demonstrated that individuals with CP with synergies more similar to typically-developing controls were more likely to have positive changes in gait after treatment [3]. The goal of this research was to extend these analyses to another clinical center and evaluate whether synergies may be useful for treatment planning.

## METHODS

Clinical pre-treatment electromyography (EMG) and kinematic data previously collected at the Clinical Motion Analysis Laboratory of the University Hospital Pellenberg, Belgium (CMAL-Pellenberg) from 174 individuals with CP were analyzed. The individuals were distributed between three treatment groups including 62 cases of botulinum toxin type A injection (BTA, M/F: 40/21, age: 6.7±2.9 yr, height: 1.1±0.2 m, mass: 20.7±8.5kg), 46 cases of selective dorsal rhizotomy (SDR, M/F: 23/23, age: 9.2±2.1 yr, height: 1.3±0.1 m, mass: 29.9±6.4kg), and 65 cases of single event multilevel orthopedic surgery (SEMLS, M/F: 38/27, age: 12.2±3.0 yr, height: 1.5±0.2 m, mass: 39.8±14.6 kg). A control group of 13 unimpaired individuals (M/F: 6/7, age: 10.1±3.0 yr, height: 1.4±0.2 m, mass: 39.6±16.4kg) was also analyzed. For each individual, EMG data were analyzed from a random limb from 4 muscles

(medial hamstrings, rectus femoris, gastrocnemius, and tibialis anterior).

EMG data were preprocessed with a 20 to 500 Hz band pass filter, then rectified, and a linear envelope was taken using a 10 Hz low-pass filter. Synergies were calculated using nonnegative matrix factorization. The total variance accounted for by one synergy ( $tVAF_1$ ) was calculated for each individual. Walk-DMC, was calculated as a z-score defined as  $100 + 10 \times [tVAF_{AVG} - tVAF_1] / tVAF_{SD}$  where  $tVAF_{AVG}$  and  $tVAF_{SD}$  are the mean and standard deviation of  $tVAF_1$  from the controls.

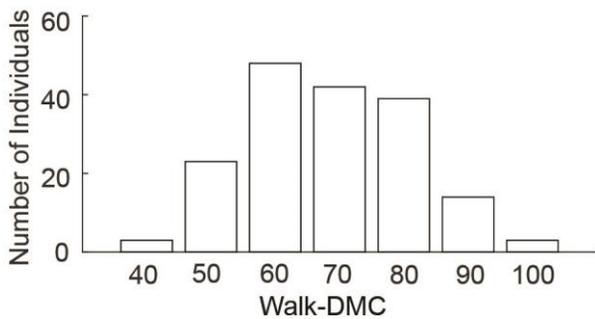

Kinematic data for each individual was evaluated pre- and post-treatment using two measures: gait deviation index (GDI) [4] and non-dimensional walking speed. A stepwise regression was used to identify a model that best fit the outcome measures of post-treatment GDI or walking speed. Regressors in the model were pre-treatment GDI or pre-treatment walking speed, walk-DMC, treatment, age, and prior surgeries (yes/no). To minimize the effect of outliers a robust fitting using a bi-square weighting algorithm was used for the output model.

## RESULTS AND DISCUSSION

Walk-DMC distribution was similar across treatment groups (Figure 1, mean 73.4, S.D. 12.6). Overall, we found that there were increases in GDI post-treatment, which were largest for the SEMLS treatment group ( $0.6 \pm 9.2$  BTA,  $1.9 \pm 11.1$  SDR, and  $10.9 \pm 9.1$  SEMLS). We also found an overall decrease in walking speed of  $-0.03 \pm 0.08$  that was similar across all three treatments.

Pre-treatment GDI, and treatment group were significant predictors of post-treatment GDI at

CMAL-Pellenberg (Fig. 2). Walk-DMC was found to be a significant predictor with a positive slope, indicating that higher walk-DMC was associated with higher post-treatment GDI. The effect sizes of pre-treatment GDI, treatment, and walk-DMC were  $43.2 \pm 7.7$ ,  $8.0 \pm 3.6$ , and  $7.4 \pm 7.2$ , respectively. The estimate of pre-treatment GDI slope and intercept by treatment were 0.57 and 24.5 for BTA, 0.99 and -6.60 for SDR, and 0.65 and 25.57 for SEMLS. This illustrates that BTA and SEMLS treatments tended to yield diminishing improvement with increasing pre-GDI. For SDR the model suggests almost no change in GDI post-treatment. The estimate of the pre-treatment walk-DMC slopes was 0.11.

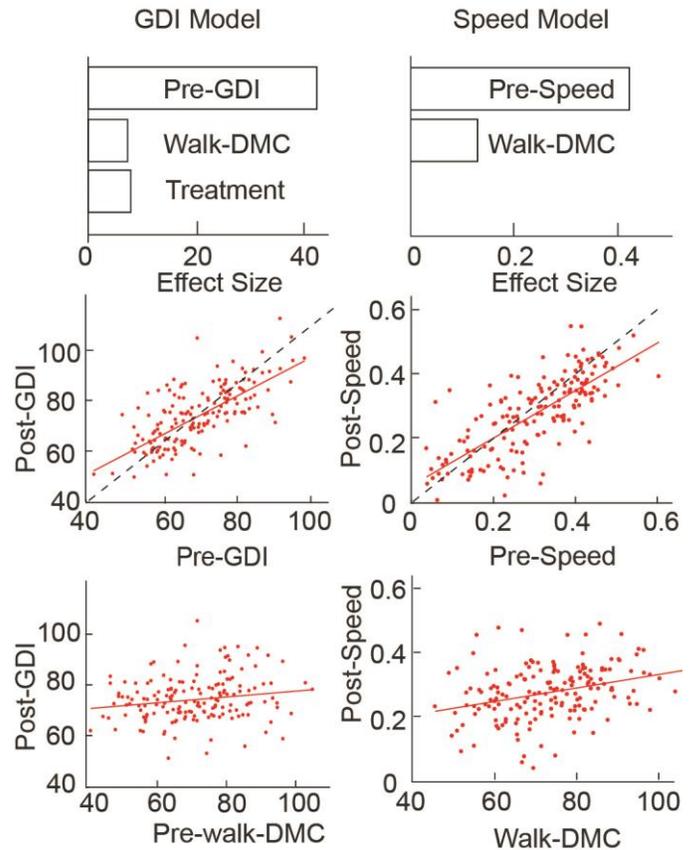

**Figure 1:** Histograms of pre-treatment Walk-DMC

Pre-treatment walking speed and walk-DMC were significant predictors of post-treatment walking speed (Fig. 2). The effect sizes of pre-treatment walking speed and walk-DMC were  $0.42 \pm 0.06$  and  $0.13 \pm 0.07$ . The estimate of the pre-treatment walking speed and walk-DMC slopes were 0.74 and 0.0021 with an intercept of -0.10.

## CONCLUSIONS

Walk-DMC was a significant predictor of post treatment walking speed, but only had a weak prediction of post-treatment GDI for children with CP at this clinical center. These findings confirm prior work finding walk-DMC to be a significant predictor of changes in walking speed after treatment, with higher walk-DMC associated with better treatment outcomes. However, the slope of walk-DMC was smaller with post-treatment GDI at this clinical center, which may be due to differences in the patient populations between centers. Walk-DMC may be most useful in identifying patients with substantial gait deviations (low GDI) but more

typical motor control (high DMC) who may benefit from treatment. Understanding the role of motor control in the evaluation of individuals with CP may help improve treatment outcomes and guide development of new interventions.

**Figure 2:** The effect sizes and adjusted response plots of the predictors included in the linear models for GDI (left column, treatment not shown) and non-dimensional walking speed (right column). Dashed lines indicate no change from pre-post.

# ANALYSIS AND MODELING OF GAIT BIOMECHANICS IN RESPONSE TO VOLUMETRIC MUSCLE LOSS INJURY

Jack Dienes, Xiao Hu, Kevin Janson, Conrad Slater, Robbie Courter, Katie McCormack, George Christ, and Shawn Russell

University of Virginia, Charlottesville, VA, USA

Email: [sdr2n@virginia.edu](mailto:sdr2n@virginia.edu)

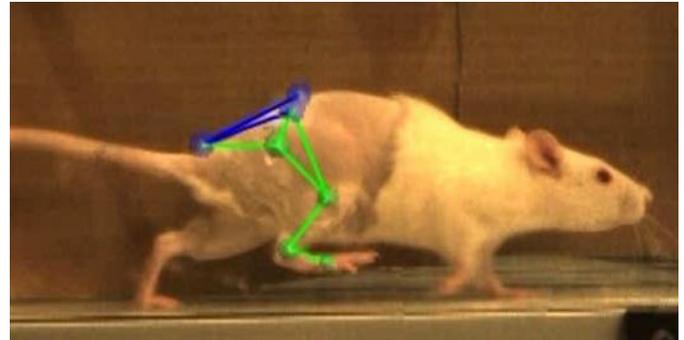

## INTRODUCTION

Much research is currently underway to develop novel methods for the regeneration of muscle tissue as treatment of volumetric muscle loss (VML) injury, but few studies have evaluated the relationship between injury and the biomechanics required for normal function. To address this knowledge gap, we have developed a novel method to quantify the changes in gait for rats with tibialis anterior VML injuries that illustrates functional deficit in response to the injury as well as recovery. The ability to measure changes in rat gait parameters will facilitate our ability to quantify relevant functional deficits that result from VML injury, as well as the functional effectiveness of regenerated muscle volume. Data developed from this rat animal model could offer new insight on how to better treat and repair large scale volumetric muscle loss in humans.

## METHODS

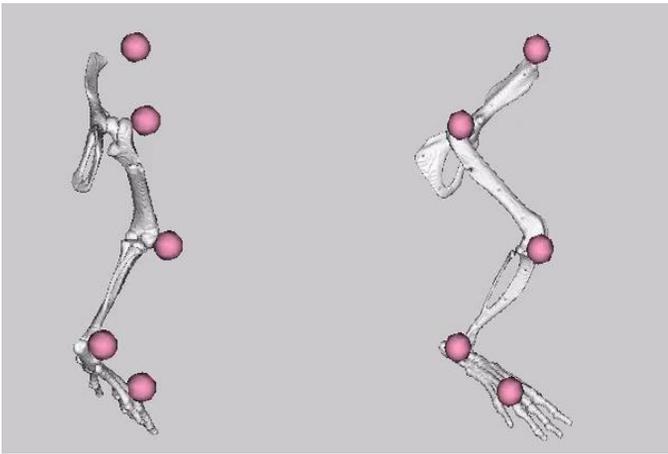

Eight (8) twelve (12)-week old female Lewis rats were tested on a Panlab Rat Treadmill at a comfortable walking pace of 40 cm/s with motion capture video recorded at 1, 4, 8, and 12 weeks (W) post-surgery, with baseline testing occurring the week prior to surgery. Before all test runs, each rat was shaved to allow for accurate placement of 3mm and 5mm reflective markers on the bony landmarks of the left anterior superior iliac crest (LASI), right anterior superior iliac crest (RASl), spine, tail, hip, knee, ankle, and toe (Fig. 1). An optimum camera placement setup and calibration frame were developed for the small collection volume necessary to accurately capture the gait of rats. Kinematic data

were collected using a Vicon 7-camera (T40) setup collecting at 120Hz.

**Figure 1.** Overlay of 3-D markers, LASI, RASI, SPINE, TAIL, HIP, KNEE, and ANKLE on typical rat while walking on the treadmill. Marker locations shown as placed on test animals.

With the cameras calibrated and in place, Vicon Nexus motion capture software was utilized to record each rat walking on the treadmill. Surgery was performed on four of the eight rats and consisted of removal of 20% of the right tibialis anterior muscle in the form of a  $\sim 0.15\text{cm}^3$  rectangular cube with the long axis aligned with the fiber direction. Additionally, the extensor digitorum longus (EDL) and extensor hallucis longus (EHL) synergist muscles were ablated. Motion capture was repeated at 1, 4, 8, and 12 weeks post-surgery on both the injured group and the non-injured control group. All data was normalized to 100% of a complete gait cycle (heel strike to heel strike), with a minimum of three cycles averaged for data at each time point and condition. Cycles were excluded if the rats deviated from a typical walking pattern in any way i.e. sitting, looking up. The 3-D location of the markers on the bony landmarks collected via motion capture was exported for post-hoc kinematic analysis of joints using an OpenSim rat hindlimb model[1] modified

**Figure 2.** Rear (Left) and sagittal (Right) views of modified rat hind limb model developed in OpenSim. Overlay of 3-D marker locations on typical rat while walking on the treadmill. Marker locations shown as placed on model.

for our trials (Fig. 2). Simulations were performed on individually scaled versions of the model to determine gait kinematics. All data was filtered at 30Hz and all post-simulation analyses were performed in Matlab.

## RESULTS AND DISCUSSION

Baseline kinematics were similar to previously reported data on the sagittal kinematics of normal gait in rats[2]. The rats exhibited maximum deviation from normal between week 4-week 8 and slight recovery towards normal by week 12 (Fig. 3). We saw more hip abduction (22.9% W4, 14.8% W12),

more hip external rotation (64.8% W4, 36.9% W12) and more ankle plantarflexion (40.8% W8, 34.9% W12) in the injured animals as compared to their baseline measurements. Data at 1 week post-op was determined to be excessively noisy due to the proximity to surgery, and in the future week 2 will be analyzed instead.

## CONCLUSIONS

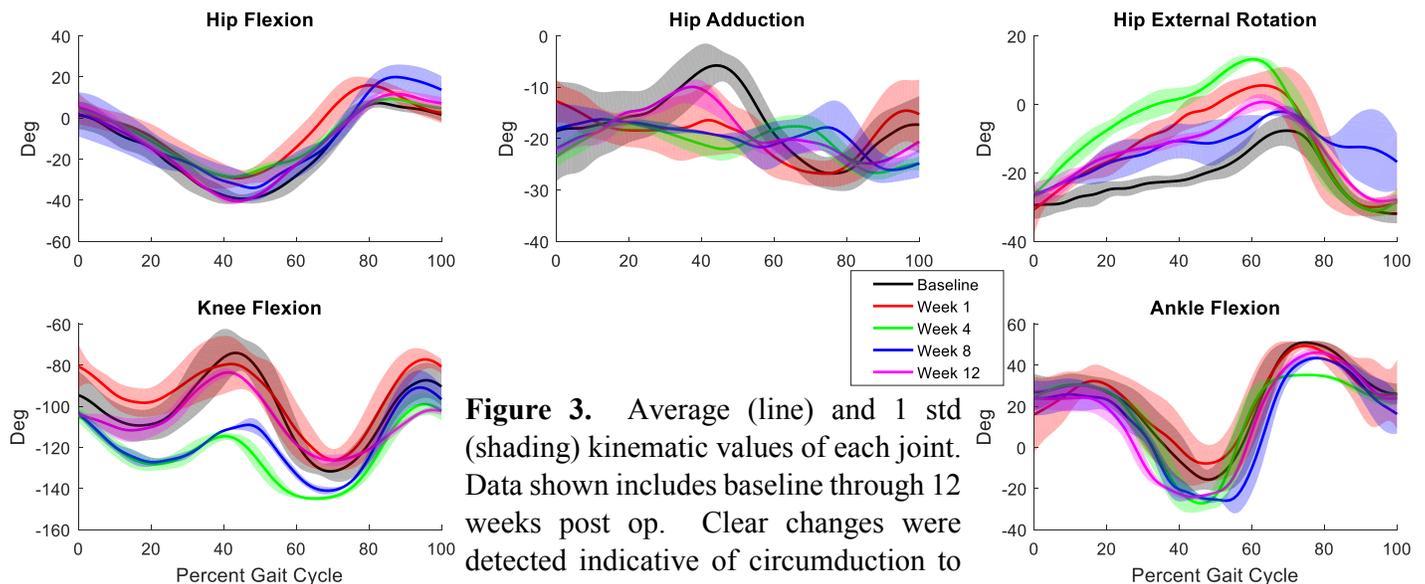

These results are indicative of circumduction, a classic compensation for drop foot. The injured rats are increasing the external rotation and abduction of the hip to swing their foot around the body due to their inability to produce sufficient dorsiflexion for foot clearance in swing. The future addition of force plates to analyze dynamics and joint torques for better understanding of musculoskeletal control and joint loads will inform the development of regenerative technologies to aid recovery from VML injuries.

## INTRODUCTION

With advancement and availability of instrumented gait analysis, large amounts of quantitative, interdependent data have become commonplace in the realm of kinematic, kinetic, and musculoskeletal simulation movement studies. However, effective statistical techniques to accurately quantify variance within and between populations or conditions is challenging. Often, hypothesis-driven movement studies target one or multiple time-independent parameters derived from kinematic or kinetic data, such as mean or peak-to-peak values. However, these coarse metrics often mask subtle, yet often clinically relevant, differences in the waveforms.

Waveform analyses derived for use in image processing and pattern recognition have also been effectively used to characterize biomechanical data to evaluate the 3-dimensional (3D) kinematic and force trajectories [1], knee loads during running [2], and muscle activity during balance perturbations [3]. For example, wavelet-based functional ANOVA (wfANOVA) provides a framework to statistically compare time-series curves within the wavelet domain. Wavelet transforms can provide a measure of both frequency content and underlying temporal structure of the data. In wfANOVA, waveform features described in wavelet transformations are statistically compared and can be reassembled in the time domain for interpretation [3].

The purpose of this study was to compare the results of wfANOVA against ANOVA of time-independent metrics (i.e., mean, range of motion) to investigate the effects of gait training on kinematics of children with cerebral palsy (CP). We hypothesized that both statistical approaches would indicate significantly different knee flexion kinematics after gait training. However, we expected that wfANOVA would reveal

additional differences in kinematics that were not apparent from time-independent metrics.

## METHODS

Seven children with spastic CP (6 diplegic, 1 hemiplegic, gross motor function classification system: 6 level II, and 1 level III, age:  $12.4 \pm 2.7$  yrs., height:  $1.48 \pm 0.2$  m, weight:  $43.5 \pm 15.3$  kg) participated in a six-week gait training program. Prior to and following gait training, each child participated in a 3D gait analysis session where lower body kinematics were collected at 120 Hz and filtered at 6 Hz during overground walking. Joint kinematics were calculated using a least-squares optimization algorithm in Visual3D and normalized to the gait cycle (GC) for five walking trials before and after training. Trajectories were generated for each child's more and less affected legs. The less affected leg was defined by higher strength in lower limb isometric joint strength tests.

A linear mixed effects two factor ANOVA model including fixed effects (Training  $\times$  Leg) and a random effect (Subject) was used to model knee flexion time-independent parameters of mean angle and range of motion. The F-test was used to statistically evaluate the effects of the fixed factors within the model ( $\alpha=0.05$ ). Post-hoc two-sample t-test comparisons with Bonferroni corrections ( $\alpha=0.05$ ) were completed where main effects or interaction terms were significant.

Waveform data analysis was completed using wfANOVA. Each knee flexion trajectory (normalized to the gait cycle) was transformed into the wavelet domain using a discrete wavelet transform. The resulting wavelet transform represents a series of coefficients that map to third order coiflet wavelets ordered in time, and grouped

in both low frequency (approximation level) and high frequency (detail level).

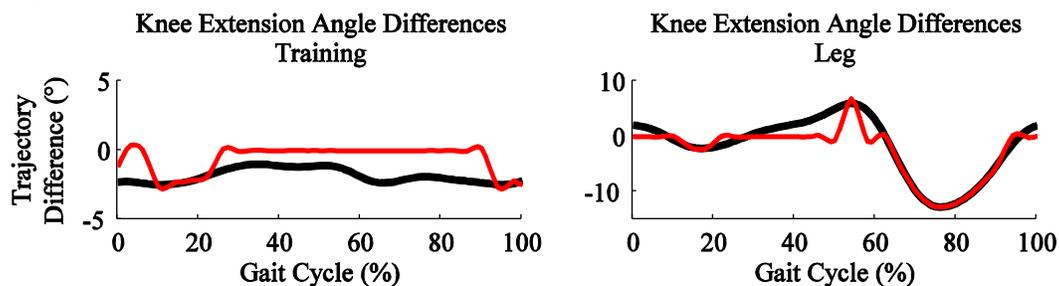

A two factor (Training  $\times$  Leg) linear mixed effects ANOVA model with Subject as a random effect was generated for each wavelet coefficient. The F-test was used to evaluate the effects of the fixed factors within the model at each coefficient level. A Bonferroni correction factor was applied to correct field-wide significance level for the F-test ( $\alpha_{\text{fieldwide}}=0.05$ ). For significant main or interaction terms, a post-hoc two sample t-tests were applied with Bonferroni corrections ( $\alpha=0.05$ ).

## RESULTS AND DISCUSSION

The wfANOVA revealed significant differences after gait training whereas the time-independent metric analyses did not. Greater knee flexion was found after training in initial stance (0-25% GC), and terminal swing (90-100% GC) using the wfANOVA (Fig. 1), noted by significant differences in the wavelet domain ( $p<0.006$ ) that were reconstructed in the time domain for interpretation (Fig. 1). Differences in knee flexion between the more and less affected legs were also found primarily during swing (60-90% GC, Fig. 1), noted by significant differences in the wavelet domain ( $p<0.0001$ , Fig. 1).

Significant differences in the knee range of motion were only found between legs, with the less affected leg having a greater range of motion ( $\overline{RoM}_{\text{less aff}} - \overline{RoM}_{\text{more aff}} = 10.8^\circ$ ,  $p<0.0001$ ).

Waveform-based analyses of biomechanical data have the capacity to reveal relevant differences in

**Figure 1:** Differences in knee flexion angle are shown between pre and post gait training (left) and between the more and less affected legs (right) averaged across the group of children. Mean contrast curves (black) and significant wavelet differences reconstructed within the time domain (red) are shown. When no statistical change in waveform was found, the wavelet reconstructed curve (red) was 0. Positive differences indicate increased knee extension after training (left) or on the less affected leg (right).

gait data that would be otherwise masked by coarse time-independent metrics. These analyses also address several challenges related to biomechanical data analysis, such as temporal dependence and the interdependence of multiple biomechanical measures. Several methods such as wfANOVA [3], statistical parametric mapping [1], and bootstrapping have been effectively used to investigate biomechanical data; however, the utility and clinical relevance of each metric compared to standard techniques should be further investigated.

## CONCLUSIONS

Waveform analyses allow the ability to test generalized hypotheses without requiring *a priori* assumptions of important time phases or specific data features. Gait training resulted in increased knee flexion during initial stance and terminal swing, as indicated by wfANOVA. Differences found using wfANOVA were not apparent when comparing overall mean and range of motion pre/post gait training.

## INTRODUCTION

Post-stroke hemiparetic gait is associated with a slow walking speed and lack of balance control. Thus, locomotor training, which consists of walking on a treadmill with partial body-weight support and manual assistance from trainers (e.g., [1]), aims to improve the overall mobility. While studies have reported improved walking speed as a result of such training (e.g., [1]), its effect on mediolateral (M/L) balance control is unclear.

One of the conditions for maintaining dynamic balance during walking is to regulate whole-body angular momentum ( $H$ ) through proper foot placement and generation of appropriate ground-reaction-forces (GRFs) (e.g., [2]). That is, the time rate of change of  $H$  is equal to the net external moment determined by foot placement and GRFs from each leg (Fig. 1). Poor regulation of  $H$  during walking results in higher peak-to-peak range of  $H$ , which has shown to be correlated with poor balance scores (Berg and DGI) post-stroke [3]. However, it is not clear if locomotor training improves dynamic balance through improved regulation of  $H$  and how walking speed is related to changes in dynamic balance.

The goal of this study was to assess the influence of locomotor training on M/L balance control during steady-state walking and identify underlying mechanisms associated with the observed changes. Additionally, relationships between the baseline walking speed and the changes in M/L balance control were examined.

## METHODS

Previously collected kinematic and GRF data [1] from 17 post-stroke subjects with hemiparesis pre-

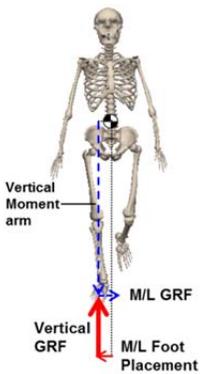

and post-training were analyzed (Table 1). Subjects participated in a 12-week locomotor training program described previously [1]. Three-dimensional kinematics and GRFs were collected within one week of training initiation and completion. Subjects walked on a split-belt instrumented treadmill at their self-selected (SS) walking speed pre-training. During post-training data collection, each subject walked at a speed matched to their pre-training SS speed.

**Table 1:** Participant characteristics: overground SS walking speed and lower extremity Fugl-Meyer (FMA) were assessed pre-training.

M/L dynamic balance was assessed using the peak-to-peak range of  $H$  in the frontal plane [3]. Subjects were divided into two groups (Group A: range of  $H$  decreased post-training; Group B: range of  $H$  increased post-training). The range of  $H$  between pre- and post-training during walking was compared

within each group using a paired t-test ( $p < 0.05$ ). A decreased range of  $H$  was associated with improved dynamic balance control. To further understand the underlying mechanisms for any observed changes in  $H$ , GRF peaks and impulses (i.e., time integral of GRFs) were calculated during early (0-50%) and late (51-100%) stance. Also, foot placement was calculated as the vector from the body center-of-mass to the center-of-pressure (Fig. 1). Step width mean and variability were also calculated. Further, Pearson's correlation analyses were performed to examine the relationship between the external moment components and the range of  $H$  in the frontal plane. This study is focused on changes in the vertical GRFs and the M/L foot placement as they are the dominant components of the net external moment in the frontal plane (Fig. 3 in [4]). Lastly, Pearson's correlation analyses were performed to examine the relationship between baseline SS walking speeds and changes in the range of  $H$  from pre- to post-training.

**Figure 1:** The components of net external moment in the frontal plane. Whole-body CoM is shown with  $\bullet$ . The GRF vectors and their corresponding moment arms appear in the same color. The higher magnitude of the vertical GRF compared to other components (after normalizing moment arms and GRFs by body height and weight, respectively) is highlighted by the line thickness.

## RESULTS AND DISCUSSION

Group A decreased their range of  $H$  (-) by 5% ( $p = 0.007$ ) from pre- ( $0.014 \pm 0.004$ ) to post- ( $0.013 \pm 0.003$ ) training. In contrast, Group B increased their range of  $H$  by 9% ( $p = 0.003$ ) from pre- ( $0.014 \pm 0.004$ ) to post- ( $0.015 \pm 0.004$ ) training.

In Group A, the paretic leg M/L foot placement decreased (became narrower) by 8.5% ( $p = 0.002$ ) post-training, which was correlated with a decreased range of  $H$  ( $r = 0.54$ ,  $p = 0.01$ ). Additionally, both step width and step width variability decreased by 5% ( $p = 0.03$ ) and 29% ( $p = 0.001$ ) from pre- to post-training, respectively. There were no significant changes in the peak vertical GRFs. However, the paretic leg vertical GRF impulses increased by 10% ( $p = 0.01$ ) from

pre- to post-training during both early and late stance. Also, the paretic leg vertical GRF impulses were negatively correlated with the range of  $H$  during both early ( $r = -0.41$ ,  $p = 0.07$ , approached significance) and late ( $r = -0.81$ ,  $p < 0.001$ ) stance. These results are consistent with previous work showing that wider paretic foot placement is strongly related to the lower weight bearing of the paretic leg [5].

In Group B, although there were no significant changes in the M/L foot placement, the range of  $H$  was correlated with step width ( $r = 0.74$ ,  $p = 0.002$ ) and the paretic leg M/L foot placement ( $r = 0.77$ ,  $p < 0.001$ ). Additionally, the peak vertical GRFs in the nonparetic leg increased by 4% during early ( $p = 0.02$ ) and late ( $p = 0.01$ ) stance post-training. Also, the range of  $H$  was positively correlated with the nonparetic leg peak vertical GRFs during late stance ( $r = 0.46$ ,  $p = 0.09$ , approached significance) and the nonparetic leg vertical GRF impulses during early stance ( $r = 0.85$ ,  $p < 0.001$ ).

As a whole group, the changes in the range of  $H$  from pre- to post-training were strongly correlated with the baseline SS walking speed ( $r = 0.7$ ,  $p = 0.001$ ). That is, those with a higher (lower) baseline SS walking speed mostly decreased (increased) their range of  $H$  post-training.

In summary, Group A improved their M/L balance control, mainly by narrowing their paretic foot placement and increasing their weight bearing on the paretic side. However, Group B did not improve their M/L balance control, and their nonparetic leg compensations increased post-training. Also, the baseline SS walking speed was a good indicator of those who would improve and those who would not improve their M/L balance control. Future work is needed to expand this investigation to lower level household and higher level community walkers.

# KINEMATIC ANALYSIS OF SIT-TO-WALK IN BIPOLAR DISORDER

<sup>1</sup> Gu Eon Kang, <sup>1,2</sup> Brian Mickey, <sup>1</sup> Barry Krembs, <sup>1</sup> Melvin McInnis, and <sup>1</sup> Melissa Gross

<sup>1</sup> University of Michigan, Ann Arbor, MI, USA

<sup>2</sup> University of Utah, Salt Lake City, UT, USA

## INTRODUCTION

Bipolar disorder (BD) is characterized by periods of mania/hypomania and depression [1]. One clinically important characteristic of BD is unusual changes in performance of daily activities depending on mood [1] but differences in movement characteristics are limited to qualitative and observational descriptors [2]. Sit-to-walk (STW) is a day-to-day activity that requires high level of coordination between two component movements, sit-to-stand and gait initiation [3]. A recent study suggested that STW kinematics change with emotion in healthy individuals [4], suggesting that STW kinematics may change with mood phase in patients with BD. Knowledge of kinematic differences in movement patterns with mood phase in BD may lead to a new quantitative clinical marker for BD. The purpose of this study was to investigate STW kinematics across mood phases in BD.

## METHODS

Twenty bipolar patients and 14 healthy controls (HC) were recruited from the Prechter Longitudinal Study of Bipolar Disorder at University of Michigan Depression Center. Participants had no history of neurological or orthopedic illness that might affect STW. Additionally, HC had no history of personal or familial major psychiatric illnesses. Mood phase of bipolar patients was assessed using the Altman Self-Rating Mania Scale (ASRM) and the Patient Health Questionnaire (PHQ-9). Then, bipolar patients were classified by mood phase into hypomania (HM; n=4; ASRM=12.5±5.2; PHQ-9=1.8±1.5), euthymia (EU; n=7; ASRM=2.0±1.6; PHQ-9=13.8±7.1) and depression (DP; n=9; ASRM=1.9±1.6; PHQ-9=14.6±6.8).

Marker data were collected using an optoelectronic motion capture system with 16 cameras at 120 Hz (Motion Analysis, Santa Rosa, CA). Participants

performed STW from a backless chair (height: 42 cm) for five trials at each of self-selected comfortable, slow and fast speeds. Marker data were low-pass filtered at 6 Hz. Visual3D (C-Motion, Germantown, MD) was used for kinematic analysis. The whole body center-of-mass (COM) was computed from marker data. We identified five events: onset, seat-off, peak vertical (VT) COM velocity, swing leg toe-off and stance leg toe-off [5]. STW duration was defined as the interval between onset and stance leg toe-off, and four relative phase durations were defined as the ratio of intervals between neighboring events to STW duration. Hesitation was defined as the ratio of COM velocity drop in the anteroposterior (AP) direction [6]. COM displacement in the AP and mediolateral (ML) directions, and peak COM velocity in the AP, VT and ML directions were calculated. One-way ANOVA with Tukey correction was used to test significant differences between groups ( $p<.05$ ).

## RESULTS AND DISCUSSION

Age (39.4±11.5 yrs) and BMI (25.8±5.4 kg/m<sup>2</sup>) did not differ between groups. STW duration was not significantly different between groups at any speed (Table 1). Relative phase durations were different between groups only for the last interval between swing leg and stance leg toe-offs (phase 4) at comfortable speed (Table 1). Relative phase 4 duration was 20.3% less for HM than for EU ( $p<.05$ ) at comfortable speed. Hesitation did not differ significantly between groups at any speed but tended to be less for HM than for EU, DP and HC at comfortable and slow speeds. (Table 1).

AP COM displacement was significantly different between groups at comfortable and slow speeds (Table 1). AP COM displacement was greatest for HM compared to all other groups at comfortable speed ( $p<.05$ ). AP COM displacement was also greater for HM than for DP at slow speed ( $p<.05$ ).

ML COM displacement was similar across groups at all speeds ( $6.1 \pm 1.7$  cm).

Similar to AP COM displacement, peak AP COM velocity was significantly different between groups at comfortable speed, and was the greatest for HM ( $p < .05$ ) (Table 1). Peak AP COM velocity also tended to be the greatest for HM at slow and fast speeds. Peak VT COM velocity ( $0.76 \pm 0.18$  m/s) and peak ML COM velocity ( $0.17 \pm 0.04$  m/s) were similar across groups and speeds.

## CONCLUSIONS

Although STW duration was not different among any of the groups, the relative duration of the terminal phase of STW was shorter for HM than for other groups. These results suggest that the time used to execute the STW task does not change with mood phase, but that HM mood phase may impact the coordination of component movements of STW. Further, the HM group maintained momentum in the AP direction more effectively than other groups, as

evidenced by the greater AP COM displacement and AP COM velocity for HM, and suggested by the tendency for hesitation to be less for HM than the other groups. The results also suggest that HM individuals may manage the transition between movement tasks differently than other groups.

# LOWER LIMB COORDINATION DIFFERENCE IN A DYNAMIC BALANCE TASK FOLLOWING STROKE

Wendy Boehm, Kreg Gruben

University of Wisconsin-Madison, WI, USA  
email: wendy.boehm@wisc.edu, web: <https://ncl.labs.wisc.edu/>

## INTRODUCTION

Humans typically accomplish walking despite the dynamic complexity of the task. Following stroke, however, hemiparesis induces additional challenge to that task, often leaving individuals permanently disabled despite therapy. Much evidence indicates that a deficit in lower limb muscle coordination contributes to that challenge, however, precise characterization of the miscoordination and how it disrupts behaviors, as well as therapy to restore walking, have not been attained.

In order to further characterize this impairment, this study analyzed the ground reaction force ( $F$ ) during a bipedal balance task similar to walking in individuals impaired by hemiparesis for comparison with non-impaired individuals. The result was a significant difference in the lower limb muscle coordination pattern between paretic (P) and non-paretic (NP) limbs that predicts walking difficulties, behavioral compensations, and therapy objectives.

Previous study of  $F$  in the sagittal-plane of non-disabled human walking has shown linear relationships between center of pressure (CP) and the tangent of  $F$  direction off vertical ( $\tan(\theta_F)$ ) [1]. During single-leg stance, that CP vs  $\tan(\theta_F)$  relationship is geometrically represented as  $F$  lines-of-action directed through a fixed intersection point above the center of mass (CM) called a divergent point (DP). When the similar relation is extracted using CP with the effect of heel-to-toe foot roll removed, the  $F$  lines-of-action intersect lower ( $xi$ ), near the CM [2].

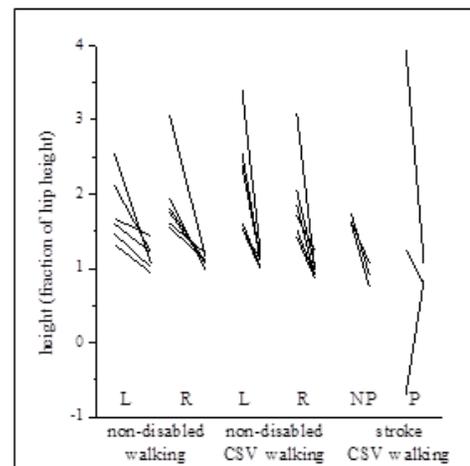

## METHODS

Nine participants (3 female, age 37-86yrs, 4 right side P) with chronic hemiplegia (>6mo post stroke) and six control (4 female, age 20-53yrs) participants walked on a custom force treadmill

with programmable motion 6-axis foot plates under each foot.<sup>1</sup> All participants walked with a simplified constant-swing-velocity (CSV) foot motion pattern. Control participants additionally walked with a typical swing velocity.  $F$  was recorded at 100Hz for 15s. The principal component of the CP vs  $\tan(\theta_F)$  relationship determined the location of the DP and  $xi$ , which was expressed as fraction of hip height.

## RESULTS AND DISCUSSION

Preliminary results using a simplified calculation of  $xi$  for a subset of subjects show that a line captured most of the CP vs  $\tan(\theta_F)$  variance with DP/ $xi$  (variance accounted for: control walk 99%/95.6%, control CSV walk 99%/97%, stroke CSV walk 93%/97.9%). The DP and  $xi$  locations for typical and CSV walking was above and near the CM (just above the hip), respectively, for the control participants and the NP limb of stroke participants (Fig. 1). In the P limb, DP location was more variable (Fig. 1) and the P  $xi$  was 0.09m anterior of the NP  $xi$  on average.

**Figure 1:** Height of intersections points for DP (left end of lines) &  $xi$  (right end of lines) show DP above the CM and  $xi$  near the CM. One line per person per leg.

The tight, anteriorly biased  $xi$  of the P limb captures a specific shift in coordination that is consistent with previously observed anteriorly biased  $F$  in seated tasks [3]. That misdirected  $F$  predicts a range of behaviors to avoid using this control for support, as is commonly observed after stroke [4]. The variable DP shows a change in strategy to accommodate this errant control such that a righting torque is still provided by  $F$  when CP shifts due to body tip.

# QUANTIFYING THE EFFECTS OF TOE AND ANKLE JOINT STIFFNESS, AND THEIR INTERPLAY, ON WALKING BIOMECHANICS USING AN ADJUSTABLE PROSTHETIC FOOT

Eric C. Honert, Gerasimos Bastas and Karl E. Zelik

Vanderbilt University

email: eric.c.honert@vanderbilt.edu, web: my.vanderbilt.edu/batlab

## INTRODUCTION

The purpose of this ongoing study is to isolate the effects of metatarsophalangeal (MTP) and ankle joint stiffness, and their interplay, on walking biomechanics. The effects of ankle stiffness (in prostheses) and quasi-stiffness (in the biological limb) have been documented in prior literature; however, the effects of MTP joint stiffness – hereafter referred to as toe joint stiffness – are less well characterized. The toe joint undergoes a dorsiflexion range-of-motion in late stance (sometimes referred to as the forefoot rocker phase) comparable to ankle range-of-motion during walking [1]. Walking models also predict that toe joint articulation may improve mechanical cost of transport [2]. However, limited experimental data exist on the effects of toe joint stiffness, or its interaction with ankle stiffness, since toe joint stiffness cannot be easily varied within the biological foot or in commercial prostheses. Here we custom-designed and tested an adjustable prosthetic foot to isolate toe joint, and ankle-toe stiffness effects. This research is expected to provide insight on the functional benefits of toe joint articulation, and may inform optimal toe joint properties to incorporate into prosthetic foot design.

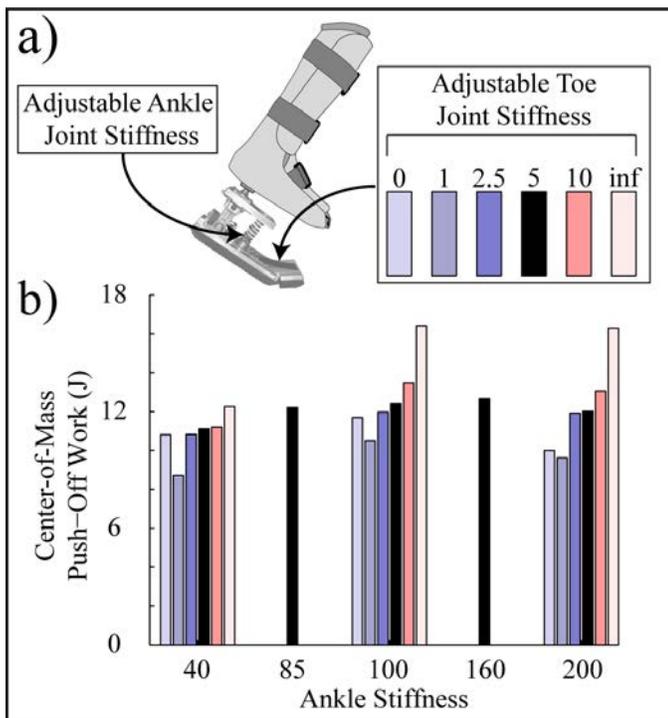

## METHODS

We designed and fabricated a (right and left) pair of adjustable foot prostheses with a sagittal rotational degree-of-freedom to approximate the ankle, and a single rotational degree-of-freedom to approximate the composite toe (MTP) joint axes in the biological foot. This design allows us to independently adjust ankle and toe joint stiffness, and other parameters such as toe length and shape.

Four healthy, non-amputee subjects (2 males, 2 females,  $22\pm 3$  yrs,  $74.8\pm 5.3$  kg,  $1.76\pm 0.07$  m) have thus far participated and provided informed consent for this gait analysis study. Subjects wore the foot prostheses bilaterally below simulator boots (which immobilize the biological ankles). Subjects walked at 1.0 m/s on a split-belt, instrumented treadmill while we recorded ground reaction forces (GRFs) and lower-limb kinematics. Each subject walked with 20 different ankle and toe joint stiffness combinations, which spanned above and below normal ranges [3]. Ankle joint stiffness was varied from 40 to 200 N·mm/deg·kg. Toe joint stiffness was varied from 0 to 10 N·mm/deg·kg, and we also tested an infinitely stiff (locked toe joint) condition. GRFs were used to compute center-of-mass (COM) power through the individual limbs method [4]. COM Push-off work was computed as one key outcome metric, based on prior literature (e.g., [4, 5]).

## RESULTS AND DISCUSSION

Preliminary findings suggest that both toe and ankle joint stiffness affect COM Push-off dynamics, and that the effect of toe joint stiffness is more pronounced with stiffer ankles. We observed that COM Push-off work increased with toe joint stiffness. Given a constant toe joint stiffness, a medium ankle stiffness (100-160 N·mm/deg·kg) resulted in the highest COM Push-off work. Additionally, the effects of toe joint stiffness were larger as ankle stiffness increased, as evidenced by the larger range of COM Push-off work: 4 J at the lowest ankle stiffness vs. 7 J at the highest ankle stiffness (Figure 1).

**Figure 1:** a) Adjustable foot prosthesis, and b) center-of-mass (COM) Push-off work during walking at 1.0 m/s for different ankle and toe joint stiffnesses (N=4). All stiffness values are reported in units of N·mm/deg·kg.

In this ongoing study, we also plan to examine GRFs, joint kinematics and kinetics, and metabolic cost. Statistical analysis will be performed after additional subjects are collected. Other foot

parameters such as toe shape, toe length, and foot length will also be varied. Results from this work will be used to inform a follow-up study on individuals with transtibial amputation.

## CONCLUSIONS

Toe joint stiffness affects Push-off dynamics in gait, and the magnitude of this effect increases with ankle stiffness.

# KINEMATIC DIFFERENCES IN PARTIAL HAND AMPUTEES USING AN EXTERNALLY POWERED HAND PROSTHESIS

## INTRODUCTION

Thirty-five percent of the two million amputees in the United States live with loss of an upper limb [1]. Amputation involving the upper limb can result in severe functional deficits, particularly if the thumb or multiple digits are lost; however, the use of an externally powered hand prosthesis can potentially restore user function but it is currently unclear how much of a difference such a prosthesis can make. In addition, it is important to examine how an amputee moves with and without their prosthesis in order to examine potential flow-through conditions due to abnormal upper limb joint motion.

The objective of this research was to identify how partial-hand amputees open a jar with and without their myoelectric hand prosthesis to determine functional differences, specifically in shoulder and elbow kinematics. We hypothesized that using the prosthesis to open the jar would result in reduced joint range of motion (ROM) compared to opening the jar without a terminal device. In addition, we hypothesized that the prosthesis condition would result in biomechanical outcomes similar to healthy cohort outcomes.

## METHODS

Amputee participants were recruited from a local prosthetic clinic. Potential amputee participants had to have a partial-hand amputation (4-digit with intact thumb or 5-digit loss) due to trauma, be over 18 years of age, have a minimum of 10 hours occupational therapy towards learning how to use their prosthesis, have good skin integrity on the residual limb, and have good strength and control of the residual limb: minimum 40° wrist range of flexion/extension, minimum 60° forearm range of supination/pronation, and minimum 10 pounds lateral thumb pinch strength, if applicable.

Healthy two-handed participants were recruited from the local community. Healthy controls had to

be over the age of 18 years and were disqualified if they had previously had surgery on their upper extremities or experienced a severe upper limb injury, such as a torn muscle, ligament or tendon, or a displaced fracture.

The amputee participants performed the testing protocol twice: once with their prosthesis and once without. The two-handed participants also performed the protocol twice: once with their dominant hand as the focus and once with their non-dominant. Condition order was randomized with a fifteen-minute break between to minimize possible learning and fatigue effects. Two trials were collected for each task within each condition for analysis.

Data collection involved collecting 3D motion capture (Vicon) while participants performed various tasks of daily living focusing on upper limb movement. The data and results presented here only encompass a jar opening task. This task was contained within the Southampton Hand Assessment Protocol which requires the participants to complete the task as fast as possible while self-timing [2]. To complete the task, participants start the timer with the hand under assessment, pick up and stabilize the jar with the contralateral hand, twist off the jar lid, set the lid and jar down, and stop the timer. Only the jar opening task is presented here as it was one of the few tasks that all the amputees could successfully complete with and without their prosthesis. In addition, analysis of the SHAP resulted in significant time and functional outcome differences between the prosthesis and non-prosthesis condition for this task.

Upper limb kinematics were calculated using custom Visual3D code. Marker data were filtered using a fourth order low-pass Butterworth filter at 6 Hz. Peak and ROM joint angles for the shoulder, elbow, and wrist were found for each participant for

each condition. The results reflect only the movement that occurred while the participant was in the act of opening the jar. The movement to start and stop the timer and pick up and set down the jar were not included in this analysis. Statistical comparison between conditions was completed using a mixed-effect model with a within-subject (prosthesis vs no prosthesis; dominant vs non-dominant) and between-subjects (amputee vs. two-handed) design with a significance level of 0.05.

## RESULTS AND DISCUSSION

Six male amputees completed the testing protocol (35.7±15.5 yrs, 175.7±7.4 cm, 86.7±20.1 kg). Three were 4-digit (27.7±8.1 yrs, 177.8±9.2 cm, 76.2±6.4 kg) and three were 5-digit partial-hand amputees (43.7±18.6 yrs, 173.5±6.4 cm, 97.2±25.3 kg). Four were amputated on their dominant right side and two on their non-dominant left side. Six male two-handed controls were used for comparison (25.5±3.9 yrs, 182.9±5.8 cm, 83.0±13.3 kg). No differences were found in age or weight between groups, but the controls were taller than the amputee group (p=0.04). Comparison of dominant, non-dominant, prosthesis, and non-prosthesis resulted in multiple significant differences (Table 1).

There were no differences between the prosthesis and either two-handed conditions, indicating that the use of a hand prosthesis does appear to normalize movement. The prosthesis condition had several lower ROMs compared to the non-prosthesis condition, though only one was significant. Shoulder and elbow flexion/extension and adduction/abduction tended towards

significance (p<0.10). Finally, the non-prosthesis condition did result in differences compared to both healthy conditions, indicating a less normative movement pattern

In addition to reducing joint ROM, the use of the prosthesis also reduced the number of attempts made to open the jar. During the non-prosthesis condition, all of the amputees required two or more attempts to twist the lid off as they struggled maintain the appropriate grip. During the prosthesis condition, almost all the amputees made only one twisting motion to open the jar.

## CONCLUSION

The preliminary results presented here indicate that an externally powered hand prosthesis restores function to partial-hand amputees trying to open a jar. Using their hand prosthesis, amputees had similar joint ROMs compared to healthy two-handed controls, while not using the prosthesis resulted in larger joint ROMs, particularly at the shoulder, a possible indicator of potential flow-through conditions.

## INTRODUCTION

Despite the large number of prosthetic feet available to persons with lower limb loss, the mechanical properties best suited to specific ambulatory tasks are largely unknown. In particular, many individuals with lower limb loss wish to engage in activities involving weighted walking - an activity for which some prosthetic feet are marketed. The biological ankle-foot complex exhibits non-linear load-deflection behavior during weighted walking (i.e., there is limited additional deformation at loads exceeding body weight), which maintains roll-over shape with added load. Non-linear stiffness may therefore prevent an effective shortening of a prosthetic foot in response to added load, keeping users from “dropping-off” their prosthesis onto their contralateral limb [1]. Thus, we hypothesized a passive prosthetic foot with non-linear (NL) vs. linear (L) stiffness properties would better accommodate weighted walking, as evidenced by lower contralateral limb loading. Note, two feet tested here were selected based on previous results of mechanical testing of nine prosthetic feet, which identified the single most L and most NL feet (quantified by the difference in maximum instantaneous radius of curvature between loaded and unloaded conditions). As a secondary goal, we also sought to understand the difference in behavior of the prosthetic feet during ambulation, particularly sagittal ankle-foot power, since previous work identified prosthetic ankle-foot power as a determinant of intact limb loading during weight acceptance [2].

## METHODS

A randomized and counterbalanced crossover design was used for eight males with unilateral transtibial amputation (mean [standard deviation] age: 36.9 [7.3] years; time from amputation: 94.2 [45.9] months) who walked along a 15 m walkway in all combinations of the NL and L feet, 2 speeds (1.34 and 1.52 m/s), and with and without added load (i.e., 22kg vest). Full body kinematics and ground reaction forces were respectively collected using an optical motion capture system (Qualisys, Gothenburg, Sweden;  $f=120$  Hz) and force platforms (AMTI, Watertown, MA, USA;  $f=1200$ Hz) embedded in the walkway. All subjects provided informed consent to procedures approved by the Walter Reed National Military Medical Center Institutional Review Board.

With a focus on limb loading and prosthetic foot mechanics, bilateral first peak vertical ground reaction force (vGRF), extrema in prosthetic ankle-foot power [3], and instantaneous roll-over shape radius of curvature of the prosthetic feet [4] were calculated using Visual 3D (C-Motion Inc., Germantown, MD, USA) and Matlab (Mathworks, Natick, MA, USA). Forces and powers were normalized to body weight and added load. For all dependent variables at each speed, two-way repeated measures ANOVAs characterized main effects of prosthetic foot type, load condition, and their first order interaction. The difference in maximum instantaneous radius of curvature between loaded and unloaded conditions was compared at each speed using a paired t-test. Statistical significance was concluded at  $P<0.05$ . All values are reported as mean (standard deviation).

## RESULTS AND DISCUSSION

In contrast to our original hypothesis, the NL vs. L foot was associated with larger intact limb loads during weight acceptance. Specifically, the first peak in intact limb vGRF was significantly larger when participants used the NL vs. L foot at both speeds, though there was no significant difference in the first peak of prosthetic limb vGRF (Table 1). Neither load condition nor the interaction between load and foot type were significant effects for any dependent variables at either speed (all  $P > 0.355$ ). Extrema in prosthetic ankle-foot sagittal power from midstance to toe-off were significantly smaller in the NL vs. L foot, which may partially explain the trends in peak vGRF (Table 1; [2]). There were no significant differences at either speed between the loaded and unloaded maximum instantaneous radii of curvatures of the prosthetic foot roll-over shapes ( $P > 0.745$ ), which were expected to differ with linearity of stiffness. In addition to decreased intact limb loading and increased prosthetic power, the maximum instantaneous radius of curvature was significantly larger in the L vs. NL foot (Table 1), representing greater stability during midstance [4].

While not presented here, the mechanical properties of the two prosthetic feet may explain the deviation from our initial hypothesis. Specifically, overall stiffnesses (%BW/mm) were larger for the NL vs. L foot (NL:  $\sim 0.04$ , L:  $\sim 0.02$  for loads up to body weight; NL:  $\sim 0.09$ , L:  $\sim 0.05$  for loads over body weight). Higher prosthetic foot stiffness has been suggested to result in larger first peak vGRFs on the intact limb [5]. Larger passive prosthetic foot stiffness results in lower energy absorption and proportional return, reducing trailing limb push off power, which is consistent with our results (Table

1). Reduced power has been previously associated with increased intact limb loading and intact external adduction moment at the knee, a biomechanical indicator of the development of intact knee osteoarthritis [2]. Other work has shown clearly that too much compliance can lead to the “drop-off” effect [6]. Together, these results suggest that there may be an optimal prosthetic foot compliance that reduces intact limb loading and provides greater stability, independent of the linearity of stiffness, when walking with added load.

## INTRODUCTION

Following lower-limb amputation, many individuals have the desire to resume physically demanding occupations that require them to carry heavy loads (e.g., military service, firefighters, and farmers). However, it is currently unclear which prosthetic feet are best designed to accommodate heavy load carriage while also providing good overall function and mobility during unweighted activities. In particular, most prosthetic feet deflect proportionally with added loads, thereby resulting in increased prosthetic ankle dorsiflexion [1, 2] and presumably, decreased roll-over shape radii [3]. This tendency suggests that many ankle-foot prostheses may not mimic the physiologic system they are trying to replace during weighted walking.

The goal of this study was to investigate the ability of currently-available prosthetic ankle-foot systems to accommodate weighted walking by examining the mechanical characteristics (i.e., stiffness linearity) and dynamic function (i.e., effective roll-over shape) of prosthetic feet designed for the highest activity users. To evaluate forefoot stiffness linearity, load versus deflection curves were obtained for nine different prosthetic ankle-foot systems. Three research participants then walked with each prosthetic ankle-foot system while quantitative motion analysis was used to obtain effective roll-over shape profiles. We hypothesized that prosthetic ankle-foot systems with a non-linear stiffness profile would better accommodate weighted walking, as evidenced by smaller changes in roll-over shape radii with added load. This study is expected to be useful in guiding the selection of prosthetic feet for high-activity users.

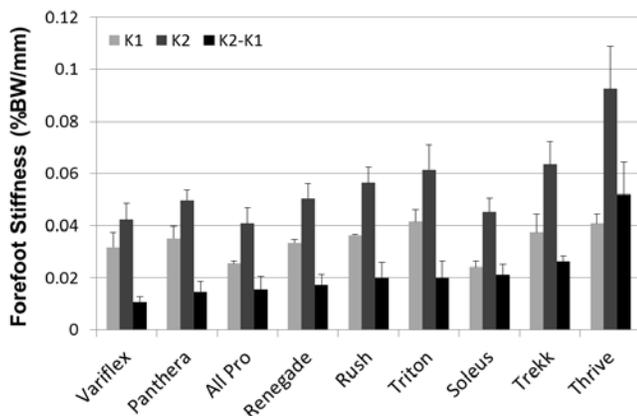

## METHODS

Nine prosthetic feet, all marketed for users in the highest Medicare Functional Classification Level (K4), were investigated in this study (Fig. 1). Load versus deflection profiles were obtained using a servohydraulic universal test frame (MTS 858, MTS, Eden Prairie, MN) with axial/torsional capabilities, a computer-based data acquisition system (Wintest, Bose, Framingham, MA), and a load cell (MTS 661-21A-01, MTS, Eden Prairie, MN). The load frame applied a uniaxial load to the foot. The foot was inserted into a boot (Reebok Hyper Velocity 8'' UltraLight Performance) and mounted in a fixture such that the plantar surface of the boot was set at a 20 degree angle from horizontal, simulating forefoot loading as defined by the ISO 10328 standard. Each foot was loaded to a maximum load of body weight + 22 kg. This represented the peak vertical ground reaction force (GRF) during single-limb support of walking while carrying an additional 22 kg load. Test loads were applied at a rate of 100 N/s, held for 1s, then ramped down at a rate of 100 N/s and held at 0 N for 1s. To compare the mechanical properties of each foot (i.e., linear versus non-linear), load versus deflection profiles were plotted from 50 N of applied load to the maximum load. The best-fit linear slope of the load versus deflection curve was then calculated between 50 N and body weight of each respective subject, corresponding to forefoot stiffness (K1) during unweighted walking. The best-fit linear slope of the load versus deflection curve was also calculated between body weight and maximum load, corresponding to forefoot stiffness (K2) above body weight. Stiffness values were normalized by body weight in order to calculate means across subjects.

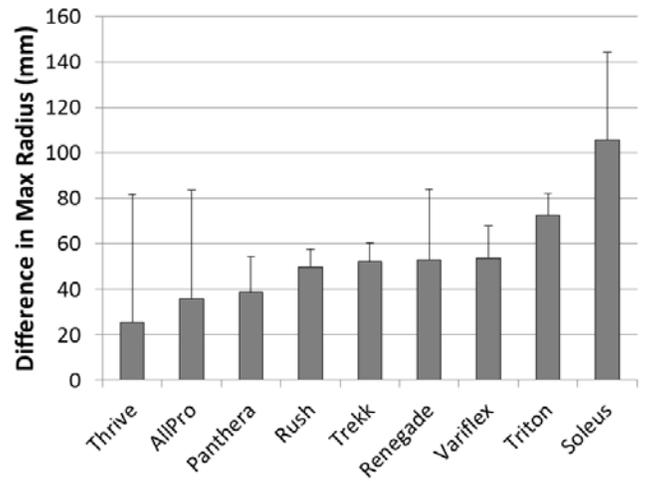

Motion analysis data were also collected on three subjects with unilateral, transtibial amputation (age 32-44 years, weight 70-97 kg, height 1.7-1.8 m). A certified prosthetist fit all study feet (tested in random order). Subjects wore the same boot that was used during mechanical testing. Reflective markers were placed on subjects to define an anatomically-relevant socket coordinate system [4]. Subjects then walked at a constant, self-selected speed with and without added weight (22 kg) across two AccuGait force platforms (AMTI, Watertown, MA; sampling rate=1200 Hz) while an 8-camera Oqus 100 motion analysis system (Qualisys Motion Capture Systems, Gothenburg, Sweden; sampling rate=120 Hz) tracked marker trajectories. To calculate roll-over shape, the center of pressure of the GRF was transformed into a socket-based coordinate system with its origin at the knee center [4]. The instantaneous radius of curvature was then calculated for each frame of stance phase [5] and the difference in mean maximum instantaneous radius of curvature was calculated (unweighted-weighted) for each foot across all subjects.

## RESULTS AND DISCUSSION

Mean forefoot stiffness values are shown in Fig 1. Interestingly, K2 forefoot stiffness was higher than K1 for all prosthetic feet tested in this study. These results indicate that to some extent, the stiffness profile of all feet were non-linear, with the Thrive being the most non-linear (i.e., largest difference).

**Fig 1.** Mean forefoot stiffness corresponding to loads up to body weight (K1) and above body weight (K2). Results are sorted by mean difference in K2 and K1, from lowest (left) to highest (right).

**Fig 2.** Mean difference (unweighted-weighted) in the maximum instantaneous radius of curvature.

Fig 2 shows the mean difference in maximum instantaneous radius of curvature across all subjects. Interestingly, the results of this analysis are consistent with the results of mechanical testing in that the Thrive, with the most non-linear stiffness, exhibited the smallest change in roll-over shape radii with added load. These results suggest that prosthetic ankle-foot systems with non-linear stiffness profiles may better accommodate weighted walking by providing the most biomimetic function for both weighted and unweighted activities. However, further testing is needed to determine the functional implications of these results.

# Effects of robotic prosthesis controllers and positive work on metabolic cost

<sup>1</sup>Matthew Handford and <sup>2</sup>Manoj Srinivasan

<sup>1,2</sup>The Ohio State University, Columbus, OH, USA

email: handford.4@osu.edu, web: http://movement.osu.edu

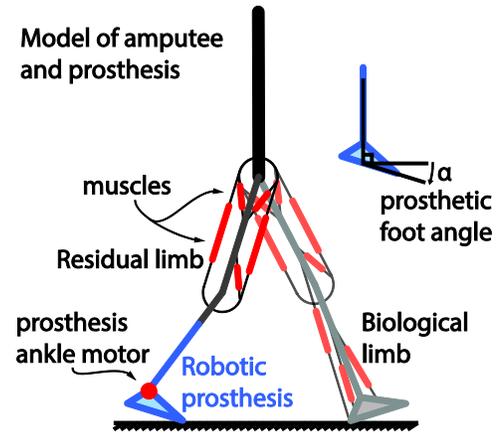

## INTRODUCTION

The vast majority of lower limb amputees use passive prostheses such as the SACH foot or the Flex foot. These devices have been around since the 1950s and 1980s respectively and have been shown to be detrimental to patients' mobility and metabolic cost. In attempting to create more comfortable prostheses which reduce the metabolic cost of the users, many recent studies sought to develop active prostheses which are capable of providing net positive work to a standard walking gait. Despite the theoretical benefits of active prosthesis, in practice, they only marginally improve amputees' metabolic cost or walking kinematics. In this study, we use a simulation of a person with an ankle-foot prosthesis to observe how increasing the work output of an active prosthesis in 3 different controllers effects the kinematics, and energetics of a walking gait. We also explore how the benefits of each controller change based on gait and environmental changes such as walking speed and ground slope.

## METHODS

Our simulation consists of a sagittal plane model of an amputee with an ankle-foot prosthesis made of seven rigid bodies. Each member is given inertial and dimensional parameters based on previous work [1]. As shown in Fig. 1, all of the biological joints are actuated using 13 uni- and biarticular muscles, whereas the prosthesis is actuated by a single torque motor.

The human-prosthesis model is used to simulate a walking gait by defining a set of contact states, based on heel and toe contact. For each of these contact states we derive ODEs to simulate motion through forward integration [1]. Collisions that occur between these contact states are assumed to be perfectly inelastic. Each of these contact states is

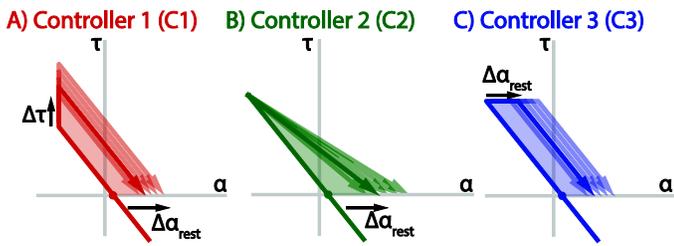

**Figure 1:** Sagittal plane model of human and prosthesis.

then split up into a series of segments to be used in a large scale optimization calculation.

Since people tend to walk in a manner that roughly minimizes metabolic energy [2], we can use energy optimization calculation to predict how a person will move while using a variety of prosthesis controllers. Therefore, we define a cost function based muscle activation, force, and shortening velocity [1], shown below:

$$C_m = \int \sum \left[ 0.05(a + a^2) + a\phi \left( \frac{v}{v_{max}} \right) \right] F_{iso} v_{max} dt$$

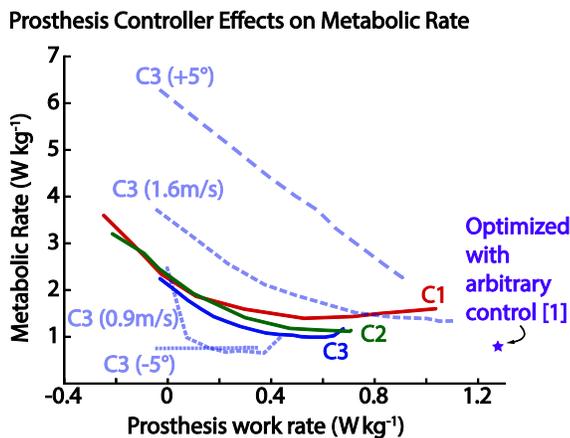

We then defined three controllers with which to actuate the ankle-foot prosthesis. The torque-ankle angle relationships are shown in Fig. 2. Each of these controllers was tested with multiple levels of net work to determine their effect on the human metabolic cost and the gait kinematics. Each controller was tested on flat ground at a walking speed 1.3 m/s. After determining that controller 3 produced the smallest metabolic cost, this controller was also tested at other walking speeds and ground slopes.

**Figure 2:** Prosthesis controller torque – ankle angle relationship.

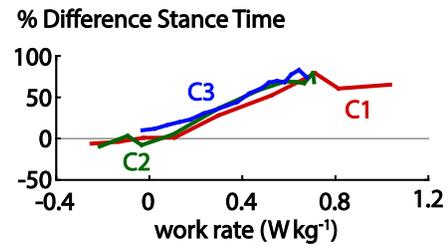

## RESULTS AND DISCUSSION

For every controller tested, similar to what has been observed in experimental studies, as the net work of the prosthesis increases, the metabolic cost to the person decreases. However, we also found that at a certain level of work, any additional positive work would produce a higher cost to the person, thus signifying an optimal work. We also found that each controller effected the metabolic cost differently. This shows that not only is work important to metabolic cost, but also the manner in which it is applied needs to be considered. Fig. 3 displays the results for each controller at various levels of work.

**Figure 3:** Metabolic rate due to various levels of work from all three controllers. Light blue lines show the results from controller 3 at various speeds and ground slopes.

As far as their effect on kinematics, we found that each controller produced an asymmetric gait with % stance time on the prosthesis side increasing along with the addition of work. These results are summarized in Fig. 4. The tendency to spend more time on the prosthesis foot rather than the biological

**Figure 4:** The difference in step time between the prosthesis and biological sides.

foot is not seen in experiment. This discrepancy is likely due to the lack of damping in the prosthesis controllers.

After determining which of the three controllers produced the lowest metabolic cost, we tested that controller at walking speeds ranging from 0.9 m/s to 1.6 m/s and with ground slopes ranging from  $-5^\circ$  to  $5^\circ$ . Fig. 3 displays the results from these simulations. For all speeds, we found that the addition of positive work produced smaller metabolic cost. For negative slopes the addition of work to the prosthesis has very little effect on the metabolic cost, while for positive slopes, the metabolic cost is linearly dependent on the work provided. These results lead us to conclude that, in order to get the maximum benefit from an active prosthesis, it may be necessary to build a slope and speed dependency into the controller.

## INTRODUCTION

Prosthetic users rely on a well-fitting prosthesis. To accomplish a good fit, the skin on the residual limb is covered by a gel liner, and then the prosthetic device goes over the biological limb and liner. The mechanical interface between the limb and liner results in a complex loading condition at the skin. These loads are contributors to the formation of skin wounds that are highly prone to infection, called ulcers. While extensive linear models have been developed, there is much yet to be understood about key contributors to ulcer formation through the use of non-linear biological tissue modeling. Since this mechanical system consists of a highly non-linear material, i.e. the skin, it is important to use an appropriate material description, otherwise the model results could dramatically overestimate or underestimate the stress magnitude on the skin. Furthermore, a deeper understanding of the interface between the gel liner and residual limb tissue is needed.

Soft tissue modeling research is limited with regard to the use of non-linear neo-Hookean materials implemented in software platforms specifically designed for biological tissues (i.e. FEBio) [1]. Currently, soft tissue models using FEBio study heel ulcers, buttock tissue damage in spinal cord injured individuals, and a single transtibial patient [2-4].

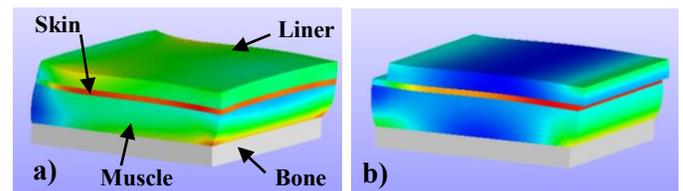

Further, experimental work by the authors [8] showed that during walking, the liner elongated at the distal end of the residual limb. To achieve these larger distal displacements, either the liner is sliding with respect to the skin or the liner is “sticking” to the skin and shearing tissues below.

The purpose of this work was to explore these two scenarios. To accomplish this we developed a soft

tissue model in FEBio and looked at a slip and no slip conditions for three different liners.

## METHODS

A finite element model with a rectangular geometry of 100 mm x 100 mm was developed to represent the body and gel liner interface for a prosthetic user. The model contained four layers: bone, muscle, skin and a gel liner (Fig. 1). Layer thicknesses were 10 mm of bone, 20 mm of muscle, 3 mm of skin, and 9 mm of gel liner [3-7]. Mechanical properties of bone, muscle, skin and a gel liner were adapted from the literature. Specifically, the bone was assumed to be a rigid body ( $E = 7$  GPa;  $\nu = 0.3$ ). The muscle ( $\nu = 0.49$ ;  $\mu = 7.124$  kPa) and skin ( $\nu = 0.495$ ;  $\mu = 31.899$  kPa) were quasi-incompressible and hyperelastic, represented by a neo-Hookean material [3-4]. The gel liner was modeled as an isotropic, linear elastic material. Three liners were modeled and were based on existing liner material: A, B and C with a poisson's ratio of 0.49 and increasing Elastic moduli of 50.05, 55.86 and 56.28 kPa, respectively [5].

**Figure 1:** a) No slip model and b) Slip model demonstrating effective stress results. Plotted at the same stress color scale, red indicates highest effective stress (Table 1) in the skin layer.

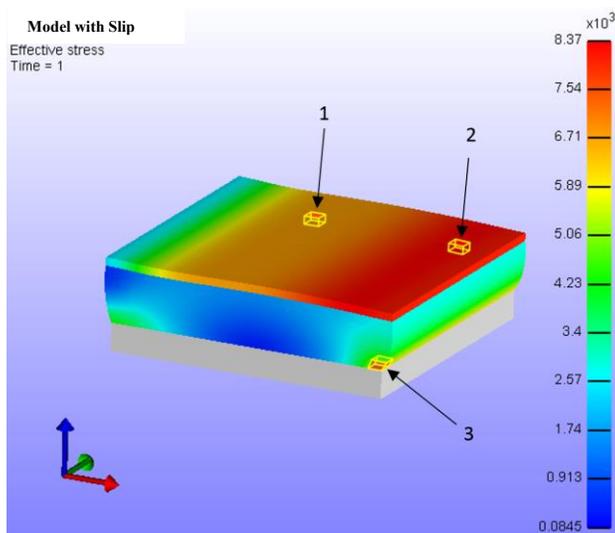

The skin to gel liner interface was modeled in two ways. First, a tied contact was used to computationally represent a no slip condition of the liner with respect to the skin (Figure 1a). Secondly, a sliding contact was defined with a coefficient of friction of 0.3 for all three liner types [5] which

computationally would allow for slip to occur if threshold was exceeded (Figure 1b).

Loading conditions consisted of a 5 kPa distributed pressure at the surface of the gel liner based on experimentally collected force data. Secondly, a prescribed displacement of 6 mm was applied to the liner to represent displacement found in the gel liner for transtibial amputees wearing a gel liner interface with a pin locking suspension design [8].

## RESULTS AND DISCUSSION

In models where slip occurred between the gel liner and the surface of the skin, effective stress was varied throughout the skin layer with the highest stresses occurring in the region identified as element 2 (Figure 2 and 1b); whereas models without slip (Fig. 1a) demonstrated even stresses throughout the interface contact.

**Figure 2:** Model with slip and gel hidden, demonstrating three locations of effective stress analysis with scale in Pa.

For liner A, with identical loading conditions, the normal compressive stress at the muscle to bone

interface was nearly doubled when compared with the model with slip (Table 1). Additionally, maximum shear stress was increased in all three locations for the model without slip. With increasing prosthetic gel liner stiffness (A to C), models without slip demonstrated slightly decreased compressive stress at the bone to muscle interface. While none of these models exceeded the published ultimate stresses for skin, the deeper tissue stresses and the repeated shear loading which cyclically occurs through the day for prosthetic users is a likely contributor to tissue wounds on the residual limb.

## CONCLUSIONS

Soft-tissue finite element models are needed to improve our understanding of the interface mechanics between prosthetic liners and underlying tissues in prosthetic users. The comparison of slip and no slip conditions present an important clinical question because clinically, slip of the liner with respect the limb is not desired. Additionally, if slip does not occur, the uneven displacements on the liner would produce a shearing of deeper tissue which is also not desirable. Further model studies and experimental data to support these models are warranted. Mechanics based data is a necessity to formulate improved prosthetic fit and design, these additional data are also helpful in guiding prosthetists in the selection of appropriate prosthetic liners for patients.

# A DART THROWER'S MOTION WRIST SHOULD IMPROVE PROSTHETICS

Matthew Davidson, Richard Weir  
University of Colorado Denver, Aurora, CO  
email: Matthew.Davidson@ucdenver.edu

## INTRODUCTION

Despite decades of improvement, upper-limb prosthetic devices still do not provide enough functionality for the 41,000 Americans with upper limb amputations. State of the art myoelectric devices work by reading electrical signals from the muscles in the residual limb and translating them into motion of the prosthesis. Non-invasive techniques, such as surface electrodes, are non-specific, picking up data from all extensors or all flexors and providing only two inputs. This means that, although the mechanical challenges of creating a hand and wrist that mimic all 27 degrees of freedom (DOF) of the anatomical limb has been largely solved (see DEKA arm, e.g.), we do not yet have a way to collect enough inputs to effectively control such a complicated device. While many other projects have focused on trying to increase the amount of control inputs, we have attempted to solve this problem by reducing the dimensionality of the device by combining DOF in the wrist into the Dart Thrower's Motion (DTM).

The DTM is a combination of wrist flexion-extension (FE) and radial-ulnar deviation (RU) in a plane rotated along the axis from pure FE. It is particularly useful in performing activities of daily living (ADL) that involve tool use [1]. We previously found this angle to be 26.8 degrees [2]. Our previous work showed that nearly 75% of the functionality of the wrist during grasping can be maintained by reducing the wrist to the single DTM DOF.

We present here the results of testing a new prosthetic device that incorporates the DTM. This device improves functionality while only adding a small amount of complexity. This has the potential to improve the lives of people with upper limb amputations by allowing them to more easily perform ADL and find better jobs.

## METHODS

In a preliminary sample, six adults (age:  $30 \pm 6$  years) with normal physiology performed the Southampton Hand Assessment Procedure (SHAP) while fitted with a splint with a terminal prosthesis simulating an amputation [3]. Participants performed the SHAP with three different wrist configurations: No Wrist, Flexion Wrist, and DTM wrist. Each configuration was tested in a separate session with at least 24 hours of rest in between sessions. At the conclusion of each session, the participants filled out the NASA Task Load Index (TLX), a validated subjective measure of task difficulty.

The SHAP is a validated and standardized measure of hand function that has become standard of care in measuring prosthetics effectiveness. Participants complete 12 movement tasks with abstract objects and 14 ADL objects. The test is based on time-to-completion and produces a score from 0 (no function) to 100 (normal function). The design of the prosthetic hand prevented participants from completing four of the ADL tasks (Buttons, Cut, Tray, and Zip). In order to prevent damage to the equipment, participants simulated pouring water by positioning the cup and counting four seconds before replacing it. Due to large inter-subject variability, we compared data with the intra-subject mean subtracted [3].

The simulated prosthesis consisted of a splint with a commercial quick disconnect attached to the end. We created a custom 1-DOF wrist with rotation and a wedge to create the DTM based on our previous work. The hand was a 1-DOF, 3 finger hand. We used a standard of care state-machine position control system where co-contraction switched between controlling the hand and wrist. The wrist control was disabled for the "no wrist" condition and rotated back to pure FE for the "flexion wrist condition".

EMG signals were recorded from the dorsal and ventral forearm with surface electrodes. The signal was processed in LabView (National Instruments, Austin, TX) and sent to the motors (Faulhaber, Schönaich, Germany) via an Arduino Uno and custom motor controllers (Sigenics, Chicago, IL).

Participants were given up to 15 minutes to practice with the prosthesis before beginning the SHAP. They were given instruction and up to 5 minutes practice time before each task.

This study was approved by the Colorado Multiple Institution Review Board (COMIRB No: 14-0838).

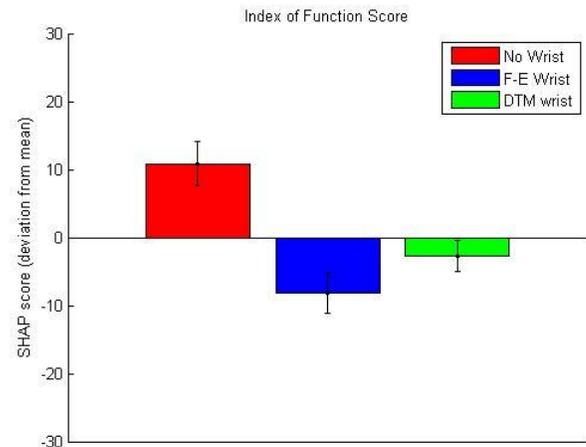

## RESULTS AND DISCUSSION

We found significant differences between SHAP scores of different wrists and that the average SHAP scores for the DTM wrist were higher than those for the FE wrist (ANOVA,  $p < 10^{-7}$ , Tukey confidence interval 95%) [Figure 1]. We also found no difference in TLX (ANOVA,  $p = 0.12$ ) [Figure 2] indicating that controlling the DTM wrist was no more demanding than controlling a FE wrist or a no-wrist system. This supports our hypothesis that including a DTM wrist in a prosthesis will improve functionality without being too difficult to use.

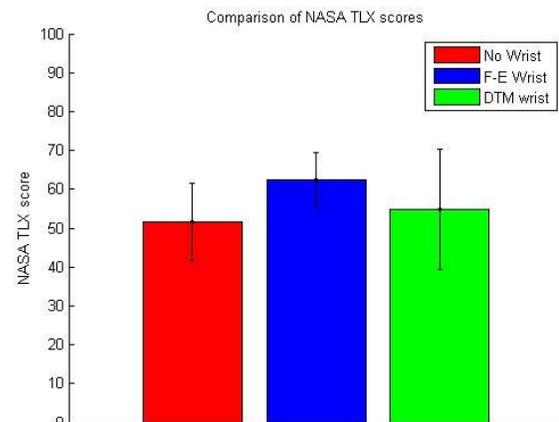

The SHAP score for the no-wrist condition is significantly higher than for the DTM and Fe wrist conditions. This is not surprising since the SHAP is a time-based test and using a second DOF of any kind will add time. Increasing the DOF improves functionality so the increase in time should be offset by a decrease in difficulty. Indeed, most participants commented on how the position of the DTM wrist made many SHAP tasks easier to perform and reduced the need for compensatory motions. In the future, we will analyze shoulder motion to quantify this effect.

Improving the prosthetic wrist can improve the lives of people with amputations by allowing to live independently, engage socially, and find employment. We have shown that the DTM wrist has the potential to be an ideal improvement that balances increased functionality with ease of use. Our next steps are including more able-bodied

participants to improve statistical power, analyzing compensatory shoulder motion, and comparing the results to people with trans-radial amputations.

**Figure 1:** Results of SHAP test (intra-subject mean subtracted) indicating that the DTM wrist improves functionality over a FE wrist (ANOVA  $p < 10^{-7}$ , Tukey HSD 95% confidence).

**Figure 2:** NASA Task Load Index for the 3 conditions. Adding FE or DTM wrist to the prosthesis did not significantly increase task load (ANOVA  $p > 0.05$ ).

## INTRODUCTION

When a device to improve the functionality of existing assistive devices is newly designed for patients with mobility impairment, the efficacy of the device needs to be evaluated. During initial prototype evaluations, collecting experimental data from actual patients might be challenging due to limited mobility to access a laboratory and possible secondary conditions prevalent among patients with mobility impairment [1]. Therefore, experiments would be conducted more safely and efficiently if individuals without mobility impairment could perform given simulated motor tasks affected by the impairment. However, the premise is that the tasks accurately represent the characteristic performance of the patients with mobility impairment. For example, unilateral transfemoral prosthetic gait (TPG) is characterized by lower self-selected speeds, shorter prosthetic stance phase, extended knee during stance phase, and increased hip flexor activity [2, 3, 4, 5].

In this study, simulated unilateral TPG performance using an in-house TPG simulator was evaluated. A previous study using a TPG simulator has shown that gait kinematics such as joint angles and stride length parameters are consistent with the data obtained from actual patients [2]. However, up to this date EMG during simulated unilateral TPG has not been analyzed. Therefore, the current study examined hip and knee angles and EMG from four muscles in the simulated prosthetic leg to compare with published data of actual transfemoral amputees.

## METHODS

*Simulator Fabrication:* The TPG simulator was constructed using a set of a mechanical knee, an aluminum pylon, a Niagara foot (Limbs Relief Knee LimbBox, Limbs Int., El Paso, Texas), and a connector (socket) constructed from a sheet of 2-mm thick stainless steel bent into a U-shape to fit around the thigh. A leg brace locked at 110-degree knee

flexion was used to immobilize the subject's lower leg and to securely attach the simulator to the subject's leg. The user wore a knee pad with Velcro to secure the knee in place with the connector (Fig. 1).

**Figure 1.** Fabricated TPG simulator

*Subjects:* Two college students participated in this preliminary study. Both subjects had no prior experience with the simulator and acclimatized themselves to the simulator until they were able to walk down a 30 m track at 60% of their normal gait speed [6]. Subjects wore their own athletic shoes for testing.

*Testing:* 34 reflective markers were attached to anatomical landmarks of the pelvis, legs and feet including the simulator. Using a motion capture system with 7 infrared cameras (T10, VICON, Oxford, UK), kinematic data were captured at 100 Hz during 6-m walk aiming at a target speed of 1.0 m/s, while the subject wore the TPG simulator on his/her dominant leg. The target speed was selected to compare with previous studies using mechanical knees, showing self-selected speeds at or near 1.0 m/s [2, 3, 4]. Five trials were performed for each subject. Wireless surface EMG electrodes (Trigno, Delsys Inc., Natick, MA) were placed on the following muscles in the simulated prosthetic limb: the tensor fasciae latae, gluteus medius, rectus femoris, and semitendinosus [5]. EMG signals were sampled at 1 kHz.

*Data Processing:* Custom-written codes using MATLAB (v8.1, MathWorks Inc., Natick, MA) were used to calculate joint angles and process the EMG data. The kinematic data of all trials of each subject were time-normalized to a full gait cycle and averaged. EMG data were low-pass filtered (10 Hz), rectified, and band-pass filtered (10-400 Hz) to generate EMG linear envelopes, then time-

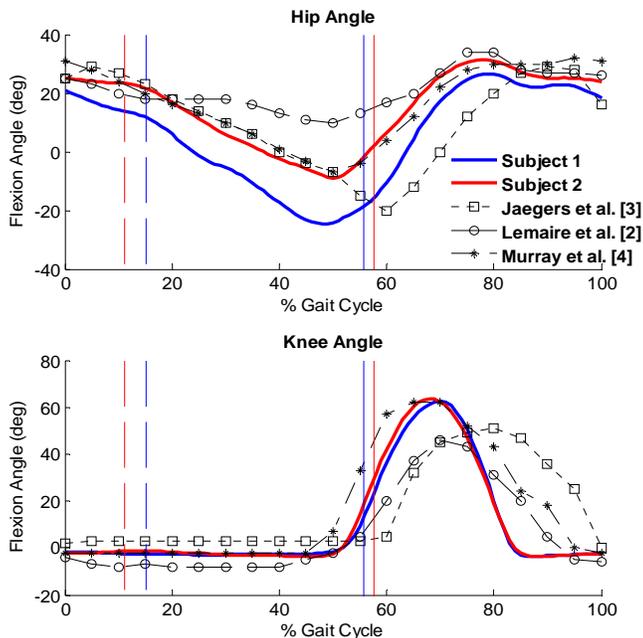

normalized to a full gait cycle. After taking intra-subject average, the EMG magnitude was normalized to the maximum value over the gait cycle.

## RESULTS AND DISCUSSION

The subjects were able to walk at the speeds near the target speed (1 m/s) after acclimatization (Table 1). The stride length was comparable to a previous study (1.26±0.14 m) with similar gait speed (0.82±0.11 m/s) [2].

**Table 1:** Subject data. Mean gait speed and stride length parameters ± 95% CI interval.

	Subject 1	Subject 2
Gender	Female	Male
Age (yrs)	21	21
Height (cm)	162.6	172.7
Weight (kg)	59.0	87.5
Acclimatization Time (hr)	3.25	1.5
Gait Speed (m/s)	0.85 ± .05	0.97 ± .09
Stride Length (m)	1.19 ± .05	1.13 ± .05

**Figure 2:** Hip and knee angles of simulated prosthetic leg over a gait cycle. Data ensembles the average of all trials. Vertical solid lines indicate the ipsilateral toe-off, and dashed lines indicate the contralateral toe-off.

The joint kinematics of the prosthetic leg (Fig. 2) were in general similar to the literature [2, 3, 4]. Subject 1 showed more extended hip positions during the stance phase, which may be due to the subject attempting to maintain the target speed with shorter single stance duration on the prosthetic side. EMG patterns in Fig. 3 also exhibit similar trends

between subjects and a previous study that exhibited large variability in EMG among three transfemoral amputees [5].

**Figure 3:** EMG linear envelopes over a gait cycle. Blue and red lines represent Subject 1 and Subject 2, respectively. The shaded area represents the range of EMG obtained from three transfemoral amputees in Wentink et al. [5].

## CONCLUSIONS

These preliminary results showed that simulated TPG using the developed simulator may be used to evaluate the efficacy of prototype devices aiming to improve the functionality of existing assistive devices such as prosthetic knees. Collecting data from a larger number of subjects and other biomechanical and physiological data is planned in the future study for further confirmation.

# ADAPTATION TO GRADUAL AND SUDDEN INCREASES IN PROSTHETIC ANKLE POWER

Brian P. Selgrade, Bretta L. Fylstra, and He (Helen) Huang

North Carolina State University/ University of North Carolina – Chapel Hill  
Joint Department of Biomedical Engineering  
email: bpselgra@ncsu.edu, web: <http://nrel.bme.ncsu.edu>

## INTRODUCTION

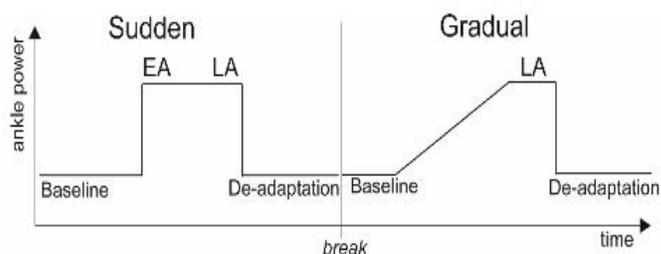

Previous work demonstrates the benefits of powered ankle prostheses, including reduced metabolic cost, increased gait speed, and reduced intact joint loading [1]. However, few studies explore how amputees adapt to increasing prosthetic joint power, a critical part of powered prosthesis adoption. Sudden perturbations challenge balance more than gradual perturbations [2]. Alternatively, people can adapt to sudden perturbations to minimize energetic cost in only a few steps [3], suggesting sudden perturbations may be preferable to induce an efficient adapted gait.

The purpose of this study was to compare amputee adaptation to sudden and gradual increases in prosthetic ankle power to determine which caused greater changes in compensation from the intact leg. We hypothesized that suddenly increased prosthetic ankle power would induce the wearer to unload the intact limb while gradually increased power would be less perceptible and thus induce less intact limb unloading.

## METHODS

One trans-tibial amputee (male, 114.5kg, 183cm tall) participated in three study sessions – powered prosthesis tuning, powered prosthesis training, and prosthetic power adaptation. In the first two sessions, the power from the BiOM prosthetic ankle (BionX, Bedford, MA, USA) was adjusted to the subject's preferred settings according to the standard BiOM tuning protocol and the subject spent several hours walking with these settings. During the third (adaptation) session, the subject walked on an instrumented treadmill (Bertec, Columbus, OH, USA) at his preferred walking speed (1.2m/s) in two conditions: sudden power increase, and gradual power increase (Fig. 1). In the sudden condition, the subject first walked with power at just below half of

his preferred power level. Next, prosthetic ankle power was increased to the subjects preferred power. After 5 minutes at preferred power, power decreased back to its original, lower level. In the gradual condition, power started at just below half of preferred power and then increased by the smallest possible increment every 15 seconds for 5 minutes, ending at preferred power. After 3 minutes at this constant, preferred power, power decreased back to the lower level.

**Figure 1:** Experimental Protocol (EA and LA signify early and late adaptation).

Kinematics and kinetics were collected using an 8-camera system and instrumented treadmill. We used inverse dynamics calculations in Visual 3D (C-Motion, Germantown, MD, USA) and Matlab (Mathworks, Natick, MA, USA) to find joint powers for each stride (Eq 1). We report peak joint powers. We calculated step length symmetry by subtracting left step length from right step length and normalizing by the sum of step lengths [4].

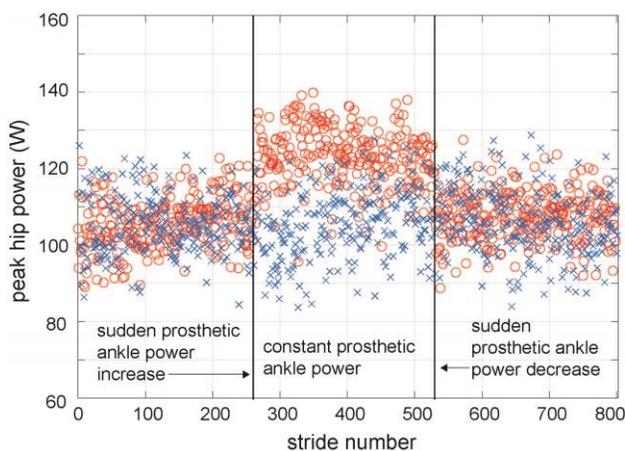

## RESULTS AND DISCUSSION

We found that, as expected, peak prosthetic ankle power increased up to the preferred power level in both the sudden and gradual conditions. However, there were no changes in intact side joint powers or ground reaction force when the prosthetic ankle power increased regardless of condition. Therefore, the hypothesis that suddenly increased prosthetic

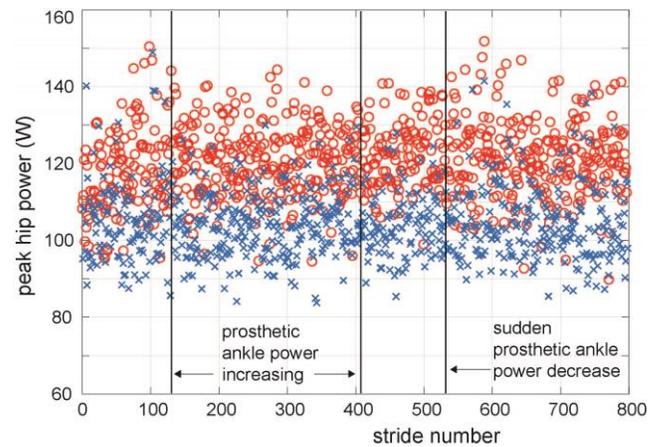

ankle power would result in unloading of the intact limb was not supported.

Whereas intact side kinetics were unchanged, peak hip power on the prosthetic side increased when prosthetic ankle power suddenly increased (Fig. 2). This increase in hip power was immediate and disappeared immediately when prosthetic ankle power decreased. This immediate response suggests that the changes in hip power in reaction to increased ankle power are solely due sensory feedback. Rather than slowly updating neural control of his prosthetic side hip, the amputee uses reactive control. Alternatively, in the gradual condition, there was no increase in prosthetic side hip power (Fig. 3), even though prosthetic ankle power was similar in both conditions. This suggests that the increased hip power in the sudden condition results not simply from mechanics but from the underlying motor control.

Despite the changes in prosthetic side joint power, step length symmetry remained constant throughout in both conditions. This apparent mismatch could have occurred because the increase in prosthetic side joint power was too small to have a clear effect on step length or because kinetic asymmetries do not always relate to kinematic asymmetries in amputees [5]. Future research with more subjects is necessary to confirm these results.

**Figure 2:** Peak hip power for intact (x) and prosthetic (o) sides when prosthetic ankle power was increased suddenly. Hip power increases at the same time as prosthetic ankle power.

**Figure 3:** Peak hip power for intact (x) and prosthetic (o) sides was unchanged when prosthetic ankle power was increased gradually.

## CONCLUSIONS

While neither sudden nor gradual increases in prosthetic ankle power altered intact leg kinetics, the two conditions did have different effects. Only suddenly increased prosthetic ankle power induced increased prosthetic side hip power, suggesting reactive control of hip power. Additionally, these changes in power did not cause step length symmetry to change. Further research is necessary to confirm these results.

## INTRODUCTION

Advances in prosthetic materials and design have provided more upper limb prosthetic options to assist individuals with limb loss to perform their daily tasks. The SoftHand myoelectric prosthesis prototype (SoftHand Pro; SHP) uses robotic technology from the University of Pisa/Istituto Italiano di Tecnologia. The SHP is an anthropomorphic prosthesis that uses standard myoelectric control. This unique, intuitive hand terminal device is light weight, underactuated, and uses a single motor to flexibly control and coordinate finger and thumb motion based on hand synergies.

Preliminary work has determined the feasibility of the SHP in subjects without limb loss during grasping, lifting and releasing objects [1]; these subjects used a 3D-printed harness attached to the forearm in place of a prosthetic socket. However, use of the SHP by subjects with limb loss has not yet been evaluated. This study was conducted to examine functional performance by subjects with transradial limb loss. The study aimed to quantify the ability of subjects with transradial limb loss and age-matched subjects without limb loss to perform a reach-grasp, lift-return (RGLR) task and how task performance may be affected by training with an occupational therapist.

## METHODS

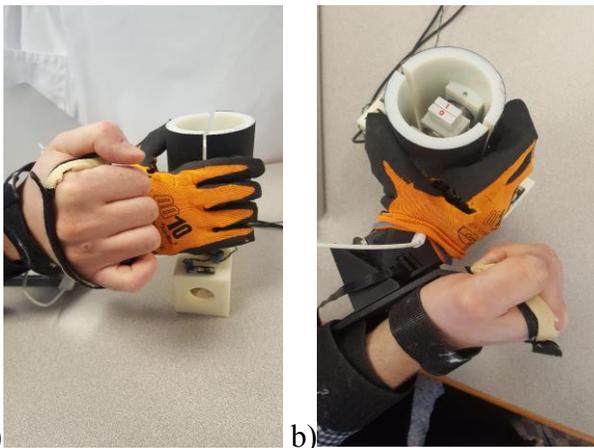

Nine subjects (8 males and 1 female) with transradial limb loss and nine age matched controls (2 males and 7 females) participated in the study.

The protocol was approved by the Institutional Review Board. Subjects with transradial limb loss were fitted with a custom socket prior to testing. The age matched controls used a 3D-printed harness to allow use of the SHP as an extension of their arm. Surface electromyographic (EMG) electrodes were attached on wrist flexors and extensors, to control the closing and opening of the prosthetic hand. Subjects were asked to perform tasks that included reaching, grasping, lifting and then returning (RGLR) an instrumented cylindrical object. The cylinder was instrumented with 6-axis load cells (ATI Industrial Automation) to measure loading applied on the object. Movement of the digits and the object was recorded with an active marker tracking system (PhaseSpace Inc, CA). Red light-emitting diodes were attached to the instrumented object base and the tips of the 1<sup>st</sup> and 2<sup>nd</sup> distal phalanges.

Subjects were seated at a desk with the SHP placed at a standardized resting position and with the instrumented object placed in front of them. After a brief familiarization period with the SHP, subjects performed the task. Subjects were subsequently trained for 6-8 hours by an occupational therapist to use the SHP. At a second data collection session after training, subjects performed the same RGLR task. The task was divided into reaching phase, gripping phase, lifting phase and returning phase. The reaching phase was defined from the point when the hand starts reaching until the hand has reached the object. The gripping phase was defined from the time the hand started to grasp the object until complete grasp was accomplished. The lifting

phase was defined from the time the object was lifted off the desk to the time the object was lifted to the maximum height. The returning phase was defined from the time the object was lowered until the time object reached the desk. Transducer and kinematic data was collected at 96 Hz. Two trials were conducted at each time point.

Data was reduced to several parameters describing key components of the task: (a) normalized arc length of the reach was measured to quantify the trajectory of the reach, (b) duration of each of the phases, (c) velocity of the SHP during each of the phases, (d) maximum loading on the instrumented object during the gripping phase. Variables were examined pre- and post-training and also between subjects with limb loss and age-matched controls with a mixed effects model.

**Figure 1.** Age-matched subject using the SoftHand Pro to grasp the instrumented object, a) sagittal view, b) transverse view.

## RESULTS AND DISCUSSION

The normalized reaching arc length was not significantly different across subjects with limb loss and age-matched controls, pre and post training. This indicates that the subjects with limb loss and controls used a similar trajectory to reach for the cylinder, despite the use of the harness in the control group. The duration of the task phases was also not significantly different across subjects with limb loss and age-matched controls, pre and posttraining for any part of the task. Absence of significant differences in duration parameters

suggests that both the subjects with limb loss and control subjects were able to perform the task in similar times and training did not improve performance within a single training session.

The maximum velocities of the lifting and lowering phases were significantly higher post-training in the subjects with limb loss. However, since, the height of the lift was not standardized, further analysis is required to understand this difference. The maximum force applied on the object was not significantly different across subjects, pre- and post-training. This suggests that irrespective of previous experience with prosthesis, both subjects exerted the same loads on the object. Further analysis is required to understand the time point at which the forces were applied and its relation to the maximum force capability of the SHP.

## CONCLUSIONS

Both transradial limb loss subjects and age-matched controls achieved similar performance during a grasping task. This study implies that the SHP is intuitive and versatile, as even subjects with no exposure to myoelectric control or upper limb prostheses were able to adapt quickly and perform a grasping task successfully and similarly to patients with limb loss.

## INTRODUCTION

Modern powered knee prostheses can more closely emulate biological lower limb muscle function than energetically-passive prostheses because they are equipped with a motor and capable of providing greater support and power to the user. Most commonly, the joint mechanics are determined by an impedance controller that modulates knee joint stiffness during predetermined phases based on prescribed impedance control parameters and the user's engagement with the device (i.e. finite state control). As expected using this technology, transfemoral amputees are able to ambulate with more normative (i.e. near able-bodied) mechanics at the prosthetic knee joint [1]. However, no studies to our knowledge report the full-body biomechanics of transfemoral amputees walking with powered knee prostheses. Is there a common gait pattern users adopt when their prosthetic knee moves more naturally?

In the study, we provided transfemoral amputees with near-normative prosthetic knee mechanics with our experimental powered device and evaluated their resulting gait behavior (e.g. center-of-mass motions). Muscle atrophy and remaining physical imbalances may prevent amputees from walking symmetrically, but we hypothesized amputees would not adopt significantly different levels of gait asymmetry with our experimental powered prosthesis. We specifically compared each subject's center of mass forward speed, push-off force impulse, and collision force impulse symmetry.

## METHODS

Three people with transfemoral amputation (20 years male, 61 years male, 27 years female) and functional level K3 (characteristic of typical

community ambulators) provided written, informed consent and participated in our IRB-approved study. A certified prosthetist fit each amputee with our experimental powered knee prosthesis [2], and a trained expert prescribed each amputee with prosthesis impedance control parameters that generated near-normative knee motion. We based this tuning process on the traditional prosthesis control parameter tuning process in a clinic. Each amputee then trained with the device for 3 or more 2-hour sessions, until they reported feeling comfortable walking with the device without assistance.

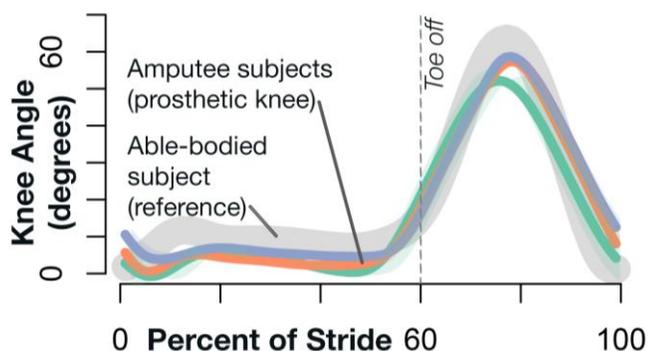

All subjects walked at 0.6 m/s for three 2-minute trials. We recorded ground reaction forces from a split-belt treadmill (1000 Hz, Bertec Corp.) and full-body motion using an 8-camera motion capture system (42 markers, 100 Hz, VICON). We used standard analysis software (Visual 3D, C-Motion, Inc.) to calculate kinematics, kinetics, and center of mass trajectories. We analyzed the last 10 consecutive strides from each trial to capture steady-state behavior. We filtered the motion and force-plate data using a 4th order Butterworth low-pass filter with a cutoff frequency of 7.5 Hz. To evaluate gait symmetry, we used a standard asymmetry index,  $\frac{(X_{Intact} - X_{Amputated})}{(X_{Intact} + X_{Amputated}) * 0.5} \times 100$ , where X was center-of-mass speed, push-off impulse, and collision impulse. To test for significant differences between subjects, we used one-way ANOVA ( $p < 0.05$ ). If subject was a significant factor, we used Tukey's honest significant difference test to identify how subjects differed.

## RESULTS AND DISCUSSION

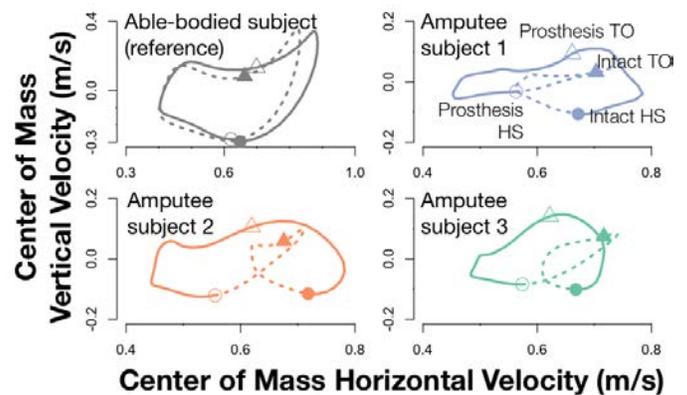

All subjects walked with near-normative knee motion at the prosthetic knee joint when using our experimental powered knee prosthesis and subject-specific impedance control parameters (Fig. 1).

Contrary to our hypothesis, all amputee subjects walked with highly varied levels of asymmetric center-of-mass motion (Fig. 2), despite having very similar prosthetic knee motion. Able-bodied people typically walk with the same forward center-of-mass speed during mid-stance, but all amputee subjects walked with varying asymmetric mid-stance speeds (i.e. faster on prosthetic limb) ( $F(2,6)=16.07$ ,  $p=0.004$ ), and subject 2's center-of-mass speed asymmetry ( $M=-31\%$ ,  $SD=3\%$ ) was significantly greater than that of subject 1 ( $M=-21\%$ ,  $SD=2\%$ ) and subject 3 ( $M=-21\%$ ,  $SD=2\%$ ).

Asymmetry in anterior-posterior ground reaction force impulses typically contribute to center-of-mass speed asymmetry. Subjects exhibited varying push-off impulse asymmetry (i.e. push more with intact limb) ( $F(2,6)=32.69$ ,  $p<0.001$ ) and braking impulse asymmetry (i.e. brake more with intact limb) ( $F(2,6)=32.10$ ,  $p<0.001$ ). Interestingly, subject 1's braking impulse asymmetry ( $M=15\%$ ,  $SD=6\%$ ) was significantly lower than subject 2 ( $M=66\%$ ,  $SD=11\%$ ) and subject 3 ( $M=50\%$ ,  $SD=6\%$ ), but his push-off impulse asymmetry

**Figure 1:** With subject-specific prosthetic knee parameters, all amputee subjects walked with a prosthetic knee angle similar to a reference able-bodied subject. All trajectories were normalized to one stride. Vertical dotted line indicates approximate toe off. Line color indicates amputee subjects 1-3 (blue, orange, and green respectively).

**Figure 2:** Each amputee subject walked with varying levels of asymmetric center-of-mass horizontal and vertical velocity compared to a reference able-bodied subject. All trajectories were normalized to one stride. Line style corresponds to subjects' each limb's initial double support and single support phases (solid for intact limb, dashed for prosthetic limb). Circles represent heel strike, triangles represent toe off, filled point characters represent intact limb gait events, and open point characters represent prosthetic limb gait events.

( $M=93\%$ ,  $SD=7\%$ ) was significantly greater than subject 2 ( $M=57\%$ ,  $SD=11\%$ ) and subject 3 ( $M=43\%$ ,  $SD=5\%$ ).

## CONCLUSIONS

Despite exhibiting similar prosthetic knee motion with our experimental powered knee prosthesis, all amputee users otherwise walked with significantly different levels of gait asymmetry. We will further analyze the force and timing variables that may be contributing to the observed discrepancy in motion to identify possible areas for improvement. With knowledge of the main factors contributing to subject variance and asymmetry, both amputees and engineers may be able make adjustments to allow amputees to reap more benefits from powered prostheses.

## INTRODUCTION

Children's prosthetic needs are complex due to their small size, constant growth, and psychosocial development (Krebs et al., 1991 and Zuniga et al. 2015). Independent of the type of limb deficiency (congenital or traumatic) muscle atrophy, loss of mobility, and asymmetry are typical characteristics of the affected limb (Krebs et al., 1991 and Zuniga et al. 2015). Most upper-limb prostheses for children include a terminal device, with the objective to replace the missing hand or fingers. Electric-powered units (i.e., myoelectric) and mechanical devices (i.e., body-powered) have been improved to accommodate children's needs, but the cost of maintenance and replacement represent an obstacle for many families (Krebs et al., 1991 and Zuniga et al. 2015). The development and use of low-cost transitional prosthetic devices to increase ROM, strength, and other relevant clinical variables would have a significant clinical impact in children with upper-limb differences. Thus, the purpose of the study was to identify anthropometric, active range of motion, and strength changes after 6 months of using a wrist driven 3D-printed transitional prosthetic hand for children with upper limb differences.

## METHODS

*Subjects:* Five children (two girls and three boys, 3 to 10 years of age) with absent digits (one traumatic and four congenital) participated in this study and were fitted with a low-cost 3D-printed prosthetic hand.

*Apparatus:* Anthropometric, active range of motion, and strength measurements were assessed before and

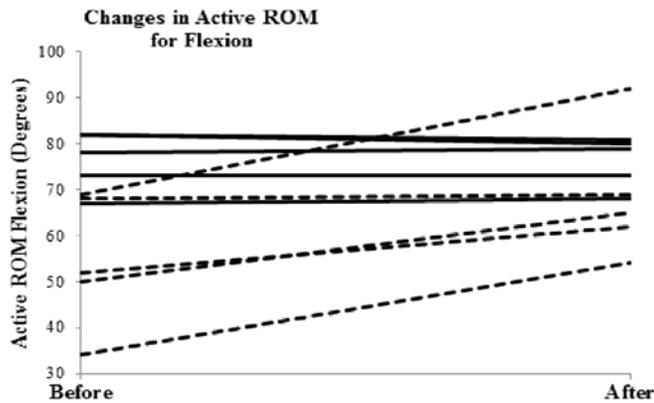

after 6 months of using a low-cost 3D printed prosthetic hand.

*Procedures:* Six variables from the affected and non-affected hand including circumferences, skin folds, and active ROM for flexion, extension, radial deviation, and ulnar deviation were measured on each research participant by a trained occupational therapist.

*Data Analysis:* Seven separate two-way repeated measures ANOVAs [2 x 2; hand (affected versus non-affected) x Time (before and after)] were performed to analyze the data. A p-value of  $\leq 0.05$  was considered statistically significant for all comparisons.

## RESULTS AND DISCUSSION

There were significant hand  $\times$  time interactions for the forearm circumference [F(1,4) = 16.90;  $p = 0.02$ ], active ROM flexion (Fig. 1) [F(1,4) = 12.70;  $p = 0.02$ ], and active ROM extension values [F(1,4) = 8.80;  $p = 0.04$ ]. There were no significant hand x time interaction, however, for wrist flexion strength [F(1,4) = 1.48;  $p = 0.29$ ], wrist extension strength [F(1,4) = 0.05;  $p = 0.84$ ], active ROM UD [F(1,4) = 0.65;  $p = 0.5$ ], active ROM RD [F(1,4) = 1.77;  $p = 0.25$ ], and forearm skinfold values [F(1,4) = 4.24;  $p = 0.11$ ].

**Figure 1.** Shows individual changes for active range of motion (ROM) for wrist flexion before and after a 6 month period of using the low-cost 3D printed transitional prosthetic device.

The main finding of the present investigation was that the usage of a low-cost 3D printed transitional prosthetic hand significantly increased forearm circumference (Before= $16.70 \pm 1.86$  cm and After= $17.80 \pm 1.48$  cm), wrist active ROM flexion (Before= $54.60 \pm 14.48^\circ$  and After= $68.40 \pm 14.29^\circ$ ), and active ROM extension (Before= $40.40 \pm 37.75^\circ$  and After= $47.00 \pm 36.42^\circ$  cm) on a small sample of children with upper-limb differences. Thus, the Cyborg Beast transitional prosthetic hand represents low-cost prosthetic solution for those in need of a transitional device to increase ROM.

## CONCLUSIONS

Although, durability and environment are factors to consider when using 3D printed prostheses, the practicality and cost effectiveness represents a promising new option for clinicians and their patients.

## CLINICAL APPLICATIONS

Six months of using this 3D printed transitional prosthesis increased forearm circumference, wrist active ROM flexion, and active ROM extension in children with upper-limb differences

## INTRODUCTION

Running specific prostheses (RSPs) used by athletes with leg amputations are made of carbon-fiber and intended to replicate the spring-like sagittal plane actions of a biological ankle. However, the passive nature and hysteresis [1] of RSPs impairs the rapid application of vertical [2] and horizontal [3] forces on the ground. Previous research has shown that use of RSPs that provide greater elastic energy return ( $\dot{E}_{RSP}$ ) improves running economy at speeds  $\leq 3$  m/s [4], but it is unclear how  $\dot{E}_{RSP}$  affects top speed sprinting. At speeds greater than  $\sim 6$  m/s, non-amputee runners progressively increase their dimensionless leg stiffness ( $K_{leg}$ ) with speed, while sprinters with unilateral and bilateral leg amputations maintain the same  $K_{leg}$  in their unaffected leg and decrease  $K_{leg}$  in their affected legs, respectively [5]. The increase in  $K_{leg}$  for non-amputee runners at faster speeds results from increased peak vertical ground reaction forces ( $vGRF_{peak}$ ), and constant leg compression ( $\Delta L$ ); leading to greater elastic energy storage and return at progressively faster speeds. We hypothesized that stiffer RSPs would allow faster top sprinting speed compared to softer RSPs due to potential increases in  $K_{leg}$ . Since  $K_{leg}$  is influenced by total leg length, we also hypothesized that increasing RSP height would permit faster top sprinting speed. Lastly, we hypothesized that RSPs with greater energy return would allow faster top sprinting speeds, compared to RSPs with lower  $\dot{E}_{RSP}$ .

## METHODS

Five male sprinters with bilateral transtibial amputations gave written informed consent prior to participation according to the COMIRB and USAMRMC Human Research Protection Office. A certified prosthetist fit each athlete with three

different models of RSPs: Freedom Catapult FX6, Össur Cheetah Xtend and Ottobock 1E90 Sprinter. The recommended stiffness category was selected based on each manufacturer's suggestion and the recommended height was set at the maximum allowable height ( $H_{t0}$ ) for each runner according to IPC rules [6]. If  $H_{t0}$  could not be set due to RSP design and residual limb anatomy, the baseline height was set as close to  $H_{t0}$  as possible.

Each sprinter performed three sets of trials at the recommended, +1, and -1 stiffness categories for each RSP model in a randomized order, while maintaining  $H_{t0}$ . Then, the category that allowed the top running speed for each model was selected and height was changed ( $\pm 2$  cm with respect to  $H_{t0}$ ).

Each set of sprint trials started at 3 m/s with speed incremented by 1 m/s until subjects approached their top speed. Then, smaller speed increments were employed until subjects reached top speed, defined when subjects could not maintain their position on the treadmill for 10 consecutive strides.

All trials were performed on a 3D force-measuring treadmill (Treadmetrix, USA) sampling at 1000 Hz. We used a custom Matlab program (MathWorks, USA) to condition signals (30 Hz low-pass 4<sup>th</sup> order Butterworth filter) and determine contact time ( $t_c$ ), aerial time,  $vGRF_{peak}$  and stance average vertical ground reaction force. We identified when the horizontal force crossed 0 N to determine braking (brake) and propulsive (prop) portions of the stance phase and calculated peak horizontal forces ( $hGRF_{brake}$ ,  $hGRF_{prop}$ ) and impulses ( $hIMP_{brake}$ ,  $hIMP_{prop}$ ). We then normalized all forces and impulses to the body weight of each subject including their running gear (both sockets and prostheses).

For each trial we calculated  $\dot{E}_{RSP}$  as:

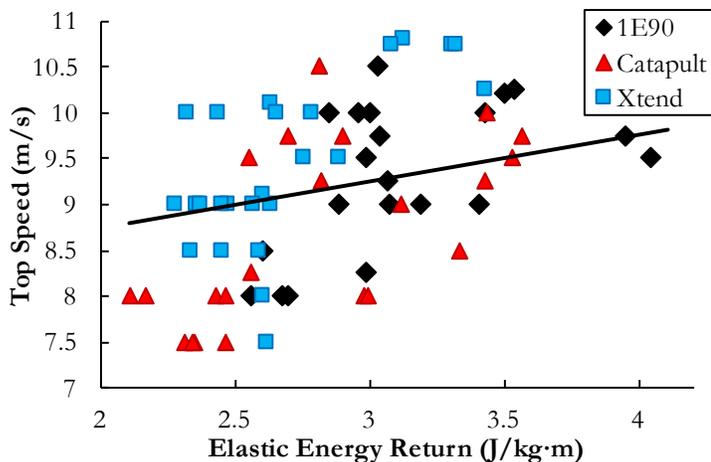

$$\dot{E}_{RSP} (J/kg \cdot m) = \frac{k_{RSP}(\Delta d)^2(1-Hst_{RSP}/100)}{2L_{step}m} \quad (1)$$

where  $k_{RSP}$  is RSP stiffness,  $\Delta d$  is RSP compression,  $Hst_{RSP}$  is percent RSP hysteresis,  $L_{step}$  is step length and  $m$  is the mass of the subject [4]. We used a linear mixed model to determine the effects of RSP model, stiffness, and height on top speed. We used a second linear mixed model to determine the effects of  $\dot{E}_{RSP}$  on top speed. We then used a third linear mixed model to predict top speed based on all the measured biomechanical parameters.

## RESULTS AND DISCUSSION

We found a significant effect of RSP model on top speed. Use of the Cheetah Xtend and 1E90 Sprinter RSPs allowed 8.0% ( $p < 0.001$ ) and 8.3% ( $p < 0.001$ ) faster top speeds, respectively, compared to use of the Catapult RSPs. We found no significant effect of stiffness category or height ( $p = 0.84$  and  $p = 0.76$ , respectively) on top speed. Elastic energy return ( $\dot{E}_{RSP}$ ) had an effect on top speed ( $p = 0.046$ ), such that a higher  $\dot{E}_{RSP}$  resulted in faster speed (Fig. 1):

$$TopSpeed = 0.514 \times \dot{E}_{RSP} + 7.712 \quad (2)$$

**Figure 1:** Top speed vs. elastic energy return. The black line is the regression line obtained from the second linear mixed model (Eq. 2).  $R^2 = 0.397$ .

We found that among all biomechanical variables,  $t_c$ ,  $vGRF_{peak}$  and  $K_{leg}$  affected top speed ( $p < 0.001$  for all 3 variables), where shorter  $t_c$ , greater  $vGRF_{peak}$ , and lower  $K_{leg}$  resulted in faster speed:

$$TopSpeed (m/s) = -65.33 \times t_c + 1.35 \times vGRF_{peak} - 0.1476 \times K_{leg} \quad (3)$$

( $R^2 = 0.924$ ) where  $t_c$  is measured in seconds,  $vGRF_{peak}$  in BW and  $K_{leg}$  is dimensionless stiffness.

## CONCLUSIONS

We found that top sprinting speed is influenced by prosthetic model but not prosthetic stiffness or height, and greater prosthetic elastic energy return allows faster top speeds in sprinters with bilateral transtibial amputations.

Across different RSPs, sprinters with bilateral leg amputations achieved faster sprinting speeds by shortening contact time, increasing peak vertical ground reaction force and reducing normalized leg stiffness.

## INTRODUCTION

There are a number of biomechanical differences between amputee gait and healthy gait. In healthy gait, the ankle plantar flexor muscles have distinct important roles; the biarticular gastrocnemius (GAS) spans both the ankle and knee joints, and helps to propel the leg into swing phase, while the uniarticular soleus (SOL) acts just at the ankle to propel the body forward [1]. The lack of the GAS muscle is associated with elevated activation of knee and hip flexors as well as decreased ankle push-off power. These differences can lead to secondary conditions such as back pain and knee pain.

Current prosthetic devices are able to recreate SOL function to some extent, but no devices have a biarticular component to replicate the functional role of GAS. To help improve amputee gait we have developed a foot-ankle prosthesis with a clutched spring that spans both the knee and ankle joints. We hypothesize that this spring element can emulate GAS function and reduce gait compensations to improve amputee walking and quality of life.

## METHODS

The biarticular prosthesis (BP) consists of the subject's prescribed socket, a pylon in series with an iPecs 6-DOF load cell, and a single axis College Park Venture foot (Fig. 1). Uprights extend from the pylon, hinge at the knee joint, and continue to mid-thigh where a thigh cuff supports the clutched spring. The tension spring is attached posteriorly, and spans both the knee and ankle joints, and a recoil spring ensures that the string remains slackless. The instrumented pylon detects

**Figure 1.** Biarticular Prosthesis. 1: iPecs 6-DoF Load Cell, 2: uprights, 3: thigh cuff, 4: ratcheted clutch, 5: spring (medium stiffness configuration).

heel strike to engage the ratcheted clutch. The ratchet coils in the string until the distance between the proximal and distal attachment points reach a minimum (at 15-20% of the gait cycle), the spring is then stretched as stance phase continues contributing to a knee flexion and ankle plantarflexion torque. Once the spring tension and pylon axial force drop below a threshold during toe-off, the clutch disengages the spring in preparation for swing phase.

With IRB approval, data was collected and analyzed for one amputee subject (to-date), female age 54, wearing the BP. Vicon motion capture tracked a marker set of 77 markers (placed on anatomical landmarks as well as in segment clusters). Ground reaction forces, BP spring force, and pylon data (from iPecs) were also recorded during bouts of treadmill walking. EMG signals were also collected for major gait muscles of the lower limb. The subject first walked on their prescribed prosthesis,

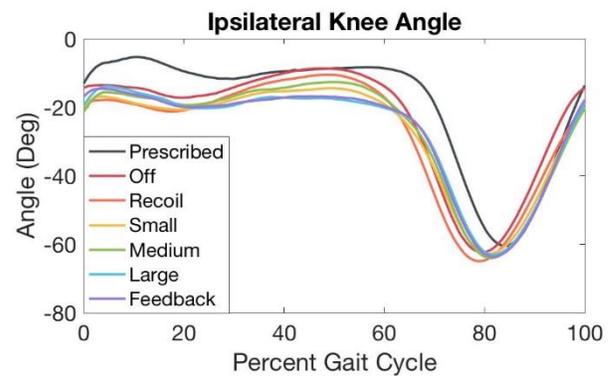

then the BP with various force conditions: off mode (spring disconnected), recoil spring only, then 1.8 N/mm, 3.7 N/mm, and 10.5 N/mm springs attached respectively. Finally, we collected data using the subject's preferred spring configuration, while providing them with feedback via a real-time plot of the BP spring force. Subjects were instructed to try to maximize the spring force peak as they walked. The one subject presented here chose the stiffest (10.5 N/mm) spring for the feedback condition.

OpenSim [2] was used to analyze the kinematics and kinetics of the collected data. We developed an amputee musculoskeletal model based on the full body model from Rajagopal et al. [3]. Mass and inertial properties of the residual limb/prosthesis were modified to match typical amputees [4,5], and the residual limb was scaled based on the socket to pylon length ratio. The model was scaled to the specific subject, then inverse kinematics and inverse dynamics were performed. The spring force measured experimentally was applied to the model as an external force, such that the joint torque contributions from the BP spring could be delineated from the internal muscle torques.

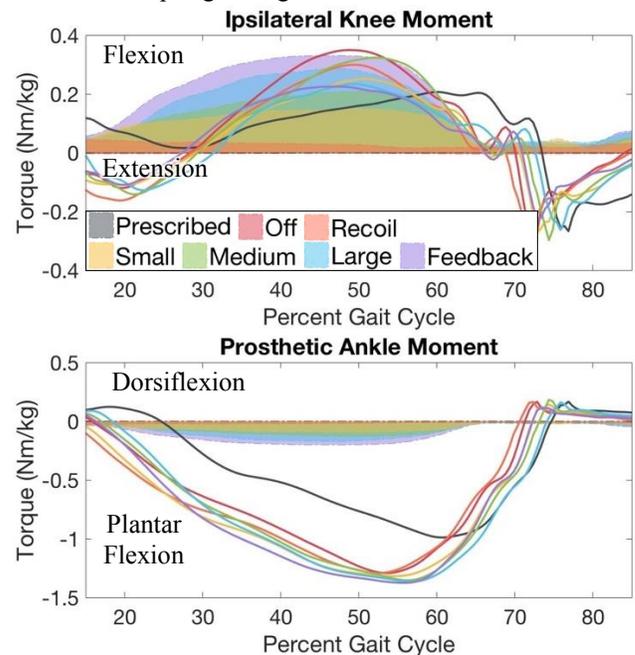

## RESULTS AND DISCUSSION

The inverse kinematics results show a difference in knee angle between the different conditions during late stance (Fig. 2). As the BP spring stiffness increased, knee extension in late stance decreased. Additionally, the BP has a substantial effect on the knee moment of the affected limb (Fig. 3). The BP pulls the knee toward flexion, particularly in mid and late stance (40-60% of gait cycle), and this flexion moment increases in magnitude as the BP spring stiffness increases. However, the net knee flexion moment is smaller in magnitude at the higher spring stiffness, which is likely due to kinematic deviations (Fig. 2). As the BP spring stiffness increased the BP contribution to ankle moment increased, but the gains were minimal.

The stiffest spring, under the feedback condition provided the largest contribution to net ankle torque, 14.64% at the peak plantar flexion moment. This same spring condition also shows the largest spring torque contribution at the knee, 147% of the total. This indicates that knee extensor muscles are

**Figure 2.** Average ipsilateral knee angle with prescribed and different BP spring configurations.

**Figure 3.** Average ankle and knee moments of the affected limb in prescribed and different BP spring conditions. Solid lines show the total joint moment, and shaded regions are the BP spring torque contribution.

over-active to counteract this large flexion torque. Data for 5 additional subjects is currently being collected to further understand the effects of a BP on amputee gait and the impacts of feedback training. Understanding whether mimicking the biarticular action of the GAS can enhance prosthetic function will inform future device design.

## INTRODUCTION

The largest population of upper-limb amputees is those with partial-hand amputations (including digit, multiple-digit, or partial-digit loss). This population outnumbers all other levels of upper-limb amputees by a ratio of 10:1 [1]. With 500,000 people in the U.S. currently living with minor upper-limb loss [1], a product effectively serving this population would have a significant clinical impact. However, current commercial products for partial-hand amputees do not satisfy all of the needs of these patients; passive fingers are seen as being difficult to fit and operate. While electric-powered fingers and their ancillary components are expensive, fragile, and cumbersome. We developed a passive, ratcheting prosthetic finger that is manufactured using metal laser sintering rapid manufacturing technology, namely the *Point Digit* (Figure 1). Here we present the mechanical design and testing of the *Point Digit* in order to validate its efficacy for use in a clinical setting.

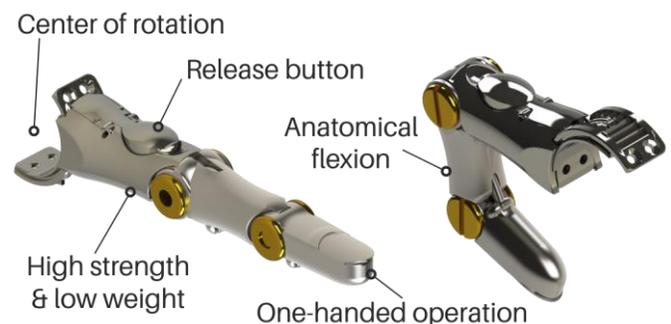

The *Point Digit* is a purely mechanical prosthetic finger (i.e., no actuation, electronics, etc.). A ratchet positions the finger into one of ten distinct levels of flexion. The ratchet ensures that the finger is non-backdrivable. An EOS M270 direct metal laser sintering 3D printer manufactures most components of the *Point Digit* using maraging steel powder (EOS MaragingSteel MS1). This material has a yield strength of 152 ksi and modulus of elasticity of 23 Msi. An internal honeycomb structure maintains strength and reduces weight of the individual components. The length of the *Point Digit* can be scaled between 80 mm to 105 mm in length, which nearly encompasses the ranges of finger lengths for 25 – 75th percentile males and 50-100th percentile females. The average finger mass of all lengths of the *Point Digit* is 50 g fully assembled.

The extension of the *Point Digit* can occur in two ways: 1) a self-locking button releases the ratchet and

extends the finger or 2) the full flexion of the finger causes the finger to spring-back to full extension. By allowing external features to position the finger in both flexion and extension, the contralateral limb is not required for use of the *Point Digit* (i.e. – one-handed operation).

A kinematic linkage system couples all three joints of the *Point Digit*. This linkage system flexes all three joints at an anatomically appropriate rate. The linkage system ensures a finger that behaves similar to the intact limb while maintaining mechanical strength.

Finally, the *Point Digit* provides an anatomically appropriate center of rotation of the metacarpophalangeal joint. This feature ensures a clinically sound system that easily integrates into a prosthetic socket. A mounting bracket provides a method for prosthetists to install the *Point Digit* into the prosthetic socket and ensure appropriate positioning of the finger with respect to the physiological limb.

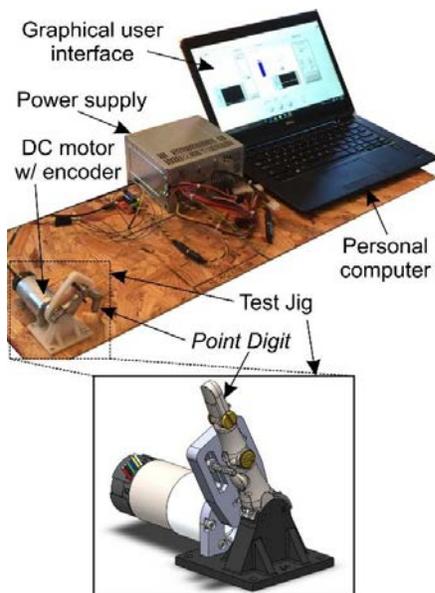

**Figure 1:** Features of the *Point Digit* include anatomically appropriate center of rotation, high strength-low weight, one-handed operation, and others.

## METHODS

Static and dynamic testing procedures were performed to determine the mechanical properties of the *Point Digit*. An Instron 5869 universal tensile testing machine performed the static testing procedure. The chucks in the Instron machine secured the finger in a partially flexed position. Then, a tensile test was performed by loading the finger in 10 lb. increments in tension until catastrophic failure. The load was released after each cycle to produce a hysteresis curve at each loading increment until failure. This loading method simulated the application of pinch forces to the distal phalange of the *Point Digit*. Two *Point Digits* were tested to failure.

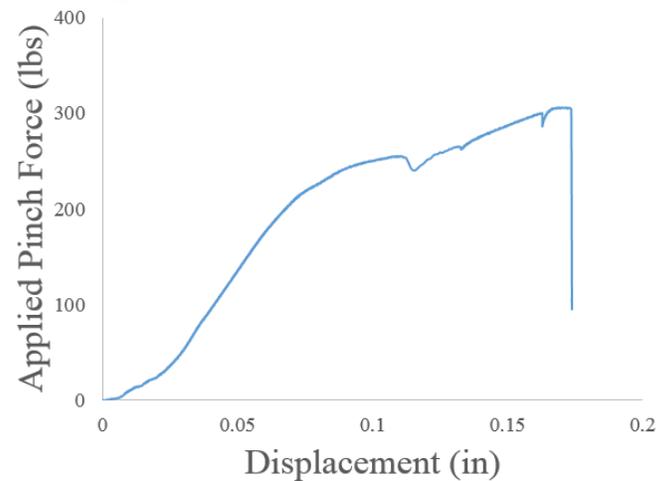

The dynamic testing was performed using a custom built finger cycler (Figure 2). The finger cycle consisted of a custom LabView program which commanded a DC motor while measuring the current and position of the finger. The finger cycler drove the finger between full extension and full flexion to ensure that the finger would ratchet, spring-back, and reset appropriately over many cycles. Five *Point Digits* were tested to 10,000 cycles.

**Figure 2:** Finger cycler for dynamic testing consisting of a computer, custom control software, power supply, DC motor with encoder, and custom mounting hardware. Finger position and current consumption were recorded.

## RESULTS AND DISCUSSION

Two *Point Digits* were tested to static failure. In both cases the digits withstood over 250lbs of pinch force before failure. The failure mechanism consisted of a direct shear failure of the proximal link bar pin. This failure mechanism proved to be an advantageous design feature where the pin can easily be replaced and thereby repair the finger. Figure 3 depicts the applied pinch force compared to the displacement of the finger over the final loading cycle before failure of the finger.

**Figure 3:** The force-displacement curve for a static failure of the *Point Digit*.

The dynamic testing of multiple *Point Digits* confirmed that the mechanism could withstand 10,000 cycles of flexion/extension. Some tests were interrupted due to replacement of linkage pins, tightening of threaded fasteners, etc. However, all fingers successfully achieved 10,000 cycles without fatigue failure or impaired performance.

The mechanical testing of the *Point Digit* confirmed that the mechanical design of the finger can withstand typical loading scenarios in a clinical setting. Future work will entail case studies with partial hand amputees and tests of activities of daily living with the *Point Digit*.

## INTRODUCTION

There are increasing numbers of children with traumatic and congenital amputations or reductions. The Centers for Disease Control and Prevention estimates that about 1,500 babies are born with upper limb reductions every year, and of these only 1 in 9,400 children is considered for prosthetic fitting. This disparity between instances of amputation/reduction and prosthesis prescription is a result of high cost and complex needs, due to children's small size, constant growth, and psychosocial development [1, 2].

Families' financial resources play a crucial role in the prescription of prosthetics for their children, especially when private insurance and public funding are insufficient. Electric-powered (i.e., myoelectric) and body-powered (i.e., mechanical) devices have been developed to accommodate children's needs, but the cost of maintenance and replacement represent an obstacle for many families. Due to the complexity and high cost of these prostheses, they are not accessible to children from low income, uninsured families, or to children from developing countries [1, 2].

Advancements in computer-aided design (CAD) programs and additive manufacturing offer the possibility of designing and manufacturing prostheses at a very low cost [2]. The purpose of the present investigation was to demonstrate the manufacturing methodology of 3D printed transitional prostheses, examine improvement in perceived changes in quality of life, daily usage, and activities performed with these types of devices.

## METHODS

Nine children (two girls and seven boys, 3 to 16 years of age) with upper-limb reductions (one traumatic and eight congenital) were fitted with our 3D printed

transitional prostheses and were asked to complete a survey.

Inclusion criteria included boys and girls from 3 to 17 years of age with unilateral upper-limb reductions.

Exclusion criteria included upper extremity injury within the past month and any medical conditions that would be contraindicated with the use of our 3D printed prostheses prototypes, such as skin abrasions and musculoskeletal injuries.

The study was approved by the Creighton University Institutional Review Board and all the subjects completed a medical history questionnaire. All parents and children were informed about the study and parents signed a parental permission. For children 6 to 17, an assent was explained by the principal investigator and signed by the children and their parents.

The survey was developed to estimate the impact of our prosthetic device including items related to quality of life, daily usage, and type of activities performed.

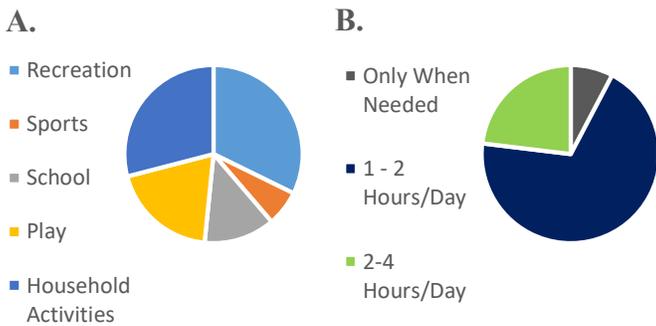

## RESULTS AND DISCUSSION

After approximately 1 to 3 months of using our 3D printed prostheses, 11 children and their parents reported some increases in quality of life (4 indicated that was significant and 7 indicated a small increase), while 1 indicated no change.

Nine children reported using the device 1 to 2 hours a day, 3 reported using it longer than 2 hours and 1 reported using it only when needed.

Furthermore, children reported using our 3D printed prostheses for activities at home (9), just for fun (10),

to play (6), for school activities (4), and to perform sports (2).

**Figure 1:** Qualitative usage metrics for 3D printed prostheses. A: Activity Type; B: Daily Hours Used

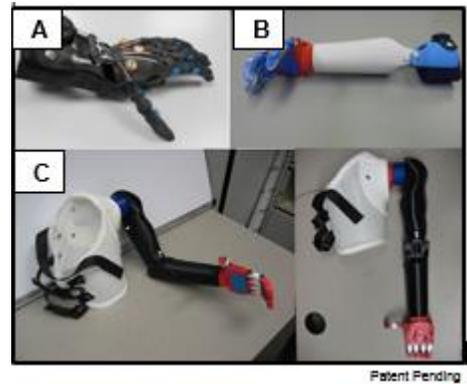

Four children reported malfunctioning and/or breaking of the 3D printed prosthetic device.

The main finding of our survey was that our 3D printed transitional prostheses have a great potential to positively impact quality of life, daily usage, and can be incorporated in several activities at home and in school. However, 36% of our research participants reported durability issues and/or malfunctioning of these devices. There is a need to develop more durable, medical grade 3D printed prosthetic devices to solve these durability constraints.

The proposed solution to this issue is a stepwise improvement of the prosthesis design through user feedback. The relative speed at which modifications can be performed through the use of CAD and 3D printing allows for many iterations of a design to be produced, fitted and evaluated over the course of weeks, rather than months, or years, as with traditional prostheses. [1]

Unfortunately, some observed inaccuracies with collected survey results have been noted in related studies, and a more quantitative method for determining usage is desired. This would allow for more informed future design modifications and more downstream functionality.

A prototype of an appropriate quantitative test apparatus for usage has been constructed, and will be validated in future studies.

**Figure 2:** Shows some of the 3D printed transitional prostheses prototypes developed by our research team. A: Hand prosthesis (Cyborg Beast); B: Below Elbow Device; C: Prosthetic Shoulder.

## CONCLUSION

Although durability and environment are factors to consider when using 3D printed prostheses, the practicality and cost effectiveness represents a promising new option for clinicians and their patients. The technology opens up the possibility to help clinicians working in rehabilitation to establish guidelines for prosthesis prescription, establish effective rehabilitation programs, and create new prosthetic designs with the ultimate goal of improving self-esteem and quality of life for children with upper-limb reductions.

3D printing technology for the development of prosthetic devices is at a very early stage. The supervision of a certified prosthetist is crucial for the proper development and use of 3D printed prostheses.

3D printed transitional prostheses have a great potential to positively impact quality of life, daily usage, and can be incorporated in several activities at home and in school.

## INTRODUCTION

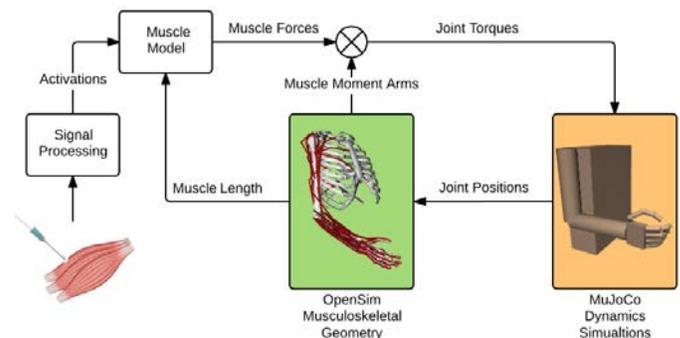

Commercial myoelectric prostheses have limited capabilities to simultaneously control multiple degrees of freedom. Although challenges exist in the mechatronics of the prostheses themselves, controlling these devices through myoelectric signals remains a significant challenge. These prostheses typically rely on signals recorded from surface EMGs placed on the residual limb, which are not the full set of extrinsic hand muscles required to actuate individual fingers. Also, standard control approaches often use pattern recognition or map the activity of a muscle (or group of muscles) to specific prosthesis movements while largely ignoring the underlying biomechanics. Here, we use a detailed musculoskeletal model that leverages anatomical and physiological knowledge of muscle function and hand biomechanics to interpret the activity of EMG signals. In addition, we use data-driven approaches to investigate the relationships between coordinated hand muscle activity, recorded using intramuscular EMG, and individual joint movements in able-bodied subjects and an amputee. The results from these analyses can be used to inform controller design for our biomimetic model.

## METHODS

All procedures were approved by the University of Pittsburgh Institutional Review Board and the US Army Human Research Protection Office. Nine able-bodied subjects and one transradial amputee were recruited for this study. We recorded intramuscular EMG (iEMG) from 16 extrinsic hand muscles targeted using ultrasound. The open-loop data collection experiments included 45 movement trials that included individual finger and wrist movements

in different wrist postures (flexed, extended, pronated, supinated and neutral). iEMG signals were recorded at 30 kHz, high-pass filtered at 20 Hz, rectified, and then low-pass filtered at 4 Hz. Kinematic data from the arm and hand were collected using 15 electromagnetic sensors (Ascension trakSTAR) and recorded at 100 Hz. We used an OpenSim upper extremity model [1] and modified it by including additional degrees of freedom (DoF) for the wrist and fingers (18 DoFs and 28 musculotendon actuators). The real-time myoelectric prosthetic simulation and control pipeline is shown in Figure 1. The real-time forward dynamic simulations were implemented in MuJoCo physics engine [2]. To speed up simulations, the moment arms matrices and muscle lengths was calculated through pre-compiled functions in MATLAB based on the OpenSim model's musculoskeletal geometry.

Principal component analysis (PCA) and hierarchical clustering analysis (HCA) were applied to the movement trials to compare EMG activity variance across all the different movements in able-bodied subjects and the amputee participant.

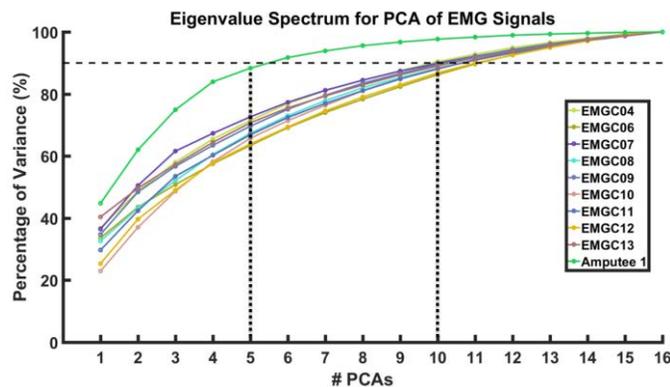

**Figure 1:** Real-time muscle-actuated prosthetic control pipeline using a biomimetic model.

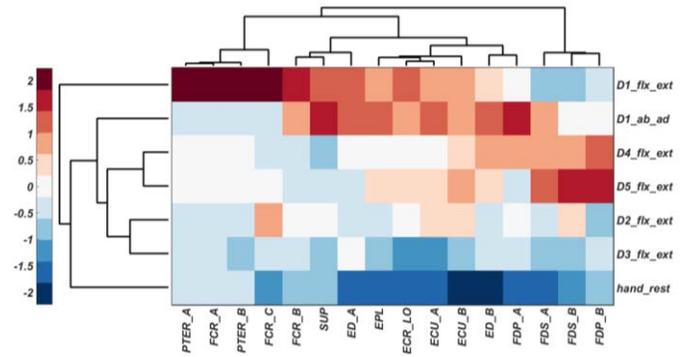

## RESULTS AND DISCUSSION

Our forward dynamic simulations in MuJoCo were achieved in less than 1 ms using our biomimetic model. Simultaneous control of 3-4 DOFs (wrist, thumb, index finger and coupled middle-ring-pinky fingers' flexion/extension) was achieved in able-bodied subjects and an amputee, although maintaining static postures currently remains a challenge. Simulations are stable, although noise in input EMG signals can result in large changes in output joint torque. Furthermore, we typically do not have complete coverage of all finger flexors and extensors, which can lead to imbalances in joint torques across the wrist and may limit current model performance.

We found a major difference in the number of principal components (PCs) required to explain 90% of the variance in the EMG data between the amputee (5 PCs) and able-bodied subjects (10-11 PCs) (Figure 2). The differences in the number of PCs between able-bodied subjects and the amputee could potentially be explained by the reduced muscle set in amputees, challenges related to muscle targeting, or more interestingly, changes in the ability to voluntarily make certain movements as a result of the chronic limb loss. HCA clustered the movement trials from all subjects into four major subgroups consisting of wrist flexion/extension, wrist pronation/supination, wrist adduction /abduction, and all fingers based on all 10 subjects' EMG activity patterns. The HCA results from the amputee subject performing 7 different finger flexion/extension movements is shown in Figure 3.

**Figure 2:** Number of PCAs representing the variance of EMG data in able-bodied subjects and an amputee.

**Figure 3:** Hierarchical clustering shows a subset of finger movements for the amputee subject using dendrogram and heat map. Each EMG channel was standardized across all movements using the z-score.

Analogous movement trials and muscle groups were clustered together. The HCA results can be used to help visualize and understand the underlying neural and biomechanical patterns of EMG activity and as a way replace the missing muscles in amputees. The results of PCA and HCA in this study will be used to improve the design of bio-inspired controllers that generate prosthesis control signals from the biomechanical function of the muscles and the resulting movement dynamics.

## CONCLUSIONS

We have created a model that enables real-time simulation of the complete wrist and hand dynamics and that can be driven by EMG signals. We believe that this biomimetic approach to controlling myoelectric prostheses has the potential to improve prosthetic performance, but can also be used to improve our understanding of the basic biomechanical functions of hand muscles and the resulting movement dynamics.

## INTRODUCTION

Transtibial amputees compensate for absent leg musculature with numerous unwanted gait adaptations. Prosthetic users generally walk with a slower self-selected walking speed, gait asymmetries, over-active hip flexors, and deficient prosthetic ankle joint power generation [1].

Prosthetic energy storage and return (ESR) feet passively approximate ankle function, but they lack a biarticular coupling between the knee and ankle. In the intact limb, this coupling is provided by the gastrocnemius muscle. Previous gait simulation studies have shown that while ESR feet can replicate soleus function, they fail to deliver the benefits of biarticular gastrocnemius function [2].

For this study, two spring-damper models of uniarticular and biarticular prosthetic ESR feet were developed to determine the importance of biarticular function in prosthetic design. These models passively generate joint moments in response to prescribed motions. We use these generalized models to determine performance bounds on the entire class of uniarticular and biarticular prosthetic ESR feet. We hypothesize that the model with both uni- and biarticular elements will generate moments more representative of healthy gait than the model with a uniarticular element only.

## METHODS

A previously developed Opensim [3] model was used to simulate healthy gait over the course of one stance period. Data collection procedures are described in [4]. The 10 degree of freedom model

was actuated by 18 Thelen muscle models, and was scaled to the 72 kg participant.

Inverse kinematics, the residual reduction algorithm, and static optimization were performed to determine sagittal plane knee ( $\theta_k$ ) and ankle angles ( $\theta_a$ ) as well as knee ( $\tau_{k,healthy}$ ) and ankle ( $\tau_{a,healthy}$ ) moments for the healthy individual. The gastrocnemius' contribution to the knee moment was calculated and defined as  $\tau_{k,healthy}^{GAS}$ . The soleus' and gastrocnemius' contribution to ankle moments were also determined.

A uniarticular prosthetic foot model (UNI) was developed with the following mathematical form:

$$\tau_a^{UNI} = a_1\theta_a + a_2\theta_a^2 + a_3\dot{\theta}_a \quad (\text{eq 1})$$

Where  $\tau_a$  is prosthetic ankle moment, and  $\theta_a$  is the ankle angle as defined above. Constant parameters  $a_1$  and  $a_2$  are linear and nonlinear contributions to rotational stiffness,  $a_3$  is damping. The rest angle of the uniarticular spring was defined to be zero degrees. By definition, this model produced no knee moments.

The biarticular prosthetic foot model (BI) was defined as:

$$\theta_{a,k} = \theta_a + \theta_k + b_1 \quad (\text{eq 2})$$

$$\tau_k^{BI} = c_1\theta_{a,k} + c_2\theta_{a,k}^2 + c_3\dot{\theta}_{a,k} \quad (\text{eq 3})$$

$$\tau_a^{BI} = c_4\theta_a + c_5\theta_a^2 + c_6\dot{\theta}_a + \tau_k^{BI} \quad (\text{eq 4})$$

For the BI model,  $\theta_{a,k}$  was defined as the rotational equivalent of the gastrocnemius musculotendon length. Ankle dorsiflexion ( $+\theta_a$ ) and knee extension ( $+\theta_k$ ) increase  $\theta_{a,k}$ ; the parameter  $b_1$  was the spring's rest angle. The BI model has one uniarticular

nonlinear torsion spring and one biarticular nonlinear torsion spring with constant stiffness and damping parameters  $c_1$  through  $c_6$ .

For both prosthetic foot models, the constant parameters were computed by solving a constrained least squares optimization problem in MATLAB. Ankle and knee angles from healthy walking were input into equations 1 through 4. The optimizer then chose stiffness and damping parameter values that minimized the difference between the models' ankle ( $\tau_a$ ) and knee ( $\tau_k$ ) moments and the target biological moments. The target ankle moment was defined as the total healthy experimental ankle moment ( $\tau_{a,healthy}$ ), while the target knee moment was only the gastrocnemius contribution to the biological knee moment ( $\tau_{k,healthy}^{GAS}$ ).

## RESULTS AND DISCUSSION

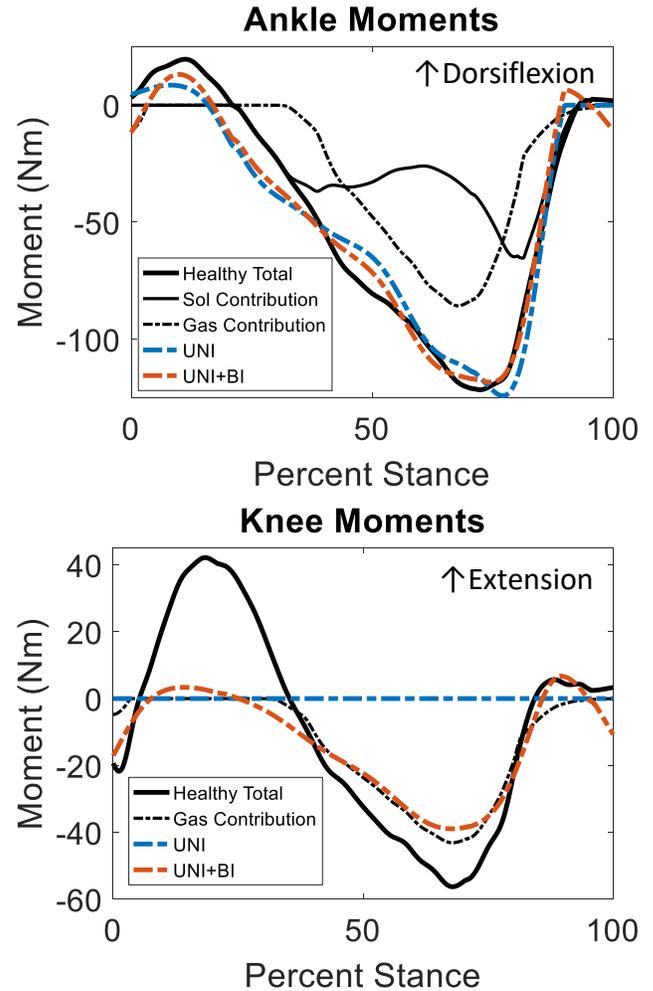

The optimizer was able to find stiffness, rest length and damping parameters (Table 1) such that both the uniarticular and biarticular models closely matched the target biological ankle moment (Fig 1).

The ability of the uniarticular model to produce appropriate ankle moments implies that ESR feet can theoretically be designed to generate both soleus and gastrocnemius contribution to ankle moment through a single uniarticular passive mechanical element.

At the knee joint, the biarticular model was able to closely match the gastrocnemius' contribution to the knee moment. As predicted, the biarticular model more closely mimics healthy human gait kinetics.

Interestingly, the optimal uniarticular ankle spring with an added biarticular component was less stiff than a uniarticular ankle spring alone. As current ESR feet are optimized to work without biarticular elements, adding these elements to existing feet may be an ineffective approach, rather, foot stiffness and

biarticular element stiffness may need to be designed in parallel for optimal performance.

# VARIABLE STIFFNESS PROSTHETIC FOOT

Evan M. Glanzer, Peter G. Adamczyk

University of Wisconsin-Madison, Madison, WI, USA  
email: eglanzer@wisc.edu

## INTRODUCTION

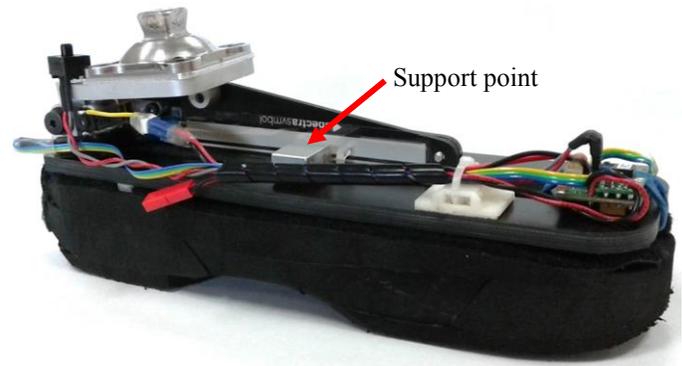

Energy storage and return (ESAR) prostheses passively store and return energy to the user through deflection of compliant leaf spring keels. The driving mechanical property in this process is the stiffness of the foot, which must be chosen to achieve an optimum in overall function across all the user's activities. Since these devices are passive, they cannot adapt to changes in activity. In contrast, the natural lower limb continuously adapts its behavior for different activities, including simple changes such as walking faster or slower, or larger changes such as negotiating ramps and stairs. For example, push-off work and peak push-off power increase with increasing walking speed in a healthy human ankle [1], whereas the prosthetic-side leg of an ESAR prosthesis user provides a constant amount of push-off work across all speeds [1].

We propose to address this shortcoming in adaptability through a new prosthesis concept, the Variable Stiffness Foot (VSF), which directly varies the forefoot stiffness of an ESAR-type foot through a low-power internal mechanism. Prior results show that a more compliant forefoot returns more energy to the user [1]; therefore, we plan to continually modulate forefoot stiffness in the VSF to achieve optimal energy return for each walking speed. We hypothesize that a softer forefoot will be better for faster walking because more energy will be returned to the user [2], which is more similar to healthy ankle function. In this study, we investigated the range of stiffness achievable in the latest VSF prototype and its effects on energy return in walking.

## METHODS

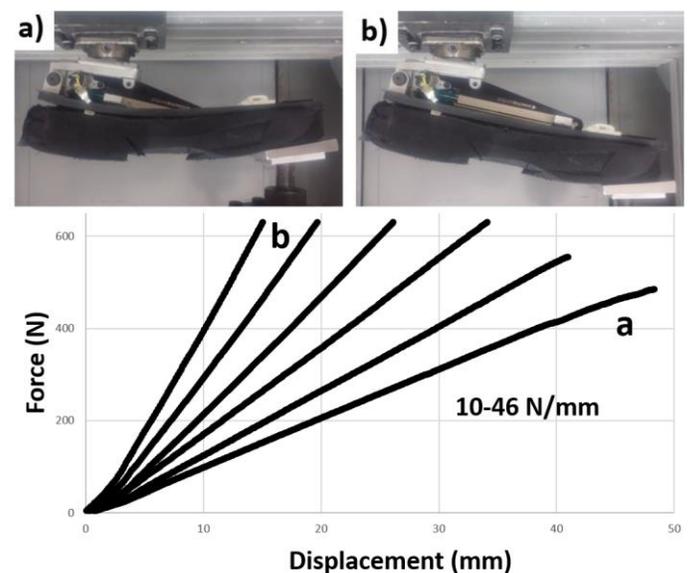

### Design

The VSF design (Figure 1) varies the forefoot

**Figure 1:** Variable stiffness foot prototype

stiffness of an ESAR-type foot by changing the position of a support point behind the flexible keel during swing phases. As this support moves, the length of the freely deflecting forefoot section is altered, which in turn changes the effective forefoot stiffness. Using linear compression testing, we estimated forefoot stiffnesses from 10 to 46 N/mm (Figure 2). In order to achieve quick adjustments, the foot was designed to complete a full-range adjustment in roughly two seconds, which represents about four swing phases of walking.

**Figure 2:** Compression testing: a) Softest b) Stiffest

## Validation

We performed a pilot study to validate the effects of the VSF mechanism on energy storage and return. Three non-amputees walked overground on the prosthesis using an ankle-immobilizing boot, with the VSF set to five stiffness levels. We estimated the power flow into and out of the prosthesis using a deformable-body model [3].

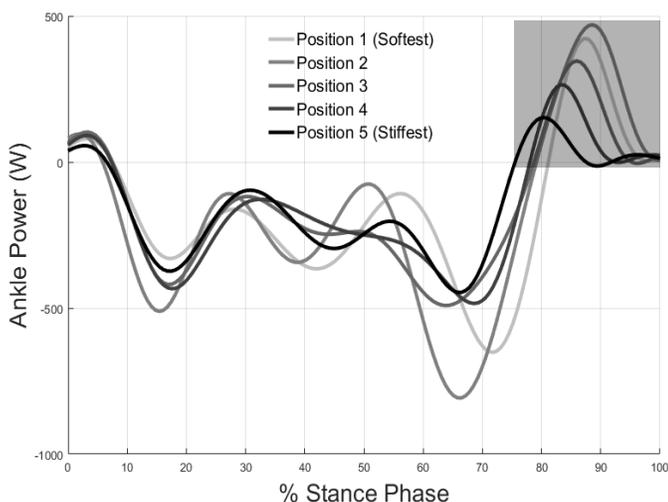

## RESULTS AND DISCUSSION

Our analysis focused on device performance rather than how the prosthesis characteristics translated to the joint mechanics of the user. Peak push-off power increased as expected with a more compliant forefoot (Figure 3). Energy returned to the user in push-off showed a similar trend (Figure 4).

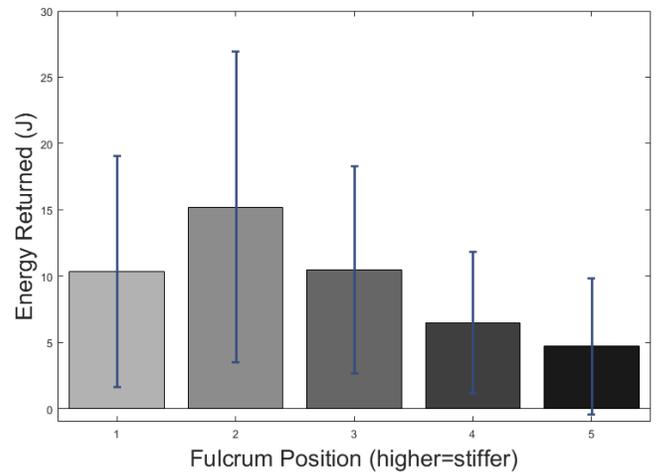

However, both peak power and energy return at the softest setting are lower than in the next stiffer setting. This is caused by the softest setting being too compliant for the subject's body mass. The forefoot has a displacement limit that is being reached causing the "bottom-out" effect. A correlation between the minimum useable stiffness and body mass could be studied in the future. This correlation could then be programmed into our controller to avoid the "bottom-out" zone.

## CONCLUSIONS AND FUTURE WORK

Our device demonstrates similar characteristics in

**Figure 3:** Peak ankle push-off power decreases with increasing foot stiffness. Push-off work is highlighted in the gray area. Data is from a single participant.

**Figure 4:** Energy returned generally decreased with increasing foot stiffness, with the exception of the first fulcrum position due to a "bottom-out" effect.

power and energy return with changing stiffness as previous studies [2]. In upcoming testing, we will use an onboard controller to adjust the stiffness of the foot in real time to match different activities in persons with amputation. First, we will investigate stiffness changes based on walking speed. This adjustment is expected to influence subjective user preference as well as biomechanical data in ways that have not been tested before. We will also use onboard sensors (Figure 1) to adapt to other foot motions, including up and down slopes and stairs, based on real-time estimates of foot trajectory [4]. Data from these trials will further inform the potential benefits of using a variable stiffness prosthesis, and provide insight into potential design improvements for future devices.

Stiffness has important consequences for proximal joints as well, such as knee moment [2]. We attempted to measure changes in knee flexion moment with changing stiffness but due to the use of the ankle-immobilizing boot, we did not observe significant correlations. Future work will investigate these effects in persons with amputation.

# TRANSFEMORAL PROSTHESIS CONTROL FOR SLOPE WALKING WITH PRINCIPAL COMPONENT ANALYSIS

<sup>1</sup> Woolim Hong and <sup>1</sup> Pilwon Hur

<sup>1</sup> Texas A&M University, College Station, TX, USA  
email: ulim8819@tamu.edu, pilwonhur@tamu.edu, web: [http:// hurgroup.net/](http://hurgroup.net/)

## INTRODUCTION

A powered transfemoral prosthesis is an assistive device for the amputees who lost their lower limb including the knee that supports their daily locomotion [1]. For the amputee patients, walking on various sloped surfaces are one of the most challenging tasks in their daily lives. However, the existing (both passive and active) prostheses cannot fully accommodate the functions.

Trajectory generation for the powered prosthesis is an important procedure to design an appropriate controller that mimics human walking. Trajectory has to be generated for each gait cycle in real time to produce stable, robust and human-like walking. However, real-time trajectory generation is not a simple task and requires high computational loads, which is usually not tractable for the low profile single board computers. Recently, an algorithm for online trajectory generation for the powered transfemoral prosthesis was proposed using spline-based real time optimization. However, this method is applicable only for the upslope walking [1].

In this study, we generate the desired trajectories for various sloped surfaces with a small set of data using Principal Component Analysis (PCA). PCA lets us reduce a complex data set to a lower dimension [2] to perform the slope walking in different inclination with the prosthesis in real-time. Through PCA, we extract two principal components and their coefficients from the ankle and the knee, respectively. By curve fitting the coefficients of the principal components, we estimate the appropriate coefficients corresponding to the slope angle. In other words, we generate the adequate trajectories from the linear combination of the dominant principal components and their coefficients using only the inclination information. We also utilize a

low gain PD controller and the spline generation [1] to adapt the unexpected slope and smoothly blend into the appropriate trajectories corresponding to the new slope.

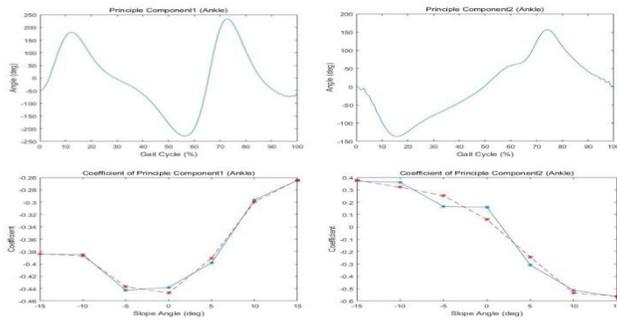

## METHODS

To collect the data for the PCA analysis, we collected human walking data and joint trajectories for the ankle and knee with a motion capture system (Oqus 210c, Qualisys North America, Inc., Highland Park, Illinois, USA). We put 13 reflective markers on the body of the healthy young adult to capture the subject's joint trajectories while walking on a treadmill. The inclination of the treadmill was varied with 7 different inclination angles:  $-15^\circ$ ,  $-10^\circ$ ,  $-5^\circ$ ,  $0^\circ$ ,  $5^\circ$ ,  $10^\circ$ , and  $15^\circ$ . We set the limit of the slope angle at  $\pm 15^\circ$  since the angles exceeding  $\pm 15^\circ$  are rarely encountered in the daily living.

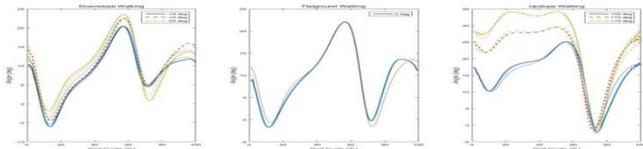

PCA was performed on the joint trajectories to extract the principal components required to reconstruct the various sloped surface trajectories. PCA provided us the most significant principal components that are the most highly correlated to human joint trajectories with a minimum amount of information [2].

It should be noted that the first gait cycle with the heel strike does not have the defined trajectories, which causes discontinuity in trajectory. To resolve this issue, a cubic spline based optimization is used to have smooth transition between each slope [1]. Also, for the slope adaptation during the heel contact, we used a low gain PD controller to avoid the discrete motion due to the new slope [1].

## RESULTS AND DISCUSSION

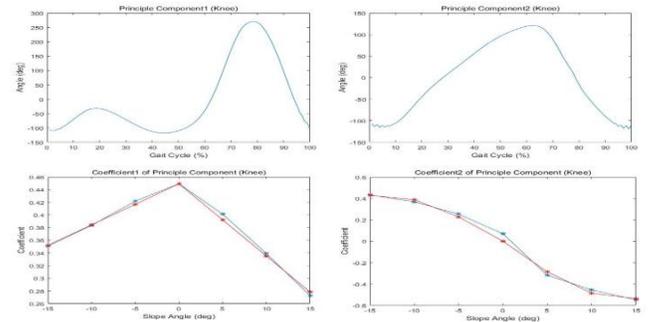

**Figure 1.** Results of PCA. The principal components (PC) of the knee joint angle (left top: 1<sup>st</sup> PC, right top: 2<sup>nd</sup> PC). The coefficients of the principal components (left bottom: 1<sup>st</sup> PC, right bottom: 2<sup>nd</sup> PC).

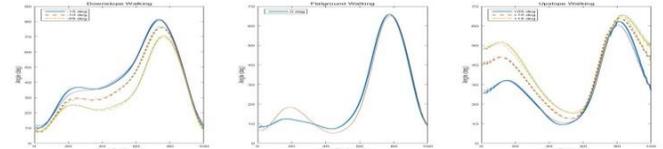

**Figure 2.** Regenerated Ankle Joint Trajectories with Optimized Coefficients and Corresponding Principal Components. Downslope walking trajectories from  $-15^{\circ}$  to  $-5^{\circ}$  (left). Flat ground walking (mid). Upslope walking from  $5^{\circ}$  to  $15^{\circ}$  (right).

It was found that the walking pattern for the downslope was different from that of upslope walking. When the subject walked on the downslope surfaces, the ankle joint angle seemed to remain the same as the level walking regardless of the inclination angles. For the knee joint, as the inclination angle increases, the deviation of the joint trajectory became significant. On the other hand, when the subject walked on the upslope surfaces, both the ankle joint and the knee joint angle increase as the inclination angle increases for the range of 0%-40% and 80%-100% of the gait cycle; interestingly, in the mid-range of the gait cycle, they merged to the flat ground walking trajectory [1].

Figure 1, 3 shows the results of PCA from the ankle joint and the knee joint, respectively. We chose two of the most dominant principal components and their coefficients to generate the joint angle pattern. We solved an optimization problem to curve the coefficient plots for calculating the appropriate coefficients corresponding to the slope angle. As Figure 2 shows, with these 2 principal components and the optimized coefficients, we could generate the ankle joint trajectories for 7 slopes with 0.9815 correlations. From Figure 4, the correlation result of the regenerated trajectories with the results of PCA was 0.9959.

**Figure 3.** Results of PCA. The principal components (PC) of the knee joint angle (left top: 1<sup>st</sup> PC, right top: 2<sup>nd</sup> PC). The coefficients of the principal components (left bottom: 1<sup>st</sup> PC, right bottom: 2<sup>nd</sup> PC).

**Figure 4.** Regenerated Knee Joint Trajectories with Optimized Coefficients and Corresponding Principal Components. Downslope walking trajectories from  $-15^{\circ}$  to  $-5^{\circ}$  (left). Flat ground walking (mid). Upslope walking from  $5^{\circ}$  to  $15^{\circ}$  (right)

In general, to generate the trajectories for each slope with the increment of  $1^{\circ}$ , we need 31 trajectories for the ankle and the knee, respectively. Yet, using PCA, we need 4 trajectories (two principal components for each joint) and the corresponding coefficients with high correlation. It was shown that all sloped trajectories within  $\pm 15^{\circ}$  with the linear combination of these components and coefficients could be reconstructed.

## CONCLUSIONS

This research showed that PCA can be used to generate joint trajectories for various slopes from the linear combination of a small number of the components and their coefficients. A low gain PD control and the spline generation along with the PCA-based trajectory generation could adapt the control of transfemoral prosthesis to various slopes without any conflicts [1]. For the future work, we expect to extend this idea to the different situations for the prosthesis control with the unified controller.

## INTRODUCTION

For children with upper-limb amputations, it is not easy to obtain prostheses. Because of their constant growth and frequent need for larger prostheses, insurance companies refuse to pay, citing cost as a prohibitive factor, and committing to payments only once children are grown. There is ample evidence, however, that early prescription and use of an upper-limb prosthesis is beneficial to amputees [1]. To better care for children and adults with upper-limb amputations, it is necessary that cheaper, more accessible prostheses are developed.

Within the last decade, consumer-grade 3D printers have experienced an explosion in popularity, due to decreasing costs, technological advances, and larger media exposure. Use of 3D printers allows cheap, rapid prototyping, and enables laypeople to quickly and easily create objects that would otherwise require prohibitive resources or expertise.

The cheap, accessible nature of 3D printing has led to the formation of large communities of enthusiasts. Subsets of these communities have, in fact, begun development of prostheses and other assistive devices – with several communities being dedicated solely to designing, printing, and donating upper-limb prostheses. In addition, many academic institutions have begun lines of research with 3D printed prostheses – but because of the field's relative infancy, there is much skepticism in regards to the use of these devices [2].

Several articles – both peer-reviewed and not [2] – suggest that 3D printed prostheses are not functional, and that these devices are little more than novelties. Negative reviews on 3D printed prostheses are frequently given, citing a dearth of evidence supporting prosthesis acceptance and durability. It is also frequently noted that few papers exist, if any, that show improvement of function

with 3D printed prostheses. Therefore, the purpose of this study was to determine whether or not upper-limb amputees improved in function with use of 3D printed prostheses.

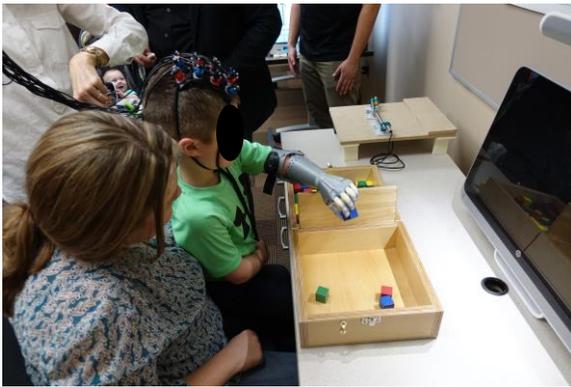

## METHODS

This study recruited 11 upper-limb amputees with no neurological deficits. All subjects were children (ages 3-15) with no physical abnormalities, aside from their amputated limb. Prostheses were designed in Autodesk Fusion 360 (Autodesk Inc., San Rafael, California, US), and were printed on Ultimaker 2 Extended+ 3D printers (Ultimaker, Geldermalsen, The Netherlands).

To properly fit prostheses, anthropometric measures are required of a subject's affected limb. Usually, these measurements are taken in-person by a certified prosthetist – however, in this study, limbs were measured at a distance in a manner previously described and validated by Zuniga et al. [3]. Subjects sent pictures of their affected limbs with measuring tapes or rulers nearby to reference for scale, and an open-source program called Tracker (Open Source Physics, Boston, MA, US) was used to determine residual limb size and range of motion. A board-certified occupational therapist and hand therapist performed final fitting procedures of each 3D printed prosthesis.

Upon receiving their 3D printed prosthesis, subjects performed the box and blocks test (BBT, Fig. 1) – a quick (1 min), simple test to assess hand function, whereby a subject uses one arm to move 2.5 cm wooden blocks over a partition, from the ipsilateral to the contralateral side. The test was completed with both the prosthetic and biological hands, and subjects revisited the lab to complete the same test 6 months later. Data was analyzed using a two-way repeated measures ANOVA, comparing prosthetic versus biological hands and BBT scores before and

after 6 months of use. Significance for this study was set at  $p \leq .05$ .

**Figure 1:** Subject completing BBT with prosthesis.

## RESULTS AND DISCUSSION

The ANOVA revealed significant differences between baseline and 6-month scores with subjects' prosthetic hands, but not with their biological hands (Table 1). Finding a change in the prosthetic hand but not the biological hand is important, as the study population consisted entirely of children. Because of their constant growth and maturation, it was necessary to rule out motor development as a reason for increased BBT scores. As there was a lack of difference in biological hand performance before and after 6 months, it can be inferred that the subjects' aging and consequent motor development did not significantly alter BBT performance.

It is important to note that no therapies or interventions were present in this study; the increases in score were due to the subjects' normal use of their prostheses, without any significant training. This lends great credence to the thought that 3D printed prostheses can, in fact, be used as functional prostheses. Furthermore, it is frequently seen that conducting therapies and teaching subjects how to use traditional prostheses (and indeed most tools) can improve function greatly. Considering the already-apparent learning that is occurring with this

3D printed prosthesis, it is logical to assume similar learning principles hold true.

Concerns over 3D printed prosthesis durability are valid, as some subjects did report breaking of prosthetic fingers – however, this study's prosthesis was designed with replacement of parts in mind, and thus it was quite easy to 3D print new fingers and replace them.

Despite the fact that the results of this study were quite expected, it is important not to ignore these findings. Several reviewers have claimed that 3D printed prostheses are not backed by research, and are not able to be used functionally; this study has shown otherwise, and has addressed concerns of function. Durability may be an issue with 3D printed prostheses, but given the ease with which broken parts can be re-printed and replaced, smart prosthetic design may allow users to overcome this. The use of 3D printers has enabled quick and cheap creation of prostheses. Several models of 3D printable prostheses have been made – and several may be flawed – however, this study has found that amputees can improve function with 3D printed prostheses, and that while prosthesis durability may be a problem, replacement of parts is not.

## CONCLUSIONS

For many, high costs prohibit purchase of an upper-limb prosthesis. Recent development in 3D printing technology has allowed cheap and rapid distribution and development of these prostheses. Many authors have suggested lack of function in 3D printed devices, but this study has found otherwise.

## INTRODUCTION

Humans are known to have less stability in the lateral direction during gait. This is especially the case for amputees. Missing one or more limbs reduces the ability to control the body's motion, making overall balance a challenge. With current technology, amputees have trouble walking on slopes and uneven ground. This is largely due to the inability to control the prosthetic ankle. Some active and semi-active prostheses have the ability to adapt their dorsiflexion/plantarflexion (DP) angle to match up- and down-slopes. However, studies have shown that lateral balance is subject to more active control compared to fore-aft balance [1]. Prosthesis users remain disadvantaged in this lateral direction, as they lack the ability to control ankle inversion/eversion (IE) in the prosthetic limb as the natural ankle does. We are developing a semi-active smart prosthetic ankle that can adapt its angle in both DP and IE directions. The prosthesis will actively adjust through angles of  $\pm 10^\circ$  from neutral, in any combination of DP and IE. For the present pilot study, we sought to verify this range of motion and perform a preliminary investigation of its effects on ankle moments in the sagittal and frontal planes during walking. We hypothesized that a plantarflexed alignment would lead to earlier increases in the measured plantarflexor moment; that dorsiflexed alignment would have the opposite effect, a delayed increase in moment; and that inversion and eversion alignment would vary the magnitude of the frontal plane ankle moment.

## METHODS

### Ankle Design

The angle of the prosthetic ankle can be controlled  $\pm 10^\circ$  about any arbitrary axis orthogonal to the longitudinal axis of the ankle module. This effectively makes a 2-axis foot that can be manipulated in both the plantarflexion/ dorsiflexion and inversion/eversion directions. The ankle mechanism is made up of two short cylindrical spacers with their mating ends cut at complementary angles of  $5^\circ$  to form two wedge-shaped inclined planes. These inclined planes rotate independently

about the longitudinal axes of the upper and lower halves of the ankle module (effectively the axis of the tibial pylon and the foot prosthesis' top surface normal). If the two planes are aligned in complementary positions, ankle alignment is neutral (Figure 2). If one plane is rotated relative to the other, the mating faces push against each other and force a change in ankle alignment. Using all combinations of upper and lower rotation angles, the ankle angle can be up to twice the face angle of the wedge ( $\pm 10^\circ$ ), in arbitrary directions including DP, IE or combinations of the two.

The inclined surface between the two plates creates a twist-out moment on each plate due to the contact force resulting from the ankle moment, which is held in balance by friction on both the angled face and the opposite flat face. Analysis of these balancing moments reveals that a friction coefficient as low as 0.05 is sufficient to ensure locking at a face inclination angle up to  $5.7^\circ$ , even in the worst configuration (Neutral). The actual friction coefficient is closer to 0.1, ensuring that the current face angle of  $5.0^\circ$  is well within the safe range. Tensile loads and internal/external rotation moments are supported by a 2-axis universal joint running axially through the center of the module.

Figure 1: Prosthetic Ankle Parts (left to right): shims, u-joint, two inclined planes with friction pads, top flat plate, and male pyramid

Figure 2: Prosthetic Ankle fully assembled

### Ankle Validation

Three able-bodied subjects wearing ankle-immobilization boots tested the ankle module in five target configurations: neutral alignment, and 10° dorsiflexion, plantarflexion, inversion, and eversion. Subjects completed 3 walking trials in each configuration, while standard motion capture and force plate data were recorded. The subjects' gait patterns were analyzed using custom MATLAB code implementing standard inverse dynamics techniques. We measured outcomes of observed ankle angle and ankle joint moment in the sagittal and frontal planes for each condition.

### RESULTS AND DISCUSSION

Stance phase data are presented in this study (0-60% of gait cycle), as the mechanics of ankle alignment primarily affect this phase of gait. Ankle angles were observed to vary in increments of roughly 10° in both sagittal and frontal plane angles, as expected from the 10° setting increments (Figure 3). Despite variance in the Neutral angle across subjects (due to variations in attachment to the ankle immobilization boot), all the different configurations followed the expected relationships among the different angle settings.

Preliminary observations suggest that plantarflexed posture leads to earlier increases in the ankle plantarflexion moment (Figure 4). The dorsiflexed posture appeared to delay the increase of ankle moment a little later in the gait cycle. Thus our hypothesis appears supported. However, later ankle moment relationships did not show a systematic trend, indicating a need for further study of the dynamic interaction between alignment and ankle mechanics.

Inversion and Eversion postures did not appear to shift the ankle moment higher or lower. This could be a result of kinematic compensation (e.g. changes in step width or leaning to the sides to cancel the effect). Further investigation will determine the adaptations the subjects used in these cases.

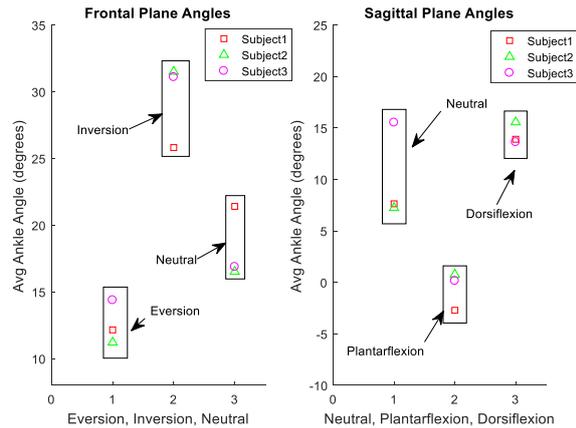

Figure 3: Average ankle angle for each subject

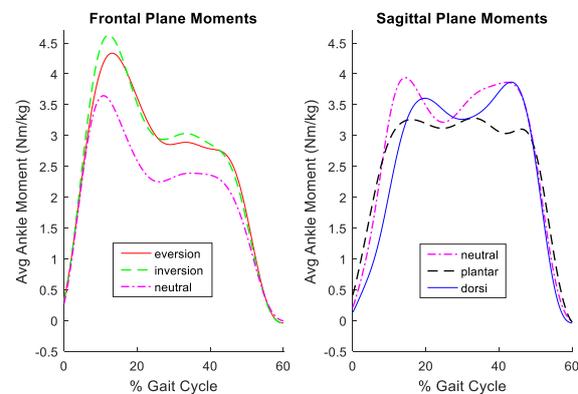

Figure 4: Example Frontal and Sagittal Ankle Moments

### ONGOING AND FUTURE WORK

Ongoing work is focused on continuing this characterization of mechanical behavior of the prosthesis and automating the ankle movement to accommodate different slopes. Automation will also ensure accuracy when changing ankle angle.

Additional work in the immediate future will focus on testing ankle, knee and hip mechanics across variations in alignment in persons with unilateral lower limb amputation.

## **INTRODUCTION**

Injuries that occur within the thoracic and lumbar regions of the spinal cord typically results in paralysis of the lower extremities and trunk. According to a study surveying 681 people with paraplegia, trunk stability is among the top functions people want restored<sup>1</sup>. For people with the inability to control their trunk, perturbations can cause destabilization and a loss of erect posture, limiting their mobility and independence. Common perturbations experienced by manual wheelchair users that contribute to destabilization are collisions and sharp turns.

Functional electrical stimulation (FES) is used to maintain trunk stability, as well as providing a method to regain an erect posture following a perturbation<sup>2</sup>. Applying FES at the onset a destabilizing event, such as a collision or sharp turn, is expected to increase trunk stability, maintain erect posture, and boost users' confidence in their wheelchair during daily activities.

The goal of this study is to automatically detect potentially destabilizing conditions faced by manual wheelchair users with spinal cord injuries and activate the appropriate muscles to prevent falls and stabilize the seated operator.

## **METHODS**

Wireless inertial measurement units with tri-axial acceleration and gyroscopic sensors were mounted on the wheelchair frames and backs of two individuals with low cervical and thoracic level injuries, see table 1. Kinetic data was collected using Vicon motion capture system, which tracked the position of the wheelchair and subject throughout each trial. Subjects sat passively in a manual wheelchair attached to a guidance track as it descended a ramp to ensure consistent velocity through a sharp 90 degree turn and sudden stop

simulating a collision. An algorithm using the accelerometer and gyroscopic data was created to detect the turns and collisions, and trigger appropriate stimulus patterns. Acceleration in the anterior and posterior (A/P) and angular velocity in the superior and inferior (S/I) direction provided distinct features to discriminate between destabilizing collisions and turns, respectively. During calibration, collision thresholds were determined by taking the mean of the maximum A/P acceleration peak from 20 trials and subtracting two standard deviations. The turn thresholds were determined in the same way using the S/I angular velocity. During testing, the algorithms were applied in real time to activate a pre-programmed pattern to oppose lateral bending or prevent forward leaning and maintain erect posture throughout the events. Subjects rated their perceptions of safety with and without stimulation via the Usability Rating Scale (URS)<sup>3</sup>. Post-processing of the kinetic data allowed calculation of the maximum lateral and forward trunk angle during turns and collisions, respectively, as well as the time to return to erect posture during collision. Erect posture was achieved when the subjects returned to less than 6 degrees of flexion.

## **RESULTS AND DISCUSSION**

Analysis of the kinetic data revealed a difference between maximum trunk angle with and without stimulation applied, as well as a difference in return time to erect posture. Table 2 summarizes the kinetic results of the collisions for both subjects. According to the URS data, subjects reported a significantly increased feeling of safety and stability during collisions ( $Z = -2.539$ ,  $p = 0.011$ ) with a median URS score of 1.5 with and -1.5 without triggered stimulation to the appropriate muscles to resist the destabilizing event. Similarly, during

turns, subjects felt a significant increase in safety and stability ( $Z = -3.100$ ,  $p = 0.002$ ) with a median URS score of 0 with and -1 without triggered stimulation.

## INTRODUCTION

Multiple sclerosis (MS) is a progressive autoimmune disease which negatively effects gait and balance. Around 60% of persons with MS (PwMS) experience falls, which often results in injuries, fear of falling, and activity curtailment [1]. Falls most commonly occur during functional mobility, and are most commonly attributed to loss of balance [2]. While fall occurrence is high, not all PwMS experience falls, potentially due to differences in motor control impairments or gait adaptations. Compared to healthy controls, PwMS have altered footfall and trunk motions during gait, however it is unclear if these alterations are specific features seen in PwMS who fall and therefore likely contribute to fall risk [3, 4]. The purpose of this study is to identify specific biomechanical features of gait which are different between fallers and non-fallers with MS by examining both foot and trunk motion. We hypothesize that fallers will 1) have increased gait variability and 2) walk more cautiously compared to non-fallers. With a better understanding of gait features which are different in fallers, we can highlight the gait features that should be monitored early in PwMS to specifically diagnose dynamic imbalance and fall risk.

## METHODS

Fifty-five PwMS (27 non-fallers and 26 fallers; EDSS<5.5) who were able to walk 25 feet unassisted were enrolled in the present study. The fallers group had 2 or more falls in the previous six months and non-fallers had no previous falls.

Subjects walked at their preferred pace on a treadmill for three minutes. Kinematic data was collected using retroreflective markers placed bilaterally over lower limb anatomical landmarks (60 Hz, 8-camera motion capture system, Motion

Analysis, Santa Rosa, CA, USA). Step length and step width were defined as the anterior-posterior (AP) and mediolateral (ML) distance between contralateral heel markers at each heel strike. Variability of both step length and step width was assessed using coefficient of variation. Margin of stability (MoS) was calculated as the distance between the extrapolated (velocity-adjusted) center of mass and the base of support, in the AP and ML direction at each heel strike. Variability of MoS was assessed using coefficient of variation.

Wireless inertial sensors (Opal, APDM, Portland, OR, USA) measured trunk accelerations (128 HZ, midline of the sternum) concurrently during the treadmill walking. Linear accelerations were measured in the AP and ML axis and analyzed independently. Root mean square transforms were used to describe the dispersion of each signal. Raw acceleration time series were then down-sampled to 60 Hz and truncated to the middle 60 strides to evaluate their temporal structure using Lyapunov exponents. Delay-embedded state spaces were reconstructed using an embedded dimension of 7 for each axis and a time delay of 6 and 8 for the AP and ML direction, respectively.

Independent t-tests were used to identify differences between fallers and non-fallers for each outcome variable. The left and right legs were treated independently for foot motion and MoS.

## RESULTS

In the ML direction, fallers had an increased ML MoS variability compared to non-fallers, with no other differences between groups identified. In the AP direction, the fallers group walked with a decreased step length, decreased AP MoS, increased variability of step length, and increased variability of AP MoS.

## DISCUSSION

Frontal plane stability requires active control where sensory feedback during mid swing is integrated

and lateral step placement is adjusted to appropriately decelerate and redirect the center of mass [5]. There were no differences between groups for step width variability or ML trunk acceleration variability but ML MoS variability, which describes the interaction between the center of mass and base of support, was increased in the fallers group. This shows that fallers were less able to appropriately control their step placement to maintain a consistent ML MoS. Similar results were obtained in the sagittal plane with an increased AP MoS variability and step length variability in the fallers group. This supports the idea that step placement in fallers likely contributed to their fall risk.

The second part of the hypothesis was that fallers would walk more cautiously than non-fallers, which was partially supported since fallers walked with slower and shorter steps than non-fallers but with a decreased AP MoS. A cautious gait would be characterized by increased MoS. Slow and short steps are also indicative of cautious gait as they minimize the forward excursion of the center of mass beyond the stance foot and allow for more response time to perturbations [6]. Previous work in PwMS who were not separated based on falls history actually showed that slower walking leads to an increased AP MoS relative to healthy controls [7]. Here, lower AP MoS in fallers compared to non-fallers is likely another indicator of their fall risk since a smaller MoS indicates the center of mass is closer to leaving the AP base of support.

The gait impairments observed could be attributed to many physiological impairments of MS including slowed neural conduction speed, sensory loss, and spasticity which could all hinder inter-stride adaptability. While these impairments are generally found in all PwMS, it's likely that fallers have more severe physiological impairment leading to worse dynamic balance.

## CONCLUSIONS

The present work provides evidence that within a group of PwMS, there are gait differences between those with a falls history and those with no fall history, specifically that foot placement in the frontal plane and AP MoS are different in the fallers. These findings are novel and significant, as the two groups studied had the same disease, were both mild-moderately disabled and ambulatory, yet they had distinct biomechanical differences in their gait. This suggests that future studies investigating gait in PwMS should include fall history as a covariate.

## INTRODUCTION

Musculoskeletal disorders (MSDs) of the hand and fingers are found to be related to occupational activities in multiple industrial sectors [1]. One of the effective intervention methods for the work-related MSDs of the hand is hand excises and rehabilitations [2,3]. The hand rehabilitation or therapy ball is one of the most popular commercially available types of hand exercise and rehabilitation equipment. The distributions of the contact pressure at the interface between the therapy ball and hand/fingers affects the joint moment of each finger, thereby affecting the distributions of the forces among the muscles of the fingers. A better understanding of the biomechanics of the therapies would help to improve the hand rehabilitation strategy and to achieve more effective outcomes. The goal of the current study is to quantify the distributions of the dynamic contact forces between the hand/fingers and therapy ball.

## METHODS

Eight female adults [age 29 (9.1) years, mass 64.6 (7.1) kg, height 163.5 (1.9) cm, hand length 17.2 (0.7) CM] participated in the study. The contact force sensors (or PPS sensor) (FingerTPS, Pressure Profile Systems, Los Angeles, USA) were attached to the distal, middle, and proximal phalanges of the four fingers excluding the thumb (Fig. 1). Each pressure sensor was individually calibrated before being used for the data collection. Subjects were instructed to perform two maximum voluntary exertion gripping tasks on a typical spherical rehabilitation ball. A quasi-static portion of each exertion was selected and the mean total force across the two trials was used to establish a maximum total grip force value, or the maximum grip (MAX). The subjects were then requested to perform a random ordering of two exertions at 25% and 50% of MAX. Subjects rested at least two minutes between trials. Before and after each trial, subjects were instructed to adopt a “handshake” posture, with the wrist neutral and fingers extended. After collection of baseline tare data at the start of the trial, an experimenter placed the ball in the subject’s instrumented hand. Subjects were instructed to not greatly adduct the fingers,

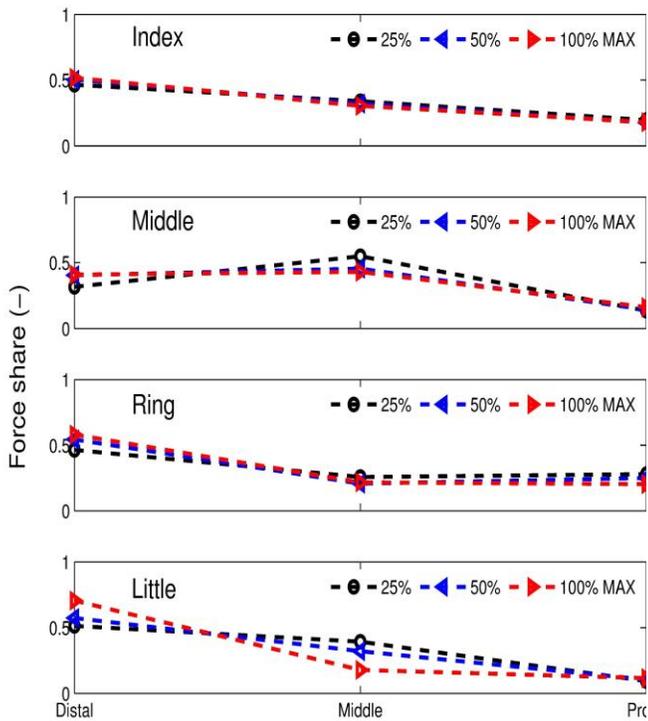

**Figure 1.** Test set-up. **Left:** A subject holds a hand rehabilitation ball, with all force sensors being attached. **Right:** The subject applied the maximal grip force to squeeze the ball.

avoiding a claw-like posture, while gripping. The force sensor data were collected at 40 Hz. The mean force values were calculated from a four-second range with the minimum total force variance during the exertion.

## RESULTS

The force share among the distal, middle, and proximal finger segments of the four fingers for grip force levels of 25%, 50%, and 100% of MAX are shown in Fig. 2. Our results show that the force sharing on the finger segments for the index finger is nearly independent of the grip force levels, whereas the grip force levels affect the force sharing on the fingers segments for the other three fingers. The force share on the distal segment increases with increasing grip force; the force share on the middle segment decreases with increasing grip force; and the force share on the proximal segment is nearly constant for all grip force levels. The results show that the distal fingers segments share approximately 50% of the total force of the finger, whereas the proximal segments took the least force share (approximately 10%). The grip force level affects the force distributions on the finger segments, however, the general trends are not changed.

The effects of the grip force on the force sharing on the four fingers are analyzed in Fig. 3. The middle and ring fingers share approximately 50% more force than the other two fingers. The force share on the ring finger decreases with increasing grip force level, while those in the middle and index fingers increase with increasing grip force level.

**Figure 2.** Force sharing in finger segments for three grip force levels.

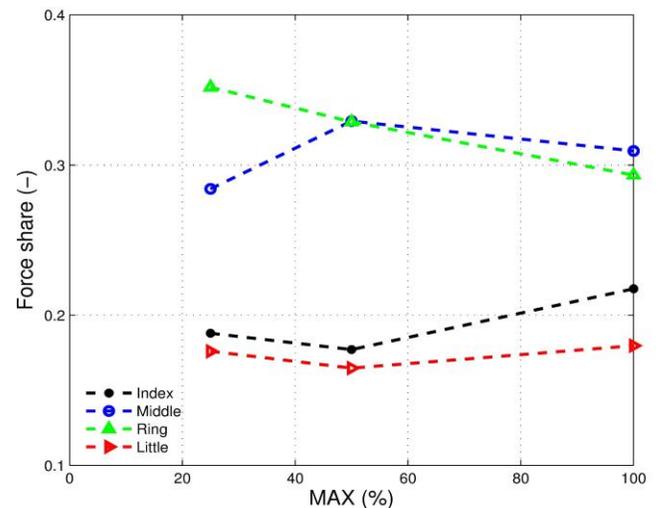

## DISCUSSION AND CONCLUSIONS

Our results indicated consistently that the hand grip force is contributed about 60% and 40% by the middle/ring fingers and by the index/little fingers, respectively, independent of the grip force levels and stiffness of the contact surface (results not shown).

For index, ring, and little fingers, the contact force is concentrated most on the distal segment during squeeze, independent of the grip force levels. However, for the middle finger, the maximal force sharing can be on the distal or middle segment, depending on the grip force level (Fig. 2). This phenomenon is different from those observed in the cylindrical grip tests, where the maximal pressure was always on the distal segment of the index finger [4]. The force share pattern in the fingers observed in

the current study is quite different from the previous study: the majority of the hand grip force is contributed by the middle and ring fingers in the spherical grip, while it is mainly contributed by the index finger in the cylindrical grip [4].

One advantage for the current study over the previous studies is that we measured the contact forces on the fingers using individual PPS sensors. In the previous studies [5], the contact pressure was measured by using pressure sensor film that was wrapped on the contact surface of the object. For the rehabilitation ball, it deforms so much during squeeze (Fig. 1, Right), that it is impossible to wrap a pressure sensor film on the contact surface. In comparison, the application of the PPS sensors is independent of the curvature of the contact surface.

**Figure 3.** Force sharing in fingers for three grip force levels.

## INTRODUCTION

Multiple Sclerosis (MS) is a chronic neurodegenerative disease that currently affects over 2.3 million people worldwide. Common symptoms include postural imbalance, postural asymmetry, and muscular weakness [1, 2, 3, 4].

Research has shown that progressive resistance training (PRT) is beneficial for improving muscular strength and functional performance in persons with MS (PwMS) [2]. However, there is contradicting evidence on the benefits of PRT for improving balance in PwMS.

The purpose of this study is to determine if a 10-week exercise training program combining balance, flexibility, and PRT will improve balance in PwMS. We hypothesized that the intervention would reduce sway velocities, ranges, and loading asymmetry (LA) during sit-to-stand movements and a hand-washing simulation (HW).

## METHODS

Twelve participants (54±8 yrs; 1.68±0.1m; 80.5±22.2kg; EDSS 4.3±1.9) diagnosed with relapsing-remitting MS participated in this study. Participants experiencing a flare-up or change in medication within the last 3 months, receiving steroid injections within the past 60 days, or having other musculoskeletal or neurological conditions were excluded from this study. Postural and strength data were collected pre- and post-intervention.

*Dynamic Posturography:* A non-functional sink was set at a standard height in front of the participant (Figure 1B). Participants were instructed not to lean or rest on the sink during the collection. Participants

simulated rinsing the hands, lathering the hands with soap (simulated by a ball of putty), rinsing the hands once again, and shutting off the faucet. Five trials were performed with one minute of rest between trials. Participants also completed 5 trials of a sit-to-stand movement at preferred (pSTS) and fast (fSTS) speeds (Figure 1A). Ground reaction forces (1000Hz) were collected for 5s during the washing portion of the HW trials and for 8s after the start of the STS movements. Center of Pressure data were calculated and used for all postural variables as described in Chung et al. [4].

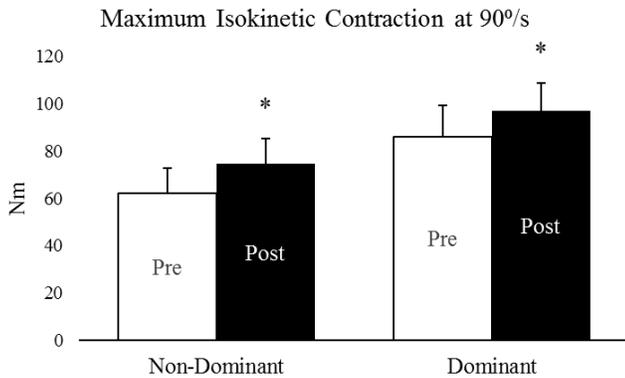

*Strength Assessment:* Participants completed three isokinetic knee extensions of each leg at an angular velocity of 90 °/s. The highest of the 3 trials was used to determine leg extension strength for each leg.

**Figure 1A-B:** 1A: Participant preparing to complete a STS movement. 1B: Participant completing a HW simulation assessment.

*Intervention:* Participants completed 10-weeks of supervised exercise training that included PRT, static stretching, and balance training. Sessions

occurred twice/week, began with a 5-minute warm-up, followed by light static stretching, balance training, and PRT. Static stretches were held for 2-sets of 30s on all major muscle groups. Balance training involved resisting perturbations to an outstretched fitness ball while standing on a foam pad. Two sets of 10-repetitions were completed for all PRT exercises targeting all major muscle groups. Resistance was increased once participants successfully completed all repetitions for a particular exercise over 2 sessions.

\* p-value <0.05 from pre to post

**Figure 2:** Strength during isokinetic knee extension in PwMS.

## RESULTS AND DISCUSSION

Results are summarized in Table 1. Significant changes were seen in isokinetic strength measures for both dominant and non-dominant legs (Figure 2). For postural measures, LA during HW decreased significantly, but no other changes were observed. The principle of specificity may help explain why improvements were only seen in the HW task as our balance training most closely resembled the HW task. It is also important to note that LA values were higher for HW compared to STS. This may be due to the dual-task nature of HW.

**Table 1:** Balance during HW, pSTS, and fSTS movements.

Variables	HW		pSTS		fSTS	
	Pre	Post	Pre	Post	Pre	Post
AP Absolute Length (mm)	251±50	255±55	371±87	379±113	376±376	364±103
ML Absolute Length (mm)	269±64	292±75	340±84	333±95	346±105	325±83
AP Max Velocity (mm/s)	239±46	232±45	357±93	330±95	406±88	378±82
ML Max Velocity (mm/s)	242±56	252±58	364±87	357±70	470±248	442±215
Loading Asymmetry	.159±.091	.125±.081*	.108±.062	.112±.069	.114±.059	.105±.074

**Legend:** HW = Hand Washing, pSTS = Preferred-speed Sit-to-Stand, fSTS = Fast-speed Sit-to-Stand, \* p-value <0.01 from pre to post

During HW, participants had to focus on operating the faucet, reaching for the soap, lathering, washing, and rinsing their hands all while trying to maintain balance. It is interesting to note however, that no changes for anterior-posterior and medial-lateral (AP/ML) stability were found during the HW tasks after the intervention.

Previous research has shown a significant relationship between LA and AP/ML stability [4]. However, our results indicate that improvements in strength and LA do not always result in changes to AP/ML stability.

## CONCLUSIONS

Muscular weakness is a commonly reported symptom of MS. Our data indicate that 10-weeks of balance, flexibility, and PRT is sufficient to elicit significant improvements in muscular strength and to reduce LA during HW.

As our sample size is small, future studies with larger sample sizes are needed to confirm our findings. Future interventions may also want to incorporate greater exercise variety. Current recommendations often include video game based programs, dual-task training, or the use of supplementary tactile feedback [3].

## INTRODUCTION

In 2016, an estimated 1.6 million people were newly diagnosed with cancer in the United States and many of them will be 65 years of age or older [1]. A common side effect of many cancer treatments is chemotherapy-induced neuropathy, which can lead to a loss of balance and an increased risk of falling [2]. Risk of falling is even greater when people have to negotiate obstacles such as curbs, stairs, or other changes in elevation. Exercise has been shown to reduce other side effects of cancer treatments, such as cardiotoxicity [3], but it is unclear whether exercise benefits gait mechanics in a way that might reduce the risk of falling and aid in obstacle negotiation for cancer survivors. Thus, the purpose of this study was to investigate the effects of a 12-week exercise intervention on joint kinetics during curb negotiation in cancer survivors.

## METHODS

Fourteen cancer survivors (8 females, 6 males, age = 64±9 yrs, height = 1.72±0.08 m, mass = 80±26 kg) participated in this study. All participants were recruited from the University of Northern Colorado Cancer Rehabilitation Institute. Each participant completed a pre-assessment session in which medical histories, aerobic fitness, and strength capabilities were assessed. These data were then used to design a specific 12-week exercise intervention for each participant. The 12-week exercise intervention included aerobic, strength/resistance, balance and flexibility training 2 – 3 times per week.

Prior to (pre) and immediately following (post) the 12-week training intervention, each participant's gait was assessed while negotiating a curb. Motion (100 Hz, VICON) and ground reaction forces (2000 Hz,

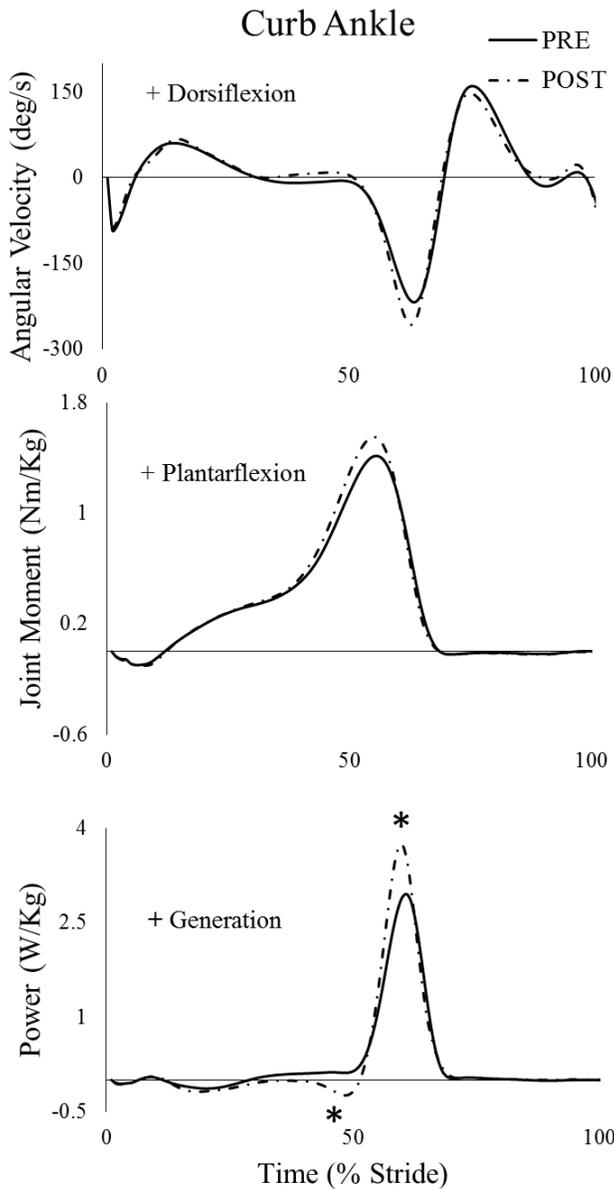

AMTI) were measured for three trials while participants walked up the curb at a freely chosen speed. Marker coordinates ( $F_c = 6$  Hz) and ground reaction forces ( $F_c = 50$  Hz) were filtered in Visual 3D (C-Motion) using a recursive Butterworth digital filter.

To recreate a curb in the laboratory, two force plates embedded in tandem in the floor and a third force plate mounted on a steel frame was placed in line with the other two force plates. The third force plate was 16 cm higher than the ground plate which modeled the sidewalk curb outside our lab. By using this set up we were able to collect a step on the ground (GROUND) prior to the curb and a step up to the curb (CURB). Sagittal plane kinematics and kinetics were analyzed for the CURB and GROUND leg during three successful trials. A successful trial occurred when complete contact was made with the force plate for the GROUND plate and the CURB plate. Peak joint angular velocities, moments, powers, as well as minimum toe clearance, center of mass velocities, and work were identified from each trial and then averaged for inclusion in statistical analyses. A series of ANOVAs were used to identify differences between pre- and post-test measures ( $\alpha = .05$ ) for the ground and curb leg.

## RESULTS AND DISCUSSION

Joint angular velocities and walking speed were not significantly different between pre- and post-test sessions. However, during late swing phase, the knee flexor moment increased significantly from pre- to post-test conditions ( $p = .006$ ) in the CURB leg. Significantly more power was absorbed at the ankle at about 50% of the gait cycle ( $p = .012$ ) and generated at about 60% of the gait cycle ( $p = .025$ ) for the CURB leg after training. Significantly more power was also generated at the hip at approximately

20% of the gait cycle for the GROUND leg. Overall, the total work performed at the ankle on the CURB increased significantly after training ( $p = .037$ ). Toe clearance over the CURB decreased significantly after training ( $p = .005$ )

**Figure 1:** Mean joint power at the ankle of the CURB leg. \* indicates significant difference between pre- and post-test sessions.

Previous studies have reported that fallers tend to generate less power at the ankle during push-off when compared to non-fallers [4]. The decrease in ankle power that has been found in previous studies is thought to be caused by a decrease in plantarflexor strength. Thus, cancer survivors in the current study likely lowered their risk of falling after the 12-weeks of training due to the increased power output at the ankle.

Recently, it was also reported that young adults transitioning from level walking to climbing stairs have a minimum toe clearance over the first stair of approximately 7 cm [5]. Given that the minimum toe clearance for study participants decreased after training, this might indicate a more confident gait for these cancer survivors after training.

## CONCLUSIONS

Ankle joint power output during curb negotiation increased following 12-weeks of exercise in cancer survivors. These observed changes in ankle power are consistent with reduced risk of falling among older adults.

## INTRODUCTION

Pelvic girdle pain (PGP) is defined as pain from the posterior iliac crest to the gluteal fold in the area of the sacroiliac (SI) joint [1]. It is estimated that PGP can be seen in approximately 20% of women [1, 2]. PGP is generated due to failure to adequately transfer load through the lumbo-pelvic region, which affects lumbo-pelvic stability [1]. Lumbo-pelvic stability, however, is influenced by the SI joint's anatomy (form closure), compressive forces acting across the SI joint (force closure) and neuro-motor control [1, 3, 4]. Compression of the pelvis often provides symptomatic relief to those suffering from PGP [5] and it has been suggested to improve lumbo-pelvic stability [4]. Thus, one of the management options for patients with PGP is the use of an SI belt [1]. Furthermore, studies have shown that the application of the belt alters recruitment of muscles during walking. Therefore, the purpose of this study was to further investigate if the application of the SI belt influences other biomechanical factors, such as stability and lower limb kinematics in women with and without PGP during standing and walking tasks.

## METHODS

This is a case-control study that enrolled five female subjects with PGP (age:  $33.8 \pm 0.8$ , parity: 1 [range: 0, 4], BMI:  $23.8 \pm 2.9$ ) and five matched control subjects (age:  $33.8 \pm 3.6$ , parity: 1 [range: 0, 3], BMI:  $24.2 \pm 3.4$ ). Women were considered cases if they presented PGP and lumbo-pelvic instability. Lumbo-pelvic instability was assessed performing four clinical tests which included the posterior pelvic pain provocative test, Fabers test, Gaenslen's test and palpation of the dorsal ligament. A subject was identified having PGP when two or more tests were positive. Additionally, the active straight leg

raise test had to be positive on at least one side. Subjects had to perform three different tasks with the belt on and off, respectively. The tasks included quiet stance on a force plate, walking over a force plate at controlled speed, and walking at self-selected speed. Pressure distribution and lower limb kinematics were collected while standing using a force plate, pressure insoles and motion capture system. Three-dimensional ground reaction forces and lower limb kinematics were collected while walking at controlled speed, and pressure distribution was collected while walking at self-selected speed.

## RESULTS AND DISCUSSION

All subjects showed a significant decrease ( $T_{1,9} = 5.564$ ,  $p < 0.001$ ) in the 95% confidence ellipse area of the center of pressure (CoP) data during standing when the SI belt was applied, regardless if they were subjects with PGP or healthy controls (Table 1). On average, the 95% confidence ellipse area of subjects with PGP ( $33.27\% \pm 4.73$ ) decreased more when the SI belt was applied compared to the group of healthy controls ( $26.35\% \pm 13.09$ ). The decrease in 95% confidence ellipse area was not statistically significant between the group with PGP and healthy controls. Four out of five patients with PGP showed a greater increase in stability than the matched control subjects. It is hypothesized that with an increase in sample size the effect of the belt between the two groups would become statistically significant.

**Table 1:** The 95% confidence ellipse area of the CoP data for subjects with PGP (S1-S5) and healthy controls (C1-C5) with and without wearing the SI belt while performing the standing task.

Subject	Belt Off [mm <sup>2</sup> ] (SD)	Belt On [mm <sup>2</sup> ] (SD)	Decrease of area [% of Belt Off condition]
S1	51.78 (1.40)	32.10 (16.43)	38.01
S2	60.01 (34.12)	44.54 (26.23)	25.78
S3	16.37 (6.74)	10.79 (7.71)	34.09
S4	26.34 (9.25)	17.86 (7.65)	32.19
S5	22.45 (2.19)	14.31 (1.61)	36.26
C1	26.54 (1.59)	21.35 (2.17)	19.56
C2	25.33 (9.52)	20.03 (0.17)	20.92
C3	31.64 (0.45)	27.63 (14.95)	12.67
C4	14.47 (0.40)	7.83 (1.82)	45.89
C5	40.16 (21.27)	27.02 (3.08)	32.72

Eight out of ten subjects showed significantly higher hip internal rotation ( $T_{1,9} = 2.680$ ,  $p = 0.025$ ) and knee external rotation ( $T_{1,9} = -3.122$ ,  $p = 0.012$ )

during the standing task while wearing the SI belt. Furthermore, all ten subjects showed a significant increase in hip abduction ( $T_{1,9} = -10.146$ ,  $p < 0.001$ ) and knee adduction ( $T_{1,9} = 5.167$ ,  $p < 0.001$ ) at heel strike while walking at controlled speed when the SI belt was applied.

## CONCLUSIONS

This study was able to provide evidence that wearing an SI belt leads to a significant increase in stability in patients with PGP and in healthy control subjects. The results showed a trend that wearing an SI belt affects patients with PGP more than healthy subjects. Furthermore, the results showed that wearing an SI belt leads to a significant change in lower limb kinematics in women who are suffering from PGP and in healthy control subjects during standing and walking.

## INTRODUCTION

Each year thousands of individuals require surgical removal of their larynx due to trauma or disease, impairing their ability to vocalize speech. Studies of alternative forms of communication have reported that synergistic activation of muscles involved in speech – which largely remain intact after laryngectomy – produce unique combinations of surface electromyographic (sEMG) signals when articulating different phonemes [1]. This is true even when speech is mouthed or spoken in a silent (unvoiced) manner, indicating that the use sEMG signals for speech recognition has the potential to be a powerful platform to help individuals communicate subvocally. Therefore, we developed a system to record sEMG signals from muscles of the face and neck during silently mouthed speech in patients with laryngectomy and translated patterns of sEMG signals into words using phoneme-based silent speech recognition.

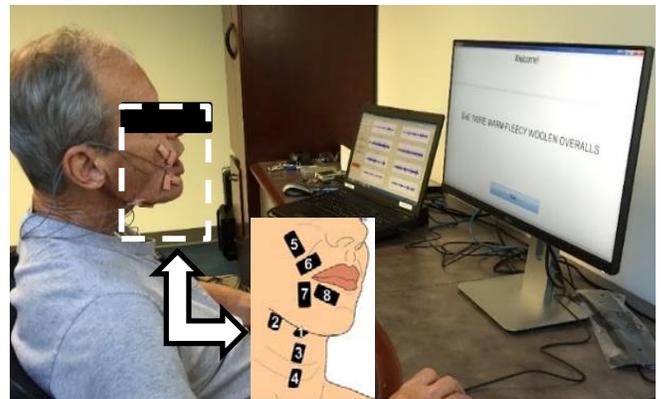

## METHODS

Experiments were conducted with n=7 participants with laryngectomy (mean 64 years). Custom-designed Trigno™ mini sEMG sensors (Delsys, Inc. Natick, MA) were strategically placed on 8 muscles of the face and neck previously identified as those most involved in the articulation of speech (Fig. 1) [1]. A vocabulary of 1000 commonly used English words primarily from the TIMIT data corpus were used to test different combinations of phonemes. Words were presented in token sentences on a computer screen for subjects to silently recite by mouthing the words. A two-stage speech recognition algorithm was designed to process the sEMG signals recorded during silent speech. First, signal segments containing speech data were

identified by a finite state Speech Activity Detection (SAD) algorithm and processed with speaker-dependent window lengths and frame rates to compute Mel-frequency cepstral coefficients (MFCC) [2]. Hidden Markov Models were used to develop a multi-stage phoneme-based speech recognition model specific to each subject. The models were trained on 550 sentences and tested on 430 sentences. All words presented in the testing data were unique and did not appear in the training data.

## RESULTS AND DISCUSSION

We found that the synergistic activation of speech muscles while mouthing different words produced discriminable combinations of sEMG signals that could be used for speech recognition. From the full 8-sensor set, word error rates were on average 11.1% for all subjects tested. When we tested the best 4-sensor combination from each subject (Table 1 and Figure 1), we found average word-errors rates only moderately increased to 14.1%, indicating the potential to simplify the system for in-home use.

**Figure 1.** Subject operating data acquisition system. The callout shows the sensor location and numbering scheme.

**Table 1. Word Error Rates (WERs - %) per subject**

Sensor#	S1	S2	S3	S4	S5	S6	S7
{1,5,7,8}	14.8	18.7	20.8	27.1	11.6	18.8	18.7
{2,4,5,7}	23.3	20.5	<b>13.8</b>	24.1	14.3	20	15.6
{2,5,6,7}	<b>10.6</b>	<b>19.2</b>	15	<b>17.5</b>	14.4	15.8	<b>14.4</b>
{3,5,6,7}	15	30.8	19.7	19.2	<b>10</b>	<b>13.1</b>	18.1
<b>8 Sensors</b>	10	13.6	13.3	12.8	8.7	8.9	10.2
<b>Mean</b>	15.9	22.3	17.3	22.0	12.6	16.9	16.7
<b>BEST</b>	10.6	19.2	13.8	17.5	10	13.1	14.4

## CONCLUSIONS

These results provide first-of-its-kind demonstration that unique combinations of sEMG signals obtained from synergistic activation of muscles involved in speech articulation can be used for recognition of silently mouthed words in patients with laryngectomy. While there is room to improve the accuracy possibly through increased training data, inclusion of further speaker-dependent parameters or alternative algorithm approaches, the ability to recognize words using phoneme-based patterns of

sEMG provides an impactful first-step towards developing a practical body-worn system for alternative communication for persons with laryngectomy.

## INTRODUCTION

Standard underarm crutches have long been used as a method to re-enable an individual to perform normal walking. An average of 6.5 million people use an assistive device such as crutches to assist with mobility in the US alone [1]. Crutches have been found to compress the radial nerve which can cause pain, tenderness, and motor weakness as well as the ulnar nerve which can lead to nerve damage and neuropathy [2-3]. The iWalk has been introduced to the market as a new type of hands free crutch in an attempt to eradicate the stress applied to the underarms with traditional crutches, however the effects of the device on walking gait have yet to be researched. Symmetrical walking gait is essential to maintain upright positioning and forward propulsion. When walking gait is rendered asymmetrical, it opens an individual up to problems such as lower back pain, osteoarthritis, and a higher potential of falling [4]. Therefore, the purpose of this study was to examine the symmetry of walking gait with an assistive device

## METHODS

Ten healthy, injury-free University female students with an average age of  $20.2 \pm 1.6$  years old were recruited to participate in the study. Prior to the study, approval by the institutional ethics review board was obtained. After obtaining approval, written informed consent from each participant was received. Each participant was allowed to become acquainted with the iWalk before beginning the walking sequence. Ten joint reflective markers were placed on both sides of the body at the shoulder (gleno-humeral joint), hip (greater trochanter of the femur), knee (lateral epicondyle of the tibia), ankle (lateral malleolus) and toe (base of the fifth metatarsal). The participant walked barefoot on a

treadmill (Model: Milestone 4200) at a speed of 1.03 m/s for thirty seconds to obtain normal lower extremity walking data. Next, the participant was introduced to the iWalk and fitted on the right leg side only for the device. Once adjustments were made to the device, straps were fitted accordingly, and balance was obtained by the participant, they began walking on the treadmill at. Three cycles of heel strike, mid-foot support, and toe off were recorded for analysis.

Two high speed Casio cameras (Model EX-FH25) were positioned to capture the sagittal views of both right and left sides at 120 Hz. Two 650W spot lights were used in conjunction with each camera to assist in joint marker identification. All video trials were transferred onto a computer in the Biomechanics Lab for gait analysis. Three successful walking gait cycles were used for analysis. To determine a successful walking gait selection, a heel strike, mid-foot support, and toe off phase needed to be present and identifiable. The instant of these three phases of walking gait were measured at the hip joint in both normal walking and iWalk conditions. A 2D kinematic walking gait analysis was conducted with Aerial Performance Analysis System (APAS<sup>TM</sup>) motion software. Dependent sample t-tests were conducted with Bonferroni adjustment and all statistical analyses were conducted with SPSS software.

## RESULTS AND DISCUSSION

Dependent sample t-tests were conducted with Bonferroni adjustment for multiple comparisons ( $\alpha = 0.05 / \# \text{ of comparisons} = 0.05 / 4 = 0.0125$ ; IBM SPSS) between right and left sides of iWalk and barefoot walking on the treadmill for each participant during heel strike, mid-foot support, and toe off phases (Table 1).

Hip kinematic alterations between the iWalk and normal walking gait were identified; specifically, the ipsilateral side iWalk vs barefoot hip angle at heel strike, mid-foot support, toe off. The iWalk decreased ipsilateral hip extension angles by 18 degrees, with minimal effect on the contralateral hip, except for mid-foot support.

Hip range of motion typically varies from 30 degrees flexion at heel strike to 10 degrees extension at push off during walking over ground [5]. The decreased ipsilateral hip flexion during swing may be due to the additional weight of the iWalk device on the lower limb as well as the subject's attempt to minimize ground impact force i.e. given the lack of dampening provided by normal knee-ankle-foot at heel strike, stride length on the ipsilateral side was foreshortened.

## CONCLUSIONS

This study used ten healthy female students to examine effects of using the hands-free crutch on the lower limb kinematics at heel strike, mid-foot support, and toe off phases of walking gait. The iWalk device permitted functional bilateral walking, though ipsi-contra-lateral gait symmetries were evident. The results showed that the iWalk does

result in a significant change to the individual's hip angle when compared to normal barefoot walking. This could result in an asymmetrical walking gait with extended use. Therefore, this study concludes the iWalk hands free crutch will indeed alter walking gait. Future studies are warranted to examine lower limb kinematics with both genders over a longer time period to address long term issues.

## INTRODUCTION

Achilles rupture and tendinopathy both are common tendon injuries in the lower leg [1]. Therapeutic exercise is thought to be beneficial to rehabilitation efforts for Achilles tendinopathy or for the post-surgical management of tendon repair. Progressive prescription of therapeutic exercises to expose patient to an appropriate load is a key factor for successful recovery from Achilles tendon (AT) injuries. The current standard rehabilitation regimens use different exercises including heel raising, squats, lunges, hopping, walking and running within different stages of rehabilitation [2-3]. The rehabilitation exercises that are used to load the AT in both a safe and progressive manner providing for a rapid return to sport remain somewhat unclear. The knowledge of AT loads during a variety of common activities is required to design a safe and effective rehabilitation regimen. Our aim was to compare the estimated AT loading during a several exercises to inform exercise progression for AT rehabilitation.

## METHODS

Eighteen healthy and physically active males were examined (Age:22.1±1.8years, height:177.7±8.4cm, weight=74.29±11.3kg). Kinematic and kinetic data were recorded respectively with 15 Motion Analysis cameras (180Hz) and force platforms (1800Hz). The kinematic and kinetic data, and muscle forces were calculated from a 44 degree of freedom (DOF) musculoskeletal model with 18 rigid segments using the Human Body Model (HBM, Motek Medical, Amsterdam, Netherlands) via inverse dynamic based static optimization routine. The muscle forces were used to quantify total AT force by summing the muscle forces of the medial and lateral gastrocnemius and soleus for each exercise. The AT stress was calculated by dividing the AT force by the participant specific AT cross-sectional area which was measured by ultrasonography. Peak stress rate was determined from the instantaneous slope of the

stress versus the time curve. Subjects performed five repetitions for all 11 exercises including tandem, Romberg, and unilateral standing (U-standing), Unilateral (U) and bilateral (B) heel raising (HR), bilateral (B) and unilateral (U) jump landing (Jump-Land), squat, forward lunge (FL), walking, and running in a random order.

A multivariate analysis of variance (MANOVA) with repeated measures ( $\alpha=0.05$ ) was used to compare the AT stress, stress rate, and force across the 11 exercises. Post hoc comparisons were performed with the Bonferoni procedure. All statistical procedures were performed using SPSS (Version 23, IBM, Armonk, NY, USA).

## RESULTS AND DISCUSSION

The MANOVA revealed differences between tasks (Wilk's lambda=0.006, P-value<0.001). Follow-up univariates depicted differences in peak AT stress, force, and stress rate during 11 exercises. Table 1 shows the mean and standard deviation for peak AT stress, force, and stress rate for each exercise.

Figure 1 depicts the AT stress time series throughout the performance of each exercise. It is observable that the timing of peak AT stress was somewhat unique for each exercise. However, some exercises showed similar AT loading patterns but with different magnitudes like the bilateral and unilateral Jump-Land (at 0-30% for landing, ≈80-100% for jumping) and during stance of walking and running. The peak AT stress for the bilateral and unilateral jump-land occurred during the jumping portion of the exercise. Similarly, during running and walking, the peak AT stress occurred during push off phase of the performance. AT stress during the Romberg, unilateral standing and tandem exercises were quite uniform loading patterns since these exercises were less dynamic with muscle force requirements needed for postural control in a set position. During both heel raise exercises (B-HR and U-HR), the peak AT stress occurred during raising portion rather than lowering

while the forward lunge showed a rather unique pattern where the peak AT stress occurred during raising ( $\approx 70\%$ ). Figure 2 depicts the AT stress in order of magnitude for all 11 exercises. Categories were determined from AT stress based on statistical differences between exercises. In general, AT rate of loading follows largely a similar pattern of loading as AT stress. In general, our AT force values are well below the reported AT failure load 5579N [4].

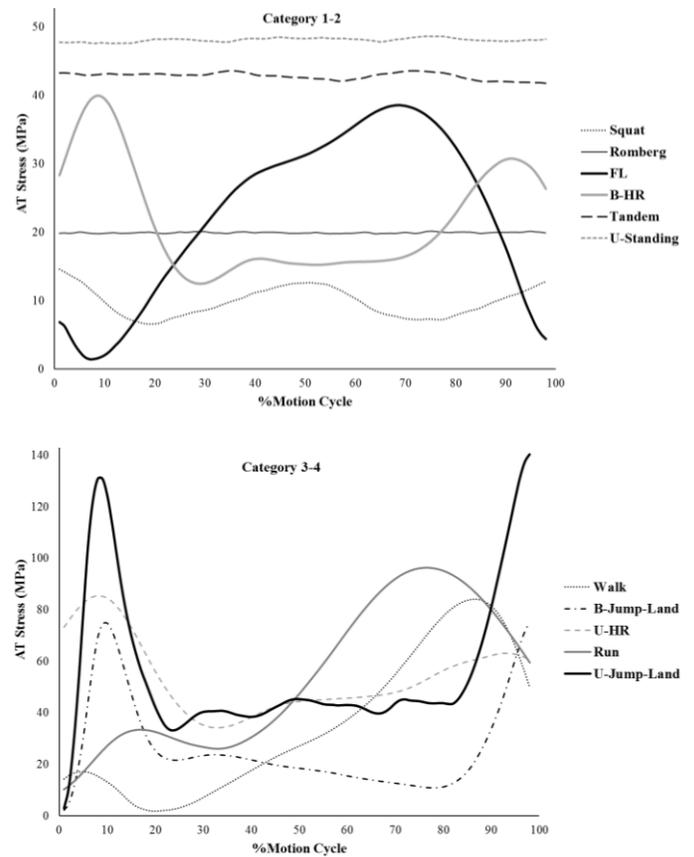

AT peak stress, force and stress rate were lowest during the Romberg and tandem exercise while standing on both legs. Changing from bilateral to unilateral exercise increased the force and stress. More dynamic exercises (squat and lunge) increased the stress rate. The bilateral and more static exercises with less stress and stress rate may be more desirable earlier in the rehabilitation process. Unilateral and more active exercises may be more useful in later exercise progressions. Understanding loading for each of these exercises may aid in planning the timing and sequencing of exercise progression in a AT rehabilitation program.

**Table 1:** Mean and standard deviation (Mean $\pm$ sd) for AT loading during each exercise.

	AT Stress(MPa)	AT Force (BW)	AT Stress Rate (MPa/s)
Squat	18.23 $\pm$ 8.10	0.77 $\pm$ 0.35	35.30 $\pm$ 18.20
Romberg	21.43 $\pm$ 6.98	0.91 $\pm$ 0.3	17.61 $\pm$ 6.00
Forward Lunge (FL)	40.96 $\pm$ 18.89	1.72 $\pm$ 0.74	128.18 $\pm$ 65.48
Bilateral Heel Raise (B-HR)	44.60 $\pm$ 11.89	1.89 $\pm$ 0.41	220.46 $\pm$ 111.47
Tandem	46.05 $\pm$ 18.88	1.93 $\pm$ 0.74	16.77 $\pm$ 8.62
Unilateral Standing (U-Standing)	52.17 $\pm$ 12.93	2.18 $\pm$ 0.38	18.29 $\pm$ 8.58
Walk	86.17 $\pm$ 28.32	3.71 $\pm$ 1.29	403.42 $\pm$ 163.20
Bilateral Jump-Land (B-jump-land)	91.90 $\pm$ 35.98	3.88 $\pm$ 1.43	1173.67 $\pm$ 618.30
Unilateral Heel Raise (U-HR)	95.07 $\pm$ 33.73	3.98 $\pm$ 1.06	296.03 $\pm$ 185.56
Run	97.80 $\pm$ 50.83	4.15 $\pm$ 2.03	1200.11 $\pm$ 561.11
Unilateral Jump Land (U-Jump-Land)	158.55 $\pm$ 71.60	6.68 $\pm$ 2.66	1985.73 $\pm$ 1036.60

## INTRODUCTION

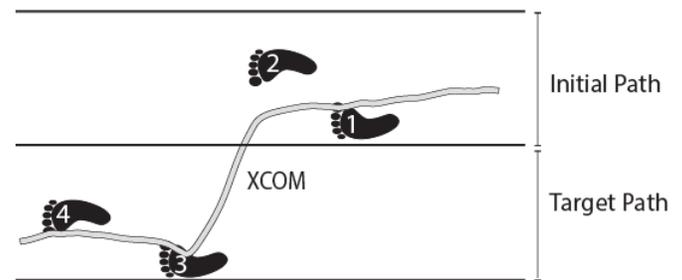

Avoiding obstacles and turning corners are essential for community ambulation but can be challenging for individuals with incomplete spinal cord injury (iSCI). To remain stable during maneuvers, people with sensory-motor deficits rely heavily on passive mechanisms (e.g. large margin of stability) that indiscriminately resist both external perturbations and volitional impulses intended to change trajectory. The proportional relationship between effort to maneuver and passive mechanisms of stability creates a speed-stability trade-off [1]. For a given volitional impulse, the speed of the maneuver will decrease as passive stability increases. As individuals with iSCI have both balance and strength deficits, situations requiring rapid maneuvers may result in a compromise between maneuver speed and stability.

In the current experiment, we examined speed-stability trade-offs as individuals with iSCI performed a simple overground walking maneuver at preferred and fast speeds. Previous studies found that non-impaired individuals reduced their lateral margin of stability (MOS) to facilitate rapid walking maneuvers [2]. Based on this finding, we hypothesized that when challenged to perform rapid walking maneuvers, individuals with iSCI would choose gait patterns that sacrifice passive stability.

## METHODS

Eleven ambulatory individuals with iSCI gave informed written consent and participated in the study. Participants performed straight-ahead walking and maneuvers at comfortable and fast speeds. For straight-ahead walking trials, participants walked

within a straight 7.5 x 0.5m path. During each maneuver trial, participants initially walked straight for 4.5m followed by a lateral maneuver to a parallel path (Figure 1). Once in the new path, participants continued walking forward. During “fast” trials, participants were instructed to walk and maneuver as quickly as possible while maintaining safety. At each speed, participants performed five straight-walking trials and 10 maneuver trials (five maneuvers to the left and right).

- 1) Setup step
- 2) Pushoff step
- 3) Landing step
- 4) Recovery step

**Figure 1:** Experimental Setup and representative locations of extrapolated center of mass (XCOM) and individual foot placements during a comfortable speed maneuver to the left.

Motion capture cameras recorded whole-body kinematics. For each trial, maneuver performance was quantified by time to complete the maneuver and center of mass (COM) path length during the maneuver. To examine lateral stability, we calculated the minimum lateral margin of stability (MOS) [3] during four maneuver steps (Fig. 1). The Setup step was initiated by the last heel strike before the maneuver began. This was followed sequentially by a Pushoff step, Landing step, and Recovery step. A decrease in MOS during a step indicates a decrease

in passive lateral stability and an increase in susceptibility to external perturbations.

Student t-tests or Wilcoxon Sign-Rank tests (when t-test assumptions were violated) were used to compare the effect of speed on performance metrics of Maneuver Time and COM Path Length. Repeated Measures ANOVAs were used to compare the effects of step (the four maneuver steps and a baseline straight-ahead walking step) and walking speed (fast and comfortable) on MOS.

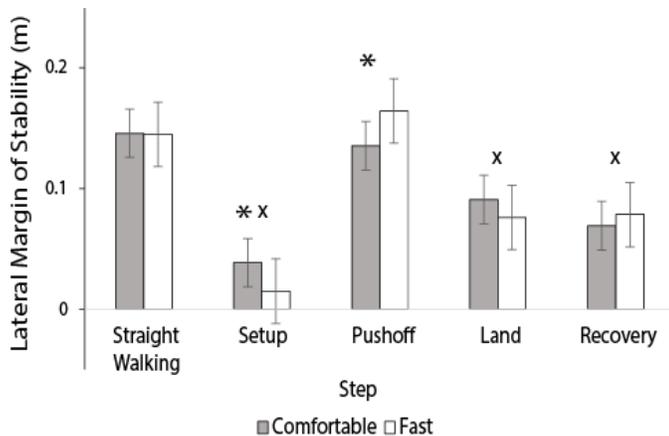

## RESULTS AND DISCUSSION

### Maneuver Performance

Maneuver Time and COM Path Length (Wilcoxon:  $p = 0.003$  and  $p = 0.041$ , respectively) were significantly decreased for fast vs. comfortable walking speeds.

### Lateral Margin of Stability

The repeated measures ANOVA found a significant main effect of step ( $p < 0.0005$ ) and significant interaction between step and speed ( $p = 0.004$ ) on Lateral MoS (Figure 2).

**Figure 2:** Minimum Lateral Margin of Stability for each step and condition. \*Significant difference between speeds. <sup>x</sup>Significant difference from Straight Walking step.

The Setup step had a significantly smaller minimum lateral MOS than every other step (Bonferroni-corrected pairwise comparisons of the Setup step vs.

Straight Walking, Pushoff, Landing, and Recovery steps all  $p \leq 0.002$ ). The minimum lateral MOS of the Setup Step decreased at the fast vs. comfortable walking speed ( $p = 0.026$ ). The minimum lateral MOS of the Pushoff step increased at fast vs. comfortable speed ( $p = 0.007$ ).

Our results show that individuals with iSCI reduce their passive lateral stability in anticipation of performing a lateral maneuver. This strategy reduces an individual's passive resistance to impulses directed in the intended maneuver direction. This reduction in lateral MOS should allow individuals to increase the rate at which they can initiate a maneuver for a given volitional impulse. However, this strategy also reduces passive stability in the maneuver direction, increasing susceptibility to external perturbations.

## CONCLUSIONS

These results suggest that individuals with iSCI choose to sacrifice stability for speed when asked to perform rapid maneuvers. This trade-off might translate to an interaction between community ambulation ability, walking speed, and fall risk. This finding also highlights how speed can be manipulated in a training environment to increase the challenge of maintaining stability during maneuvers.

## INTRODUCTION

Quadriceps muscle weakness has profound functional consequences after unilateral total knee arthroplasty (TKA). Compared to healthy controls, patients take twice as long to ascend and descend a flight of stairs, and report moderate to extreme difficulty [1]. A direct mechanism related to functional performance may be asymmetrical compensatory movement patterns. Characterized by low knee extension moments (KEM) and chronic quadriceps disuse in the surgical limb, these patterns promote quadriceps weakness and chronic functional limitations. The existence of these patterns pre-TKA suggest they are learned as compensation for chronic unilateral knee osteoarthritis pain. However, resolution of pain post-TKA has no effect on movement pattern resolution. Instead, innovative biofeedback training may remediate these atypical movement patterns. A strength of this study is that the tools and strategies are commercially available and simple to apply in real-world settings, including the clinic, patient home, and community. The purposes of this study were 1) to assess asymmetry in KEM during step ascent/descent, and 5-time sit-to-stand; 2) to determine if asymmetry was associated with impairment and function; and 3) to compare long-term quadriceps strength outcomes to controls without biofeedback after TKA.

## METHODS

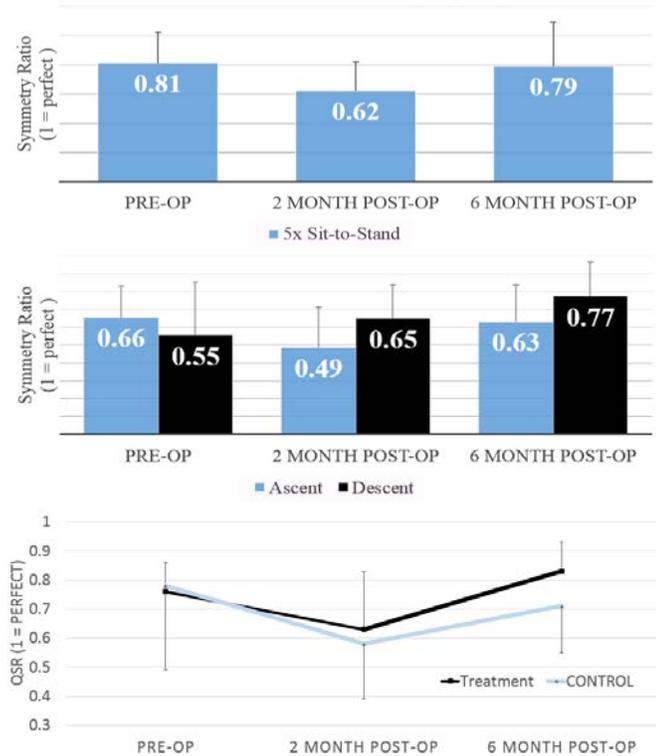

7 older adults (63±7yrs; 5M/2F) received biofeedback during rehab from Pedoped instrumented insoles (Novel) for 8 weeks. Pedopeds give patients weight-bearing feedback in dynamic tasks such as level ground walking and stair climbing. Movement pattern training was integrated into a progressive rehab program, involving ROM, strengthening, and stretching exercises. Intervention acceptance was

measured with the IMI interest and enjoyment subscale, with a mean score of  $\geq 5/7$  considered positive. All patients were tested within 2 weeks prior to TKA, and 2 and 6 months after TKA. 3D kinematic and kinetic data were collected from an 8 camera motion analysis system (100Hz) and force plates (2000Hz). A 15 segment, subject specific model was used, and joint moments calculated using inverse dynamics. 5 sit-to-stand transitions assessing movement quality were performed to a metronome to control speed (1.5Hz). 3 trials were performed bilaterally for step ascent and descent. The ascent leading limb and descent trailing limb were used for analysis. KEM symmetry was calculated as surgical divided by non-surgical limb values. Knee pain was rated by self-report (NPRS). Knee total active range of motion (AROM) was quantified by goniometer. Quadriceps strength (QSR) was calculated using max isometric knee extension torque recorded from an electromechanical dynamometer (CSMI). AROM and strength were converted to a symmetry ratio. The stair climb test (SCT) assessed the ability to ascend/descent a 10-step flight of stairs. A separate 5-time sit-to-stand test (FTSST) measured the time needed to perform 5 transitions as fast as possible. A control group (n=11; 67±8yrs; 5M/6F) with TKA provided QSR data. They received identical rehab but no biofeedback. Differences in KEM symmetry between pre-op and 6-months post-op were calculated using a paired samples t-test. Pearson's  $r$  were calculated between KEM and outcomes measures. Difference in 6 month post-op QSR between groups was calculated using an independent samples t-test.

## RESULTS AND DISCUSSION

The intervention was acceptable to patients, with a mean IMI score of 6.2 (1.1). In the treatment group, sit-to-stand and ascent KEM symmetry returned to pre-op levels at 6 months ( $p=.87$  &  $.89$ , respectively);

descent KEM symmetry was trending towards improvement compared to pre-op ( $p<.1$ ) [Fig. 1]. KEM symmetry during ascent/descent were positively correlated with QSR at 2 and 6 months [Table 1]. Descent KEM was negatively correlated with SCT time at 2 months post-op. Compared to controls, the treatment group was trending ( $p<.1$ ) towards better QSR at 6 months [Fig. 1].

**Figure 1.** KEM symmetry with sit-to-stand (top) and ascent/descent (middle). QSR over time (bottom). Mean (SD) bars shown.

While motor learning through feedback and practice schedules is not a novel rehab tool in neurological populations, use of the methods for retraining movement patterns is innovative for rehab after TKA. Initial data presented elsewhere suggest that this approach also improves patient engagement in rehab post-TKA [2]. The ability for patients to

receive biofeedback during routine daily activity adds significant breadth to the number of home- and clinic-based functional tasks used in the movement pattern training. These results support associations previously found between quadriceps strength and loading asymmetry during functional tasks in patients with TKA [1, 3]. While TKA improves in pain and ROM, these do not correlate with improved movement symmetry. Based on these preliminary results, movement asymmetry may be a modifiable target during rehab, and the remediation of asymmetry through motor learning feedback may reduce deficits in quadriceps strength and function.

## CONCLUSIONS

The results provide preliminary support for the hypotheses that adding rehab with novel movement pattern training may improve KEM symmetry, which may be linked to recovery of QSR. It is reasonable to consider KEM symmetry as an important component to early rehab after TKA, and further study through a large RCT is warranted, investigating whether targeting asymmetry early may attenuate prolonged strength and function deficits. Normalizing movement patterns may also reduce contralateral joint disease and the need for a future TKA.

## INTRODUCTION

People with spinal cord injury (SCI) experience rapid and severe bone loss in their lower extremities. Decreased bone mineral density and associated deteriorations to bone structure significantly reduce proximal tibia and distal femur strength. As a consequence, individuals with SCI have a high risk of fracture at these regions [1].

Reducing the rate of fractures in this population through interventions that strengthen bone remains an important clinical goal. In this context, therapies that prevent bone loss or that stimulate an anabolic response in bone have been proposed. Zoledronic acid (ZA) is a potent and long-acting bisphosphonate that inhibits osteoclastic resorption and is commonly prescribed for osteoporosis. It has been shown to decrease hip bone loss in acute SCI [2]. Functional electrical stimulation (FES) assisted rowing is an exercise that includes mechanical stimulation to the lower extremities, which is potentially osteogenic. The degree to which FES-rowing, ZA, or a combination is effective in improving distal femur or proximal tibia mechanical behavior in SCI is not known. Our **purpose** was to measure changes to torsional and compressive stiffness at the proximal tibia among people with SCI who underwent FES-rowing training with or without ZA treatment.

## METHODS

### Subjects

Seventeen subjects were selected from a cohort of adults with SCI (**Table 1**) who participated in a one-year clinical trial that included interventions for FES-rowing and ZA. Subjects were excluded if they did not row, or if they received treatments other than rowing and ZA that could affect bone turnover (ie. statin use).

### Finite element (FE) predicted stiffness

Each subject received two CT scans of their knee region before and after the intervention. Each scan included a calibration phantom (MindWays, Austin, TX) to convert CT Hounsfield units (HU) to bone equivalent density ( $\rho_{ha}$ , g/cm<sup>3</sup>). A 0.15 g/cm<sup>3</sup> threshold was used to identify the periosteal surface. Segmented integral bones were resampled to isotropic voxels with 1.5 mm edge length and directly converted to voxel based FE models with linear hexahedral elements using established methods [3]. Elements were assigned material properties based on density-elasticity relationship of  $E_3 = 6570 \rho_{app}^{1.37}$ , where  $E_3$  is axial elastic modulus (MPa) and  $\rho_{app}$  is apparent density ( $\rho_{app} = \rho_{ha}/0.626$ , g/cm<sup>3</sup>) [4, 5]. Anisotropy was assumed to be the same throughout with  $E_1 = 0.574 \cdot E_3$ ,  $E_2 = 0.577 \cdot E_3$ ,  $G_{12} = 0.195 \cdot E_3$ ,  $G_{23} = 0.265 \cdot E_3$ ,  $G_{31} = 0.216 \cdot E_3$ ,  $\nu_{12} = 0.427$ ,  $\nu_{23} = 0.234$ , and  $\nu_{31} = 0.405$ , where subscripts 1 and 2 denote the medial and anterior directions, respectively [6].

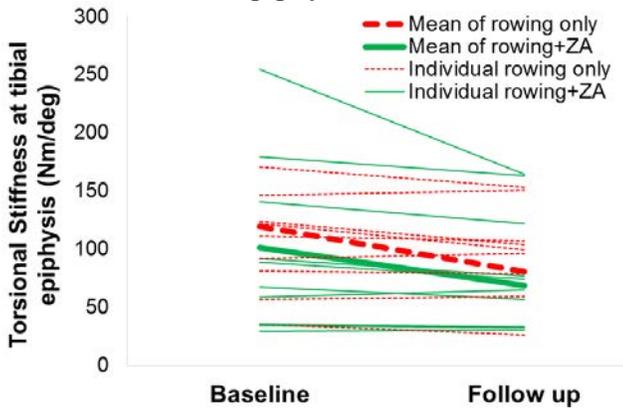

Epiphyseal and metaphyseal regions were defined as 0 – 10% and 10 – 20% tibia length, as measured from proximal end. The FE model of each region was subjected to either a fixed axial (compression) or torsional displacement. Surface nodes at distal end of tibial models were fully constrained. The reaction force, or torque, was used to calculate compressive (K; kN/mm) and torsional (T; Nm/deg) stiffness [3].

### Statistical analyses

Repeated measures analysis of variance (RMANOVA) was performed with factors of time (baseline versus follow up), intervention (rowing vs. rowing+ZA), and site (epiphysis vs. metaphysis). Student's t-tests were used to compare total and monthly change between the acute (injured 0-3 years) and chronic group (injured >3 years).

## RESULTS AND DISCUSSION

We observed an interaction between site and time in T ( $p = 0.039$ ), and a main effect for time and site on all variables. Overall, bone stiffness decreased over the intervention period, and the change was significant in both K ( $p = 0.013$ ) and T ( $p = 0.013$ ) for epiphysis, but not metaphysis (**Figure 1**). Although the interventions did not result in increased bone stiffness, previous studies have shown dramatic bone loss in individuals with recent SCI (injured <6 months) [3]. In our cohort, we observed monthly losses in K and T that were greater in acute vs. chronic groups, but that were overall much smaller than those previously reported with recent SCI (**Figure 2**). The present cohort showed similar patterns of stiffness loss as reported in those with recent SCI, with the epiphysis most affected.

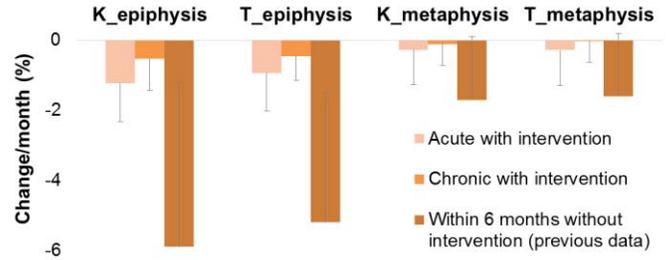

**Figure 1.** Torsional stiffness at epiphysis of rowing and rowing+ZA groups at baseline and follow up.

Both rowing only and rowing+ZA groups showed decreases in bone stiffness. However, some individuals had increases (**Figure 1**). Based on their training record, rowing dose was not related to K or T, indicating that additional factors are contributing to an individual's overall response.

Interestingly, we found that baseline tibial stiffness is a good predictor of its monthly changes at the epiphysis region ( $R^2 = 0.766$  and  $0.634$  for K and T, respectively; **Figure 3**). In other words, people with

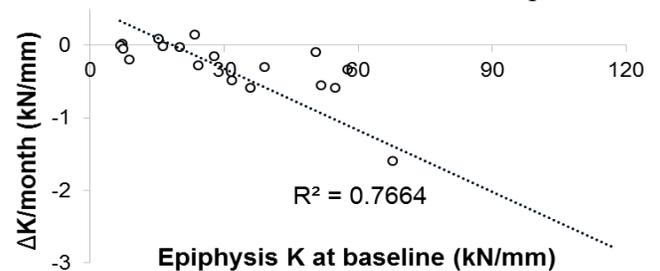

stronger bones tend to lose strength faster, which may suggest an asymptotic approach towards a “physiologic endpoint” for bone loss after SCI.

**Figure 2.** Monthly change in compressive (K) and torsional (T) stiffness between baseline and follow up.

## CONCLUSIONS

FES-rowing with and without ZA appears to attenuate loss in bone strength in individuals with SCI. Further investigation is needed to elucidate the factors that causes different individual responses.

**Figure 3** Relationship between baseline compressive stiffness (K) and monthly change post injury.

## INTRODUCTION

Multiple sclerosis (MS) is a neurological disorder that affects approximately 400,000 people in the US. The primary cause of MS is a loss of myelin that reduces signal transmission and processing within the nervous system. Common symptoms reported in the first year of the disease include sensory impairment, fatigue, reduced mobility, and declines in hand function [1]. Sensory symptoms, such as numbness, tingling, or the sensation of pins-and-needles, are observed in ~69% of individuals with MS [2]. The onset of these symptoms varies, but 39% of individuals with MS exhibit these symptoms in the early stages of the disease [3]. There is a strong association between loss of sensation in the limbs and declines in both walking performance and manual dexterity. Interventions that target sensory systems can elicit significant symptom relief and gains in clinical measures of physical function.

The purpose of the current study was to assess the influence of sensory stimulation using augmented transcutaneous electrical nerve stimulation (aTENS) applied to leg and hand muscles on clinical tests of motor function in individuals whose mobility had been compromised by MS. The tests assessed walking endurance, walking speed, sit-to-stand ability, and manual dexterity. We hypothesized that aTENS would acutely improve performance on the clinical tests of motor function and reduce self-reported levels of walking disability (MS Walking Scale-12).

## METHODS

The ongoing study has enrolled 10 of the planned 15 participants. The age (mean  $\pm$  SD) of these individuals was  $55 \pm 5$  yrs and their Patient-Determined Disease Steps (PDDS) scores were  $2.6 \pm 1.4$  (0 = no disability, 8 = bedridden) and the MSWS-12 scores were  $35.5 \pm 12.2$  (12 = no walking disability, 60 = extreme disability).

Participants visited the lab on two occasions with one week between visits. Each visit involved the participant performing four tests of motor function and completing two health-related questionnaires (PDDS and MSWS-12). The four clinical tests were the chair-rise test, assessment of maximal walking speed (25-ft walk test), measurement of walking endurance (6-min walk test), and a test of manual dexterity (grooved pegboard test). The pads through which aTENS was delivered were attached to the limbs during both visits and were placed over the hip flexors and dorsiflexors for the affected leg, and over the median nerve and the thenar eminence of the dominant hand. However, current was only delivered to the pads during the second visit while participants performed the four tests of motor function. The stimulation comprised asymmetrical rectangular, biphasic pulses (0.2 ms) at a rate of 50 Hz.

## RESULTS AND DISCUSSION

The participants experienced statistically significant improvements (Table 1) in the chair-rise test (30-s count), walking endurance (distance walked in 6 min), and pegboard time, but not the time to walk 25 ft (maximal walking speed). Also, they reported a statistically significant reduction in walking disability (MSWS-12 score), but not the PDDS score.

The average improvement after acute exposure to aTENS was (mean  $\pm$  SD) 3.3  $\pm$  4.1% for the 6-min distance, 21.2  $\pm$  14.2% for the chair-rise test, 10.3  $\pm$  10.9% for the pegboard test, and 20  $\pm$  13% for the MSWS-12 score. The magnitude of the benefit that can be obtained with more prolonged treatment remains to be determined.

## CONCLUSIONS

Stimulation of sensory fibers with augmented TENS evoked clinically significant improvements in three of the four tests of motor function and the self-reported level of walking disability in persons who were moderately disabled by MS. Moreover, the improvements in function were immediate.

## INTRODUCTION

Balance control plays a crucial role during locomotion in humans with SCI. Recent studies indicate that there is a strong relationship between balance and walking capacity in patients with SCI [1]. Improved balance control allows a patient to walk with fewer assistive devices and therefore walk faster and more efficiently for both short and long distances. Therefore, it seems that balance is one of the most important factors affecting walking in chronic SCI patients. Thus, we postulate that improved balance control, particularly lateral balance, which needs active control to stabilize lateral motion in humans walking, may facilitate locomotion in humans with SCI. However, current balance training paradigms in patients with SCI primarily focus on standing or sitting balance, which may have limited transfer to walking [2], suggesting a need for developing new dynamic balance training paradigms.

The goal of this study was to examine the neuromuscular responses of humans with SCI when a perturbation force was applied during walking. We hypothesized that a pelvis perturbation force in the mediolateral direction during walking would provide additional challenges to the balance system of humans with SCI and evoke postural reactions to counteract the external perturbation force.

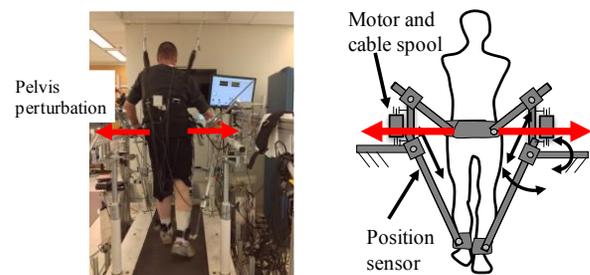

## METHODS

Ten individuals with chronic (> 12 months) motor incomplete SCI (i.e., AIS, C or D) were recruited to participate in this study. All research on human subjects were conducted with authorization of the Northwestern University Medical School Institutional Review Board. Written informed

consents were obtained from all subjects before their participation.

A custom designed cable-driven robotic system was used to apply controlled pelvis perturbation force. The cable-driven system consists of 2 nylon-coated stainless-steel cables (1.6mm), driven by 2 motors (AKM43H, Kollmorgen, Drive amplifier, Servostar 30661) and cable spools, and affixed to a custom waist belt that is strapped to the pelvis.

A controlled lateral force with the magnitude was set at ~9% of body weight, which was adjusted based on the tolerance of each subject, was applied bilaterally to the pelvis while subjects walked on a treadmill. The perturbation force was applied at 3 different phases (i.e., early stance, late stance, early swing phase) with the order of test session was randomized across subjects with 1 minute standing break was inserted between two test sessions. Electromyograms (EMG) from 8 muscles on the weaker leg were recorded using surface electrodes with a sampling frequency at 500 Hz.

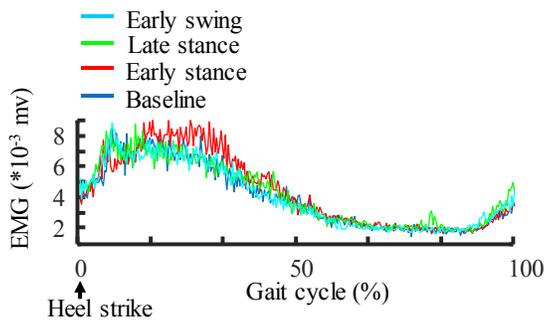

**Figure 1:** This figure illustrates the cable-driven robotic system. A PC was used to control coordinate movement of two motors.

All EMG data were filtered, rectified and smoothed using a second order Butterworth filter with a low-pass cutoff frequency at 20 Hz. The smoothed EMG

signals were averaged over the middle consecutive 10 strides for each condition, and normalized to the peak EMG signal obtained from the maximum walking speed trial. EMG activity was further integrated during stance and swing phase of gait. A repeated measures ANOVA was used to compare the difference with significance was set at  $\alpha < 0.05$ .

## RESULTS AND DISCUSSION

**Figure 2:** The ensemble average traces of the rectified EMG of the hip abductors (ABD) during baseline, with early stance, late stance, and early swing phase pelvis force perturbation. Data shown were average across 10 subjects.

Applying lateral pelvis perturbation force induced enhanced muscle activities of the hip abductors (ABD) and rectus femoris (RF) of the ipsilateral leg during stance phase. Specifically, the integrated muscle activities of ABD significantly increased when lateral pelvis perturbation force was applied ( $p = 0.002$ , ANOVA). Post-doc test indicated that the integrated EMG of ABD significantly increased from  $51.1 \pm 33.1$  at baseline to  $60.0 \pm 36.9$  (normalized) when perturbation force was applied during early stance phase ( $p = 0.002$ ), and increased to  $56.0 \pm 36.1$  when the force was applied during late stance phase, although this was not significant ( $p = 0.11$ ), and slightly increased to  $53.5 \pm 33.0$  when the force was applied during swing ( $p = 0.65$ ). In addition, the integrated muscle activity of RF significantly increased when the perturbation force was applied ( $p = 0.003$ ). Post-doc test indicated that the integrated EMG of RF significantly increased from  $48.0 \pm 30.1$  at baseline to  $57.8 \pm 37.7$  when perturbation force was applied during early stance phase ( $p = 0.06$ ), and increased to  $63.2 \pm 40.7$  when the force was applied during late stance phase ( $p = 0.002$ ), and slightly increased to  $53.9 \pm 37.1$  when the force was applied during swing phase ( $p = 0.41$ ).

Applying lateral pelvis perturbation force during walking may induce enhanced muscle activities of ABD and RF, suggesting subjects may increase muscle activation of hip ABD and RF to counteract the pelvis perturbation force and stabilize the standing leg during walking. Further, we observed a greater increase in muscle activities of hip ABD during early stance phase than that during late stance phase. A possible reason may be because the direction of perturbation force is consistent with the lateral movement of the pelvis when the force was applied during early stance phase. Thus, the perturbation force may facilitate pelvis movement to the lateral direction, which may force subject to generate additional torque to counteract the perturbation force. In contrast, when the perturbation force was applied during late stance phase, the direction of perturbation force is opposite to the movement of the pelvis. Thus, the effect of perturbation force on the hip ABD was damped. In addition, we observed no significant changes in muscle activity of hip ABD when the perturbation force was applied during early swing phase of the ipsilateral leg, probably due to subjects were primarily relying on the contralateral leg (i.e., the standing leg) to stabilize the pelvis for this case.

## CONCLUSIONS

Applying a lateral pelvis perturbation force may provide additional challenges to the mediolateral balance control in humans with SCI during walking. Repeated exposure to pelvis perturbation training may improve motor control of hip abductors, which may facilitate improvements in lateral balance of humans with SCI during locomotion.

## INTRODUCTION

People with traumatic and non-traumatic spinal cord injuries (SCIs) make up 20% of the 1.5 million manual wheelchair (MWC) users in the U.S., with 12,000 traumatic SCIs occurring every year [1]. Shoulder pain is the most common musculoskeletal pain site in MWC users [2] and can significantly limit function and quality of life, with an incidence ranging from 31 to 73% [3]. It is often caused by rotator cuff tears and tendinopathies resulting from shoulder impingement [4]. Overuse, particularly during overhead and weight bearing movements, is thought to be a major causal factor [5]. However, little is known regarding MWC users' cumulative exposure of the shoulder joints to activities of daily living (ADLs) which pose impingement risk.

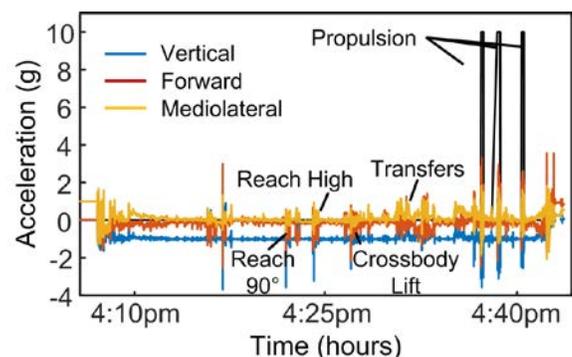

To better understand the link between MWC use and shoulder impingement, it is important to objectively classify the type and quantify the frequency of ADLs performed in MWC users' everyday life. Previous studies have used multiple accelerometers or a single body-worn accelerometer in combination with a gyroscope-based wheel rotation monitor to identify wheelchair propulsion from other activities mostly unrelated to shoulder overuse [6]. An ADL classification method using fewer monitors would be less cumbersome and including more ADLs related to shoulder overuse could provide additional information in regards to estimating shoulder impingement risk.

This study's aim is to develop and validate an algorithm in a semi-controlled laboratory setting with the potential to accurately detect and classify shoulder overuse activity and identify wheelchair propulsion from non-propulsion activity in MWC users in their natural environment.

## METHODS

Two 25 year old male MWC users with SCIs have been recruited for this study to date. Inclusion criteria include use of a MWC as the primary mobility mode for at least one year, C6 and below traumatic or non-traumatic SCI, and active shoulder range of motion within limits needed for the tasks performed during the study. The study protocol was approved by the Mayo Clinic IRB and written informed consent was obtained before participation.

The subjects performed multiple trials of MWC-related activities of daily living including (1) reaching for an object with 90° of shoulder elevation, (2) reaching for an object overhead, (3) cross-body lifting of backpack between the ground and a table, (4) wheelchair transfers, (5) wheelchair propulsion on a ramp (15 propulsion cycles), and (6) wheelchair propulsion on level ground for a two minute duration (Fig. 1).

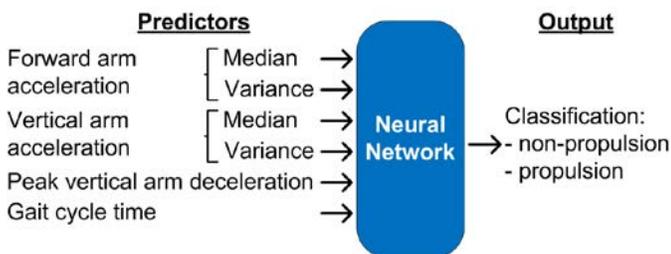

**Figure 1:** Raw tri-axial upper arm acceleration data for one subject during the lab-based protocol.

Continuous tri-axial acceleration data were collected at 128 Hz from one Opal IMU (APDM Inc, Portland, OR, USA) secured to the left upper arm with a strap. Continuous video data were

simultaneously acquired at 60 Hz.

Activity was detected from the acceleration data and peak detection was performed on all identified activity segments using our activity and adaptive threshold peak detection algorithms previously developed for activity and step detection in able-bodied subjects [7] in MATLAB (Mathworks, USA). Active time in seconds and propulsion peaks were validated by comparison to video recordings. Activity cycles were then identified as the acceleration time series data between consecutively detected peaks within identified activity segments. For each activity cycle, six features were extracted for use as predictors (Fig. 2). These resulting six predictors were then fed into a neural network designed using the single layer perceptron architecture. After splitting the data into class-stratified training and test sets, a grid search was conducted over tunable network parameters and model performance was evaluated via five-fold cross validation. The top performing model had a weight decay of 0.1 and 19 nodes in the hidden layer.

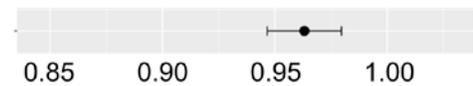

**Figure 2:** Pattern classification algorithm.

## RESULTS AND DISCUSSION

The accuracy of detected active seconds during propulsion and non-propulsion activities was 100% and 93% for subject 1 and 100% and 86% for subject 2, respectively. Propulsion peaks were detected with 100% accuracy with no false positives or negatives detected. The out-of-sample cross validation performance yielded an area under the receiver operator curve (AUC) of 0.97 for differentiating between propulsion and non-propulsion activity (Fig. 3), while its holdout set AUC was 0.95. The model's sensitivity, specificity and accuracy, when using a classification threshold

of 50%, were 0.96, 0.95 and 0.95, respectively, similar to or greater than previous studies [6].

**Figure 3:** Area under the curve estimation for differentiating between propulsion and non-propulsion activity using five-fold cross-validation.

The algorithm is being further developed and validated to discriminate between the other investigated activities based on their distinct acceleration patterns and in combination with IMU-derived shoulder kinematics. Future work will determine the frequency with which MWC users perform the specific ADLs in their free-living environments and combine this exposure data with the relative impingement risk of ADLs to determine a measure of cumulative impingement risk of MWC-associated ADLs.

## CONCLUSIONS

The high AUC obtained with cross-validation suggests that our feature extracting algorithm may be able to accurately identify and differentiate between propulsion and non-propulsion activity of MWC users in their free-living environments using one IMU worn on the upper arm, which remains to be confirmed with additional subjects currently being recruited.

## INTRODUCTION

Manual wheelchair users often participate less in physical activities (PAs) than able-bodied individuals [1], which increases cardiovascular disease risk and incidence of secondary medical conditions. New wheelchair designs and enhanced self-awareness of activity level could help manual wheelchair users increase their PA levels and to have a healthier life style. Previous research has indicated that using geared wheels, a novel technology for manual wheelchair users, may enhance individuals' function and participation due to significant reductions in biomechanical demands [2,3] and shoulder pain [4]. However, the impact of geared wheels on metabolic demands during manual wheelchair mobility has yet to be investigated.

The objectives of this study are to compare metabolic demands during standard and geared manual wheelchair mobility and to identify the contributing factors impacting energy expenditure during manual wheelchair propulsion. Using a repeated measures design, the following hypotheses were tested:

- Manual wheelchair mobility energy expenditure increases with the use of geared wheels in comparison to standard wheels
- Wrist acceleration and heart rate during manual wheelchair propulsion are significant factors contributing to the variability of energy expenditure

## METHODS

Three able-bodied individuals (males, age: 21 years, height:  $180 \pm 6$  cm, weight:  $89 \pm 15$  kg) were recruited for this study. This study was approved by the University of Wisconsin-Milwaukee (UWM)

Institutional Review Board (IRB). On the first day, anthropometric and demographic information were collected at the UWM Physical Activity and Health Research Lab and resting metabolic rate (RMR) was measured following an overnight fast. Respiratory exchange measurements were determined by an indirect calorimeter (ParvoMedics 2400 TrueOne, Sandy UT) using a flow-through canopy hood [5].

PA assessment was completed at the UWM Mobility Lab on the second day. Participants were asked to propel both standard (direct drive) and geared (gear ratio 1:1.5) manual wheelchairs on a passive wheelchair ergometer instrumented with a speedometer for seven minutes at two different speeds (1.5 and 2 mph). Participants used a Breezy manual wheelchair (Sunrise Medical LLC.) equipped with geared wheels (IntelliWheels, Inc., Champaign, IL). Seven minutes of rest separated each activity. Oxygen consumption was measured using the COSMED *K4b<sup>2</sup>* portable gas analysis system (COSMED, Rome, Italy) during manual wheelchair propulsion. The COSMED *K4b<sup>2</sup>* software was used to establish summary estimates of energy expenditure, including oxygen uptake [ml/min], and energy expenditure [kcal/min]. PA energy expenditure (PAEE) was calculated as the difference between the energy expenditure measured during PA testing and the resting energy expenditure (calculated from RMR). Participants wore accelerometers (ActiGraph GT3x, ActiGraph LLC, Fort Walton Beach, FL) over the posterior dorsal aspect of their wrists. Heart rate was also recorded throughout testing using a heart rate monitor (Polar, Polar Electro Inc., Lake Success, NY, USA) secured around the chest. Stroke cycle frequency during the tasks was calculated based on the sagittal plane kinematics of the third metacarpal marker, using a

3D Vicon T-series motion capture system (Vicon Motion Systems, Oxford, UK).

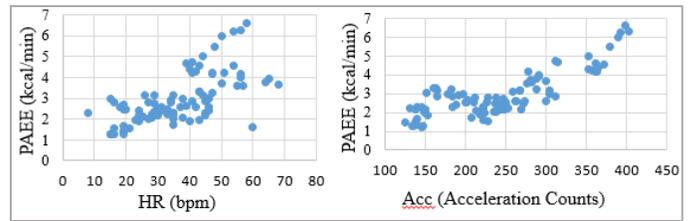

Steady-state or near-steady-state (<15% coefficient of variation) energy expenditure data were obtained by averaging breath-by-breath measures across 30-second periods [6] to derive oxygen consumption values for 3-7 mins. Oxygen consumption measured from each participant was divided by their measured RMR value to compute subject specific metabolic equivalent tasks (METs) [5]. Statistical analyses were conducted using IBM SPSS software; analysis included paired samples t-test ( $p = 0.05$  significance level) and multiple linear regression analysis.

## RESULTS AND DISCUSSION

The results indicated that METs increased during geared wheel compared to the standard wheel (direct drive) condition, see Table 1. METs increased by 15% ( $p = 0.001$ ) during the geared wheel condition and 1.5 mph speed. Dominant wrist acceleration and relative heart rate (recorded heart rate minus resting heart rate) were significantly correlated with PAEE by Spearman ranks of 0.74 and 0.66, respectively (Figure 1). Using dominant wrist acceleration (Acc) and relative heart rate (HR) as predictors in a multi-regression model explained 78% of the variability in PAEE ( $PAEE = 0.012 \text{ Acc} + 0.23 \text{ HR} - 0.66$ ). The addition of relative heart rate to a wrist acceleration only model significantly improved model performance ( $p < 0.01$ ). The notable increase in the stroke frequency during geared wheel condition (Table 1) could be the main reason for the observed increase in METs and energy expenditure.

## CONCLUSIONS

Using the proposed method, the difference in energy expenditure during use of geared wheels and direct

**Figure 1:** Relative Heart rate with PAEE (left) and wrist acceleration with PAEE (right) scatter plots.

drive wheels was detected successfully. Further investigation is underway with a larger population of manual wheelchair users with spinal cord injury. Development of activity specific models for predicting energy expenditure with acceleration and heart rate as primary predictors and wheel type as a covariate at various speeds is warranted. Mixed models with random intercept or slopes will be investigated. The outcomes from this study may ultimately improve manual wheelchair prescription and long-term transitional care for individuals with spinal cord injury.

### INTRODUCTION

Despite the importance of lower extremity power absorption during gait [1,2], deficits in power absorption and associated eccentric motor control after incomplete spinal cord injury (iSCI) have yet to be characterized in humans. An animal model of iSCI, found that aberrant, prolonged semitendinosus (ST) burst activity occurred predominantly during eccentric phase of gait known as weight acceptance (WA) [3]. Specifically, the length of eccentric contraction in ST during WA correlated to recovery level, as measured in open field walking, with shorter ST bursts in WA correlating to better open field walking function ( $r^2=0.9697$ ;  $p<0.05$ ). The purpose of the current study was to provide the first translation of these animal model results to human health and provide a preliminary evaluation of ST eccentric activity in WA among individuals with iSCI. We hypothesized that individuals with incomplete spinal cord injury (iSCI) would show more eccentric ST activity in WA than healthy controls walking at speed-matched or self-selected pace.

### METHODS

Research was reviewed and approved by The Ohio State University's Institutional Review Board for Biomedical Human Subjects Research. Data from three individuals with iSCI who used a walker as an assistive aid and three individuals with no neurologic impairment are presented (see Table 1 for matching characteristics). Individuals with iSCI had previously participated in locomotor training within a physical therapy clinic, but had been discharged from that training at least 6 month prior to participation in the current study.

Individuals with iSCI were asked to walk at their comfortable walking speed using the assistive aids each individual typically used in their community. Healthy controls were asked to walk at their self-selected, or freely chosen, pace (SS) and at their slowest possible pace (SLOW). Bilateral joint power and muscle activity data were collected during walking and reduced using Visual 3D software as follows. Kinematic data were collected (Vicon) at 200Hz using a point cluster technique (PCT) marker set of 47 lower extremity markers tracked during dynamic trials plus 8 markers placed on anatomic landmarks during an initial static trial then filtered (Butterworth, low pass 8 Hz). Ground reaction forces (GRFs) were acquired at 2000 Hz from a series of 6 force platforms (Bertec) mounted flush with the surrounding floor and filtered (critically damped low pass filter, 10Hz). Muscle activity was recorded at 2000 Hz from the semitendinosus bilaterally then reduced in custom software written in Matlab (Butterworth low pass 6 Hz). We defined a muscle as "on" within dynamics trials if activity exceeded the resting activity mean plus 2 standard deviations. All data were interpolated to 1000 points per stride. Interpolated EMG data were converted to root-mean-square (RMS) of the signal (50 sample window; 10 sample overlap) and normalized to the max RMS value per trial.

We defined the weight acceptance phase as starting at foot contact with the force platform and ending at the first peak in the vertical GRF. Hip and knee joint power information was used to determine if ST was acting concentrically, eccentrically, or isometrically while on. To characterize the amount of ST eccentric activity during the WA phase we

calculated the negative “work” done by the ST by integrating the area under the muscle activity curve [4] while the muscle was acting eccentrically and refer to this as ST eccentric contribution to WA. To characterize the duration of eccentric activity in WA we calculated how long ST was acting eccentrically as a percent of the phase duration.

When comparing motor control between pathologic and non-pathologic there is precedent for matching self-selected walking conditions [4] as well as for speed-matching [5,6]. Because there is a compelling argument for each approach, matching by comfort vs matching by speed, we compared iSCI free walking, which was typically slow ( $0.291 \pm 0.133$  m/s), to healthy controls walking at two different speeds: their slowest possible speed ( $0.258 \pm 0.133$  m/s; no metronome used) and their SS speed ( $1.410 \pm 0.137$ ). To evaluate differences in ST behavior between these conditions, Student’s t-tests (2 tailed; heterogeneity assumed; performed in Microsoft Excel) were used to compare variables of interest between each healthy control walking speed condition and SCI free walking.

**RESULTS AND DISCUSSION**

Individuals with iSCI demonstrated more ST eccentric contribution during WA (mean  $-0.251 \pm 0.145$ ) than did healthy controls walking at slow ( $-0.069 \pm -0.020$ ;  $p = 0.0263$ ) or SS pace ( $0.0 \pm 0.0$ ;  $p = 0.008$ ). In addition, eccentric activation lasted longer among iSCI participants ( $29 \pm 13\%$  of WA) than among healthy controls walking at slow ( $9 \pm$

$2\%$  of WA;  $p = 0.011$ ) or SS pace ( $0 \pm 0\%$  of WA;  $p = 0.026$ ).

**CONCLUSIONS**

ST eccentric activity is aberrant (prolonged) during WA among individuals with iSCI. Because ST activity in WA has been found to play a role in central pattern generator signaling [see 3 for review], refinement of ST eccentric activity during WA might represent a promising clinical target. Future work will evaluate the effectiveness of interventions targeted to improve ST eccentric activity during WA.

## INTRODUCTION

Preservation of shoulder function is important for manual wheelchair (WC) users with spinal cord injury (SCI). Manual WC propulsion is an effective form of low-cost wheeled mobility as it preserves upper body strength, cardiovascular conditioning, and community participation. Clinicians and researchers have suggested that the repetitive mechanical loading of the shoulder during propulsion may be a factor contributing to the high prevalence of shoulder pain among the SCI population. Current experimental research and clinical guidelines promote improved interaction between the individual and the WC as a means to mitigate detrimental mechanical loading of the shoulders[1]. The mechanical demand imposed on the shoulder (net joint moment (NJM)) is affected by orientation of the resultant reaction force (RF) relative to the forearm[2,3]. Model simulation results indicate a 2-fold increase in RF magnitude can result in minimal changes in shoulder NJM magnitude without decrements in performance if the orientation of the RF relative to the upper extremity segments is modified[2]. The aim of this study was to determine if individuals using manual WCs use the same propulsion technique over time, and if not, what aspects of their technique were regulated and were there observed differences in technique between individuals that did and did not develop shoulder pain over 18 months.

## METHODS

One hundred sixteen experienced manual WC users with paraplegia ( $9 \pm 6$  yrs post SCI, 103 Males, 13 Females) from the Rancho Los Amigos National Rehabilitation Center outpatient clinics volunteered in accordance with the Institutional Review Board. Individuals were excluded from participation if they

reported a history of shoulder pain at entry into the study. Participants were classified as having developed shoulder pain over the longitudinal study if their score on the Wheelchair User's Shoulder Pain Index increased by  $\geq 10$  in the three year follow-up period (48 developed shoulder pain, 68 remained pain-free). Upper extremity kinematics (VICON, 100Hz) and pushrim RF (SmartWheel, 200Hz) were collected during manual WC propulsion on a stationary ergometer at self-selected fast condition at entry into the study (Baseline) and 18 months later (Follow Up). Upper extremity joint kinetics were calculated using custom MATLAB code. Within-subject comparisons were done using a modified step-down Fisher-type method to test for statistical significance.

**Figure 1:** RF impulse ( $RF_{imp}$ ) is parsed into intervals based on RF orientation relative to forearm: RF orientated posterior to forearm ( $RF_{post}$ ), inline ( $\pm 5$  deg) with forearm ( $RF_{inline}$ ), anterior to forearm but posterior to shoulder ( $RF_{ant}$ ), and anterior to shoulder ( $RF_{antSh}$ )

Mechanical demand on the shoulder was quantified as the integral of the shoulder NJM ( $NJM_{imp}$ ) during

contact with the handrim. Factors influencing the shoulder  $NJM_{imp}$  also analyzed included  $RF_{imp}$ ,  $RF_{imp}$  parsed by intervals based on RF orientation relative to the forearm (Fig. 1) and contact duration. The shoulder NJM depends on the proximal distal moments created by the Net Joint Forces about the center of mass (CM) of the forearm and upper arm segments as well as the adjacent joint NJM at the elbow. When the RF is oriented anterior to the forearm CM but posterior to the shoulder joint, an elbow extensor NJM is needed to achieve the observed motion and contributes to a smaller required shoulder NJM because the elbow NJM is in the same direction as the shoulder NJM. In contrast, when the RF is oriented posterior to the forearm CM or anterior to the shoulder, a larger shoulder NJM is required to achieve the observed motion because elbow NJM is opposite the direction of shoulder NJM. When the RF is inline with the forearm CM, the affects of the elbow NJM on shoulder NJM are minimized because elbow NJM is at its smallest magnitudes. Modifying more  $RF_{imp}$  to be generated during  $RF_{inline}$  and  $RF_{ant}$ , while keeping total  $RF_{imp}$  the same would reduce shoulder  $NJM_{imp}$ .

## RESULTS AND DISCUSSION

The results indicate manual WC users modify their propulsion technique over time. Specifically, 46/48 of the individuals developing pain and 60/68 individuals remaining pain-free altered some aspect of shoulder  $NJM_{imp}$ ,  $RF_{imp}$ , RF orientation relative to the forearm, or contact duration. Nineteen subjects among the pain-free group showed reductions in shoulder  $NJM_{imp}$  and on average reductions were 40% ( $\pm 20\%$ ) of their  $NJM_{imp}$  during the Baseline collection. Eight subjects among the pain group showed reductions in shoulder  $NJM_{imp}$  and similarly reductions were 43% ( $\pm 13\%$ ) of their  $NJM_{imp}$  during the Baseline collection. RF orientation,  $RF_{imp}$ , and contact

duration were manipulated in both directions by subjects in both pain-free and pain groups( Table 1). Only 27 subjects out of the total population of 116 made technique modifications contributing to reductions in  $NJM_{imp}$ . Strategies chosen to reduce  $NJM_{imp}$  among those 27 subjects were varied and involved combinations of one or more modifications in the features analyzed. The most common technique adjustment to accomplish the reduction in  $NJM_{imp}$  among the population was to reduce  $RF_{imp}$  (19/27). Ten subjects decreased contact duration and five re-oriented RF. These results indicate modifications in RF orientation relative to the forearm,  $RF_{imp}$ , and contact duration were technique modifications implemented by individuals that remained pain-free or developed pain over 18 months. These results indicate that individuals with and without pain can modulate these attributes known to contribute to the mechanical demand imposed on the shoulder during manual WC propulsion at self-selected fast speeds.

## CONCLUSIONS

Knowledge of how experienced manual WC users adapt their propulsion technique over time provides an important step in identifying effective and feasible propulsion strategies for mitigating mechanical demand imposed on the shoulder and preserving shoulder function.

## INTRODUCTION

Adult degenerative scoliosis (ADS) is associated with progressive and asymmetric degeneration of the disc and facet joints, which typically lead to stenosis.[1] By virtue of the narrowed spinal canal associated with the degeneration these patients frequently develop back pain, as well as leg pain, weakness, and numbness.[2] Patients with degenerative adult scoliosis demonstrate an altered gait pattern.[3] For many patients with ADS a walking aid is beneficial to offset the increased energy expenditure, reduce muscle effort and assist with balance. Walkers are frequently prescribed in an effort to improve balance, mobility, and reduce lower back pain, but a review of the literature reveals conflicting evidence regarding their effectiveness.[4] Clinical experience has shown the use of walking sticks rather than a walker promotes a more upright posture. The walking sticks are beneficial pre-operatively not only in terms of deformity progression and line of sight, but also for patients postoperatively to help maintain surgical correction of their kyphotic deformities. The purpose of this study was to evaluate the impact of different assistive devices on the neuromuscular control of the trunk and lower extremities during gait in preoperative ADS patients.

## METHODS

Eighteen subjects (Age:  $67.3 \pm 7.2$ , H:  $1.65 \pm 0.07$  m, W:  $78.8 \pm 21.7$  kg, 10 females) with symptomatic degenerative scoliosis (VAS low back:  $6.09 \pm 2.36$ , VAS leg:  $5.62 \pm 3.29$ ) who have been deemed appropriate surgical candidates performed gait analysis under 3 testing conditions; 1. with walking sticks, 2. with walker, and 3. without any walking device a week before the surgery. Ag/AgCl surface EMG electrodes were bilaterally placed on the following muscles: external oblique (EO), Multifidi (MF) at level of L5, Erector Spinae (ES) at level of L1, Rectus Femoris (RF), Semitendinosus (ST), Gluteus Maximus (GM), Tibialis Anterior (TA), and Medial Gastrocnemius (MG). EMG data were

recorded using a Delsys® system (2000 Hz) along with locations of 51 markers using 10 camera Vicon® (100 Hz) as the patient walked barefoot at his/her self-selected speed along a 10m walkway for 5 acceptable trials. RMS EMG was scaled to the peak value of the BASE RMS EMG. A repeated measurement ANOVA ( $p < 0.05$ ) design for peak RMS, onset times, Time to Peak and onset durations was used to compare the walking conditions. Post hoc pairwise t-tests with Bonferroni corrections were used if group main effects were found.

Figure 1. Gait with walking sticks and with walker in adult degenerative scoliosis patients

## RESULTS AND DISCUSSION

Only significant main effect for groups for peak RMS activation was observed for left MH but pairwise comparisons displayed no differences. (Table 1). Significant group effects for onset times were observed for left and right EO, MF, ES, left MH (no pairwise differences) and left and right GA and TA with earliest activation in walking sticks, followed by walkers and then unassisted gait (Table 1). Walking sticks group had the smallest onset time (earliest activation in the gait cycle) compared to walkers or no device. This suggests early core muscles activation need with walking sticks to potentially help in stabilizing the pelvis as the lower limbs advance during the gait cycle. Significant group effects for time to peak were observed for right EO and MF, right and left RF and left MH, and right GA and TA (Table

1). Time to peak was highest for walking sticks compared to gait unassisted or with walkers. Pairwise differences were mainly observed between walking sticks and unassisted but not with other comparisons except for left RF and MH. Lastly, significant group effects for onset durations were only observed for right RF and, left GA and right TA (Table 1). Pairwise comparisons for all three of the above comparisons showed shortest onset durations with walking sticks followed by unassisted and then walkers.

Overall, minimal to no differences in peak RMS magnitudes were observed between the three test conditions during the gait cycles but some differences were observed for the temporal variables of activation. Classifying these muscle groups based on their location and actions, explains their purpose during the gait cycle and how it changes with different gait conditions. Based on early onset of activation and greater time to peak for trunk muscles, it is suggested that during locomotion with walking sticks, core muscles are working to stabilize the pelvic motion early in the gait cycle potentially for postural control and limiting non essential trunk movements but this activation is not sustained. Walkers provide a longer and sustained core muscle activation, which could possibly be caused by the forward trunk lean posture assumed with walkers. At the hip and knee joints, quadriceps were active early in the gait cycle with both walkers and walking sticks very similar to unassisted walking. The group differences observed were of relatively very small magnitudes. At the ankle joint, both GA and TA were active for similar durations and peaked about the same time in walking sticks, with largest differences observed between

walking sticks and walkers. This suggests individuals co-activated these muscles throughout the gait cycle but no differences in peak magnitudes were observed between assistive devices.

## CONCLUSIONS

Results suggest that walking sticks can potentially promote trunk and lower extremity gait mechanics and thus neuromuscular control comparable to that of gait without any assistive device. With preoperative walking stick training, surgical correction of deformity, and postoperative use of walking sticks, improvement in both sagittal parameters and kinematics as compared to a walker can be expected. Although the differences in magnitudes between comparisons was small and should be cautiously interpreted on a case-by-case basis, we anecdotally recommend the use of walking sticks to assist with ambulation in symptomatic adult degenerative scoliosis patients. Further studies are in progress to fully understand the effect of assistive devices in facilitating and promoting normal neuromuscular control during ambulation in ADS patients.

## INTRODUCTION

The palm and hand of Lofstrand crutch users can experience up to 50% body weight along with hyperextension of the wrist during swing-through gait [1]. Such repetitive, large loads and extreme wrist posture may lead to wrist strain and the development of carpal tunnel syndrome [2]. To address these issues, we previously developed a passive orthosis that attached to the crutch and reduces wrist extension and redistributed palmar loads away from the carpal tunnel region to the adductor pollicis area (Fig. 1a) [3]. However, all loading still passed through the palm.

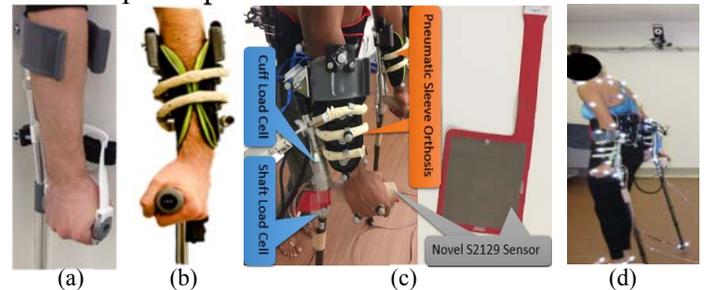

Thus, we designed a second version with an active pneumatic sleeve orthosis attached to the crutch cuff that was made to transfer loads from the palm to the forearm (Fig. 1b) [4]. The sleeve orthosis is composed of a coiled soft pneumatic Fiber Reinforced Elastomeric Enclosure (FREE) actuator [5] constrained at both ends by hinged splints attached to the crutch cuff. Once pressurized with air to 206.84 kPa (30 psig), the FREE contracts in the longitudinal direction and expands in the radial direction, providing a constriction pressure supporting the forearm while holding the wrist in a more neutral position. As a consequence of the constriction pressure on the forearm, movement of the forearm tendons and ligaments are restricted and has the added benefit of potentially reducing wrist extension.

This paper describes biomechanical testing to evaluate the effectiveness of the pneumatic sleeve orthosis on healthy adults performing swing-through gait. We hypothesize that the pneumatic sleeve orthosis transfers load from the handle to the crutch cuff, reduces and redistributes palm pressure, and reduces wrist extension.

## METHODS

### Subjects

Eleven able-bodied subjects (5M; 18-32 yrs; average height 171.6 cm; average weight 67.4 kg) were evaluated. The study was approved by the Institutional Review Boards at the University of Wisconsin – Milwaukee (UWM) conducted at the Mobility Lab at UWM and consent was obtained from all participants.

**Figure 1:** (a) Passive Orthosis, (b) Pneumatic Sleeve Orthosis, (c) Testing equipment, (d) A subject in the test

### Data Collection

Kinematics, crutch forces, palmar and forearm pressure data were collected during the tests. Kinematic data were collected at 120 Hz using a 15-camera motion capture system (T-series, Vicon, Oxford, UK) and custom upper extremity marker set (Fig. 1d) [6]. A pair of custom instrumented Lofstrand crutches with three-axis embedded load cells located below the cuff and handle bilaterally were used to collect crutch forces at 960 Hz (Fig. 1c) [7]. Palmar pressure on the dominant side was measured at 60 Hz with a 16 × 16 flexible matrix array (S2129, 1cm × 1cm unit cell, Novel Inc., Germany) wrapped around the grip using established method (Fig. 1c) [3]. Four low-pressure sensors (S2011, 1 cm diameter, Novel Inc.) were spaced around the inside of the sleeve to collect sleeve constriction pressure.

### Experimental Protocol

Each participant was given 15-30 minutes to acclimate to the swing-through gait pattern. Participants were asked to perform swing-through gait over a 6m-long walkway at a self-selected

speed for two testing conditions: with and without the pneumatic orthosis (randomized order). Five trials were collected for each condition with at least one minute of rest time between trials.

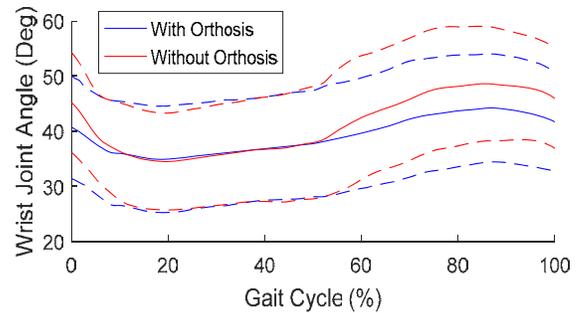

#### Data processing

Kinematic data were post-processed using Vicon Nexus and MATLAB software. Wrist flexion/extension angle was computed and averaged over five gait cycles with and without the orthosis for each subject. Mean peak wrist extension and wrist flexion/extension range of motion (ROM) were reported for each subject. Peak crutch cuff and shaft forces (normalized by body weight) on the dominant side were calculated in MATLAB. Palmar and sleeve pressure data were analyzed using Novel Pliance and MATLAB. Due to presentation of asymmetric swing through gait, the data for two subjects were not included in this analysis. Parameters analyzed were peak wrist extension angle, flexion/extension ROM, peak palmar pressure, and peak cuff and shaft forces. A repeated measures MANOVA was run to assess the effect of orthosis use (SPSS v23). Follow-up univariate ANOVAs were examined for significant parameters. Significance level was set at  $\alpha = 0.05$ .

### RESULTS AND DISCUSSION

The MANOVA test ( $p=0.004$ ) and follow-up univariate ANOVAs identified significant effects of the pneumatic orthosis use during swing-through gait of healthy participants (Table 1). Kinematic results indicated a significant reduction in peak wrist extension angle (-7.84%,  $p=0.005$ ) and wrist flexion/extension ROM (-35.50%,  $p=0.001$ ) when using the orthosis. The mean wrist extension angle was lower during the body swing phase of the gait cycle (Fig. 2). Normalized peak cuff force was significantly higher with orthosis use ( $p<0.001$ ), while there was no significant difference in forces recorded in the shaft ( $p=0.7$ ). These results indicated a transfer of forces to the crutch cuff of 10.3% instead of the majority of the load going through the handle. The normalized peak palm pressure was also reduced significantly with

orthosis use by 7.5% ( $p=0.023$ ). Mean pressures in the sleeve remained under 3.79 kPa (28.46 mm Hg) while using the orthosis. (Sustained constriction pressures above 4.67 kPa (35 mm Hg) can cause blood flow restriction [8])

**Figure 2:** Mean wrist joint angles in the sagittal plane (extension (+)). Group mean profile (solid line) and  $\pm 1SD$ (dotted line), 0% and 100% gait cycle is defined as heel strike.

### CONCLUSIONS

We have shown the effectiveness of the pneumatic sleeve orthosis in transferring loads from the Lofstrand crutch handle to the crutch cuff, significantly reducing wrist extension angle and decreasing peak palmar pressure. This promising device may ultimately decrease the risk of wrist strain and carpal tunnel syndrome for long-term Lofstrand crutch users.

## INTRODUCTION

Peripheral artery disease (PAD) is a common manifestation of atherosclerosis affecting the blood flow to the legs. The most common presentation of PAD is intermittent claudication; a condition in which when the patient walks the metabolic demands of the lower limbs exceed the limited supply of blood, causing ischemia, and exercise-induced discomfort and decreased walking ability [1]. Walking exercise is the first line of treatment in patients with claudication with the best results achieved in patients undergoing supervised exercise therapy for at least three months. Supervised walking exercise results in increased maximum walking distances comparable to those seen following surgical revascularization, despite the fact that blockages remain [2]. With this study we tested the hypothesis that supervised exercise training of PAD patients with claudication improves walking distances in association with improved gait biomechanics.

## METHODS

Forty-seven patients (age:  $69.2 \pm 7.0$ ; height (m):  $1.75 \pm 0.7$ ; mass (kg):  $89.4 \pm 18.7$ ) were seen at the Omaha Veteran Affairs Medical Center vascular clinic and evaluated by one of two vascular surgeons. Patients had no history of previous revascularization and were absent of all musculoskeletal and neurological symptoms that could limit gait in addition to PAD. Informed consent was obtained from all subjects prior to starting the twenty-four week (three sessions per week), supervised walking exercise therapy. Therapy protocol was designed following recommendations by the American College of

Sports Medicine and in concordance with previous studies that best produced increases in walking distances [3]. Each session included a 5 minute warm-up, 50 minutes of intermittent exercise on a treadmill, and 5 minutes of cool down activities.

All patients underwent gait analysis before and immediately following exercise therapy. First patients performed the Gardner Max Walk Test [4]; a progressive, graded treadmill protocol at 0.89 m/s that begins at 0% grade, and increases by 2% every two minutes. Initial claudication distance was recorded as the first indication of claudication pain from the patient. The total distance patients were able to walk before stopping because of pain was recorded as maximum claudication distance.

After sufficient rest, each participant was instructed to walk over a 10-meter pathway at a self-selected pace to commence the overground trials where marker trajectories (Motion Analysis Corp, Santa Rosa, CA) and ground reaction forces (kinetics; 600 Hz; AMTI force platforms) were recorded. Each patient was tested before (pain free) and after (pain) the onset of claudication pain. After completing the pain free condition, symptomatic claudication pain was induced by completing the six minute walk test [3]. All patients at baseline experienced a "moderate to severe level of pain" in the leg used for analysis. Immediately after, patients returned to the walkway to perform the walking trials for the pain condition. Five walking trials were collected from each leg of the participants in both conditions.

Joint kinetics and kinematics were calculated for the sagittal plane during the stance phase of walking. Ground reaction forces and joint angles, torques, and powers for the ankle, knee and hip were

analyzed using MATLAB (Mathworks, Inc., Natick, MA) and Visual 3D (Germantown, MD, USA). A paired t-test evaluated walking distances and a two-factor, intervention (pre/post) and condition (pain free/pain), repeated measures ANOVA evaluated gait dependent variables ( $p < 0.05$ ).

## RESULTS AND DISCUSSION

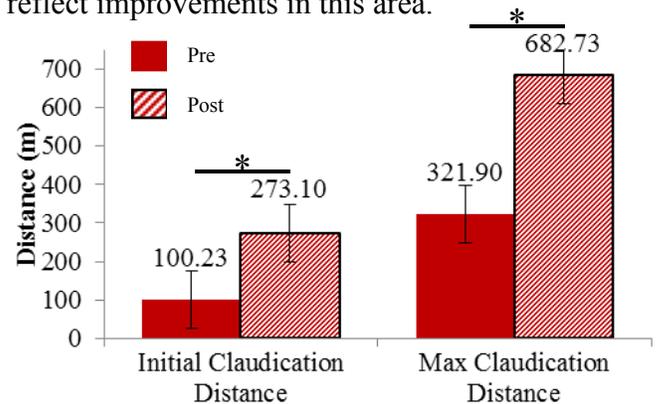

Our hypothesis was partially supported. Both walking distances (Figure 1) and several, but not all, gait biomechanics variables significantly improved following supervised walking exercise therapy.

Gait, Intervention Factor. In the weight acceptance phase of stance, a main effect was found for hip extensor torque and peak lateral ground reaction force. In the single-limb support phase of stance, a main effect was found for ankle power absorption. In the propulsion phase of stance, main effects were found for ankle and hip power generation (Table 1), and peak propulsive ground reaction force. The mean values improved from pre to post intervention, becoming more similar to normative data for healthy controls, for all main effects [4].

Gait, Condition Factor. In the weight acceptance phase of stance, a main effect was found for ankle, knee, and hip joint angles as well as ankle torque, braking impulse, and the peak lateral ground reaction force. In single-limb support phase of stance, a main effect was found for ankle power absorption. In the propulsion phase of stance, main effects were found for ankle angle, torque, and power generation, knee power absorption, peak ground reaction propulsive force and push-off vertical force. In all main effects, mean values worsened in the pain condition compared to pain free in both sessions.

Weakness in the posterior compartment muscles of the calf is a consistent and key factor underlying the gait adaptations patients with PAD experience at

baseline [4]. Improvements in ankle power during single support and the propulsion phase of gait before and after the onset of claudication pain reflect improvements in this area.

**Figure 1.** Walking distances before (pre) and after (post) the exercise intervention therapy.

## CONCLUSIONS

Six months (72 sessions) of supervised exercise therapy produces significant increases in the treadmill walking distances of patients with claudication. These increases are associated with concurrent improvements in gait biomechanics at the level of the ankle and the hip. Exercise therapy produces strengthening of the gluteus and the foot flexor muscles and this strengthening appears to be the main mechanism producing the improvements of the walking ability of patients with claudication.

# DESIGN OF A COMPACT AND PORTABLE HAND REHABILITATION DEVICE FOR STROKE-SURVIVORS

<sup>1</sup> Namita Anil Kumar and <sup>1</sup> Pilwon Hur

<sup>1</sup> Texas A&M University, College Station, TX, USA  
email: namita.anilkumar@tamu.edu, pilwonhur@tamu.edu

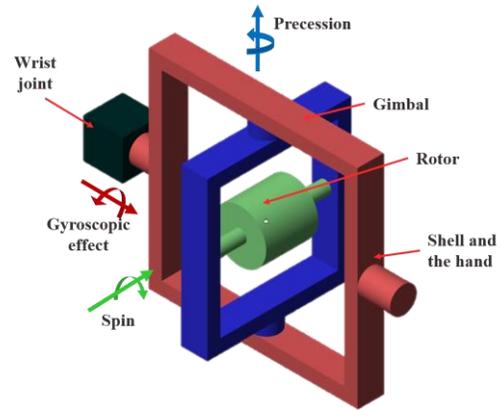

## INTRODUCTION

About 795,000 people experience strokes in the US, annually [1], with many suffering from the hand disabilities post stroke. The effects of such disabilities include weakened grip strength, lack of muscle coordination, and hand spasticity [2]. Although commercially available products like Saeboglove, Musicglove and Exo-Glove enable in-home hand rehabilitation, they have limitations that considerably prevent their broader usage: (i) they focus on specific hand functions, (ii) they require a considerable active range of motion to operate, and (iii) they are inapt for patients with hand spasticity [2]. Hence, a new compact and portable Hand Rehabilitation Device (HRD) is proposed that would rehabilitate the hand in a holistic manner. The HRD (US Patent Application: 62/413,130) is a fully actuated rotor-gimbal assembly, which when actuated imposes a gyroscopic torque on the user's hand. Unlike the current products, the developed gyroscopic torque does not demand the user's input.

## METHODS

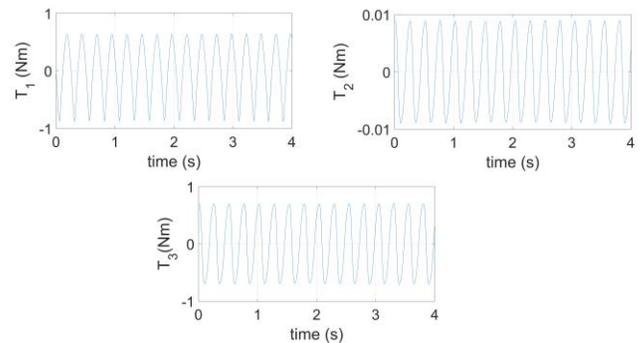

Based on a customer needs analysis and a competitive benchmarking, it was gathered that a device that imposes a torque on the hand would aid in rehabilitation. There are two kinds of therapies that can be implemented with such a device: one involving synchronization of the hand movement with the generated torque and another requiring the user to resist the torque. While the former relaxes the hand muscles and combats hand spasticity [2], the latter increases hand muscle strength and coordination [4]. It was decided that the HRD should produce a minimum 0.7Nm gyroscopic torque (the amount required to open a jar's lid – an activity performed during physical therapy) [5]. The mass of the device was limited to approximately 550g (mass of a commonly carried half-liter water bottle) so that

the device does not strain the user's hand. Portability is another desired feature so that users can undergo rehabilitation anywhere and at any time.

**Figure 1:** A schematic of the device

Consider Fig. 1 where red, blue and green components represent the user's hand, gimbal and the rotor, respectively. When the rotor spins about its axis and the rotor-gimbal assembly precess about the gimbal's axis, a gyroscopic torque is generated and acts on the user's hand. To understand the working principle, a proof-of-concept (POC) model and mathematical simulations were created.

**Figure 2:** Theoretical torques achievable by the device for the specifications provided in Table 1.  $T_1$  is the torque about wrist flexion and extension,  $T_2$  is the torque about radial and ulnar deviations, and  $T_3$

is the torque about pronation and supination of the wrist.

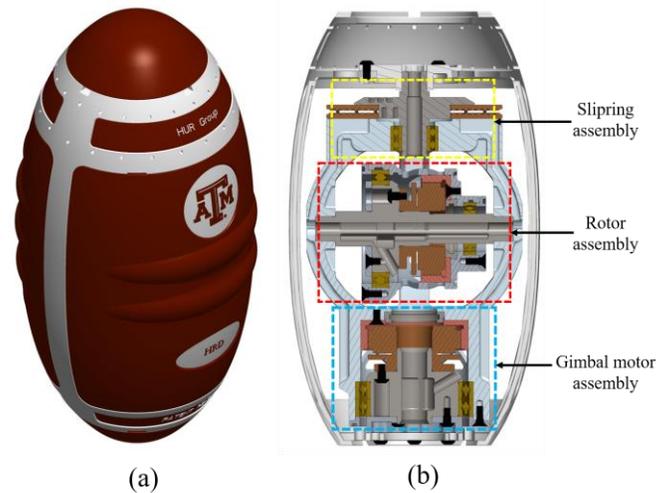

The POC consisted of a fully actuated rotor-gimbal assembly was constructed. It was observed that the hand was forced to move about the wrist in a circular manner when no restriction was posed against the torque. Additionally, imposed hand motion can be manipulated by varying the motion of the rotor-gimbal assembly. Further the mathematical simulations revealed that for given parameters of the device, such as inertia and mass, a torque of magnitude 0.8Nm was attainable. These simulations were used to select the design parameters of the device.

## RESULTS AND CONCLUSION

The greatest challenge of the design process involved lessening the weight and size of the device. Owing to the size requirements of the embedded subsystems, the desired spherical shape could not be acquired and thus an oblong shape had to be adopted. The final product was designed to resemble an American football, so that it would appeal to the user and prospectively add a fun element to the rehab process. To make the device portable, the electronics were initially conceived to be embedded in the device. Since this idea conflicted with the need for compactness and lightness, the electrical systems are placed external to the device in a satchel that the users can wear. While the wires to the gimbal's motor are easily drawn through a hole in the bottom end cap, the wires for the rotor assembly are mechanically coupled to the motor's leads via a slip ring assembly. This enables the free precession of the rotor assembly without any entanglement of wires. To ensure symmetry in the design and to avoid rotary imbalances, the rotor and the gimbal housings were directly integrated with the permanent magnet rotor of the chosen brushless DC motors.

Currently, a dynamic analysis of the design is being carried out to determine the output torques, which will be followed by a biomechanical analysis to i) attest the safety of the device and ii) examine muscle activation patterns due to the output torque. Upon fabrication, the device's performance will be evaluated by investigating the relation between the muscle activation patterns and the hand functional

recovery of stroke survivors. Fugl-Meyer hand function will be evaluated.

**Figure 3:** (a) Isometric view of the device (b) Cross-sectional view of the device with major subsystems highlighted.

Given the novelty of the device, more efficient and affordable hand rehabilitation for stroke patients is expected. In addition, the application of the device can be extended to other patients with hand function problems including patients with arthritis, Carpal Tunnel Syndrome, and those recovering from hand injuries/surgeries.

# EFFECTS OF PUSH-UP PLUS VARIANTS ON UPPER EXTREMITY MUSCLE DEMANDS

<sup>1</sup>Alan C. Cudlip, <sup>1</sup>Andrew J. Ho, and <sup>1</sup>Clark R. Dickerson

<sup>1</sup>Department of Kinesiology, University of Waterloo, Waterloo, ON, Canada  
email: accudlip@gmail.com, web: <http://ahs.uwaterloo.ca/kin/research/diesel/index.html>

## INTRODUCTION

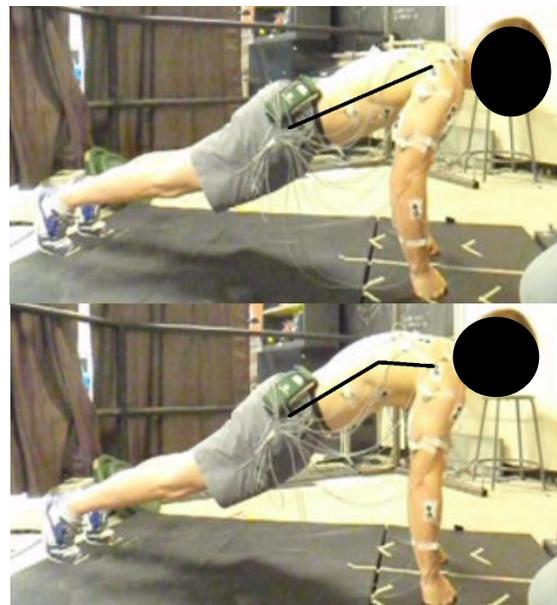

The push-up plus requires virtually no equipment and be performed almost anywhere, making it a staple exercise in fitness and rehabilitation programs. The push-up plus (PUP) variation adds active scapular protraction to the end range of a regular pushup to emphasize serratus anterior activation, a muscle active in preventing scapular “winging” [1]. Alterations to the PUP technique can help to meet specific exercise goals, but is used to increase serratus activation in rehabilitation studies. Other alterations of the standard pushup include changes in hand location or internal/external hand rotation, but little is known on how modifications affect upper extremity activation levels. Effective quantification of the effect of altering hand and arm setups during push-up plus on muscle activation levels (particularly in the serratus) would provide clinicians with insight for exercise prescription, particularly in cases of scapular dyskinesis. The purpose of this study was to examine the upper extremity when manipulating hand position, arm position and contact area during the PUP exercise.

**Figure 1.** Participants completed PUP exertions in combinations of hand contact area (knuckles or palms), arm rotation (neutral, internal or external rotation) and arm location (shoulder height, superior or inferior).

## METHODS

Twenty university-aged males ( $23.1 \pm 2.4$  years,  $1.75 \pm 0.09$  m,  $77.7 \pm 13.1$  kg) completed 18 PUP trials with 3 factors: contact area (knuckles/palms), arm rotation (neutral/ $60^\circ$  internal rotation/ $60^\circ$  external rotation) and hand location (shoulder height/ $\pm 30\%$  arm length superior/inferior) (Figure 1).

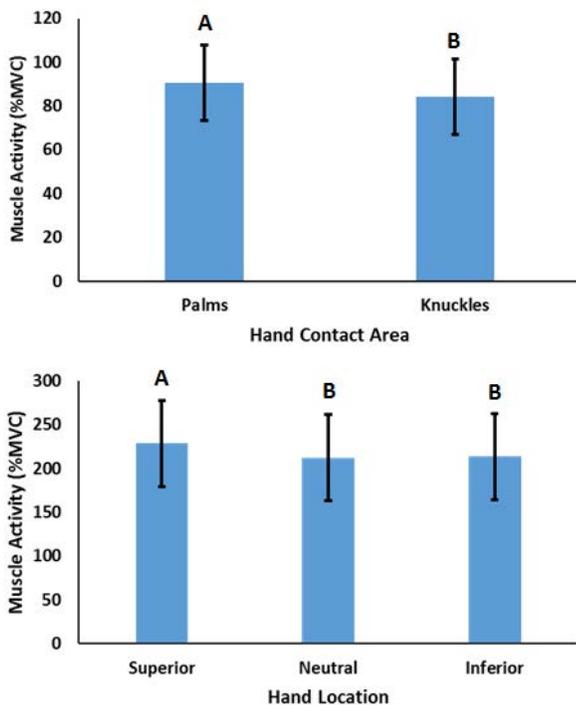

**Figure 2.** Participants completed a standard pushup (top), then moved into the PUP extension (bottom), designed to elicit serratus activity. The black line indicates changes in body posture from increased scapular protraction during the PUP.

All trials were completed on a gym mat, and used a fixed cadence for two repetitions per trial, totaling 18 trials (Figure 2). Surface electromyography was collected from 14 sites overlying muscles of the right arm and shoulder at 1500Hz (Noraxon Telemetry 2400 T G2), linear enveloped and normalized to muscle specific maximal outputs. Cadence was fixed for each trial, with 4s per rep: 1s eccentric loading, 1s concentric pushing up, 1s to push upward to the PUP extension, 1s to return to neutral. Mean and peak values were extracted for each muscle, and a 3-

way ANOVA (2 contact areas \* 3 arm rotations \* 3 hand locations) including interactions was used to determine effects of PUP variants on normalized EMG.

## RESULTS AND DISCUSSION

Hand\*Location interactions occurred in mean activity for 6 of 14 muscles ( $p=0.0001-0.0228$ ), with inferior arm positions and palms contact generally eliciting greater activation. This interaction resulted in increases of up to 20 %MVC in mean infraspinatus activity (from 23% to 43%MVC) and a 33%MVC in peak triceps activation from 37% to 70%MVC. Hand\*Rotation interactions were present in the biceps, triceps, and forearm muscles ( $p=0.0001-0.0449$ ), with knuckles increasing mean and peak activation, and external rotation increasing biceps activation, while the opposite increased triceps activation. A main effect of hand location existed in 85% of mean or peak EMG tests ( $p=0.0001-0.0155$ ), with inferior hand positions increasing activation and superior positions decreasing activations compared neutral, with some exceptions. These changes were as high as 18 %MVC increased from superior to

**Figure 3.** Few statistical significant effects existed for serratus, with main effects of hand contact area ( $p=0.0033$ ) and hand location ( $p<0.0001$ ) altering mean and peak activation, respectively; significant differences denoted by letters.

inferior hand positions in infraspinatus, and 34 %MVC increases in lower trapezius.

Serratus activation did vary across most scenarios, with only main effects of hand contact area in mean activity ( $p=0.0033$ ) and arm location in peak activity ( $p<0.0001$ ) (Figure 3). Serratus mean activity increased using palm contact surfaces, and peak activity increased in superior hand positions, but both of these increases were less than 10% increases in activation compared to standard postures. Hand rotation did not increase serratus activation, contrary to previous findings [2]. If the goal is to increase serratus activation in the PUP, altering location or contact surface beyond the standard position appears to provide only marginal benefits.

Altering hand location was the most common and largest influence on mean or peak muscular activity, modulating activity in every muscle except the wrist extensors. Moving the hand to an inferior position increased activation. Smaller elevation angles in the flexion plane decrease available moment arms for some muscles of the upper extremity [3], including the middle deltoid and pectoralis major, prime movers during the push-up. While significant differences exist between these positions for most muscles, some differences in activation may be unobserved using our current methods. Examining only mean and peak muscle activation across all phases of the lift may have washed out some phasic differences. Our future work will examine potential phasic differences on muscular activation, as well as examination of activation ratios between synergistic muscle pairs.

## CONCLUSIONS

Clinicians commonly prescribe the PUP to increase serratus activation, but little evidence exists to support potential benefits from moving beyond the standard pushup position to modify this activation. However, there were many activation increases in other muscles, warranting consideration for rehabilitation of other muscles beyond serratus.

# ANALYSIS OF RESORATIVE PREDICTORS OF GLENOHUMERAL CAPSULE PPLICATION

<sup>1</sup>Andrew Kraszewski, <sup>1</sup>Andreas Kontaxis, <sup>2</sup>Stephanie Mayer, <sup>1</sup>Russell Warren

Hospital for Special Surgery, New York, NY; Children's Hospital Colorado, Aurora, CO  
email: kraszewskia@hss.edu, web: [https://www.hss.edu/research-staff\\_kraszewski-andrew.asp](https://www.hss.edu/research-staff_kraszewski-andrew.asp)

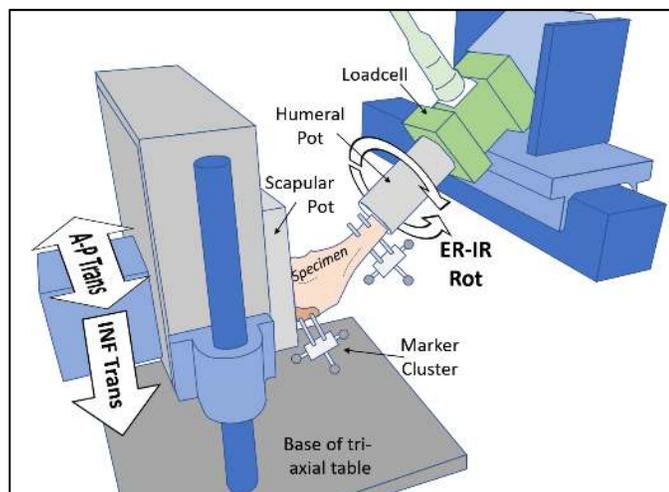

## INTRODUCTION

Glenohumeral capsule plication aims to restore the mechanical properties of the tissue to a pre-pathologic state. There is a lack of biomechanical data to guide surgical technique. Clinicians assess shoulder laxity and diagnose pathology using manual load-response (laxity) testing. The predictive accuracy of laxity tests is not well understood.

**Objectives were to: 1) estimate the magnitude of restorative plication, and 2) find laxity predictors of restoration in terms of direction and elevation.**

## METHODS

*Specimen Preparation & Testing.* Fourteen fresh frozen cadavers were CT-scanned, and then dissected down to the capsule. Marker clusters were rigidly attached and anatomic landmarks calibrated with 3D motion capture (0.2mm average residual). Each specimen was potted in rigid fixtures then attached to a glenohumeral laxity device (Figure 1).

**Figure 1:** Illustration of capsular laxity testing device. The specimen (center) was inverted.

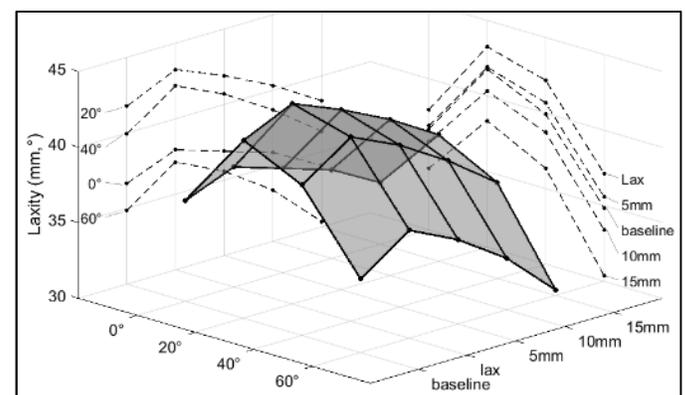

Translational laxity in anterior, posterior and inferior directions was measured at 10lbs applied force. Rotational laxity in external and internal axial

directions was measured at 2.0Nm applied moment. Laxity was tested across five physical levels (baseline, lax, and 5mm, 10mm, 15mm plication) and four positions (0°, 20°, 40°, 60° scaption).

*Data Analysis & Prediction.* Laxity values were offset to the baseline. The Lax level was set equal 0mm. Simple linear regressions (SLRs) were run with the x-intercept calculated as  $-\beta_0/\beta_1$ , to represent restorative plication magnitude (Figure 2).

The scalar plication independent variables were converted to ordinal categorical dependent variables. An ordinal multinomial logistic regression was run for every unique combination of physical and position level, totaling  $\sum_{i=1}^{20} \binom{20}{i} = 1,048,575$  models. Model performance criteria were AIC, classification (C1%), and a custom criterion  $C_p = -AIC + C1\%$ , where AIC is the Akaike Information Criterion and C1% is the classification percentage of the nearest physical level (Lax, 5mm, 10mm, or 15mm) to the average restorative magnitude.

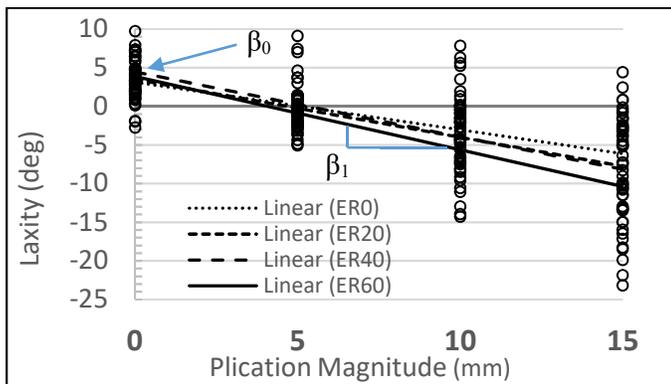

## RESULTS AND DISCUSSION

**Figure 2:** Glenohumeral laxity (vertical = direction-averaged laxity) across physical level and position.

The laxity response was complex and varied with physical level and position (Figure 2). Based on these values SLR x-intercepts were calculated for 20 tests (Figure 3, Table 1). Of them, 15 had significant slope

parameters – none were anterior tests. 10 had significant y-intercepts and slopes, the majority being rotational laxity tests. For these the average restorative plication magnitude was  $6.2 \pm 2.5$ mm.

**Figure 3:** External rotation SLR per position. The horizontal axis is plication magnitude (Lax = 0mm).

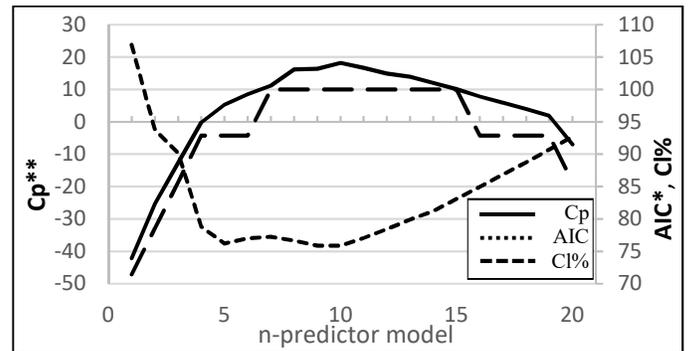

**Table 1:** SLR results: All laxity tests with significant  $\beta_1$  (2nd). X-intercepts for significant  $\beta_1$  (4<sup>th</sup> col) and significant  $\beta_0$  and  $\beta_1$  (5<sup>th</sup> col).

Laxity Test	$\beta_0$ p-value	$\beta_1$ p-value	x-inter. $\beta_1$	x-inter. $\beta_0$ & $\beta_1$
POST <sub>0</sub>	.104	.003	5.0	
POST <sub>20</sub>	.253	<.001	2.6	
POST <sub>40</sub>	.296	.001	2.8	
POST <sub>60</sub>	.044	<.001	3.8	3.8
INF <sub>20</sub>	.068	.001	4.7	
INF <sub>40</sub>	.021	<.001	4.3	4.3
INF <sub>60</sub>	.085	<.001	3.4	
ER <sub>0</sub>	.044	<.001	5.1	5.1
ER <sub>20</sub>	.002	<.001	4.7	4.7

IR <sub>20</sub>	<.001	<.001	8.1	8.1
IR <sub>40</sub>	<.001	<.001	9.4	9.4
IR <sub>60</sub>	<.001	<.001	11.0	11.0
<b>AVG (SD)</b>			<b>5.4 (2.4)</b>	<b>6.2 (2.5)</b>

The average restorative magnitude was closest to the 5mm level, and this classification percentage (CI%) was calculated with the other performance metrics (Figure 4). The best Cp model had 10 predictors where the best AIC model had 5 predictors, and the best CI% model had 7 predictors.

The best model per criterion are shown in Table 2. Common tests among models were ANT<sub>20</sub> and IR<sub>40</sub>. Best Cp had similar classification to AIC but double

the predictor count. A 7-predictor model achieved 100% classification of the 5mm category.

**Figure 4:** Criterion performance metrics. \*Smaller AIC is better. \*\*AIC, CI% lines do not sum to Cp.

**Table 2:** Best model per criterion, showing # of predictors, 5mm classification and laxity predictors.

Model	# Pred	5mm %	Laxity Model Predictors
Cp	10	<b>75.9</b>	ANT <sub>20</sub> , INF <sub>40</sub> , INF <sub>60</sub> , ER <sub>0</sub> , ER <sub>20</sub> , ER <sub>60</sub> , IR <sub>0</sub> , IR <sub>20</sub> , IR <sub>40</sub> , IR <sub>60</sub>
AIC	5	<b>78.6</b>	ANT <sub>20</sub> , POST <sub>40</sub> , INF <sub>60</sub> , ER <sub>20</sub> , IR <sub>40</sub>

## CONCLUSIONS

We have presented experimental shoulder laxity data and an analysis to estimate restorative capsule plication magnitude. The 5-predictor AIC model was parsimonious, but costly in classification compared to the accurate 7-test model. Clinical metrics, e.g. Grade, were not collected, but recent work suggests a moderate relationship between objective laxity and Grade.[1]

A customizable framework was offered to assess accuracy of clinical shoulder tests. Our work stresses the importance of combining translational and rotational tests to refine prediction. Future work will validate with more clinical metrics and outcomes.

# MINIMUM DETECTABLE CHANGE VALUES FOR UPPER LIMB KINEMATICS IN HEALTHY ADULTS

Susannah M. Engdahl and Deanna H. Gates

University of Michigan, Ann Arbor, MI, USA

email: sengdahl@umich.edu web: <http://rehab-biomech-lab.kines.umich.edu/>

## INTRODUCTION

When evaluating upper limb performance, it is important to choose tasks that challenge the limits of a patient's ability [1]. For example, the tasks should require use of the distal joints if distal joint deficits are expected. However, it can be difficult to decide which tasks are most relevant for an evaluation since the kinematic redundancy of the upper limb makes it possible to accomplish any task using a variety of movement patterns. In order to select appropriate tasks, it is helpful to understand which joints are most important for accomplishing the task and how reliably movements made with those joints can be measured.

A useful metric for quantifying expected variation in a movement is the minimum detectable change (MDC), or the smallest change in a measurement that is above the level of error [2]. Large MDCs may indicate high levels of natural variability in a movement (or high levels of measurement error), suggesting that task might be inappropriate for use in an evaluation. Therefore, the purpose of this work was to quantify MDCs for upper limb kinematic measurements during activities of daily living (ADLs). The ADLs used in this study were specifically selected for their suggested relevance to functionality in individuals with stroke and upper limb loss.

## METHODS

Nineteen healthy, right-handed adults (mean age = 22 +/- 4 yrs; 9 male) participated in this study. Participants completed two identical experimental sessions, at least one day apart. During each session, participants performed six ADLs with the right arm: 1) apply deodorant to the contralateral axilla (DEO), 2) turn a doorknob (DOOR), 3) answer a desk telephone (PHONE), 4) place a pushpin in a bulletin

board (PIN), 5) wipe a plate with a towel (PLATE), and 6) pour a glass of water from a pitcher (WATER). Each ADL was repeated ten times at a comfortable pace.

Twenty-four reflective markers were placed on the arms and trunk to track the movements of seven body segments using a 19 camera motion capture system. Marker position data were filtered using a fourth-order low-pass Butterworth filter with a 6-Hz cutoff frequency. Joint angles for the trunk, shoulders, elbows, and wrists were computed using rotations defined by ISB [3] and time-normalized to 100% of task completion.

For each joint, the specific peak angles necessary to perform each ADL were determined. Within- and between-session MDCs for the peak angles were calculated according to  $MDC_{95} = SEM * 1.96 * \sqrt{2}$ , where 1.96 corresponds to a 95% confidence interval and SEM (standard error of measurement) is the square root of the mean square error term from the two-way ANOVA [4]. Within-session MDCs were calculated using the 10 individual repetitions from the first session. Between-session MDCs were calculated using averages of the 10 repetitions from each session.

## RESULTS AND DISCUSSION

There was considerable variability in the MDCs (range: 0.7° - 24.6°) depending on the ADL and joint angle (**Fig. 1**). The average within-session MDC was 7.4° (trunk: 3.6°, shoulder: 8.0°, elbow: 8.7°, wrist: 9.6°). In general, between-session MDCs were slightly higher than within-session MDCs. The average between-session MDC was 10.6° (trunk: 3.4°, shoulder: 13.0°, elbow: 12.9°, wrist: 13.3°). This trend is likely due to the fact that there are more potential sources of variation when measurements are made during multiple sessions compared to a

single session. Specifically, small differences in the experimental set-up and marker placement between sessions may lead to higher between-session MDCs.

There is no universally accepted standard for interpreting MDC magnitude. Instead, MDCs should be considered in context of the specific joint and ADL for which they were quantified. This is especially true given the smaller magnitude of trunk and wrist angles compared to shoulder and elbow angles. Consequently, the trunk and wrist MDCs tended to represent a larger percentage of the average peak angles than the shoulder and elbow angles. For example, the within-session MDCs for the wrist and trunk respectively represented 55% and 64% of the average peak angles, while the shoulder and elbow MDCs represented only 14% and 21%.

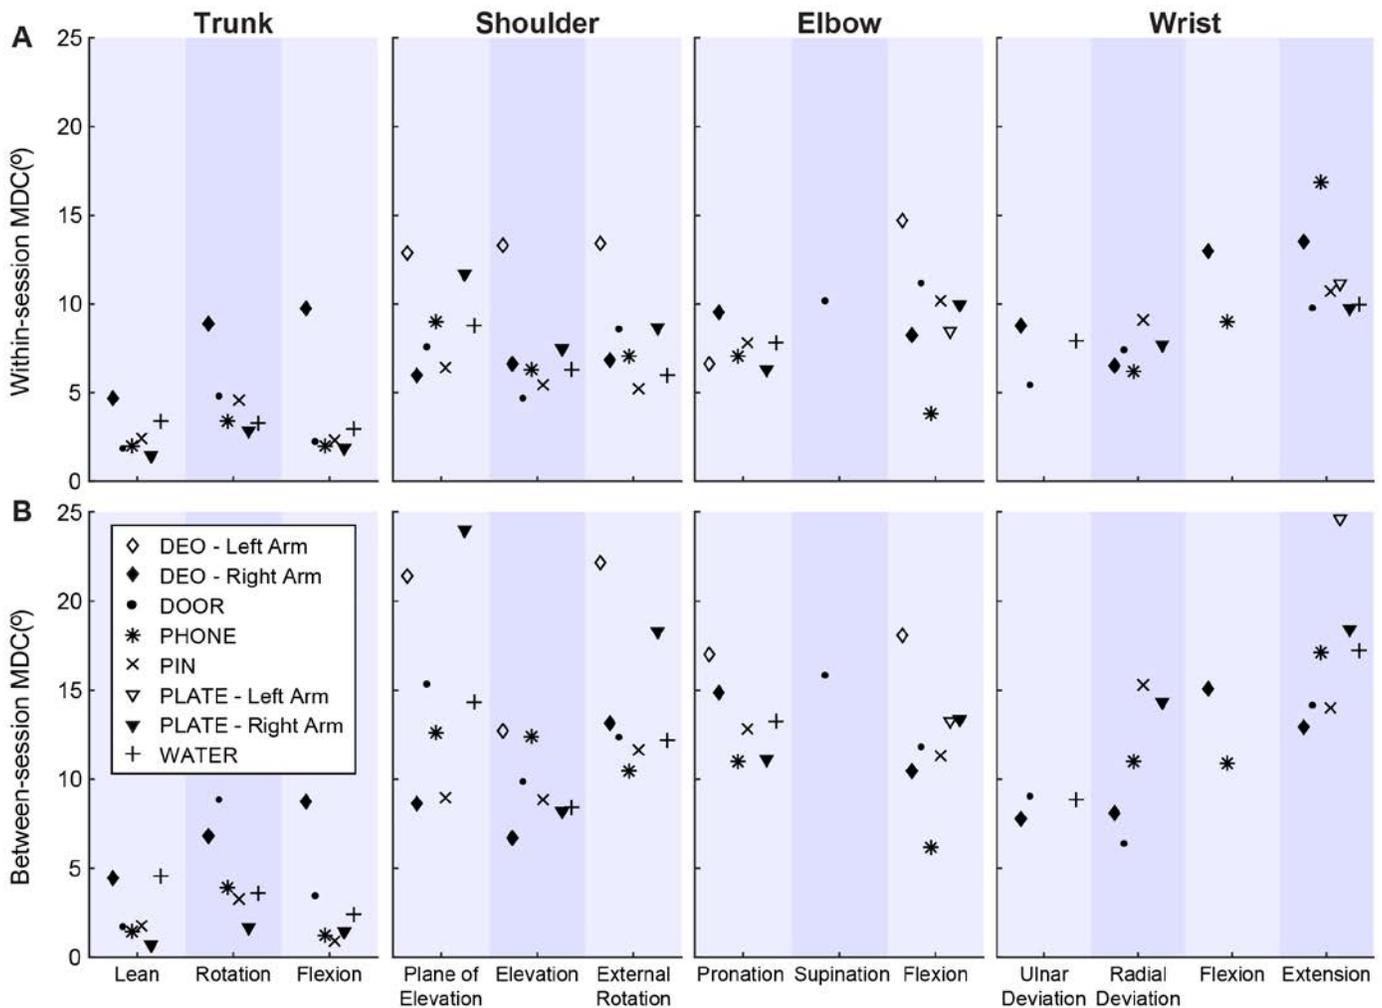

These results demonstrate the importance of selecting ADLs for assessing upper limb

performance based on which joint angles are important to the assessment. For example, PHONE had low MDCs for elbow flexion but high MDCs for wrist extension. PHONE might be a good choice if elbow flexion is important, but not if wrist extension is important. Another ADL (such as DOOR) would be more appropriate for assessing wrist extension.

Although this work focused on healthy adults, the results will eventually be used to help choose tasks for evaluating patient performance. Future work will also quantify MDCs for a broader range of ADLs.

## INTRODUCTION

Musculoskeletal models are commonly used in biomechanics research and allow for the evaluation of physical phenomena that cannot be measured or are difficult to measure directly, such as muscle forces. The utility of these models relies on the accuracy with which they were developed.

In musculoskeletal shoulder models, kinematics of the scapula relative to the thorax are commonly described using regression models. Regression models have defined equations that can predict the orientation of the scapula based on humerothoracic motion [1-3] and have been built into commonly used musculoskeletal models [4].

The existing scapular regression models were developed using the movement of non-pathological individuals during elevation in multiple planes with or without varying degrees of axial rotation [1-3]. These have been subsequently applied to model a wide range of activities including manual wheelchair (MWC) propulsion [5-6]. It is possible that different types of activities, such as propulsion, and/or individuals with neuromuscular impairments will utilize different rhythms between the scapula and humerus. Therefore, a regression model based on elevation data in able-bodied individuals may not be the best option for modeling MWC propulsion. *The purpose of this study was to develop a propulsion-specific shoulder regression model that predicts scapulothoracic motion from humerothoracic motion in individuals with spinal cord injury and to compare the accuracy of the output to a previously published regression model.*

## METHODS

Data from two IRB-approved studies that included a kinematic evaluation of MWC propulsion were compiled to create the data set for developing the

regression models. All participants had spinal cord injury (SCI) or spinal cord disease that led to at least one year of MWC use. Additional information about the primary studies has been published elsewhere [7-8].

Participants propelled in their personal MWC on a custom set of stationary rollers at a self-selected speed. Data were captured at either 120 or 240 Hz with electromagnetic sensors (Liberty, Polhemus) placed on the thorax at the sternum, scapula at the acromion, and humerus via thermoplastic cuff. The thorax, scapula, and humerus segment coordinate systems were defined according to ISB standards [9]. Motion was quantified with Euler sequences: humerothoracic (HT, YX'Y'') and scapulothoracic (ST, YX'Z''). Data captured at 240 Hz were down-sampled to 120 Hz.

The three HT rotations (plane of elevation [Y], elevation [X'], axial rotation [Y'']) were used as input variables for predicting ST motion via multivariable regression. A regression model was developed for each ST rotation (internal/external rotation [Y], upward/downward rotation [X'], anterior/posterior tilt [Z'']) during both the push and recovery phases of propulsion (6 regression models total). All frames of data during each phase of propulsion were utilized. Due to strong correlations between the HT input variables, these predictors were transformed using principal components analysis. Five parameters were estimated for each regression analysis (3 linear terms, 1 quadratic, and an interaction.) After estimating the regression parameters, the coefficients for the principal components were transformed to coefficients for the original predictors to define the regression model equations. Lastly, previously published shoulder regression models [3] were applied to the data set.

## RESULTS AND DISCUSSION

A total of 31 individuals (25 male, 42±11 years old, 16.0±9.6 years of MWC use) were included in the data analysis. SCI levels ranged from C6/7 to L2.

Individual regression models were defined for each of the ST rotations in both push and recovery utilizing individual HT variables, squared factors, and interaction factors. (Table 1). Each participant contributed an average of 520 data points (range 353 to 700).

The root mean square error (RMSE) of the six regression models ranged from 7.3 to 10.0° (Table 2). The mean square errors (MSE) of the regression models developed in this study were found to be roughly equivalent to, if not smaller than, the errors produced by an established shoulder regression model [3] when predicting ST motion (Table 2).

## CONCLUSIONS

The regression models presented here demonstrate similar levels of accuracy in predicting ST motion during propulsion as other regression models have demonstrated for elevation-based tasks [1-3]; though both the established regression models and this one leave room for improvement. Propulsion-specific regression models may better predict

certain ST motions during propulsion (namely upward/downward rotation and anterior/posterior tilt during the push phase and anterior/posterior tilt during the recovery phase) than a model developed from elevation-based motion. Investigation is ongoing to determine if including participant factors in the regression improves the prediction accuracy.

# A Method for Estimating the Load Distribution in the Anterior Bundle of the Ulnar Collateral Ligament (UCL)

## INTRODUCTION

Ruptures of the medial ulnar collateral ligament (mUCL) of the elbow are a frequent occurrence for athletes who engage in repeated overhand pitching motions. The mUCL experiences distraction as the joint opens with a valgus load, leading to damage that ultimately can lead to complete failure. While the general mechanical behavior of the mUCL is known [1], a greater understanding of the load distribution between the anterior, middle, and posterior bands of the mUCL can help the development of improved repair options. In order to load the UCL in a manner analogous to the opening of the joint with a valgus load, a special fixture and experimental protocol were developed to adapt a biaxial load frame to elbow testing. The fixture had to grip the ulna and humerus with an intact mUCL while a series of displacement-controlled loads were imposed on the specimen at different flexion angles. Repetition of the test protocol after sequential transection of the anterior band then could provide the necessary data to determine the loads borne by each band of the ligament, using the principle of superposition. The working protocol hypothesis was that the anterior band would support more of the overall imposed load than the posterior band at lower flexion angles.

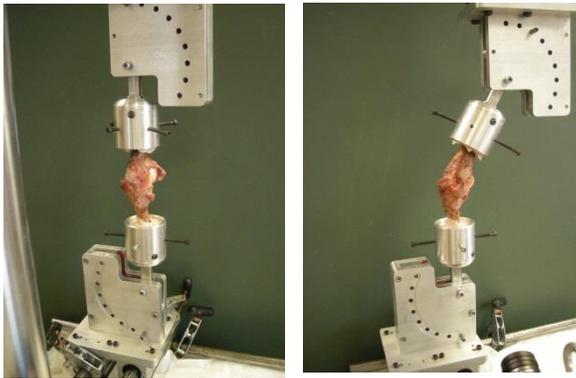

## METHODS

The method for estimating the load carried by the anterior band of the mUCL is made possible by a customized fixture which allows application of load at multiple flexion angles. There are three main aspects of the fixture. The first is the inclusion of elbow flexion angle as an independent variable in the experiment. The fixture allows the flexion of the mounted specimen through a range of angles that vary in increments of fifteen degrees up to a maximum flexion angle of 105°. The second feature of the fixture allows for the displacement-

controlled distraction of the mounted specimen along the long axis of the ulna at different speeds. This action subjects the specimen to loading scenarios that mimic the valgus opening of the joint. The loads needed to achieve the imposed displacements are monitored in the output. The third feature utilizes the loadframe's rotational degree of freedom. This feature enables the carry angle of the mounted specimen to be adjusted as needed in order to maintain proper joint capsule contact and alignment. In that the ulna is aligned along the distraction axis of the loadframe, rotation of the humerus by means of the loadframe's axial rotation accommodates the differences in alignment caused by the carry angle.

An initial experiment to test each of these features was performed on a single cadaveric specimen. The experiment began with the dissection of the specimen and exposure of the mUCL. Tracking markers of 0.8 mm diameter were fixed with small amounts of cyanoacrylic adhesive to the anterior and posterior bands of the anterior bundle of the mUCL. The ulna and humerus of the specimen were then each mounted into aluminum cylinders filled with polyester resin and stabilized with hardener (Fig. 1). The specimen was then positioned into the loadframe (MTS 858 Bionix) to undergo distraction at 0-105° of flexion with 15° flexion angle increments. The anterior band of the mUCL was then transected from the ligament and the test was repeated. Data processing included the construction of force-strain plots fitted to the standard piecewise model for biological tissues [2]. The strain in the posterior band was quantified in both displacement-based ulnar distractions and this posterior band strain was used to align the force-strain plots of the intact and partial ligament. Through the use of the superposition principle, an estimated force-strain profile was constructed for the transected anterior band. The loads in the

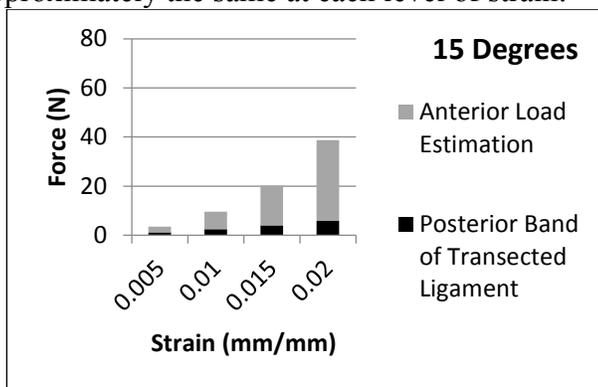

anterior and posterior bands were collated for chosen strain values: 0.5%, 1%, 1.5%, and 2%.

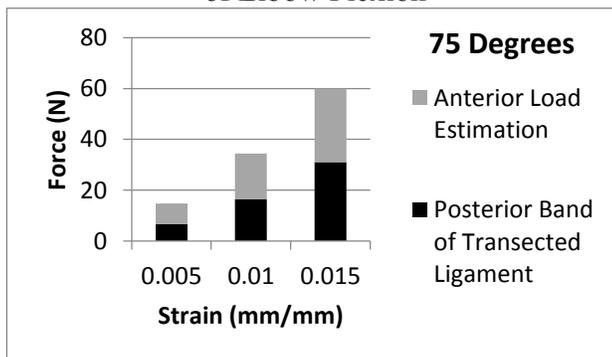

**Figure 1:** Specimen in the Test Fixture

## RESULTS AND DISCUSSION

The load borne by the posterior band increased with flexion angle as evidenced by increases seen between the case of 15° of flexion (Fig. 2) and 75° (Fig. 3) of flexion. The total load in the ligament and the load in the posterior band are the measured values and the anterior band load estimation is the difference. The load in the anterior band remained approximately the same at each level of strain.

**Figure 2:** Anterior Load Estimation for 15 Degrees of Elbow Flexion

**Figure 3:** Anterior Load Estimation for 75 Degrees of Elbow Flexion

The anterior band supported most of the load in the mUCL at 15° of elbow flexion. Similar results were observed for angles up to 60° of flexion. This result agrees with the previous observations by Regan et al. that the anterior band of the mUCL remains taught at angles lower than 85° during valgus loading [1]. It was also noted that as the flexion angle increased, the load for the posterior band of the transected ligament increased in percentage of the total load imposed, consistent with the findings of Lee et al. who showed a positive correlation between posterior band strain and flexion angle, concluding that its contributions toward valgus stability increased with increasing flexion angle [3].

## CONCLUSIONS

The initial results demonstrate that the proposed method for estimating the load carried in the anterior band of the mUCL was effective. The features of the fixture permitted load consistent with ulnar distraction, permitted complete elbow flexion and accommodated difference in elbow orientation caused by the carry angle. Confidence in the method is derived from the initial results which follow a consistent trend and display behavior that is in agreement with the accepted literature.

Future iterations of the experiment will exploit the method more fully in order to investigate the consistency of these results across a larger sample size. The addition of a marker set for the middle band and an added experimental set with removal of this middle band will allow a better estimation of load distribution.

### INTRODUCTION

The wrist joint permits complex motion of the upper extremity that is crucial for both precision and power movements during daily activities; therefore, wrist injuries which result in osteoarthritis (OA) come at a significant socioeconomic cost due to time off work, surgical fees and associated morbidity. Injury to the scapholunate interosseus ligament (SLIL), which connects the scaphoid and lunate bones in the proximal carpal row, is one of the most important and common upper extremity injuries. Accurate diagnosis of the location of SLIL injuries is crucial for providing the most effective treatments so that the location of the tear can be considered in a tailored treatment plan.

Current diagnostic approaches for SLIL injury include magnetic resonance imaging, which lacks the specificity to assess injury location, and wrist arthroscopy, which is invasive and results in an injury grade that is subjective and prone to interobserver variability. We believe that our high spatial and temporal resolution 4D (3D + time) CT technique (4DCT) has the potential to enable accurate quantification of key metrics during wrist motion in patients with SLIL injury, leading to improved clinical practice by replacing invasive and inaccurate diagnostic tests.

### METHODS

Six patients (2 females, 4 males) were recruited as part of an IRB-approved pilot study, demonstrating the novel information obtained from 4DCT. All ten patients had clinical suspicion of unilateral SLIL injury, including tenderness over the scapholunate joint, negative radiographs, equivocal MRI, and no history of wrist injury. They underwent 4DCT imaging on each wrist separately during flexion-

extension, radial-ulnar deviation, and dart thrower's motions. Each wrist was scanned for 2 seconds as the patients moved their wrists using an established non-gated 4DCT technique [1]. Dynamic scans during each of the motions resulted in 18 image volumes across the 2 second trials. Two patients, 53 year old female (Case 1) and 44 year old male (Case 2), underwent diagnostic wrist arthroscopy and the presence of scapholunate instability was confirmed. The first patient (Case 1) had Geissler 3 instability; the second (Case 2) had Geissler 4 [2] findings [3].

4DCT image sequences obtained from the individual cases were further analyzed to map the distance between the scaphoid and lunate during the wrist motions using established image processing techniques [1, 4]. Distance maps are color representations of the distances calculated between the two bone surfaces. These maps provided insight into the magnitude and location of diastasis at the scapholunate joint.

### RESULTS AND DISCUSSION

The distance maps for the radial-ulnar deviation motion in two cases are shown in Figure 1, indicating dorsal diastasis (suggesting dorsal ligament injury alone) (Fig. 1: Case 1) and subtle uniform diastasis (suggesting complete dorsal through volar ligament injury) (Fig. 1: Case 2). Distance maps for four more subjects (who did not have confirmation of injury with arthroscopy) are shown in Figure 2.

The abnormal motion between the scaphoid and lunate can be accurately quantified using the described technology to potentially allow surgeons to more accurately diagnose the location of SLIL injury.

**Figure 1.** (Case 1, LEFT) Sagittal view of the articular surface of the lunate. Color corresponds to interosseous distances at flexion/extension extrema during 4DCT imaging. The injured side (bottom row) exhibits considerable dorsal diastasis during extension, suggesting dorsal ligament disruption. (Case 2, RIGHT) The injured side (bottom row) exhibits uniform, though moderate diastasis. Red indicates the scaphoid and lunate are closer together (ligaments are intact) and blue demonstrates the carpal bones are separated after a ligament injury Note: patient right-side lunate mirrored for comparison purposes.

**Figure 2.** Sagittal view of the articular surface of the lunate for four additional patients. Color corresponds to interosseous distances at flexion/extension extrema during 4DCT imaging. The injured side (bottom row) exhibits variable amounts of gapping across subjects, likely indicating different ligament injury locations.

# SYNERGISTIC SHOULDER MUSCLE ACTIVATION DURING ARM ELEVATION IN DIFFERENT BODY POSITIONS

## INTRODUCTION

In non-pathological shoulder complex function, the humerus and scapula move in a predictable pattern identified as “normal scapulohumeral rhythm”, viewed on the scapular plane as the relative motion between the scapulothoracic and glenohumeral joints [1]. This rhythm is largely dependent on the activation pattern of the muscles that move and stabilize the shoulder complex. The activation of these muscles seems to increase with increased humeral elevation [2] and was shown to operate in synergistic activation patterns which are affected by pathology and level of impairment [3].

Gravitational compensation affects the amplitude of the shoulder kinematics and muscle activity during reaching tasks [4]. The direction of external force and gravity relative to the shoulder complex was also found to affect the normal glenohumeral joint mechanics [5] and was shown to predict scapular motion [6]. In this study we attempt to quantify the synergistic activation between each of the three parts of the deltoid (anterior, middle and posterior; AD, MD and PD, respectively) and the upper trapezius (UT) during elevation of the arm in flexion and abduction. Analysis of these elevation tasks was completed in four body positions commonly used in evaluation and intervention protocols which affect the gravitational load direction relative to the shoulder complex.

## METHODS

Eighteen (18) right-handed male adults aged 24.0 ( $\pm 1.68$ ) years with no history of shoulder pathology participated in the study. Subjects were asked to perform abduction and flexion of the right arm (without additional load) in seated, sidelying, prone, and supine positions from a resting arm position (at the side of the body) to 120°. Motion capture (10-

camera Motion Analysis Corp.) was used to track the elevation of the arm (using planar projection of the torso and the upper arm on the movement plane). Surface electromyography (EMG) data for the AD, MD, PD, and UT was recorded using the MA-300 system (Motion Lab Systems, Inc.). EMG signals were differentially amplified and sampled at 1200 Hz per channel using a 16 bit A/D convertor.

Data analysis was performed using MATLAB. Activation patterns were demeaned, band-pass filtered (10-450 Hz), and enveloped via RMS. Manually resisted muscle specific maximum voluntary isometric contractions were used to normalize the data. The activation level was assessed on three 30° elevation segments (between 0-90°) measured by motion capture. The synergistic activations for each of the deltoids paired with the UT (AD-UT, MD-UT, and PD-UT) averaged over the elevation segment were evaluated using an activity-scaled co-activation (AsCA) algorithm.

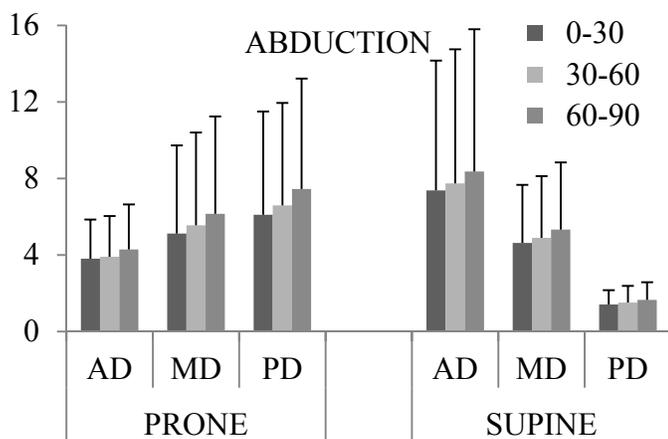

$$AsCA = \left( \frac{EMG_1}{EMG_2} \right) * (EMG_1 + EMG_2) * 100$$

where,  $EMG_1 < EMG_2$ . Three-way RM-ANOVA (task by position by elevation segment) was used to analyze the paired synergistic activations (AsCAs).

## RESULTS AND DISCUSSION

There was a 3-way interaction effect only for the PD-UT ( $p < 0.05$ ). Position by elevation and task by elevation, 2-way interaction effects were found for all muscle pairs ( $p < 0.01$ ), and position by task 2-way interaction effects were found for PD-UT ( $p < 0.01$ ) and MD-UT ( $p < 0.05$ ) muscle pairs only.

The synergistic activation between UT and each of the deltoids showed significant arm elevation main effects ( $p < 0.001$ ) (Figure 1). These observed arm elevation effects reflect increased co-activation and

**Figure 1:** AsCAs (mean  $\pm$  SD) for the abduction task in prone and supine positions. Arm elevation and position effect on co-activation between the UT and each of the 3 parts of the deltoid are shown.

suggest higher demands for scapular stability with arm elevation regardless of task and position. Significant ( $p < 0.001$ ) position main effects were also observed for all AsCAs. There was higher co-activation for seated and sidelying as compared to prone and supine positions for the abduction task. During flexion the seated co-activation was the highest for the AD-UT and the lowest for MD-UT and PD-UT, highlighting the anterior deltoid role. Interestingly, the co-activation of the MD-UT and PD-UT were highest in the sidelying position during flexion, underscoring the demand on these muscles to counter gravity in this position. Task main effects were only found for MD-UT and PD-UT ( $p < 0.001$ ).

There was a synergistic co-activation arm elevation trend for all muscle pairs and highest co-activation

values were observed for the AD-UT in the seated and supine positions ( $p < 0.05$ ) (Table 1). The PD-UT showed highest co-activation in the prone position for both tasks ( $p < 0.05$ ). Relatively high MD-UT co-activation was observed, only during abduction, for seated and sidelying positions (Table 1). Co-activations (while relatively high) in sidelying position were not significantly different amongst muscle pairs. The low co-activation values observed were due to the nature of the tasks evaluated. The role of the serratus anterior and lower trapezius was not assessed.

## CONCLUSIONS

The observed modulation of the expected co-activations between the upper trapezius and the deltoids by arm elevation, body position, and task should be accounted for during clinical protocols. Further investigation of additional synergies under more demanding tasks will refine and enhance rehabilitation protocols and improve biomechanical models of the shoulder.

## MOVEMENT TOWARD PREDICTIVE HAND FORCES

Joshua P. Drost, Tamara Reid Bush  
Michigan State University, East Lansing, MI, USA  
email: drostjos@msu.edu, reidtama@msu.edu

### INTRODUCTION

Almost everything people do in their daily lives uses their hands. Therefore, when the hand is impaired, it is critical that we understand how much function was lost and where, so that the best possible treatment can be provided. Currently, loss in hand function is determined using surveys, pain scales and radiological exams, all of which are subjective; objective methods to quantify changes in hand function are needed [1, 2]. A hand model that includes the total *force and motion* abilities of a patient will allow health care experts to easily compare changes in hand function, leading to improved rehabilitation and treatment strategies.

Previously, we modeled changes in the motion abilities of the hand caused by arthritis [3]. This model included the full range of motions of the hand; however, force data for each finger were not incorporated into that model. Both motion and forces are necessary to generate a comprehensive hand model for clinical use. To facilitate translation into a clinical environment, it would be optimal to take only a few force measures and be able to predict the forces occurring in the range of movement.

Thus, the goal of this work was to develop a model that could predict the forces over the kinematic workspace of participants with and without reduced hand functionality.

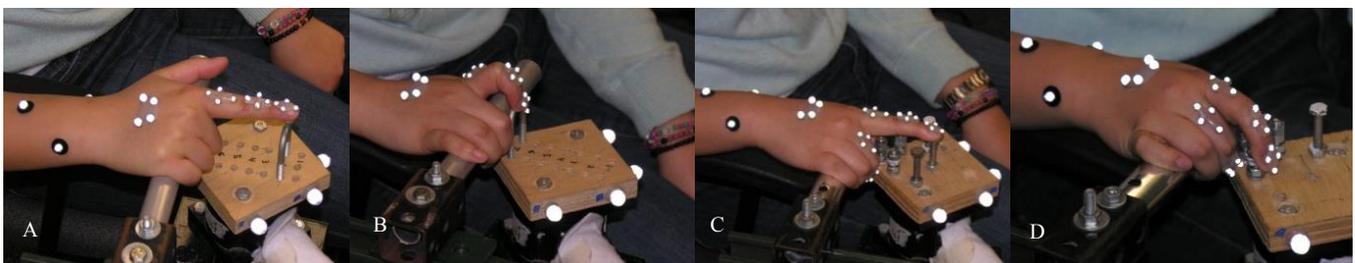

### METHODS

Sixteen participants (7 female and 9 male, average age 25.6 years, SD 6.1 years) without any reported injury or arthritis, termed “Healthy”, and fifteen participants (13 female and 2 male, average age 73.5, SD 4.8 years) with doctor diagnosed osteoarthritis, termed “Arthritic”, were included in this study.

Forces due to changes in flexion/extension of the index finger were measured using a “U-shaped” metal bracket placed in seven positions along a line, each 15mm apart. The participant was asked to push on the bracket, and then pull with maximum force using the pad of the index finger (Figure 1 A&B).

Maximum abduction/adduction forces were also measured in six positions. Three of the positions were at maximum extension (called “Adduction/Abduction Push”—Figure 1C) and the other three were at a mid-range flexion of the interphalangeal joints (called “Adduction/Abduction Pull”—Figure 1D).

After collection, the data were analyzed in terms of the 1) fingertip posture ( $x,y,z$  coordinate) 2) the direction of the force applied as an angle in the sagittal plane ( $\theta$ ), and 3) force magnitude. A linear mixed effect model was then created for each health and gender population. The model included the covariates of normalized distal and palmar displacement ( $x, y$ ), angle ( $\theta$ ) and angle squared ( $\theta^2$ ) along with their interactions. Subject number was used as a random variable to remove variance between subjects.

**Figure 1: Experimental setup and force data for (A) flexion/extension push, (B) flexion/extension pull, (C) adduction/abduction push and (D) adduction/abduction pull trials**

## RESULTS AND DISCUSSION

Sagittal plane views of force data from the arthritic female population are presented in Figure 2 (Left). Forces were plotted based on the finger posture in 3D space and normalized for finger length. The origin for all data was at the MCP (metacarpal phalange) joint of the index finger. The plots are oriented so that a fully extended index finger sits along the horizontal axis with the pad of the index finger pointing in the positive vertical direction.

The population forces as predicted by the model are also shown (Fig. 2, Center). The covariates (fingertip position and force direction) are the same as the observed data, but the forces have been predicted using the model. As can be seen, our model can closely predict the forces over the range of motion tested. The model was also used to estimate forces over the entire range of motion for the index finger for the both the healthy and arthritic populations.

Figure 2 (Right) shows the predicted force for the entire kinematic space. The multi directional arrows, show the range of force directions the positions of application, and the colors indicate magnitudes of force. The subject variance has been removed, so this represents the average abilities of an arthritic female.

This prediction model is the first step in being able to use limited clinical measures to create a complete mapping of the forces of the hand. Such a model will

give clinicians an additional tool for diagnosing disorders, tracking therapy, and identifying treatment to help patients gain back function.

Currently the model has been developed for the index finger. Future work will include forces and associated models for all fingers. Also, measures of motion and force will be gathered prior to intervention; mid-way through rehabilitation and after rehabilitation is complete to test its usefulness in a clinical situation.

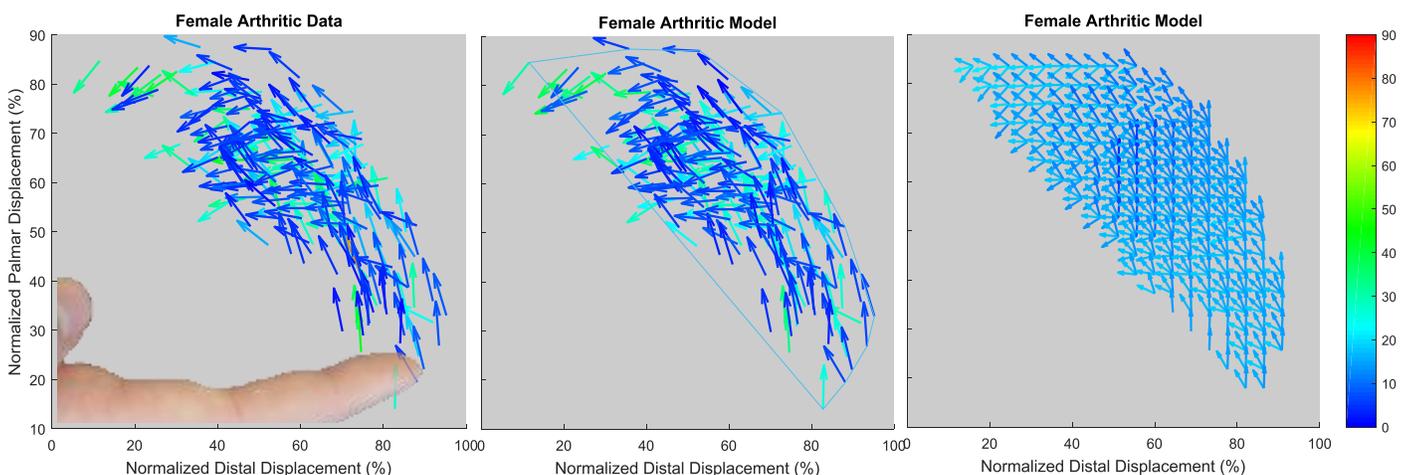

There is a need for an objective method for diagnosing loss in hand function. This model is highly innovative and useful: comparisons between and individual's abilities and the population models will allow clinicians to determine what function was lost and how much was restored due to treatment.

# THE EFFECT OF SIMULATED ROTATOR CUFF TEAR SEVERITY ON GLENOHUMERAL JOINT FORCE

<sup>1</sup>Rich Arce, <sup>1</sup>Meghan E. Vidt

<sup>1</sup>Exercise Science and Health Promotion, Arizona State University, Phoenix, AZ, USA  
email: mvidt@asu.edu

## INTRODUCTION

Increased age is associated with rotator cuff (RC) tears [1], which can affect the integrity of tendons and muscle force distribution across the glenohumeral joint [2]. A change in force distribution across the glenohumeral joint can affect resultant joint contact force (JCF), potentially affecting stabilization, and increasing risk of joint damage or injury progression. The RC musculature is critical for stabilizing the humeral head in the glenoid fossa. However, it is unknown how alterations to these muscle forces affect loading at the glenohumeral joint. While JCF cannot be feasibly measured *in vivo*, computational musculoskeletal models enable prediction of these forces under different scenarios of muscle force contribution to gain insight into resulting joint forces, and to make inferences about possible implications for the RC tear population. The purpose of this study is to use a simulation-based approach to evaluate the effect of systematic variations of muscle force distribution on glenohumeral joint force.

## METHODS

A computational musculoskeletal model of the upper limb [3] representing the muscle force characteristics of a healthy older adult male [4] was implemented in OpenSim [5]. Peak isometric muscle force of each RC muscle path in the model was systematically reduced to a percentage of maximum force to simulate increased RC tear size (Table 1). Modulations were made to supraspinatus (S), infraspinatus (IS), subscapularis (SS), and teres minor (TM). A baseline configuration, in which all muscle forces were maintained at nominal older adult values (i.e. 100%), and 7 tear sizes, in which RC muscle forces were reduced incrementally, were evaluated. The influence of static posture on

glenohumeral joint contact force was evaluated. Static postures included 30°, 45°, 60°, and 90° thoracohumeral elevation in the frontal plane. In all assessments, shoulder rotation was set to 0°, elbow flexion was 90°, and forearm rotation was 0°. Dynamic simulations of movement were performed for each static posture and tear size, for a total of 32 simulations. Simulations were conducted using the computed muscle control (CMC) tool [6] in OpenSim, with static postures for model degrees of freedom used as an input. Muscle excitation time histories calculated by CMC were used to calculate glenohumeral JCF with OpenSim's joint analysis tool. Output from 0.25-0.5sec of each 2sec static trial was evaluated to ensure consistency across output for each posture and tear scenario.

**Table 1:** Increased tear size was simulated by decreasing peak isometric force for model muscle paths. Percentages represent the proportion of the model's nominal peak isometric force. S=supraspinatus; IS=infraspinatus; SS=subscapularis; TM=teres minor.

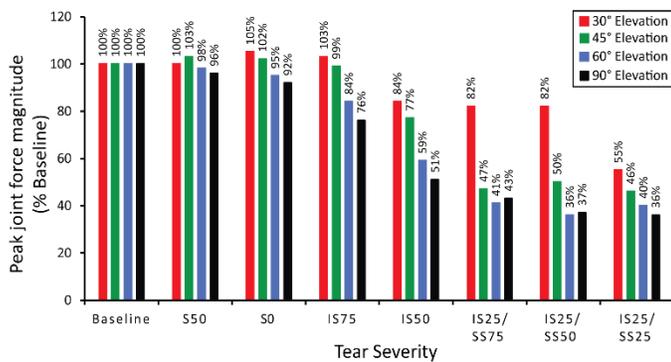

Tear Scenario	S	IS	SS	TM

Results of the joint force analysis were evaluated using a custom Matlab (The MathWorks Inc, Natick, MA) program. Data was filtered using a dual pass windowing filter. Force components were transformed into the scapula's reference frame, which is aligned with the scapular plane, by applying a 30° anterior rotation about the superior-inferior axis. The resultant JCF was calculated and the peak resultant force identified. Magnitude of peak

resultant force and its compressive component were compared to baseline for each RC tear scenario at each elevation angle. Resultant force components were projected onto the glenoid fossa to assess changes to peak resultant joint force location with each tear scenario and for each elevation angle.

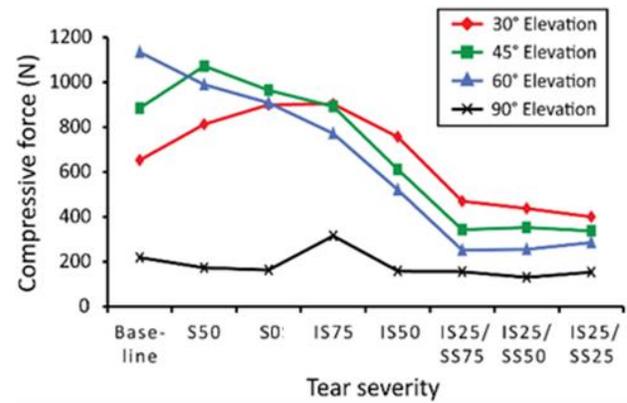

## RESULTS AND DISCUSSION

Increased simulated tear severity resulted in a decrease in overall force production for most trials (Fig. 1). The 30° posture maintained a peak JCF of at least 82% for all scenarios until both IS and SS were at 25% of nominal force. The 45° posture declined to <50% of nominal peak resultant joint force when SS was at 75% of nominal force. Postures at 60° and 90° showed a JCF reduction with increased RC tear severity. It is likely that a smaller moment contribution from upper limb mass contributed to the smaller changes in JCF observed for 30° and 45° postures compared to 60° and 90° postures. Both the 60° and 90° postures experienced a decrease of 60% and 64%, respectively, from baseline to the most severe RC tear.

**Figure 1:** % change from baseline in peak JCF magnitude with increased RC tear severity and elevation angle.

There was an overall trend of decreased compressive force with increased RC tear severity, which supports the effect of decreased compressive contributions from markedly reduced muscle force generating capacity from a RC tear. For all elevation postures examined, compression was lowest and remained consistent once SS tear was introduced. While some increases in compression were observed for 30° and 45° postures for smaller simulated RC tears (Fig.2), the corresponding magnitude of the resultant JCF (Fig.1) was not markedly increased, suggesting that

**Figure 2:** A: Regression of compression force as tear severity rises.

remaining musculature in small RC tears may prioritize compression to maintain joint stability. In all simulations, peak resultant force was maintained within the glenoid boundary. Forces were localized at the inferior-posterior aspect for 30°, 45°, and 60° postures, with a more anterior-inferior location observed for 90° postures.

## CONCLUSIONS

We conclude that both posture and increased RC tear size influence the magnitude and compressive component of JCF. Despite the increased risk associated with decreased compressive components of joint force, all peak forces were localized within the glenoid for these static simulations, suggesting that these postures pose less of a risk than those in which forces are not localized within the glenoid boundary. Additional work is currently underway to examine the influence of postures in other planes (e.g. scapular plane), and apply these methods to detailed analysis of dynamic functional tasks, which are most relevant to patients with RC tears.

## INTRODUCTION

Degenerative changes in both cartilage and bone typify thumb carpometacarpal (CMC) osteoarthritis (OA). Despite the prevalence of thumb CMC OA, which affects 20-25% of adults over the age of 50 – and up to 80% of those aged 71-80 – the natural history of the disease is not well characterized. Physical examination and plain radiographs are used for staging OA disease, with progressive joint narrowing associated with more advanced disease. However, limited data exists on typical rates of this disease progression in the thumb. Therefore, the two aims of this study were to estimate the rate of cartilage thinning in early thumb CMC OA, and to determine whether the rate differs between men and women.

## METHODS

OA progression and cartilage thinning were assessed using a large database of clinical, image, and biomechanical data collected as part of a longitudinal study of thumb CMC biomechanics and OA progression. This specific study focuses on the rates of clinically-staged disease progression and cartilage thinning.

Study subjects included 92 patients with nascent thumb CMC OA at enrollment, defined as pain and positive clinical signs with at most minor radiographic changes (49F and 43M between the ages of 45 and 75 yrs); as well as 46 healthy subjects (Controls) recruited to meet specific age and sex criteria (12 young females (YF) and 10 young males (YM) between the ages of 18 and 25 yrs, and 13 older females (OF) and 11 older males (OM) between the ages of 45 and 75 yrs). IRB

approval was obtained before enrollment. Assessments were performed on all subjects at enrollment (Yr 0 or baseline), and at 1.5 and 3 years post-enrollment for the OA patients.

Clinical stage was assigned using a modified version of the Eaton-Glickel radiographic classification system (Stage 0: Pain, but normal radiographs. Stage 1: Mild joint widening or narrowing. Stage 2: Narrowing, debris < 2mm, sclerosis, contour changes. Stage 3: Marked narrowing, debris > 2mm, contour changes. Stage 4: Stage 3 + additional joints). Cartilage thinning was assessed using high-resolution CT volume images (voxel size 0.4x0.4x0.625mm<sup>3</sup>) of the thumb in a splinted neutral position (HiSpeed Advantage 16 slice scanner, GE Medical, Milwaukee, WI). Bone surface models were generated via semi-automated thresholding/manual editing, and the trapezial and MC1 subchondral articular facets were modeled as NURBS surfaces (Geomagic 12, 3D Systems, Rock Hill, SC. USA). Interbone distances, calculated as the shortest distances between vertices on the overlapping regions of the NURBS surfaces, were used to estimate total cartilage thickness (trapezium + MC1). The interbone distances were averaged to yield a single mean joint space width for each joint analyzed.

Linear regressions of OA Grade and mean joint space as functions of time were used to estimate the rate of disease progression and cartilage thinning. A one-way ANOVA (with Tukey's post-hoc multiple comparisons) was used to compare the mean joint space width of the Controls (grouped by age and sex) to those of the patients (at baseline, year 0 and year 3).

## RESULTS AND DISCUSSION

In our study population, thumb CMC OA progressed at a rate of 0.3 OA staging points per year over the evaluation period ( $P < 0.001$ ), resulting in an average increase of one OA stage by the 3-year follow-up (Fig. 1). There were no significant differences in the rate of disease progression in men and women.

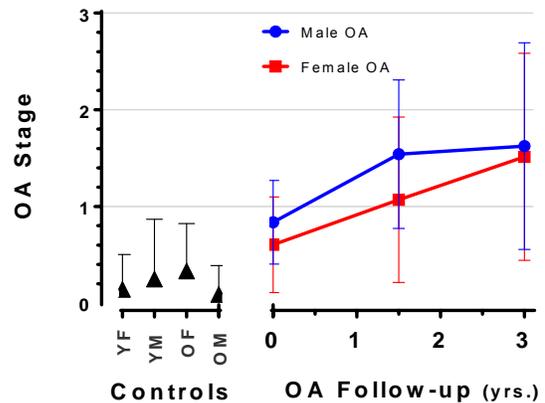

The mean ( $\pm 1$  SD) joint space of the younger Controls was 1.4 mm ( $\pm 0.2$  mm), which was not significantly different than that of the older Controls ( $1.3 \pm 0.2$  mm) (Fig. 2). However, the mean joint space at enrollment in patients with early thumb CMC OA was 0.35 mm narrower than the average joint space of the healthy Controls ( $P < 0.001$ ) (Fig. 2). Over the 3 year course of follow-up there was significant ( $P < 0.03$ ) joint space narrowing in the OA patients, at a rate of approximately 0.07 mm/yr. This rate of narrowing amounted to an average loss of joint space width of 0.22 mm (or 20%) over the 3 year period. There was no difference in the loss of joint space between males and females.

In this study we quantified rates of disease progression and cartilage thinning using data from a longitudinal study of thumb CMC biomechanics and OA progression. Our primary assumptions were that our study populations were representative of the general population, and that interbone distance is a reasonable surrogate for cartilage thickness. We found steadily decreasing cartilage thickness with disease progression between enrollment and our 3 year follow-up. Our disease progression data suggests a 10-12 year horizon to end-stage (Stage III/IV) disease; our estimated 0.07 mm/yr. rate of cartilage loss predicts ~50% cartilage thinning by 7 years, and complete erosion by 14 years. Interestingly, our OA patients presented at baseline with significantly thinner cartilage (narrower interbone distance) than our normals (1.0 mm vs. 1.3 mm). This may reflect pre-symptomatic disease-related thinning or, possibly, congenitally thin cartilage. We are currently unable to differentiate between the two. Future follow-ups will allow us to refine the rate of OA progression, and the timing of surgical intervention, which we anticipate will be

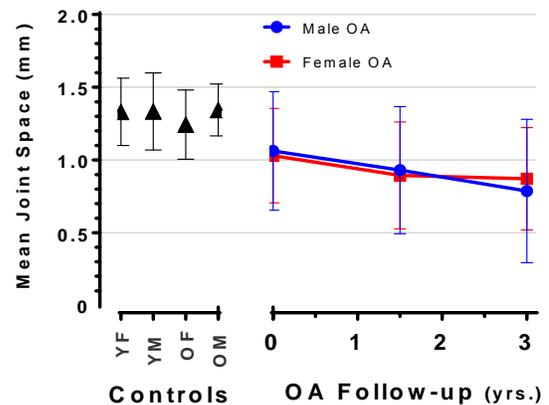

influenced by symptom severity (i.e. pain, function) rather than solely anatomy-related.

## CONCLUSIONS

Early thumb CMC osteoarthritis was demonstrated to progress in the first three years after diagnosis. Despite sex-related differences in prevalence, sex was not a factor in progression in our cohort.

**Figure 1.** Radiographic OA stage for Controls (younger females (YF), younger males (YM), older females (OF), and older males (OM)) at their single assessment and for patients with early stage OA at baseline, 1.5 and 3 yrs. follow-up.

**Figure 2.** Mean (SD) joint space width, a surrogate for cartilage thickness, of the Controls and the patients over the 3 years of the study.

# OPTIMAL PLACEMENT OF ULTRASONIC SENSORS FOR IMPROVED MEASUREMENT OF SCAPULAR KINEMATICS

Anthony Vicini and Michelle Sabick

St. Louis University, St. Louis, MO USA

Email: [avicini@slu.edu](mailto:avicini@slu.edu)

## INTRODUCTION

Historically, x-ray imaging has been used to quantify scapular position, but it suffers from inaccuracies due to its 2D nature and involves ionizing radiation. The gold standard for tracking scapular motion is to use bone pins; however this method is invasive and not suitable for clinical situations [1]. Skin mounted optical sensors are an attractive method of quantifying scapula kinematics, but they are not accurate for overhead arm motions [1].

The major issue in tracking scapular kinematics with optical sensors is relative motion between the skin and scapula. Marker placements have been optimized into locations where the skin lies in close proximity to the bone in order to minimize such error. However, ultrasound coupled sensors have the ability to resolve the position of bone relative to skin, making this constraint unnecessary. Following work presented at ASB 2016 in which the quantity of ultrasound coupled sensors required for scapular tracking was optimized, the purpose of this study was to identify appropriate sensor locations to maximize the accuracy of scapular measurement using a reasonable number of sensors [2].

## METHODS

In this study, we built upon previous work, where the quantity of sensors was optimized [2]. Based on these results, a simulated annealing procedure was used to identify optimal locations to place sets of 3,

4, or 5 ultrasound sensors over the scapula to track its position and orientation.

Scapular models used in this experiment were extracted from CT images from the Laboratory of Human Anatomy and Embryology, University of Brussels (ULB), Belgium. CT images were created using a pitch of 0.7, increment of 1.0 mm, voltage of 120 kV, and amperage of 266 mA. Images were thresholded at 266 HU before manual adjustment to yield only the underlying bone. The files were then processed using Python 3.6.

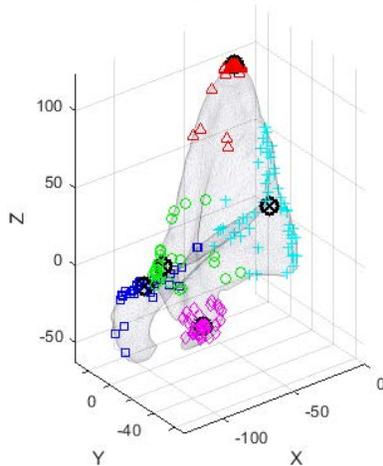

Points on the scapula were randomly selected from a subset of locations visible to ultrasound sensors mounted on the skin to simulate a sensor pointed at each coordinate. Noise was added to points to correspond with error seen in ultrasound imaging of bone [3]. Each point was then rotated and translated by values meant to simulate realistic scapular displacement relative to the skin in overhead arm movements [4]. Displaced points were matched back to their most likely initial positions on the scapula using an iterative closest points algorithm.

After measuring the target registration error (TRE), new points adjacent to the previous ones were selected. The procedure was repeated with these points, and a subsequent trial was repeated using points based off of either the first or second trial. Which set was used to continue was based on the TRE and the current “temperature” of the simulation, which decreased over the course of the run to converge upon a specific point. By allowing worse performing points to be accepted in this

algorithm, the simulated annealing protocol is able to better converge upon complex data like the optimum sensor position [5].

The simulated annealing procedure was conducted on the Kepler supercomputing system at St. Louis University. Fifty simulations were repeated for each quantity of sensors (3, 4, or 5), each of which took approximately 9 hours to run. The data was analyzed using K-means clustering, which had cophenet values of approximately 0.86, representing a moderately high quality solution.

## RESULTS AND DISCUSSION

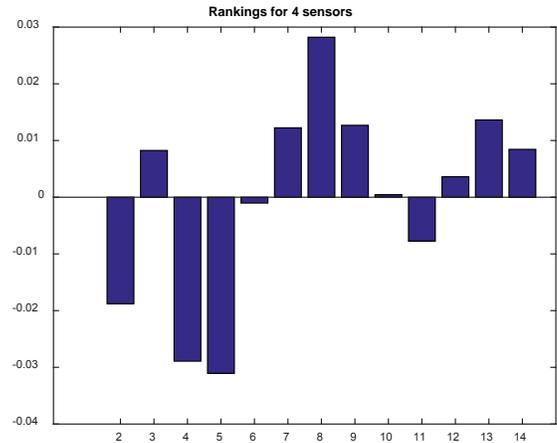

**Figure 1:** Predicted locations of ideal sensor placements using a set of five sensors.

The result of each run was a set of points that corresponded to the ideal placement location of ultrasonic probes to measure scapular location. The final positions of these sensors were overlaid in 3D on the scapula model (Fig 1). Predicted sensor locations tended to be in areas of sharp geometry changes on the bone.

K-means allowed determination of the relative accuracy of each pattern of sensor placements, where low values represent a greater likelihood of the number of unique sensor clusters (Fig 2). Similarly valued numbers at lower quantities than the number of sensors used would imply that one of

the clusters is not needed, whereas higher quantities would imply that there is more than one distinct pattern.

**Figure 2:** Rankings using 4 sensors show that there are 5 distinct clusters and multiple ideal arrangements are possible.

## CONCLUSION

This data represents the initial analysis of ideal ultrasonic sensor placement for tracking of scapular position in simulations representing overhead arm positions. Higher precision trials are currently running on the Kepler supercomputer to refine sensor placement, which minimized the error from over 80 mm of RMS error to sub-millimeter levels in simulations. Subsequent clinical testing is in planning.

## INTRODUCTION

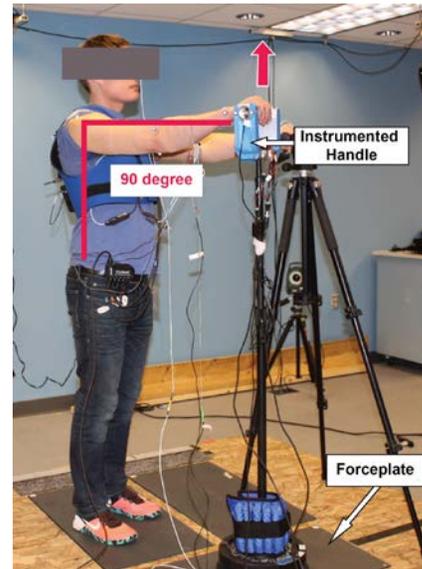

Muscle fatigue is a complex, multifaceted phenomenon and is most commonly defined as an inability to maintain a required force level after prolonged use of the muscle [1]. It is generally accepted that muscle fatigue is associated with the initiation and development of musculoskeletal disorders (MSDs). In order to reduce work-related MSDs, ergonomic solutions, such as various wearable robotics, have been proposed and developed. Since the initial goal of the engineering intervention is to reduce the muscular fatigue of the workers, the assessment of the muscle fatigue becomes a critical step to evaluate the efficiency and effectiveness of an ergonomic product. The purpose of the current study was to evaluate the characteristics of the electromyography (EMG) and vibromyography (VMG) signals of the upper extremity during a fatigue protocol. We were especially interested in the frequency domain of these signals, since they were less noisy and were found to be associated with the muscle fatigue of the rectus femoris (RF) and vastus lateralis (VL) in the literature [2].

**Figure 1.** VMG and EMG sensors/ electrodes on the subject's right arm.

## METHODS

A healthy male subject (24 years old, 77.6kg, and 1.75m) consented to participate in this ongoing NIOSH IRB-approved study. The EMG and VMG signals were measured during controlled pulling tasks from three muscles of the subject's dominant right arm (biceps brachii, flexor carpi radialis, and

**Figure 2.** Side view of one selected test setup: a subject grips and pulls the instrumented handle with the shoulder flexion/extension at a 90-degree angle.

extensor carpi radialis, Fig 1). The loading system consisted of an instrumented handle and a pole (Fig 2). The height of the pole was adjustable to fit each subject and to assure predetermined posture. Grip force was measured by a pair of force sensors (Interface SML-100) within the instrumented handle, and the lift force was measured by the force plate (Bertec, 4080-10). The subject was instructed to pull the handle vertically while keeping the shoulder flexion/extension angle at 45, 90, or 135 degrees, and the elbow flexion/extension angle always at 0 degrees. Posture-specific pulling maximum voluntary contraction (MVC) was determined first. Then, during each test trial, after approximately 10-seconds in position resting, the subject was required to exert 60% pulling MVC and report fatigue onset. After self-reported fatigue, the subject was advised to try keeping the loading level for up to 10 seconds. There were three-minute rest breaks between trials.

A multi-channel EMG system (Motion Lab Systems Inc., MA-300) with pre-amplified electrodes (MA411) were used to acquire surface EMG signals. The EMG electrodes were placed on the skin surface approximately along the muscle fiber directions. The VMG signals were measured using tri-axial accelerometers (Endevco, M35B, mass = 0.55g). The

accelerometers were glued onto 3D-printed flat adapters, which were attached to the skin surface using double-sided adhesive tape (Fig 1). The sensors and electrodes were then wrapped with elastic cloth wrap to secure their placement. Both EMG and VMG signals were recorded in a motion capture software (Vicon Motion System Ltd., Nexus 2.3) at 1000 Hz, and analyzed in Matlab (Mathworks, Inc.). Root mean square (RMS) value of the raw EMG and VMG (total tri-axial acceleration) and the spectra characteristics (median and peak frequency) of filtered EMG and VMG were calculated for one-second non-overlapped sliding windows.

## RESULTS

Representative results from a specific trial with 90-degree arm posture are displayed in Figure 3. The top two plots show the magnitude (RMS) of VMG and EMG during the entire hold-until-fatigue test trial, which clearly demonstrated the onset of the muscle activities associated with fatigue. The EMG magnitude of the biceps and forearm extensors seem marginally increased during the stage when the subject reported fatigue. The most commonly identified trend of decreasing median frequency (MDF) during fatigue process was only found in EMG. However, the magnitude of the VMG spectra were obviously lower in the fatigue stage compared to that in the earlier part of 60% MVC. As expected, magnitude and spectra at resting were small.

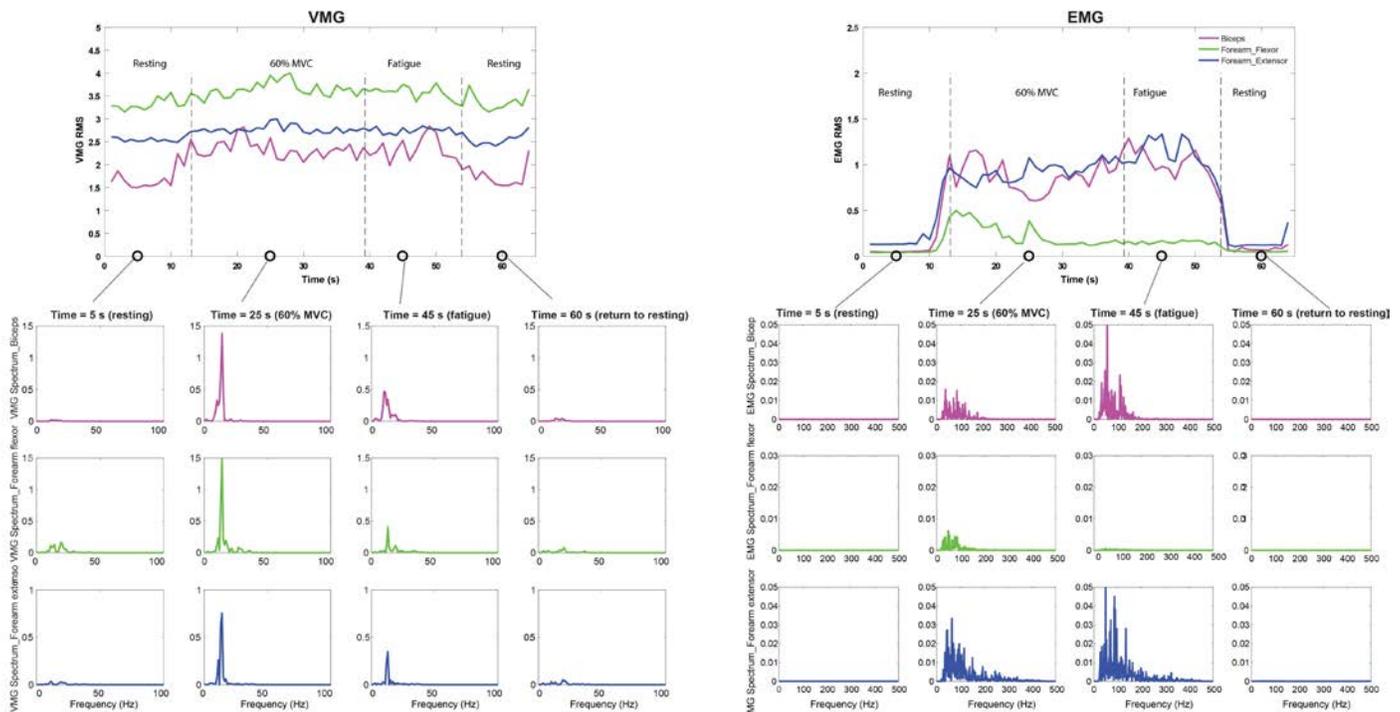

## DISCUSSION AND CONCLUSIONS

Combining VMG and EMG might be a potential tool to evaluate muscle fatigue. In addition to observing the MDF change to assess muscle fatigue as suggested in the previous study [2], we suggest also considering the frequency and magnitude of the major peaks in the VMG spectra. In general, we want to draw attention to magnitude analysis of the signals besides the conventional frequency domain investigation. When tracking the entire resting-hold-until-fatigue process, the MDF might not be appropriate to detect the muscular fatigue status. Since the VMG at resting contains only background noise and is negligible, MDF calculated from these noise signals are meaningless. Further analysis of EMG and VMG data is needed to confirm the findings in this pilot study.

# THE INFLUENCE OF RESTING PECTORALIS MINOR MUSCLE LENGTH ON SCAPULAR KINEMATICS

Travis Pollen, Jason Mohring, Kelly Gerrity, Noel Goodstadt, Margaret Finley, and David Ebaugh

ReHAB Group, Drexel University, Philadelphia, PA, USA

email: [trpollen@drexel.edu](mailto:trpollen@drexel.edu), web: <http://drexel.edu/cnhp/academics/departments/Physical-Therapy/>

## INTRODUCTION

Based on the Alignment-Impairment model resting length of the pectoralis minor muscle (PMm) is believed to have a significant effect on scapular alignment and movement [1]. It has been shown that individuals with short resting PMm length have increased scapular internal rotation (SIR) and reduced scapular posterior rotation (SPR) during constrained humeral elevation tasks compared to individuals with long resting PMm length [2]. Moreover, these altered scapular rotations have been linked to subacromial impingement, rotator cuff disease, and glenohumeral instability [3,4]. Based on this information, clinicians often attempt to stretch the PMm of their patients with shoulder pain.

It is currently unknown, however, whether scapular rotations differ between individuals with short and typical resting PMm length. From a clinical perspective, this comparison is generally more pertinent than the comparison between groups with short and long resting PMm length. Additionally, typical human movement is rarely restricted to any one plane of motion, and scapular kinematics have been shown to differ between constrained and unconstrained tasks [5]. Therefore, the purpose of this study was to determine whether scapular rotations during constrained and unconstrained overhead reaching differ between individuals with short and typical resting PMm length.

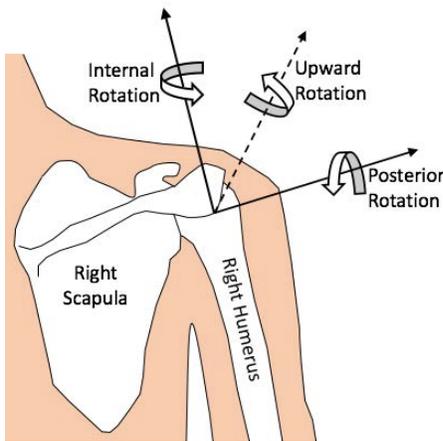

## METHODS

Twenty-six individuals (sex = 17 females, age =  $26 \pm 4$  years, height =  $1.69 \pm 0.08$  m, mass =  $66.3 \pm 10.4$  kg) volunteered to participate in the study. Participants provided informed consent as per the research protocol approved by Drexel University's Institutional Review Board. To determine resting

PMm length, the coracoid process and fourth rib were palpated and marked. The distance between these marks was measured with the Palpation Meter (Performance Attainment Associates, St. Paul, MN). Resting PMm length was normalized to height to calculate the pectoralis minor index (PMi) [2]. Groups were assigned as follows: short ( $PMi < 8.9$ ) and typical ( $8.9 \leq PMi < 10.5$ ).

Flock of Bird sensors (Ascension Technology Corporation, Burlington, VT) were affixed to the participants' sternum, upper arm, and acromion on their dominant side and their trunk, humerus, and scapula were digitized using The Motion Monitor™ software (Innsport Inc., Chicago, IL). Three-dimensional kinematics were collected for three repetitions each of four arm elevation tasks: constrained = flexion, abduction, and scaption; unconstrained = overhead reach to a shelf. The shelf was set to a height above the participant's shoulder equal to 50% of their arm length [5]. Task order was randomized. For constrained tasks, participants were instructed to raise their arm over three seconds and lower over three seconds. For the unconstrained task, participants were instructed to imagine they were picking up an object from the shelf with their palm facing down.

Data were processed in Matlab (MathWorks, Natick, MA) using a custom-written program. For each task, SIR, SPR, and scapular upward rotation (SUR) (Fig. 1) were extracted at four points of humeral elevation ( $30^\circ$ ,  $60^\circ$ ,  $90^\circ$ , and  $120^\circ$ ) and averaged across repetitions. Twelve mixed model ANOVAs were conducted (one for each scapular rotation and overhead reaching task) with humeral elevation as the within-subjects factor and PMi group as the between-subjects factor. Main effects and interactions were deemed significant for  $p < 0.05$ .

**Figure 1:** Posterior view of the right scapula and coordinate axes about which scapular internal/external, upward/downward, and posterior/anterior rotations occur.

## RESULTS AND DISCUSSION

No significant interactions occurred between humeral elevation and group for any of the four tasks. Significant main effects of group were noted for SUR in scaption ( $F(1,24) = 4.447, p = 0.046, \eta_p^2 = .156$ ), abduction ( $F(1,23) = 4.408, p = 0.047, \eta_p^2 = .161$ ), and the shelf ( $F(1,24) = 4.628, p = 0.042, \eta_p^2 = .162$ ). On average, individuals in the short group had  $6.3^\circ$ ,  $7.2^\circ$ , and  $5.8^\circ$  more SUR than individuals in the typical group for scaption, abduction, and the shelf task, respectively. No other significant main effects of group were noted. Significant main effects of humeral elevation were observed for 9 out of the 12 scapula rotations. However, these main effects were not of interest to our research question.

Our results differ from those reported by Borstad and Ludewig [2], who found increased SIR and reduced SPR in individuals with short resting PMm length compared to those with long resting PMm length. We found no differences in those scapular rotations. However, we found more SUR for the short group on three of the four tasks tested. The discrepancies between our results and Borstad and Ludewig's may be attributable to the differences in the groups compared within each study. In our study, we compared individuals with short and typical resting PMm length, while Borstad and Ludewig compared individuals with short and long resting PMm length.

The comparison of short and typical resting PMm length may be more relevant to clinicians, who generally wish to know how their patients compare to a typical population.

A previous study found differences in scapular kinematics between constrained and unconstrained tasks [5]. Thus, the fact that the short group in this study exhibited increased SUR for the unconstrained shelf task in addition to the constrained scaption and abduction tasks lends further support to our findings. However, the cause of this increased SUR is unclear at this time. Our next step will be to determine whether the observed differences fall within the limits of normal movement variability. Regardless, the majority of previous studies of individuals with shoulder pathology identified decreased (not increased) SUR as a potential risk factor [3]. Thus, from a clinical perspective, a greater amount of SUR in a patient may not be cause for concern.

## CONCLUSIONS

In this study, individuals with short resting PMm length exhibited more SUR during both constrained and unconstrained overhead reaching tasks than individuals with typical resting PMm length. Because there is little evidence correlating increased SUR with shoulder pathology [3], the common clinical practice of stretching the PMm in individuals with a short resting PMm length may not be appropriate.

# ASSESSING GLENOHUMERAL JOINT CONFORMITY WITH A STATISTICAL SHAPE MODEL

Irene Sintini<sup>1</sup>, William Burton<sup>1</sup>, James Brownhill<sup>2</sup>, Peter Laz<sup>1</sup>

<sup>1</sup>Center for Orthopaedic Biomechanics, University of Denver, Denver, CO, <sup>2</sup>DePuy Synthes, Warsaw, IN  
email: Irene.Sintini@du.edu, Peter.Laz@du.edu

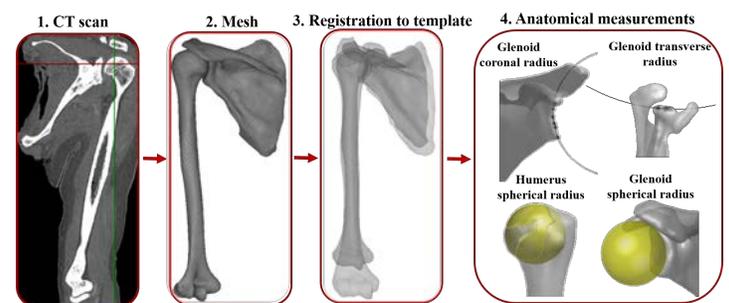

## INTRODUCTION

The mechanics of the shoulder are dependent on the underlying anatomy. Specifically, glenohumeral conformity, defined as the ratio between the humeral and glenoid radii of curvature, influences the contact mechanics and kinematics (translations) of the joint. The glenohumeral joint presents different curvatures in the coronal and transverse planes and, in both planes, has minimal geometrical constraint, deriving most of its stability from the surrounding soft tissue [1]. Further, when considering total shoulder arthroplasty (TSA), a major cause of revision is loosening of the glenoid component [2], which is influenced by implant conformity [3]. Noting tradeoffs between load transfer and constraint, recommendations on implant conformity remain unclear [3]. A systematic quantification of natural joint conformity can support implant design. Prior studies have assessed variation in glenohumeral anatomy with 2D [4] and 3D [2] measurements, relying on manual processing of the geometries. Statistical shape models (SSM) describe the full 3D shape of a bone and enable consistent, automatic anatomical measurements on populations. Prior studies have assessed morphological variation in the shoulder [5,6], but have not investigated joint conformity. The objective of this study was to develop a joint-level SSM of the humerus and scapula to investigate variation in 3D shape, with a focus on conformity.

## METHODS

The training set consisted of 37 left humeri and scapulae from healthy subjects and cadavers (age:  $73 \pm 14$ , 17 females and 20 males, 10 Caucasians and 27 Asians). Bones were segmented from CT scans and the reconstructed geometries were meshed with triangular elements (Fig. 1). A median geometry was chosen as the template; all subjects were registered to the template to establish nodal correspondence. The SSM was created by applying

principal component analysis to the nodal data representing each subject. Only geometry, and not joint alignment, was considered. Modes of variation described the anatomic variation present in the population, and each instance was represented as a series of principal component (PC) scores. Anatomical measurements were automatically performed, including humeral head and glenoid radii of curvature from best-fitting circles in the coronal and transverse planes, and from the best-fitting sphere (Fig. 1) [2]. Glenohumeral conformity and radial mismatch were computed as the ratio and difference, respectively, between the radius of the humeral head and the radius of the glenoid [2,3]. Anterior-posterior (AP) width and superior-inferior (SI) height were computed for the glenoid. Anatomical measurements and PC scores were assessed with Pearson's correlation coefficients (R).

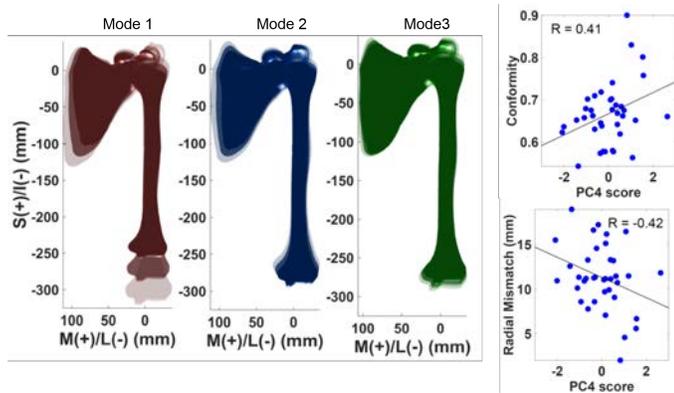

**Figure 1:** Workflow to create a statistical shape model of the shoulder.

## RESULTS AND DISCUSSION

Variation in the humeral anatomy was described as a series of modes of variation (Fig. 2); mode 1 described scaling of the bones (56% of variation explained), while mode 2 (12%) and mode 3 (6%) captured morphological changes in the distal humerus, including the epicondyles, and shoulder blade. Mode 1 was correlated with the head radius ( $R=0.71$ ), glenoid dimensions ( $R=0.66$  for SI height,  $R=0.61$  for AP width), conformity in the transverse plane ( $R=0.48$ ) and the glenoid spherical

radius of curvature ( $R=0.44$ ). Mode 4 (5% of variation explained) was correlated with spherical glenohumeral conformity ( $R=0.41$ ) and radial mismatch ( $R=-0.42$ ) (Fig. 2).

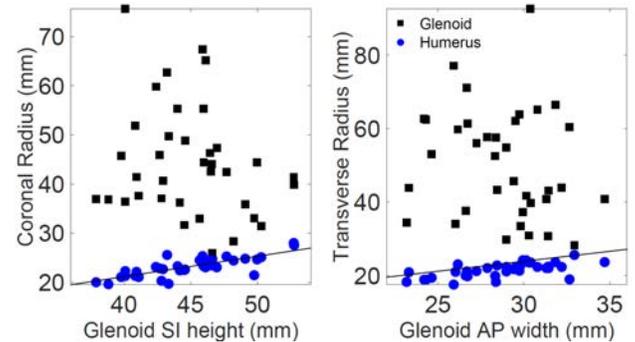

**Figure 2:** Shape modes for the first three principal components shown at mean  $\pm$  2 standard deviations (left). Correlation between the fourth PC and spherical conformity and radial mismatch (right).

Measurements of humeral and glenoid radii of curvature (Table 1) for the training set were consistent with values in the literature [2,4]. A large range of variation was observed in conformity, as evidenced by the standard deviations (Table 1) and scatter in radii data (Fig. 3). The radius of the humeral head was highly correlated ( $R=0.83$  for both AP and SI) with the size of the glenoid (Fig. 3); however, only a moderate correlation was found between the humeral head and the glenoid radius of curvature in the transverse plane ( $R=-0.44$ ), and no correlation in the coronal plane.

The current analysis was based on bone; studies have reported that the glenoid cartilage surface has a smaller radius of curvature than the subchondral bone [1]. Accuracy of the measurements was limited by the resolution of the CT scan (1 mm slice thickness) and the segmentation process. With the ability to characterize 3D variation in anatomy, the joint-level SSM developed in this study is well

suiting to investigate natural glenohumeral conformity, and to inform the design and sizing of TSA implants to restore normal biomechanics.

**Figure 3:** Relationship between glenoid and humeral head radii of curvatures with glenoid size. Note: an outlier with a flat glenoid was excluded.

## CONCLUSIONS

A joint-level SSM quantified the shape variation of the glenohumeral joint, which is important to understand natural shoulder constraint and support the design of shoulder implants. A large range of variation was observed in glenohumeral conformity. The humeral radius was strongly correlated with glenoid size, but not with glenoid radii of curvature.

# A FINITE ELEMENT MODELING APPROACH TO STUDYING INSTABILITY IN REVERSE SHOULDER ARTHROPLASTY

Vijay Permeswaran, Jessica E. Goetz, Donald D. Anderson

The University of Iowa, Iowa city, IA, USA  
email: vijay-permeswaran@uiowa.edu, web: <https://uiowa.edu/uiobl/>

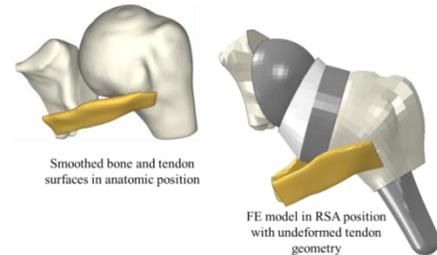

## INTRODUCTION

Reverse shoulder arthroplasty (RSA) is an effective treatment for relieving pain and restoring function to individuals suffering from glenohumeral arthritis secondary to rotator cuff deficiency[1]. However, RSA has suffered from high early to mid-term rates of complication, with instability one of the most common complications. To study instability following RSA, we modified a previously reported finite element approach [2, 3] to include continuum elements representing the stabilizing influence of the subscapularis and infraspinatus tendons.

## METHODS

Axial PD Cube sequence MRI images were obtained of an intact cadaveric shoulder on a 3T GE Discovery 750W MRI Scanner (GE Healthcare, Chicago). The MRI images were segmented using Seg3D (CIBC, Salt Lake City, UT) to produce bone and tendon surfaces, as well as tendon insertion site data. The bone surfaces were smoothed using Geomagic Studio (3DS, Rock Hill, SC).

RSA implant hardware was placed within the bony geometry of the shoulder following manufacturer guidelines. This involved adjusting the humerus surface from an anatomic position into an RSA position (medial and inferior to anatomic) using Geomagic. Fully hexahedral meshes were generated in TrueGrid (XYZ Scientific Applications, Livermore CA). All resulting FE analyses were run in Abaqus/Explicit (Dassault Systemes, Vélizy-Villacoublay, France). The tendon surfaces were meshed in an undeformed state, and then displaced within the model along with the humerus (Figure 1).

**Figure 1:** Original anatomic position of bone and tendon surfaces (left), with the RSA position of the meshed humerus and tendon in the undeformed state (right).

All tendons were assigned hyperelastic material properties using the *data point input* option in Abaqus. Source stress and strain data were from previously performed physical testing of the rotator cuff tendons.

The FE analyses consisted of three separate steps, the first two of which were used to tension the tendons while the position and rotation of the humerus was fixed. In the first step, the proximal free ends of the tendons were displaced toward their anatomic origins and 5 mm outward from the joint, to avoid any contact with bone or implant surfaces. In the second step, the proximal ends of the tendons were displaced 5 mm towards the joint, with contact now enforced between all surfaces, effectively wrapping the tendons around the glenosphere, polyethylene liner, and humeral tray.

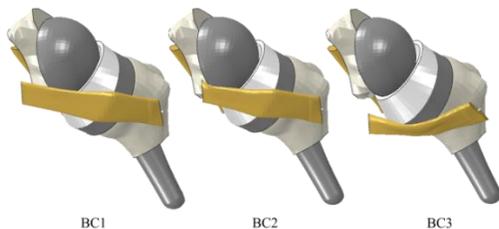

During the third step, the humerus was prescribed to externally rotate about its long axis from neutral to 45° of external rotation. The translations of the humerus were free to displace, such that the tension and wrapping of the soft tissue dictated the position of the humerus during rotation. Three different combinations of proximal-end-tendon boundary

conditions (BCs) were evaluated during the external rotation step to represent the antagonistic eccentric contraction of the subscapularis during external rotation: (BC1) holding the proximal end of the tendon fixed in all translations, (BC2) fixing only the AP and superior/inferior (SI) translations while applying a 1000 N medially-directed load, and (BC3) applying a 1000 N load along the line of action of the tendon while allowing free translation. The subluxation of the humerus was measured for all three BCs, where subluxation was measured as the distance between the centers of rotation of the polyethylene liner and glenosphere.

## RESULTS AND DISCUSSION

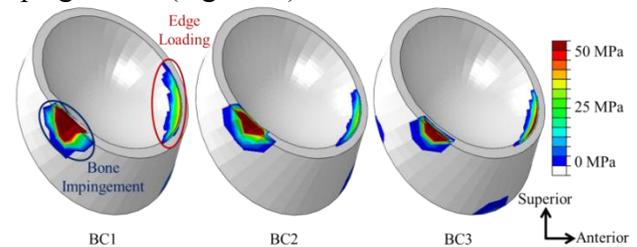

For each of the three BCs, impingement was computed between the polyethylene liner and inferior glenoid bone. The primary impingement occurred at the same amount of external rotation for all cases. However, different behavior of the subscapularis tendon was observed for each, as well as different amounts of humeral subluxation. The least subluxation was computed for BC1 (2.99 mm), followed by for BC2 (3.67 mm), and the humerus subluxed the most for BC3 (4.93 mm).

The BC1 case created stable behavior of the tendon, and the tendon orientations stayed relatively fixed during the external rotation. However, excessive force (3123 N) was generated in the tendon, with associated high contact stresses (560 MPa) at the impingement site. In the BC2 case, the proximal end of the tendon translated only 8.8 mm laterally, with significantly less force developing in the AP (400 N) and SI (594 N) directions. Finally, the BC3 case displayed the most interesting result, as the tendon slid inferiorly under the humeral tray during external rotation (Figure 2).

**Figure 2:** All cases are shown at the end of external rotation movement. The sliding inferior translation of the tendon is shown on the right model.

The benefit of this approach over those previously used is the inclusion of continuum tendon elements. Previously, rotator cuff soft tissues were represented as spring elements with no contact modeling to apply a buttressing, distributed load over the polyethylene liner (as would be seen *in vivo*). This new continuum element approach also provides the ability to study edge loading that develops in the polyethylene liner during impingement (Figure 3).

**Figure 3:** Contact stress plots of the BC1, BC2, and BC3 cases. The large contact patch located posteriorly is the impingement site with the bone, while edge loading can be seen anteriorly and inferiorly in all models

## CONCLUSIONS

We developed a finite element modeling approach to study stability in RSA using continuum element representation of soft tissue constraints, including the subscapularis and infraspinatus tendons. The boundary conditions explored at the proximal ends of these tendons influence the mechanics of the joint and need to be validated. The modeling approach allows computation of complex tendon wrapping and instability of an *in vivo* joint.

# WRIST BIOMECHANICAL PROPERTIES VIA SIX DEGREE-OF-FREEDOM ROBOTIC TESTING

<sup>1</sup> Rohit Badida, <sup>1</sup> Joseph Crisco, <sup>1</sup> Douglas Moore

<sup>1</sup> Department of Orthopaedics, Warren Alpert Medical School of Brown University and Rhode Island Hospital, Providence, Rhode Island, USA

## INTRODUCTION

Clinically, mobility of the wrist is described in terms of the four anatomical directions of motion: flexion, extension, radial deviation, and ulnar deviation. However, the normal activities of daily living involve coupled motions that are combination of these directions. For example, the path from radial extension to ulnar flexion, commonly termed the “dart thrower’s motion”, is crucial for many of the activities of daily living, as well as for occupational and recreational hand use [1].

Determining the biomechanical properties of the wrist in all directions of physiological motion is required to characterize the mechanical properties of the wrist joint. Fully characterizing the mechanical properties of the wrist will advance our understanding of this complex joint. In doing so it will aid in improving orthotic and wrist implant designs, and provide a benchmark for the evaluation of treatments. Characterizing the wrist’s six degree-of-freedom (DOF) flexibility requires a sophisticated six DOF testing strategy.

Accordingly, the objective of this study was to develop a protocol for determining the complete mechanical properties of the wrist using a six degree-of-freedom (DOF) robot musculoskeletal simulator.

## METHODS

Our approach to six DOF robotic wrist simulation was based upon previous experimental protocol that used a two DOF standard material tester [2]. A six axis industrial robot (KUKA KR 6 R700, Augsburg, DE) was integrated with simVITRO labview-based control software (Cleveland Clinic, Ohio, US). The robot is equipped with a multi-axis load cell (ATI, Apex, NC) at the end effector for the measurement of forces and torques in all three Cartesian directions. This interface provides a flexible

musculoskeletal simulator to control and report joint kinetics and kinematics.

To evaluate the protocol a single forearm/hand specimen was prepared by 1) K-wire pinning to fix neutral pronosupination, 2) resection of the digits (at the metacarpophalangeal joints) and proximal 1/3 of the radius and ulna, and 3) potting in fast-setting urethane resin (Smooth-On, Easton, Pennsylvania). The distally-potted metacarpals were mounted to the robot end effector and the proximally-potted forearm was fixed to a mounting pedestal rigidly affixed to the robot base.

After mounting, the spatial relationships between the robot, load cell and the specimen were established using a 6-DOF digitizing probe (Optotrak, NDI, CA). Radius- and 3<sup>rd</sup> metacarpal-based coordinate systems were generated via the digitization of bone-based anatomic landmarks determined within a specimen-specific CT scan.

The Radial coordinate system construction:

$O_r$  – An origin at the midpoint of a line passing from the radial styloid to the ulnar styloid ( $Z_R$  axis)  
 $R_y$  - Pointing proximally, through the centroid of four points digitized around radial and ulnar shaft  
 $R_x$  - Pointing volarly, generated by crossing  $R_y$  and the  $Z_R$  axis  
 $R_z$  – Pointing radially, generated by crossing  $R_x$  and  $R_y$ .

The 3<sup>rd</sup> Metacarpal coordinate system construction:

$O_m$  – An origin at midpoint of ulnar and radial margins of the base of MC3 ( $Z_M$  axis)  
 $M_y$  - Pointing proximally, from the centroid of four points around the distal end of MC3 to  $O_m$ .  
 $M_x$  - Pointing volarly, generated by crossing  $M_y$  and the  $Z_M$  axis  
 $M_z$  – Pointing radially, generated by crossing  $M_x$  and  $M_y$ .

The wrist was tested using pure and combined wrist rotations produced using defined rotational trajectories in each of the four anatomic directions, as well twenty coupled directions (e.g. radial flexion or radial extension). End effector motion was controlled using a hybrid protocol. Rotations were controlled using position control and translations were controlled using force control. Supination/pronation rotation was set to zero. Joint forces were set to 0N and the joint translations were recorded. For each trajectory, the wrist was ramped to 150° in the specified direction and was terminated on reaching a resultant torque of 2 Nm. Data was acquired digitally at a rate of 50 Hz. Torque-rotation curves for each trajectory were reduced to yield ROM and average stiffness. The ROM and stiffness envelopes were constructed by compiling the respective values for each testing trajectory and plotting them on polar plots.

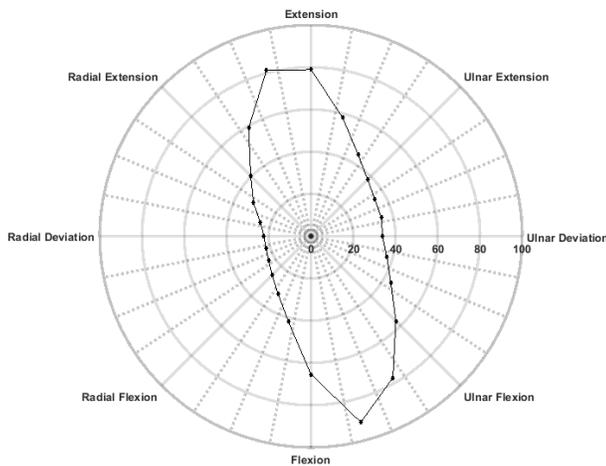

Figure 1 – Wrist ROM envelope (Degrees)

## RESULTS AND DISCUSSION

The principal direction of the wrist ROM envelope was oriented obliquely to the anatomical directions, from radial extension to ulnar flexion (Fig. 1). The largest wrist range of motion was 91.2° in the direction of ulnar flexion, 15° oblique from pure flexion. The values in the orthogonal directions of flexion and extension were 65.4° and 75.9° respectively. The largest range in the extension component was in radial extension, 15° from extension with a value of 81.3°. The ROMs in pure ulnar and radial deviation were 33.8° and 22.3°, respectively. Thus, the largest range of motion for

the wrist was oriented obliquely from radial extension to ulnar flexion.

The smallest stiffness value of 0.02 Nm/Deg was in the ulnar flexion direction and the largest stiffness value of approximately 0.1 Nm/Deg in the radial flexion direction. The principal axis of the stiffness envelope was oriented orthogonal to the principal axis of the ROM envelope.

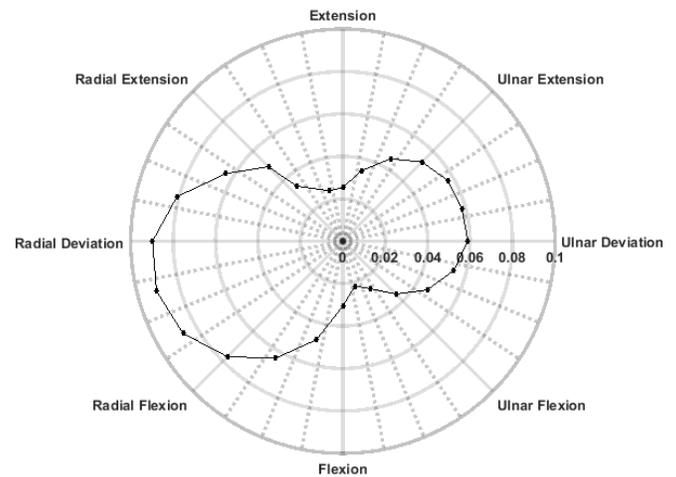

Figure 2 – Wrist stiffness envelope (Nm/Degree)

Musculoskeletal simulation using robotic testing provides an innovative and powerful technique to understand wrist biomechanics because of its multi-dimensional characteristics. A previous robotic wrist study employed a Gough-Stewart testing platform [3], but it had limited ROM (<20°). Our robotic test interface allows us to produce pure and coupled motions about wrist circumduction at 1° interval with range of motion up to 150°.

## INTRODUCTION

Impairments of the hand drastically impact an individual's ability to live independently. Neuromuscular injuries such as cerebral palsy, stroke, and spinal cord injury, in addition to arthritis and traumatic injury cause hand impairments for 15.2 million people in the United States alone. Joint stiffness is a key characteristic of many hand impairments. Comorbidities such as fixed contractures, hypertonia, atrophy due to disuse, and spasticity affect joint stiffness. Quantifying the finger joint stiffness of healthy individuals is an important first step to subsequent analyses of individuals with impairment. Careful quantitative measurement of joint stiffness has the potential to improve the diagnosis and treatment of diseases that affect the hand.

This paper presents results from a study quantifying the passive torque required to extend the index finger about the metacarpophalangeal (MCP) joint, in a quasi-static manner, from flexion to extension among unimpaired individuals.

## METHODS

In a study approved by the Institutional Review Board at the University of Washington, the extension torques for the second MCP joint were measured on both hands for 22 healthy subjects without hand impairments recruited from the University of Washington. Two subjects had incomplete datasets and were excluded. The subjects were equally distributed between males and females; all were right hand dominant. Detailed anthropometric measures, both summary body measures such as age, height, weight (Table 1), and hand specific measures such as lengths and volumetric data of the hand, and index finger were collected.

**Table 1:** Average anthropometric data, 20 subjects.

	Age (Years)	Height (m)	Weight (N)
Males (10)	26.4 ± 4.8	1.78 ± 0.07	701 ± 94
Females (10)	23.9 ± 4.0	1.65 ± 0.06	613 ± 70

Passive joint torque about the second MCP joint was measured at different angles during the extension of the second digit using a novel device that applies an external torque to the digit, while constraining the wrist at 0 degrees of extension (Fig. 1). We measured the passive internal joint extension torque in two conditions randomized on each index finger: a splinted condition (S), with extended and locked proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints, and the second, the non-splinted (NS) with a neutral and unlocked PIP and DIP joint.

Angular information was collected with a video camera, in synchrony with force information ( $F_{LC}$ ) collected using a load cell (25 lbs). The video data was used to compute the angle of the MCP joint,  $\theta_{mcp}$ . These data ( $30 \pm 8$  trials) for each hand were used to compute the net passive extension torque over the range of motion for each subject computed as the difference between the torque applied by the taut string and the torque due to gravity. Dynamics were ignored because of the quasi-static nature of the test. The finger was slowly moved from 50 degrees of flexion to 0 degrees, corresponding to the long axis of the proximal phalanx aligned with the long axis of the metacarpal.

We used a two-sample t-test for independent means and unequal variance, to test our hypothesis that the mean passive extension torque about the MCP joint at 0, 10, 20, 30, 40 and 50 degrees of flexion are the same for males and females, and for dominant and

non-dominant hands. For testing the hypothesis that the mean passive extension torque about the MCP joint at 0, 10, 20, 30, 40 and 50 degrees of flexion are the same for the splinted and non-splinted conditions for each subject, we used a two-sample paired t-test. We tested our hypothesis that S and NS conditions would not affect the torque significantly with a two-sample paired t-test.

**Figure 1:** Extension torque about the MCP is measured as the difference between the torque due to the string and the torque due to gravity.

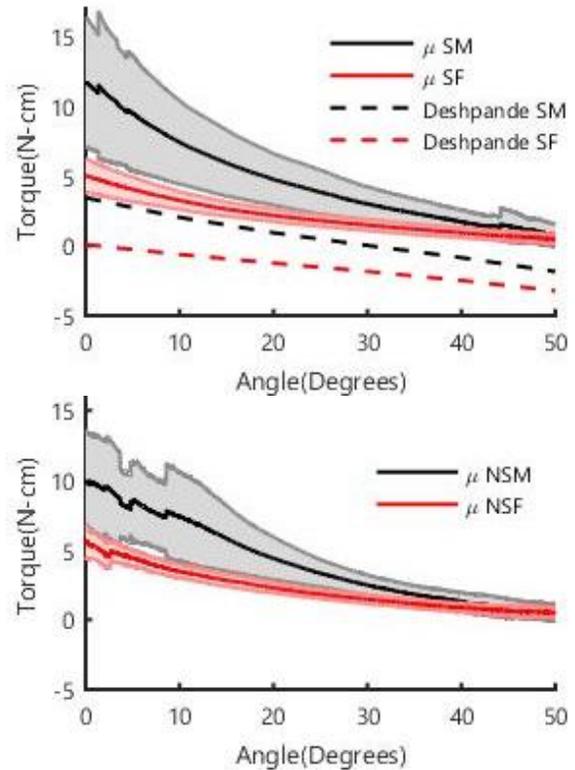

## RESULTS AND DISCUSSION

The extension torque, when the finger was in full extension (0 degrees, splinted, dominant hand), was  $10.95 \pm 2.38$  N-cm for males, and  $5.03 \pm 1.60$  N-cm for females (Fig. 2). Males had significantly higher torques for 0, 10, 20, and 30 degrees of finger flexion ( $p < 0.0029$ ). The extension torques about the MCP joint of the dominant hand were not found to be significantly different from the non-dominant hand for males ( $p > 0.6300$ ) or for females ( $p > 0.2200$ ). In the non-splinted condition, the extension torques were found to be significantly higher than the splinted condition among females, for 0, 10 and 20 degrees of flexion ( $p < 0.0120$ ). No significant difference was observed in the extension torques for males between the splinted and non-splinted conditions ( $p > 0.0930$ ), however.

We also found that torques at full extension, (0 degrees, splinted, right hand) are significantly higher than previously reported values [1], both among males ( $p < 0.0485$ ) and among females ( $p < 0.00018$ ). Interestingly, we also observed that the males have higher variance in both the splinted and non-splinted

case, which increases as the finger is extended further.

Normalizing the splinted torque by body weight times height (BWH), hand weight times hand length (HWHL) and finger weight times finger length (FWFL) decreased inter-subject variability by 9%, 18% and 21% respectively, demonstrating that finger specific measures are a better normalizing parameter for hand torques.

**Figure 2:** Top: torque vs angle curves for splinted males (SM) and females (SF) compared to results reported by [1], bottom: torque vs angle curves for non-splinted males (NSM) and females (NSF)

# DETERMINING RETURN OF SCAPULOHUMERAL RHYTHM IN PATIENTS AFTER REVERSE SHOULDER ARTHROPLASTY

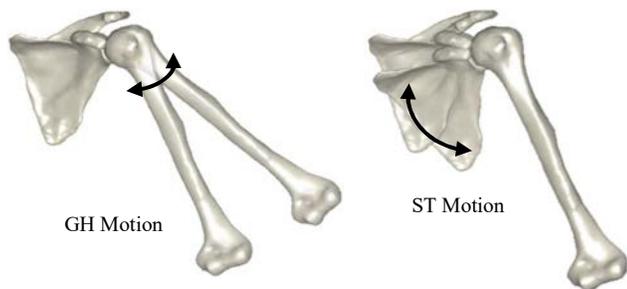

Vijay N. Permeswaran, James R. Hall, Andrea P. Caceres, Donald D. Anderson, Jessica E. Goetz, and Carolyn M. Hettrich

The University of Iowa, Iowa City, IA, USA  
email: andrea-caceres@uiowa.edu, web: <https://uiowa.edu/UIOBL>

## INTRODUCTION

Reverse shoulder arthroplasty (RSA) is used for restoring pain-free function and range of motion to patients with glenohumeral arthritis and rotator cuff deficiency [3]. By reversing the ball-and-socket anatomy of the shoulder, the deltoid can compensate for rotator cuff weakness that limits arm elevation. Despite high success rates in terms of restoring pain-free mobility, patients with RSA suffer from high midterm (6-12 month) complication rates [2]. The most common complication, scapular notching, occurs when undesired contact between the humeral cup and inferior glenoid damages the implant and/or scapular bone.

Scapulohumeral rhythm (SHR) is the ratio of glenohumeral (GH) to scapulothoracic (ST) motion (Figure 1). Studies of scapular notching have presumed an immediate return to normal SHR post-RSA, which omits the recovery time and any residual abnormalities in ST motion that may influence the risk or severity of scapular notching. This study used an EOS radiographic system to image the scapula and humerus at 3 poses 6 months and 12 months post-RSA implantation to determine if a healthy SHR had returned.

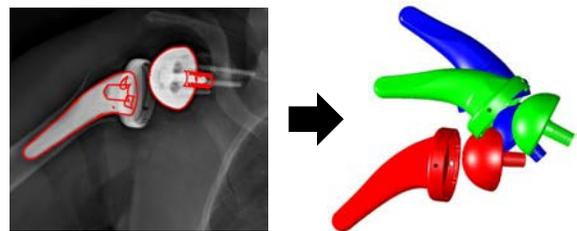

**Figure 1:** Scapulohumeral rhythm (SHR) is the ratio of glenohumeral motion (left) to scapulothoracic motion (right).

## METHODS

EOS radiographic images of the shoulder were captured for 9 patients 6 and 12 months after RSA with a Tornier Aequalis Ascend Flex (Wright Medical, Memphis, TN). EOS uses low dose x-rays to acquire simultaneous orthogonal radiographs. Images of the scapular plane and a plane orthogonal to it were acquired with the patient holding their arm at 60°, 90°, and 120° of abduction (Figure 2).

The RSA implant geometries (provided by Tornier Inc.) were imported into MATLAB (MathWorks, Natick, MA). A 3D-to-2D model image registration method previously reported by our group [1] was used to obtain the 3D pose of the glenosphere and humeral stem.

**Figure 2:** EOS images were aligned in 3D and then used to find the exact angle of the glenoid and humeral component.

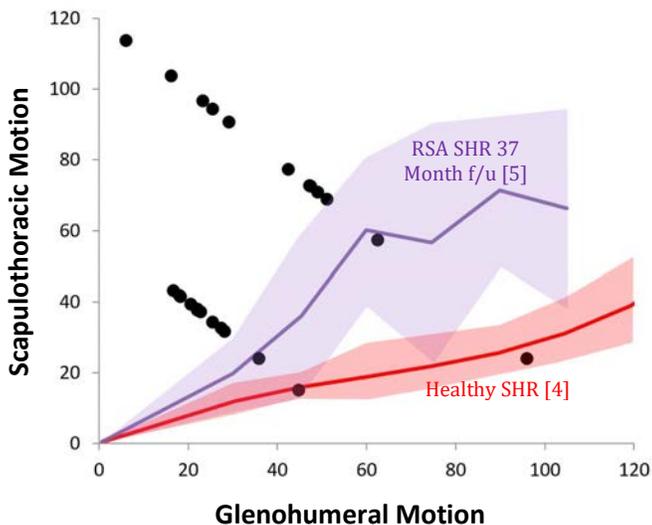

From the 3D coordinates, humeral and scapular angles were calculated for the three arm abduction positions. Using Geomagic software, cylinders were fit to the distal aspect of the stem and glenosphere post to represent functional axes of the humerus and scapula, respectively.

The known axes of the cylinders of the humeral stem and glenosphere post were transformed from Cartesian coordinates to Euler coordinates using the values calculated from the alignment algorithm. This determined the angle between each component to a

neutral arm position for each angle of abduction (Figure 2). The SHR was then calculated between 60° and 90° and again between 90° and 120° using the formula ( $SHR = (\Delta H - \Delta S) / \Delta S$ ), where  $\Delta H$  and  $\Delta S$  represent the change in rotation of the humerus and scapula respectively [5]. The SHR was then divided into glenohumeral and scapulothoracic components for subjects at 6 and 12 months.

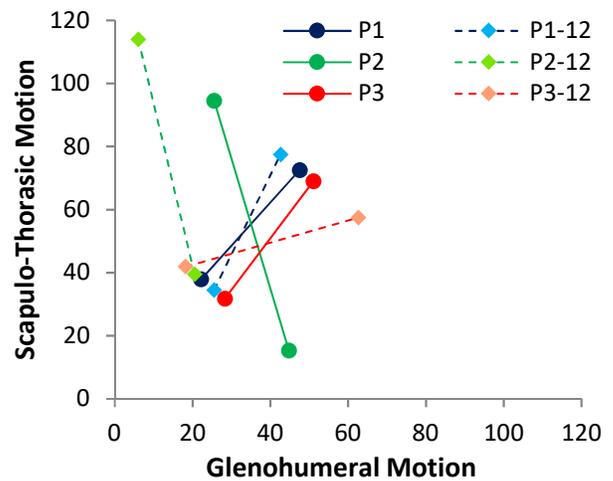

## RESULTS AND DISCUSSION

Patients 6 months post-RSA had an average SHR rhythm from 60° to 90° of 0.97:1 while 90° to 120° was 0.86:1. The average SHR of 0.91:1 calculated in this study for patients 6 months post-RSA differs from previously reported 37 month post-RSA value 1.3:1 [5] and the normal SHR of 2:1 [4] (Figure 3).

**Figure 3:** SHR values plotted as contributions of glenohumeral and scapulothoracic motion to total abduction value for all subjects at 6 and 12 months.

Preliminary data suggests high variability between each patient's 6 month and 12 month scans (Figure 4). Whereas two patients experienced lower SHRs at 12 months, one had a higher SHR.

**Figure 4:** Comparison of GH and ST data for patients 6 months and 12 months post-RSA.

## CONCLUSIONS

The return of scapulohumeral rhythm may be important in understanding complications such as scapular notching in patients with RSA. Patients in this study are likely still regaining strength and function at 12 months post-RSA. Variations in recovery regimen and preexisting conditions may have influenced 6 and 12 month scapulohumeral rhythm data. These results indicate abduction ability is regained post-RSA implantation, but with increased ST motion producing a greater likelihood of impingement, which may partly explain why scapular notching is so common after RSA.

## INTRODUCTION

Joint motion simulators (JMSs) are cadaveric testbeds for joint related orthopaedic research. Typically, a JMS rigidly fixes one side of a joint while actuating the free side with cables attached to its tendinous insertions with the goal of generating motion and joint loading that is as physiologic as possible. State of the art JMS control systems mix feedforward and feedback methodologies to control joint position and tendon tension [1].

Numerous factors complicate JMS control. Moment arms are a nonlinear function of joint position. Cable slack prevention, an added stability condition, arises from the uni-directional nature of cable actuation and is further complicated if small tendon tensions are desirable. Some muscles affect multiple degrees of freedom (DOFs) demanding more complicated multivariable control methods. Specimens vary in size and degrade quickly making modeling and / or identification difficult.

This study validates a combination of three control methods applied to an existing elbow JMS [2]: decoupled feedback control, antagonist tension switching, and iterative learning control (ILC). These methods combat the aforementioned control complications. Mixtures of decoupled feedback control and switching control have already been successfully applied in anthropomorphic robotics [3]. Here, the additions of ILC and a different kind of switching control, the tension measurement that closes the tension control loop is switched instead of the actuator that receives the tension controller's output signal, make this approach unique.

## METHODS

The AGH elbow JMS simulated four muscles (brachialis, biceps, pronator teres, and triceps) to actuate both kinematic DOFs: flexion / extension (FE) and pronation / supination (PS). A proportional controller generated control signals from comparisons of references and measurements for both joint position and antagonist tension. A linear map formed from identified stiffnesses and moment arms decoupled these control signals into individual muscle commands. A switching algorithm closed the antagonist tension control loops with the smaller of the brachialis and triceps tensions for FE and the smaller of the biceps and pronator teres tensions for PS preventing slack while allowing low tendon tensions. After each trial, an ILC generated new references for the next trial as a function of the previous trial's references and tracking errors.

Two fresh-frozen cadaveric elbows were chosen to bound typical cadaveric elbow sizes. The specimens were transected mid humerus and the hands were removed. The four simulated muscles were dissected down to their forearm insertions.

The JMS was commanded to track three motion types: PS while maintaining constant FE, FE while maintaining constant PS, and simultaneous FE and PS. Motions were smooth curves from 30° to 120° to 30° in 5s; 15° to 105° to 15° was used for the large arm's PS ROM because of a lack of pronation. Fixed angles were set at 30°, 90°, and 120°; 15°, 90°, and 105° were used for the large arm's pronation angles. Antagonist tension references were 0.75 LBS. The elbow was oriented with either a horizontal or vertical flexion plane. Forty iterations of the ILC were performed. RMS and max errors were calculated in both DOFs for joint position and antagonist tension.

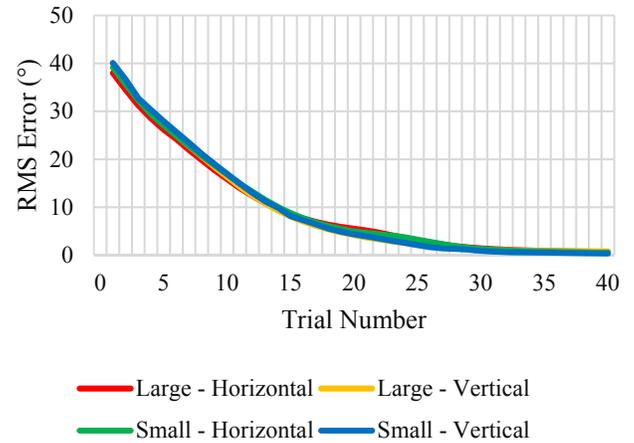

## RESULTS AND DISCUSSION

After 40 trials (Table 1), RMS (max) joint position errors were between 0.1° and 1.4° (0.1° and 3.2°). RMS (max) antagonist tension errors were between 0.1 LBS and 0.2 LBS (0.1 LBS and 0.7 LBS) after 40 trials.

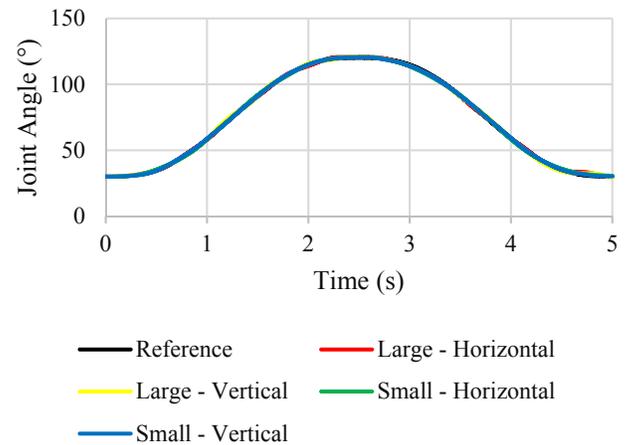

**Table 1:** RMS (and max) joint position errors. The left-hand column describes first the motion DOF and second the constant DOF's reference.

Over 40 trials, RMS joint position errors in the DOF with motion were reduced nearly monotonically (Figure 1). By the 40<sup>th</sup> trial, joint position tracking in the DOF with motion was similar regardless of specimen or flexion plane orientation (Figure 2). Joint position in the constant DOF and antagonist tension typically showed less dramatic error reductions because they started with smaller errors prior to the ILC application. The large arm suffered from oscillations at the FE natural frequency which increased errors in joint position and antagonist tension. An elbow JMS [1] designed to actuate an elbow in any orientation was tested in the horizontal and vertical configurations (and two others) tested here and produced RMS FE joint position errors of 2.2° and 1.7°, respectively.

**Figure 1:** RMS FE joint position error during simultaneous FE and PS.

**Figure 2:** FE joint position tracking during simultaneous FE and PS during the 40<sup>th</sup> trial.

## CONCLUSIONS

JMS control is complicated by nonlinear moment arms, uni-directional actuation, muscles that interact with multiple DOFs, and specimens that vary in size and degrade quickly. Despite these difficulties, this abstract shows a combination of decoupled feedback control, antagonist tension switching, and ILC allows for accurate joint position control in both FE and PS with small antagonist tensions.

## INTRODUCTION

The thumb carpometacarpal (CMC) joint produces complex movements and is responsible for nearly 50% of upper arm function [1]. In half of aging adults, osteoarthritis develops in the thumb CMC joint impairing thumb range of motion (ROM). In this population, attenuated thumb function is presents with difficulty completing activities of daily living, buttoning clothing and opening tasks [2]. In severe cases, thumb CMC joint OA is debilitating and patients lose their functional independence.

Although many studies have evaluated thumb CMC joint motion, few have looked at motion outside of anatomical planes. In a clinical setting, goniometry is used to measure ROM, but it can only measure motion in a single anatomical plane at a time and has poor interrater reliability with differences of 7-9° between providers [3]. Current methods to measure thumb motion solely within anatomical planes has little relevance in functional hand use. For example, when reaching to grasp an object, we generally have our thumb partially radially abducted and partially palmarly abducted, resulting in motion in both the radial abduction-adduction and palmar abduction-extension planes. We hypothesize that motion capture analysis of thumb motion can be used to improve upon our knowledge of functional thumb motion, providing new measures to evaluate the differences between thumb motion in healthy and disease states.

## METHODS

Standard ROM (Figure 1) and maximal spread between index and thumb finger (functional abduction) were measured in three asymptomatic participants (ages 22-29, 1 male and 2 females).

**Figure 1:** Range of motion series. a) adduction, b) radial abduction, c) extension, and d) palmar abduction.

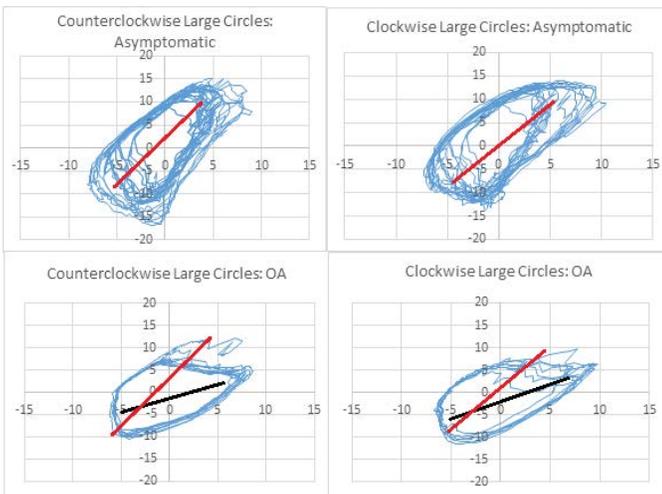

**Figure 2:** Placement of motion capture targets on hand to capture 3D functional movements.

Repetitive thumb circumduction was evaluated in two asymptomatic participants (ages 19-22, female) and 1 osteoarthritic participant (age 66, female). Motion data were collected using a motion capture system. A total of 15 reflective targets (8 markers and 7 pods shown in Figure 1) were used to identify thumb motion and interactions with the index finger.

## RESULTS AND DISCUSSION

Each participant completed a series of motions (Figure 1) to obtain the standard clinical measures. Additionally, 3D functional measurement were captured. Functional movements consisted of

**Figure 3:** Repetitive thumb circumduction (top) asymptomatic participant and (bottom) OA participant. Line overlays show the orientation of the circular movement is shifted between the two participants. The largest radii (red line depicts asymptomatic) is shifted in the OA participant (black line).

maximal thumb and index finger spread and thumb circumduction tasks. Functional abduction was the sum of motion found in radial and palmar abduction directions but allowed for greater spread between the thumb and index finger than isolated palmar or radial abduction alone (Table 1). The larger distances translate to larger motions.

On average, our OA participant took longer to complete thumb revolutions than the asymptomatic participants in the circumduction task. The axis of CMC joint motion was altered in our OA participant and had limited motions compared to asymptomatic controls (Figure 3 and Table 2). Based on our initial findings, OA participants may demonstrate a shift in their axis of motion during circumduction tasks,

**Table 1:** Maximum distance between distal pods during range of motion, a larger distance indicates a larger angle. For abduction tasks, distance was measured between distal thumb and index phalanges markers. For opposition, distance was measured between the distal thumb marker and the marker at the base of the 5<sup>th</sup> metacarpal.

	Asymptomatic #1	Asymptomatic #2	Asymptomatic #3
Radial abduction	154.4 mm	133.4 mm	139.9 mm
Palmar abduction	150.6 mm	140.8 mm	141.5 mm
Functional abduction	168.4 mm	145.1 mm	152.9 mm

**Table 2:** Average time for a revolution (seconds/revolution) in clockwise (CW) and counterclockwise (CCW) circumduction tasks.

Task	Asymptomatic #1	Asymptomatic #2	OA
CW	1.89 ± 0.1	2.12 ± 0.2	2.47 ± 0.3
CCW	2.1 ± 0.2	1.9 ± 0.2	2.01 ± 0.3

however additional data are necessary to confirm this trend. These initial results also suggest that functional measures indicate a larger motion, and by gathering both dynamic data sets and movements that relate to functional measures, we may be able to improve our understanding of kinematics in OA participants. In particular, if we can identify measures that are more sensitive to changes, early onset of functional loss could be identified and interventions prescribed earlier.

Functional measures differ from the planar measures that are typically gathered in a clinical setting and may provide additional insight with regard to joint laxity issues or changes that occur during therapies. A limitation of this work is that our sample is small and results are initial data sets. Additional data collection is ongoing and will be compared in depth to standard clinical measures.

# A SUBJECT-SPECIFIC SHOULDER CAPSULE MESH MDOEL TRAINED WITH IN-VITRO DATA

Andrew Kraszewski, Andreas Kontaxis

Hospital for Special Surgery, New York, NY, USA

email: kraszewskia@hss.edu, web: [https://www.hss.edu/research-staff\\_kraszewski-andrew.asp](https://www.hss.edu/research-staff_kraszewski-andrew.asp)

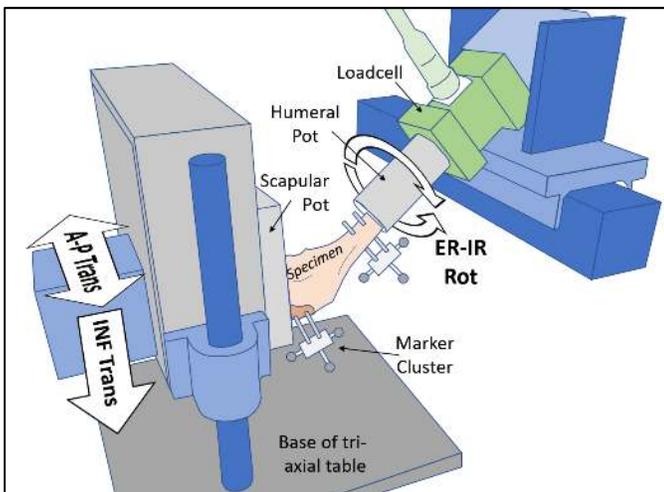

## INTRODUCTION

The contribution of the glenohumeral shoulder capsule to glenoid loading is only generally understood. Upper extremity musculoskeletal models do not typically include this soft tissue. Better understanding of its function through computer simulations is necessary.

**The objective of this work was to: 1) describe a mesh wrapping model of the glenohumeral capsule, and 2) train the mesh with an in-vitro laxity dataset and report its accuracy.**

## METHODS

*Specimen Preparation & Testing.* Fourteen fresh frozen cadavers were CT-scanned, and then dissected down to the capsule. Marker clusters were rigidly attached and anatomic landmarks calibrated with 3D motion capture (0.2mm average residual). Each specimen was potted in rigid fixtures then attached to a glenohumeral laxity device (Figure 1).

**Figure 1:** Illustration of capsular laxity testing device. Each specimen (center) was inverted.

Rotational laxity in external and internal axial directions was measured at 30fps at  $5.0^{\circ}\text{s}^{-1}$  of applied rotation, up to 2,000 N-mm. Laxity was tested across

five physical levels (baseline, lax, and 5mm, 10mm, 15mm plication) and four positions ( $0^{\circ}$ ,  $20^{\circ}$ ,  $40^{\circ}$ ,  $60^{\circ}$  scaption).

*Data Processing & Modeling.* The training data subset was internal and external axial rotation trials recorded in the baseline condition in all four scaption positions. Six degree-of-freedom glenohumeral position and axial torque were normalized to integer frame increments of axial rotation from zero to maximum torque. Four points on the glenoid capsule insertion and five on the humeral insertion were taken from 3D CT reconstruction. They were interpolated using a cubic spline to 24 origin to insertion points. Five transverse (circumferential) lines were used between origin and insertion (Figure 2). The articular humeral surface was a 23.0mm radius sphere modeled after the CT.

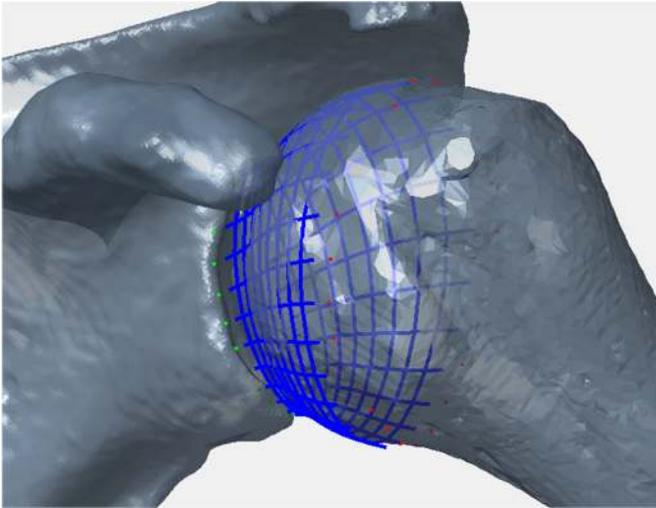

Per frame, mesh nodes were solved for with nonlinear optimization by minimizing a cost function summing the weighted squared inter-node lengths. Origin to insertion line lengths were weighted per published data.[1,2] Slack length was set to zero and the nodes were constrained not to penetrate the sphere.

Then, the mesh stiffnesses (weights) and slack lengths were trained (optimized), keeping the mesh coordinates constant, by minimizing the sum squared error between the mesh-estimated torque and in-vitro torque. Torque RMSE was calculated between the in-vitro data and the model for each direction-position combination. All mesh calculations were performed in MATLAB.

## RESULTS AND DISCUSSION

A single specimen's data was used to train the subject-specific mesh model. The torque-angle profiles (Figure 3) show good agreement with the mesh model and experimental values for external rotation, averaging 82.2 N-mm error. Internal

rotation agreement was worse, averaging 287.7 N-mm (Table 1). For internal rotation, as scaption increased so did RMSE error; furthermore, errors at the beginning and end of the trials were higher than external rotation.

**Figure 2:** Example 3D rendering of the capsule mesh model.

## CONCLUSIONS

The capsule mesh model torque prediction was better in external rotation than in internal rotation. Mesh models are more computational efficient than finite element models, and can be more easily combined with musculoskeletal models. Therefore, they can be viewed as an intermediate solution between current independent muscle lines and more sophisticated approaches.

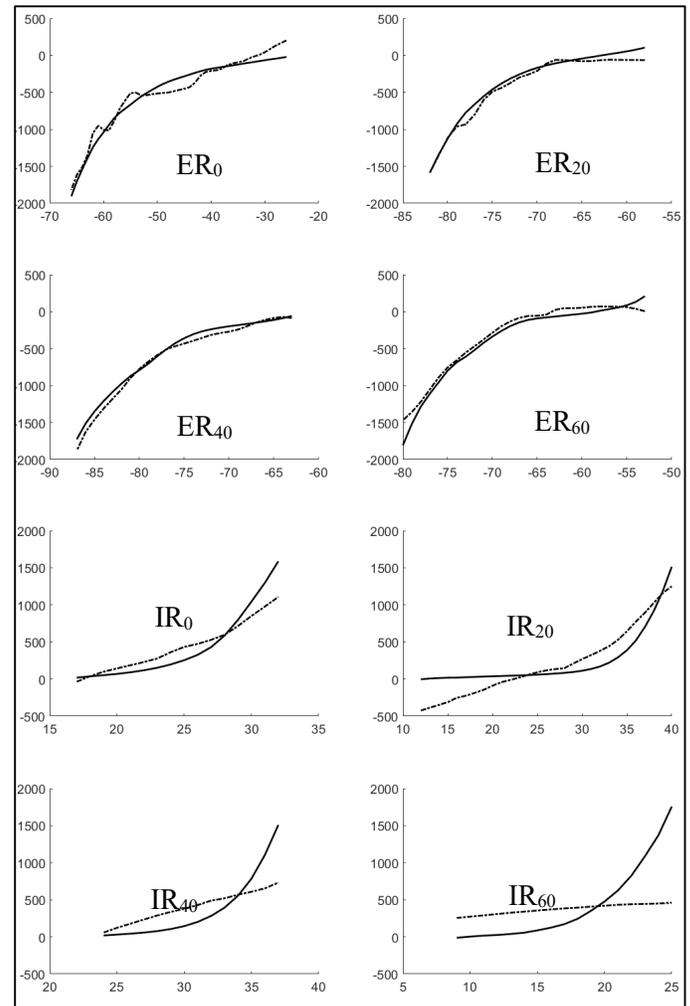

Future work will refine the model using a broader approach that includes simultaneous optimization of element properties and mesh coordinates. Mesh models are expected to have important applications in both orthopaedic and sports performance arenas.

## INTRODUCTION

Hamstring musculo-articular stiffness ( $K_{HAM}$ ) is a modifiable neuromechanical property that may contribute to anterior cruciate ligament (ACL) loading and noncontact ACL injury risk by helping control sagittal-plane tibiofemoral forces and motions. Individuals with higher  $K_{HAM}$  display biomechanical characteristics associated with lesser ACL loading during controlled non-weight bearing perturbations [1] and double-leg jump landings [2] compared to individuals with lower  $K_{HAM}$ . However, these associations have been made with males and females combined in the same analyses, and without equal sex-stratification. Because females display lesser  $K_{HAM}$  [3], and biomechanical characteristics indicative of greater ACL loading [4], compared to males, it is difficult to tease out the unique contribution of  $K_{HAM}$  to ACL loading characteristics versus other sex-dependent factors. Additionally, noncontact ACL injuries more frequently occur during single-leg rather than double-leg jump landings [5]; however, the extent to which  $K_{HAM}$  contributes to ACL loading characteristics when landing on a single leg is unknown. Therefore, the purpose of this study was to determine, within each sex, the extent to which  $K_{HAM}$  predicts biomechanical characteristics of ACL loading during a single-leg stop-jump (SLSJ) task, after controlling for body positioning at initial ground contact (IC).

## METHODS

$K_{HAM}$  and SLSJ landing biomechanics were assessed in 36 males ( $21.5 \pm 2.0$  yrs,  $1.8 \pm 0.1$  m,  $81.4 \pm 11.0$  kg) and 33 females ( $21.1 \pm 2.0$  yrs,  $1.7 \pm 0.1$  m,  $63.0 \pm 9.1$  kg) following a 5-minute warm-up.  $K_{HAM}$  was assessed via free-oscillation, using a standardized assessment load equal to 10% body mass [1, 3]. SLSJ

landing biomechanics were assessed via a force platform integrated with an 8-camera motion tracking system. The SLSJ consisted of the following: 1) a single-leg forward broad jump to the force platform from a starting distance equal to 40% body height, 2) a single-leg landing on the force platform followed by an immediate single-leg jump for maximum vertical height, and 3) a second single-leg landing back on the force platform. Data from 5  $K_{HAM}$  trials and 5 SLSJ trials were averaged.  $K_{HAM}$  data were normalized to body mass whereas force-related data were normalized to body weight.

Sex differences were confirmed via separate one-way analyses of variance. The extent to which  $K_{HAM}$  predicted ACL loading characteristics, after controlling for body positioning at IC (i.e. trunk center-of-mass position relative to the center-of-pressure, hip-flexion angle =  $HF_{IC}$ , and knee-flexion angle =  $KF_{IC}$ ), was determined via separate, sex-specific, hierarchical multiple linear regression analyses. A single ACL loading characteristic (i.e. anterior tibial translation = ATT, anterior tibial acceleration = ATA, or proximal tibia anterior shear force = PTASF) was used as the criterion variable in each model. Body positioning variables were collectively entered into the first block as suppressor variables, and  $K_{HAM}$  was entered into the second block to determine its independent contribution.

## RESULTS AND DISCUSSION

Females were significantly shorter ( $p < .001$ ), had less body mass ( $p < .001$ ), displayed greater  $K_{HAM}$  ( $13.4 \pm 2.6$  vs  $15.1 \pm 2.3$   $N \cdot m^{-1} \cdot kg^{-1}$ ,  $p = .005$ ), and performed the SLSJ with less  $KF_{IC}$  ( $2.9 \pm 6.9$  vs  $-0.9 \pm 8.1^\circ$ ,  $p = .041$ ) than males. Our finding that females displayed lesser  $KF_{IC}$  than males is consistent with previous work [6]. However, this is the first study to

our knowledge to observe higher normalized  $K_{HAM}$  in females compared to males, as previous work has found females to display lesser  $K_{HAM}$  using identical assessment methodology [1]. Nonetheless, these between-sex differences indicate that our decision to use sex-specific regression models was justified.

When examining the extent to which  $K_{HAM}$  predicted ACL loading characteristics, after controlling for body positioning at IC, only the full prediction models for ATA (females) and PTASF (males and females) were significant. When predicting ATA, the linear combination of body positioning and  $K_{HAM}$  predicted 28.0% ( $p = .049$ ) of the variance in ATA. Once differences in body positioning were controlled for ( $R^2 = .277, p = .023$ ), the  $K_{HAM}$   $R^2$  change was not significant ( $R^2\Delta = .003, p = .720$ ). Additionally, only the parameter estimate for  $HF_{IC}$  was significant ( $0.074, p = .014$ ); and the relationship was such that, after holding all other predictors constant, greater  $HF_{IC}$  predicted greater ATA. Similarly, the combination of body positioning and  $K_{HAM}$  predicted 36.9% ( $p = .005$ ) and 33.7% ( $p = .018$ ) of the variance in PTASF for males and females, respectively. Once differences in body positioning were controlled for (males:  $R^2 = .295, p = .010$ ; females:  $R^2 = .319, p = .010$ ), the  $K_{HAM}$   $R^2$  change was not significant for either sex (males:  $R^2\Delta = .074, p = .065$ ; females:  $R^2\Delta = .018, p = .393$ ). Only the parameter estimate for  $KF_{IC}$  was significant (males:  $p < .001$ ; females:  $p = .005$ ); and the relationship was such that, after holding all other predictors constant, greater  $KF_{IC}$  predicted greater PTASF. These findings collectively indicate that  $K_{HAM}$  was not a unique predictor of ACL-loading characteristics in either sex when landing on a single leg.

While higher  $K_{HAM}$  values have been shown to be associated with lesser ATT and PTASF, these relationships were established using non-weight bearing perturbations [1] and double-leg jump landings [2], respectively, whereas we used a SLSJ as our model for injury. This distinction between tasks is important because between-task differences have the ability to influence initial body positioning, which can in turn influence the functional role of the hamstring and quadriceps muscles on knee-joint biomechanics, and ultimately ACL loading

characteristics. In this regard, it is likely that the SLSJ used in this study elicited a more upright landing style (more posterior trunk center-of-mass position and lesser  $HF_{IC}$  and  $KF_{IC}$ ) compared to the double-leg jump landing used previously [2], which may have reduced the hamstrings ability to effectively resist ACL loading characteristics. Thus, between-task differences may have contributed to our contradictory findings, and caution should be taken when attempting to compare our findings to prior work.

## CONCLUSIONS

After controlling for initial body positioning,  $K_{HAM}$  was not a significant predictor of ACL loading characteristics during the SLSJ in either sex. These findings differ from previous work examining other tasks and suggest that  $K_{HAM}$  may not be as effective at resisting biomechanical characteristics of sagittal-plane ACL loading during a single-leg landing, which is performed in a more upright/erect landing style. While additional studies are needed to better understand the functional role of the hamstrings during dynamic single-leg movements, current injury prevention strategies are encouraged to equally focus on improving  $K_{HAM}$  and promote safer (more flexed) landing positions.

## INTRODUCTION

Approximately 100,000 ACL reconstructions (ACL-R) are performed in the United States each year.<sup>1</sup> Physicians commonly prescribe the use of a functional knee brace for ACL-R patients as they resume activity to protect the knee and reduce re-injury risk. The effects of these braces on movement and loading patterns have been previously analyzed, specifically to assess the brace's effect on side-to-side symmetry in movement and loading patterns.<sup>2</sup>

Previous work has examined the utility of different movement tasks in assessing return-to-sport (RTS) readiness. Assessing side-to-side symmetry in hop distance during a series of single-leg hopping tests has been the primary method of determining RTS readiness, but these tests have not been previously characterized by measures of movement quality.<sup>4</sup> Therefore, the purpose of this study was to examine loading patterns during a variety of single leg and bilateral jumping tasks in ACL-R patients in order to quantify the effects of time since surgery and functional knee bracing on loading symmetry using a novel, single sensor insole. Based on previous work, we hypothesized that brace wear and time since surgery would affect side-to-side symmetry in loading patterns.

## METHODS

Thirty ACL-R patients (9 males, 21 females; 19.4±4.2 years old; 1.73±0.07m; 72.36±13.50kg; 6.8±1.2 months after ACL-R) participated in the study. Subjects were tested at the time of physician clearance to return to sport-specific activities, and 17 of the subjects repeated the testing again three months later. All subjects received a custom fit, extension constraint functional knee brace (DonJoy Orthopaedics, Vista, CA) prior to participation. Subjects were instructed to wear the brace during all

activities more dynamic than walking throughout the course of the study. All subjects signed either an IRB approved consent or assent form prior to testing.

The testing protocol consisted of a battery of tests done in a braced and a non-braced condition, with testing order being randomized between conditions for each subject. The test battery included three countermovement jumps and a series of single-leg hops. The single-leg hop tasks included two trials each of a single (SH), triple (TH) and crossover (CH) hop for maximum distance and a 6-meter speed hop (6m).<sup>5</sup> These tasks were completed first on the nonsurgical limb followed by the surgical limb. A set of single-sensor force-sensing insoles (pedoped, Novel Electronics, St. Paul, MN) was used to record the normal force between the foot and the shoe during all tasks (100Hz). Data was collected and stored on an iPad via Bluetooth. Physical performance metrics were also recorded and included countermovement jump height, hop distance and hop speed.

A custom written Matlab (MathWorks, Natick, MA) program was used to analyze each limb's peak load during all tasks. In addition, loading rate (LR) was determined for the single hop and countermovement tasks. Values were averaged across trials for each subject, for each limb for every movement task. A limb symmetry index (LSI) was calculated for each variable based on the following equation:

$$LSI = \frac{|X_{Sx} - X_{NSx}|}{0.5 * (X_{Sx} + X_{NSx})} * 100\%$$

where  $X_{Sx}$  and  $X_{NSx}$  denote data for the surgical and contralateral limbs, respectively. This created a set of LSI values for each variable at each time point and in each bracing condition. A Shapiro-Wilk test for normality revealed that many of the variables were

not normally distributed. As a result, a series of Kruskal-Wallis ANOVAs were performed to detect differences in the LSI values with regards to testing timepoint and bracing condition ( $\alpha=0.05$ ). All statistical analysis was performed in JMP Pro 12 (SAS, Cary, NC).

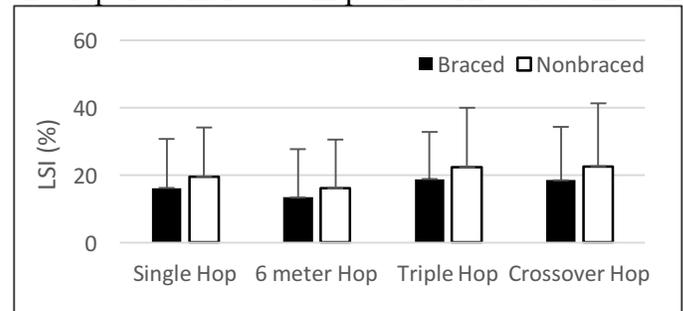

## RESULTS AND DISCUSSION

Side-to-side symmetry in the single hop peak load was significantly improved at the second testing time point (Table 1). No other significant differences were observed for the other variables of interested when examining changes based on brace condition or time.

The LSI values for peak load during the single leg hopping tasks fell mostly below the 10% symmetry benchmark that is used to determine RTS readiness. However, the LSI values for peak load during the countermovement jump were above this benchmark, meaning that considerable loading asymmetry between limbs existed during this task. This agrees with previous work that has shown significant side-to-side differences in peak vGRF during bilateral landing.<sup>2,3</sup> These data show that ACL-R athletes may utilize different landing strategies between single leg and bilateral tasks. Additionally, the LSI values given for loading rates during the single hop and countermovement jump tasks were also well above the clinical asymmetry benchmark. This is in agreement with other work that has reported significant side-to-side asymmetry in loading rates during a bilateral landing task.<sup>6</sup> These results indicate that loading rate may be an important metric to consider when assessing an ACL-R athlete's readiness to return to sport.

The data show that the presence of the brace did not significantly change side-to-side symmetry in

loading parameters or in performance metrics (Figure 1). These results differ from previous work that reported increases in peak vGRF values in both

**Figure 1:** LSI Values for Hop Distances Between Bracing Conditions

limbs while wearing a brace during a bilateral landing task.<sup>2</sup> The lack of differences between the braced and non-braced conditions could have been altered based on subjects' compliance to the brace wear instructions. Future work is needed to assess brace wear compliance as well as assessing potential sex-specific response to brace wear.

## INTRODUCTION

Anterior Cruciate Ligament Reconstruction (ACLR) after a complete tear is intended to restore stability and functionality of the limb. At the conclusion of an athlete's rehabilitation, it is common practice to undergo return to sport (RTS) testing focused on assessing strength and function. Tests involving unilateral hops, isokinetic strength and postural stability are conducted to ensure a safe RTS. RTS testing has become common practice, as young athletes have a high secondary reinjury rate of 23%<sup>1</sup>. Reinjury often leads to removal from sport, diminished quality of life, and greater potential for long-term degeneration<sup>1,2</sup>. Limb asymmetries could potentially lead to re-tear of the affected limb (AL) or a new tear of the contralateral unaffected limb (UAL). Therefore, the objective of this study was to compare the performance of the AL and UAL >12months post-ACLR during RTS testing and to interlimb differences observed in healthy controls. Secondary objective was to correlate isokinetic movement tests and functional RTS testing procedures.

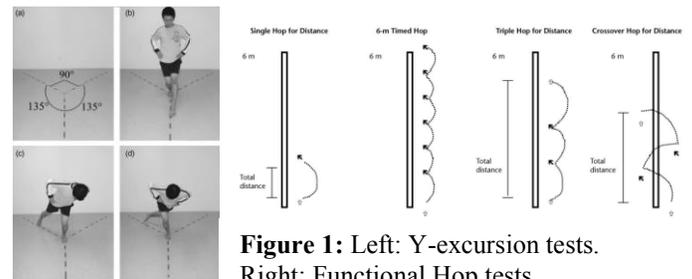

## METHODS

11 ACLR subjects (9 females, 2 males,  $22.4 \pm 3.7$  years old,  $5.4 \pm 4.2$  years post-op) participated in this study. The RTS protocol for this study included the following: Y-excursion tests, single hop for distance (SLH), triple hop for distance (TH), triple cross-over hop for distance (TCH), and timed 6m hop (**Figure 1**). Y-excursion was performed anteriorly (Y-A), posteriolaterally (Y-PL) and posteriomediaally (Y-PM). All RTS tests were performed and recorded over 3 acceptable trials per limb. Additionally, participants performed a Weight-Bearing Lunge (WBL) recorded over 6 acceptable trials per limb. Lastly, isokinetic testing of concentric peak torque of quadriceps and hamstrings at 60°/sec, 120°/sec, and 300°/sec using Biodex System 4 Dynamometer MVP™. The AL ACLR was compared to the dominant limb (DL) and the UAL was compared to the non-dominant

limb (NDL) of controls. DL was determined by which leg subjects choose to kick a ball<sup>3</sup>. The LSI was calculated using the formula  $LSI = 100*(AL/UAL)$  or  $100*(DL/NDL)$  to determine the percentage of ability between limbs. An  $LSI < 85\%$  or  $LSI > 115\%$  is considered a clinically important difference. Correlation statistics were collected to identify potential relationships between isokinetic and functional testing performed.

## RESULTS

For all RTS measures, no clinically important differences were found when comparing LSIs for subjects post-ACLR. When comparing those subjects to healthy controls, no clinically important differences were found as well. Full LSI data can be seen in **Table 1**. Correlation statistics between RTS tests and isokinetic tests of subject's post-ACLR are shown in **Table 2**. For the affected limb, isokinetic testing for knee flexion at 300°/sec showed a moderate correlation to all Y excursion tests and isokinetic testing for knee extension at 300°/sec showed a moderate correlation to all hop tests. Small correlations were found between all isokinetic testing <300°/sec and functional tests.

**Figure 1:** Left: Y-excursion tests. Right: Functional Hop tests

## DISCUSSION

For athletes >1 year post-ACLR, no clinically important differences in LSI were found between the affected and unaffected limbs for RTS testing. Additionally, no clinically important difference in LSI was found when compared to healthy controls. However, the high rate of a second ACL tear on the affected or unaffected side continues to be a common concern reported in the literature<sup>1</sup>.

This is likely due to the complex anatomical and pathomechanical nature of the injury. Although the results show minimal differences in LSI, RTS testing may need to be qualitative as well as quantitative, including evaluations of proper landing mechanics and patient reported outcomes. Evaluating kinematics during RTS testing may improve the sensitivity of this assessment.

High speed knee extension isokinetic testing at 300°/sec moderately correlates to SLH ( $r = 0.67$ ), TH ( $r=0.66$ ), and TCH ( $r=0.63$ ). High speed knee flexion isokinetic testing at 300°/sec moderately correlates to Y-A ( $r=0.56$ ), Y-PM ( $r=0.53$ ), and Y-

## CONCLUSION

RTS tests did not produce any clinical differences between the limbs or groups. This protocol, commonly used by clinicians, evaluates an individual's ability to safely return to high-level athletics post-ACLR. Given the high prevalence of reinjury, all objective data should be utilized from functional and isokinetic testing. Future study should include kinematic and kinetic assessment during functional testing along with their relationship to isokinetic testing to test for an athlete's readiness for return to sports.

PL ( $r=0.55$ ). It is important to note the small correlation between both isokinetic tests at  $<300^\circ/\text{sec}$  and functional tests ( $r=0.01-0.44$ ). Isokinetic testing can provide detailed objective data, such as quadriceps:hamstring ratio, peak torque, and peak torque/body weight. Functional testing can provide information regarding landing mechanics and gross power produced by the limb. Isokinetic and functional testing each provide specific information to fully assess an athlete's readiness for return to sport.

## INTRODUCTION

Females have an increased risk of injury to the anterior cruciate ligament (ACL) compared to their male counterparts [1]. Additionally, 75% of these ACL injuries are non-contact in nature, which indicates that neuromuscular and biomechanical kinetics and kinematics are significant risk factors for this injury. Consequently, it is important to understand the underlying mechanisms of ACL injury to determine the factors that increase ACL injury risk in females. Improved knowledge of the mechanisms of ACL will enhance injury prevention, rehabilitation, and return to sport (RTS) criteria for these athletes.

This current study was designed to investigate the sex differences of loading at the knee that cause ACL and MCL strain during a common athletic task – a drop vertical jump (DVJ). It was hypothesized that female limbs would demonstrate increased ACL strain compared to males and that MCL strain would not vary between sexes.

## METHODS

A custom-designed cadaveric impactor was utilized to simulate athletic DVJs in lower extremities of 35 specimens (22M:13F). Ages of specimens ranged from 24 to 52. Inclusion criteria for the specimens were: no evidence of significant trauma/surgery to lower extremity and no evidence of extended chemotherapy. All specimens were CT and MRI imaged prior to dissection. Specimens were prepared according to specifications outlined in a recent methodology manuscript [2].

*In vivo* kinetics and kinematics of 70 healthy athletic subjects were calculated to determine tertiles of risk (i.e. low, medium, and high) in three degrees of knee forces/moments [i.e. knee

abduction moment (KAM), anterior tibial shear (ATS), and internal tibial rotation (ITR)]. Pneumatic cylinders then applied the designated knee forces/moments calculated from the *in vivo* subjects at the tibia and then a gravity-driven drop sled of 0.5 body weight (34 kg) was released from a height of 31 cm with quadriceps and hamstrings co-contracted with a 1:1 ratio. Single axis and 6-axis load cells recorded vertical ground reaction forces (vGRF) and forces and moments at the knee, respectively. In addition, two differential variable reluctance transducers (DVRTs) were implanted into the medial collateral ligament (MCL) and the ACL, respectively, for measurements of ligament strain during simulation. Six specimens were excluded for unsuitable tissue quality or complications that arose during the experimental protocol. 29 specimens remained for analysis (18M:11F; **Table 1**).

**Table 1:** Specimen Demographics by Sex.

	<b>Males</b>	<b>Females</b>	<b>p-value</b>
<b>Age (yrs)</b>	42.7 ± 7.8	40.9 ± 9.7	0.5843
<b>Mass (kg)</b>	96.3 ± 19.5	73.4 ± 17.7	0.0037
<b>Height (cm)</b>	181.5 ± 5.5	166.0 ± 3.3	<0.0001

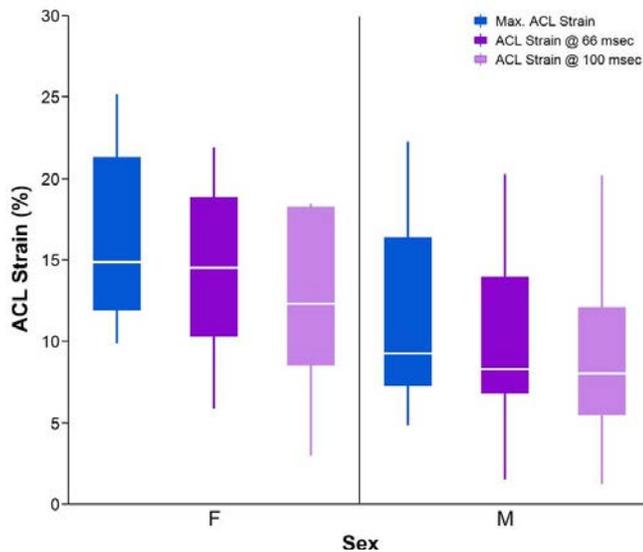

Statistical analyses were performed with JMP 10 (SAS Institute Inc., Cary, NC) with utilization of one-way ANOVA.

## RESULTS AND DISCUSSION

The cadaveric impactor reliably reproduced clinical ACL ligament ruptures (i.e. 17 femoral avulsions, 6 mid-substance ruptures, and 2 tibial avulsions) in 25 of 29 specimens included in this analysis (86.2%). With males and females combined, the average maximum ACL and MCL strain was  $14.5 \pm 9.0\%$  and  $6.8 \pm 8.2\%$ , respectively. These data indicate that even with high levels of knee abduction

loading, the ACL bears more load than the MCL during functional movement of the DVJ [3].

Comparison of maximum, minimum, initial contact, and post-impact (33, 66, and 100 msec) ACL strain of males vs females did not demonstrate any significant differences. However, there are trends indicative of increased ACL strain in females and the average strain of females with each analysis was a higher value than that of males, although not significantly different (**Figure 1**).

**Figure 1: ACL Strain by Sex.** Females demonstrate higher values of ACL strain at maximum, and 66 and 100 msec post-impact than males.

As ligament failure strength can be dependent upon the cross-sectional area of the ligament, we normalized ACL strain by ACL cross-sectional area. After normalization, significant trends became apparent with females exhibiting greater ACL strain at maximum ( $F_{1,28}=4.1350$ ;  $p=0.0519$ ), and at 66 msec ( $F_{1,28}=4.1660$ ;  $p=0.0511$ ) and 100 msec ( $F_{1,28}=3.0014$ ;  $p=0.0946$ ) post-impact.

Comparison of maximum, minimum, initial contact, and post-impact (33, 66, and 100 msec) MCL strain of males vs females did not demonstrate any significant differences between sexes. After normalization by cross-sectional area of the MCL, no additional significance between sexes was observed with all previous comparisons.

For additional comparisons of ACL and MCL strain values, we compared 25 specimens (17M:8F) that all had successfully acquired data for the randomized loading trial of 67% KAM, 67% ATS, and 67% ITR. Analysis demonstrated that there were no significant differences between sexes with or without normalization to cross-sectional surface area. However, females demonstrated higher ACL strain values as reported earlier (**Figure 1**).

The current state of this study (with fewer female specimens tested than males and with 9 additional female specimens to be tested) may significantly under power the statistics reported in this abstract. We anticipate that the outcomes of ACL strain will demonstrate improved significance with females with further testing that will equal power between sexes. Another limitation of the study is the large variability that DVRTs are known to exhibit when implanted in soft tissue structures. However, even with the high variability of DVRTs, we have maintained consistency with sensor placement and calibrations.

## CONCLUSIONS

Females exhibit greater values of ACL strain than males during similar loading trials and greater ACL strain values at maximum strain, and at 66 and 100 msec post-impact, although these findings are not currently significant.

# SHORT-TERM EFFECTS OF FEMORAL NERVE BLOCK ON SAGITTAL PLANE GAIT MECHANICS IN INDIVIDUALS FOLLOWING ACL RECONSTRUCTION

<sup>1</sup> Christopher Nagelli, Stephanie Di Stasi<sup>2</sup>, Albert Chen<sup>2</sup>, Timothy E. Hewett<sup>1</sup>

email: nagelli.christopher@mayo.edu

## INTRODUCTION

Anterior cruciate ligament reconstruction (ACLR) is a common outpatient knee surgery. Femoral nerve blocks are often, though somewhat randomly used to manage postoperative pain and improve patient satisfaction and function. A systematic review of pain management after ACLR observed that a single-shot femoral nerve block provides superior analgesia compared to placebo for up to 24 hours. However, the use of nerve block in these patients has also led to apparent quadriceps motor deficits. This is evident in recent studies that have reported that patients who were treated with a femoral nerve block during ACLR demonstrated significantly greater deficits in isokinetic knee extension and flexion strength 6 months after ACLR.<sup>1</sup> These same patients who received a nerve block were also 4 times less likely to meet return-to-sport criteria 6 months after ACLR.<sup>1</sup>

Residual movement deficits are commonly observed in patients following ACLR. Changes in ambulatory kinematic and kinetic measures persist for several years following ACLR and are directly implicated in the development of post-traumatic osteoarthritis.<sup>2</sup> To date, no study has described the short-term effects of temporary blockade of sensorimotor pathways for ACLR on gait biomechanics. Therefore, the purpose of this study was to determine the impact of femoral nerve block on ambulatory biomechanics 6 and 12 weeks after ACLR. We hypothesized that patients who received femoral nerve block would demonstrate significantly greater sagittal plane asymmetries at the hip and knee joints during ambulation.

## METHODS

With IRB approval, 16 patients scheduled to undergo ACLR were randomized into a group that received a femoral nerve block (ACLR-NB; n=7) or

a control group (ACLR; n=9) (Table 1). All patients received a hamstrings autograft during a standardized ACLR surgical procedure. The patients randomized into the nerve block group received a standard-of-care single-injection bupivacaine femoral nerve block for ACLR. Post-operative physical therapy was implemented per the institution's clinical practice guidelines following ACLR.

Patients were assessed 6 weeks after ACLR. Gait analysis was performed using a 12 infrared camera, 3-dimensional motion analysis system (Cortex, Motion Analysis Corporation, Santa Rosa, CA). Patients were fitted with 55 retroreflective markers in a modified Helen Hayes configuration and completed 5 successful trials during which they walked over ground-embedded force plates at a consistent, self-selected speed (Bertec, Columbus, OH). Sagittal plane hip and knee joint angles at initial contact and peak extension and flexion moments were reduced using custom software (Matlab and Visual 3D). A 2x2 analysis of variance was performed to assess the interaction and main effects of group and limb. *Post-hoc* t-tests will be used to test for significant differences between limbs ( $\alpha=0.05$ ).

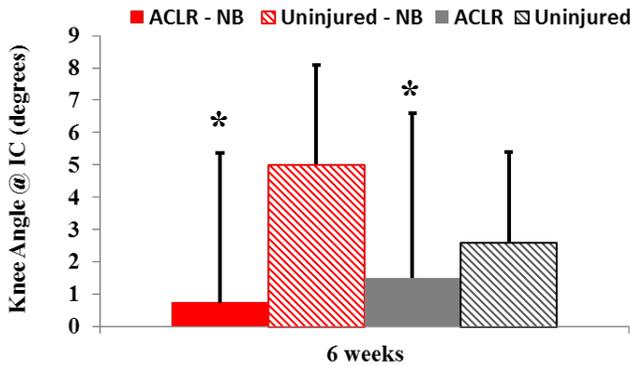

**Table 1: Study Cohort Demographics**

Group	Subjects (M/F)	Age (yrs±SD)	Height (m±SD)	Weight (kg±SD)
Nerve Block	7(6/1)	28.4±11.9	1.75±0.1	81.6±14.5
Control	9(7/2)	19.8±8.5	1.73±0.1	76.2±13.1

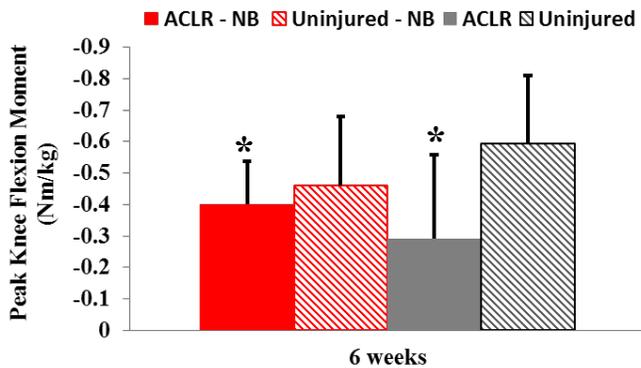

## RESULTS AND DISCUSSION

No significant interactions were observed for any of the sagittal plane hip and knee angles and moments. However, a significant main effect ( $p=0.001$ ) of

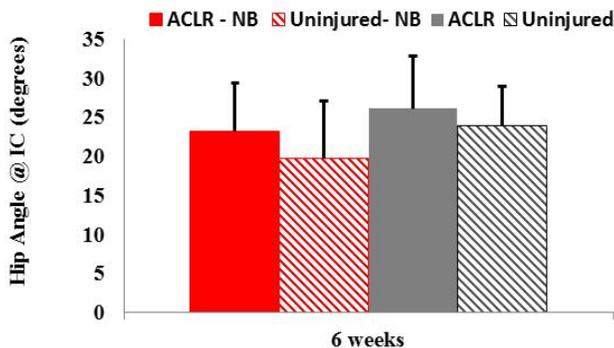

limb was observed for knee flexion angle at initial contact (**Figure 1**). Also, a significant main effect ( $p=0.041$ ) of limb was observed for peak knee flexion moment (**Figure 2**). The ACLR limbs demonstrated lower knee flexion angles at initial contact and peak knee flexion moments than the uninjured limbs.

**Figure 1:** Knee Flexion Angle at Initial Contact for the Nerve Block and Control Groups 6 weeks after ACLR. \*ACLR limbs significantly different from uninjured limbs.

**Figure 2:** Peak Knee Flexion Moment for the Nerve Block and Control Groups 6 weeks after ACLR. \*ACLR limbs significantly different from uninjured limbs.

**Figure 3:** Hip Flexion Angle at Initial Contact for the Nerve Block and Control Groups 6 weeks after ACLR

We anticipated that the femoral nerve block group would demonstrate more pronounced sagittal plane

deficits than the control group. Recently published work from this cohort showed that participants who received a single shot femoral nerve block demonstrated larger deficits in isometric quadriceps strength 6 weeks after ACLR compared to those who did not receive a nerve block.<sup>3</sup> However, this preliminary study is limited by the minimal number of patients in each group. Interestingly, the nerve block group's involved limb did demonstrate lower hip and knee flexion angles (**Figure 2 and 3**) than the control group, which indicates the potential for additive, detrimental biomechanical effects induced by a temporary cessation of sensorimotor activity. Significant side to side differences found in this study are consistent with the literature that has reported altered hip and knee mechanics during gait in patients assessed early after acute ACL injury.<sup>4</sup>

The present findings indicate that continued evaluation of gait abnormalities in a larger sample of patients is important for determination of the potentially harmful effects of femoral nerve blocks on knee function following ACLR. Differentiation of the effects based on the type and duration of nerve block is critical for finding safe and effective means for analgesia for outpatient ACLR.

### CONCLUSIONS

To the investigators' knowledge, this is the first study to investigate the effects of femoral nerve block on early post-operative gait mechanics in patients undergoing ACLR. The results of the study indicate that the use of femoral nerve block for ACLR may be associated with adverse effects on hip and knee function during gait. Restoration of normal biomechanics during gait is important for mitigation of the risks for the long-term sequelae such as osteoarthritis. Further investigation of the effects of nerve block on function in a larger sample is required as these findings may have important clinical relevance.

# INTER-JOINT COMPENSATIONS DURING EARLY GAIT IN INDIVIDUALS FOLLOWING ACL RECONSTRUCTION

<sup>1</sup> Paige E. Lin, <sup>1</sup> Ming-Sheng Chan, and <sup>1</sup> Susan M. Sigward

<sup>1</sup> University of Southern California, Human Performance Laboratory, Los Angeles, CA, USA  
email: paigeeli@usc.edu, web: <http://pt.usc.edu/labs/hpl/>

## INTRODUCTION

Restoration of normal gait mechanics is observed clinically by 3 months post-anterior cruciate ligament reconstruction (ACLR) [1]. However, biomechanical studies have reported reductions in knee flexion range of motion across stance throughout rehabilitation [2-4]. The presence of altered knee kinematics in the absence of observable gait deficits suggests individuals are compensating for such deficits to normalize gait.

While biomechanical studies suggest a persistence of altered knee kinematics during gait, no differences between limbs in peak or average hip or ankle kinematics have been reported in the literature [3,4]. The absence of kinematic differences at adjacent joints may suggest that individuals do not alter kinematics at adjacent joints to compensate for limited knee flexion. It is also possible that these alterations are not reflected in peak or average angles. Thus, these analyses may not be sensitive enough to identify intralimb compensations, as they are limited to angles identified at discrete time points and peaks for each joint. Further, the timing of these peaks do not necessarily correspond across joints, limiting our understanding of how joints coordinate their actions to compensate for altered knee mechanics.

The purpose of this study is to quantify lower extremity joint coordination and identify compensatory strategies by comparing inter-joint coordination in sagittal plane kinematics during gait between individuals 3 months post-ACLR and controls.

## METHODS

Thirteen individuals (9F,  $23 \pm 7.0$  yrs)  $91 \pm 18$  days post-ACLR without observable gait deficits and thirteen healthy controls (4F,  $24 \pm 5.7$  yrs) walked at a standardized velocity of 1.4m/s ( $\pm 5\%$ ). Five

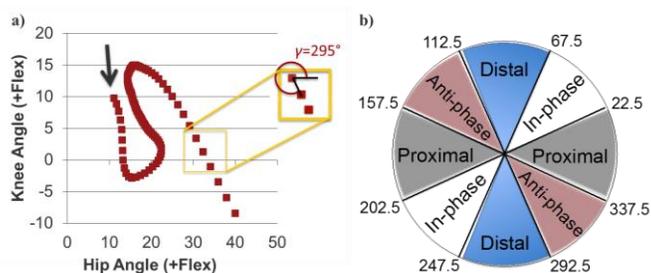

successful stance phase trials were collected for each limb: ACLr and non-surgical (NS) for the ACLr group and the control (CTRL) limb. Control limbs were averaged for analyses.

Three-dimensional kinematics were collected using an 11-camera motion capture system (250 Hz; Qualisys, Inc. Sweden) or a 14-camera motion capture system (340 Hz; BTS Bioengineering Corp., Italy). Sagittal plane ankle, knee and hip angles were calculated and stance phase was normalized to 101 data points for further analysis.

Inter-joint coordination was quantified from joint angle-angle plots by calculating coupling angles ( $\gamma$ ) between the joints at corresponding time points. Coupling angles were determined using vector coding techniques by connecting two consecutive time points on an angle-angle plot and determining the counterclockwise angle of this line relative to the right horizontal (Figure 1a). A custom MATLAB script was used to calculate coupling angles between two sagittal plane joint coordination couplings: hip-knee and knee-ankle using the following question:

$$\gamma_{j,i} = \tan^{-1}((y_{j,i+1} - y_{j,i}) / (x_{j,i+1} - x_{j,i}))$$
where  $0^\circ \leq \gamma \leq 360^\circ$ , and  $i$  is a percent of stance of the  $j$ th trial.

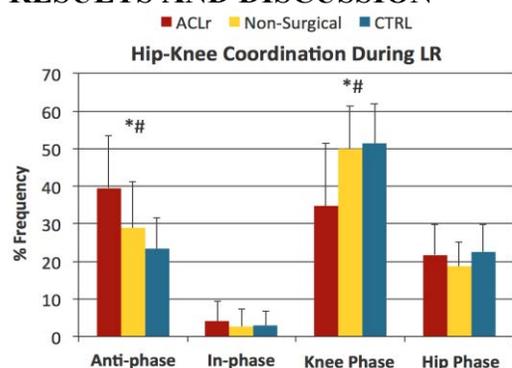

Coupling angles of hip-knee and knee-ankle angle-angle plots were calculated between all adjacent time points in the ACLr, NS, and CTRL limbs during loading response (LR; 0-25% of stance). Coupling angles were categorized into one of four coordination patterns: in-phase, anti-phase, knee phase, and ankle or hip phase (Figure 1b). The frequency of phase angles that fell into each coordination pattern was determined for each trial during LR and expressed as a percentage of coordination pattern frequency.

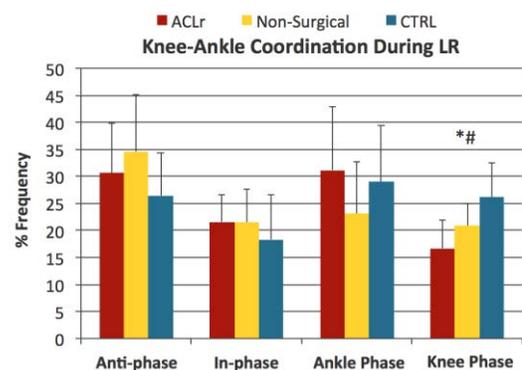

**Figure 1:** a) Determination of coupling angle with arrow denoting heel strike of stance; b) Categorization of coupling angles into coordination patterns.

The dependent variable, coordination pattern frequency, is a discrete variable; therefore, non-parametric Kruskal Wallis tests were used to compare mean rank differences in coordination pattern frequency (anti-phase, in-phase, proximal phase, or distal phase) between limbs. Mann-Whitney U tests were used for post hoc analyses;  $\alpha=0.05$ .

## RESULTS AND DISCUSSION

**Figure 2:** Hip-knee coordination during loading response in the ACLr, NS, and CTRL limbs (\* $p<0.05$  ACLr-NS; # $p<0.05$  ACLr-CTRL).

**Figure 3:** Knee-ankle coordination during loading response in the ACLr, NS, and CTRL limbs (\* $p<0.05$  ACLr-NS; # $p<0.05$  ACLr-CTRL).

During LR, the frequency of knee phase motion was reduced in the ACLr limb compared to the NS and CTRL limbs for hip-knee (35% vs. 50% and 51%, respectively;  $p=0.017$ , Figure 2) and knee-ankle (17% vs. 21% and 26%;  $p=0.001$ , Figure 3) couplings. Anti-phase hip-knee coordination was greater in the ACLr limb (40% vs. 29% and 23%;  $p=0.001$ , Figure 2). No differences in inter-joint coordination between the NS and CTRL limbs were observed.

## CONCLUSIONS

Decreased knee phase motion in both couplings is consistent with limited knee motion previously reported. Differences in inter-joint coordination indicate intralimb hip and ankle compensations in the ACLr limb that occur at a time when gait is normalized clinically. Specifically, the decrease in knee phase motion and concurrent increase in anti-phase motion seen in hip-knee coordination was driven by increased hip extension in the surgical limb during early LR. In knee-ankle coordination, a decrease in knee phase motion was driven by increased plantarflexion motion in the surgical limb. The lack of differences between the non-surgical and control limbs suggests that inter-joint coordination is not altered in both limbs following ACLr.

The intralimb compensations in the surgical limb may aid in restoring the appearance of unimpaired gait following ACLr. This is of concern as altered gait mechanics have been attributed to the development and progression of knee osteoarthritis in this population. Future work is needed to investigate how alterations in inter-joint coordination relate to changes in knee loading.

## INTRODUCTION

Prevention of anterior cruciate ligament (ACL) injuries continues to allude researchers and practitioners. More recent literature has tested lower extremity and ACL loading mechanisms in a reactive test in an attempt to better reflect athletic on-field experiences [1]. This has led to an inflation in methodological complexity [2] that may reduce duplicability and ecological validity, and complicate subsequent implementation by researchers in slightly different settings.

As such, the current project was performed in order to improve upon previous methods [2] by simplifying the task in order to increase ecological validity and decrease independent variable space while producing similar responses.

## METHODS

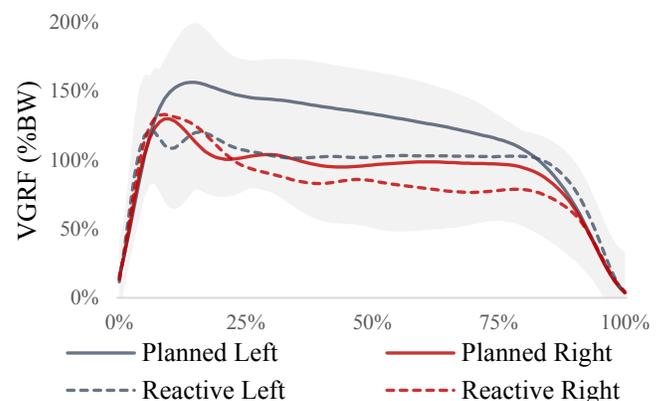

Ten recreationally-active, uninjured students were recruited as participants (5 females and 5 males;  $21.6 \pm 1.7$  years;  $1.75 \pm 0.04$  m tall;  $71.5 \pm 13.6$  kg). They individually completed an informed consent process, performed a warm-up, and then practiced the following movement before data collection.

Similar to previous research [2], participants started on a 30cm tall block placed 50% of their height away from a landing zone. They jumped forward from this block and landed bilaterally with each foot on a force platform (1600 Hz, Advanced Mechanical Technology Inc., Watertown, MA). Participants then quickly jumped to the left or right  $60^\circ$  from their initial forward direction as far as possible. This angle was chosen instead of  $90^\circ$  after feedback from a focus group indicated it was more natural of a performance.

The direction of the jump was indicated to the participants by one of two LED lights placed at eye

level in front of the jumping area. Controlled by an Arduino Mega microcontroller, the lights were illuminated either before the participant began the trial so they could pre-plan their movement or only after the participant landed on the force platforms, so participants had to react to the direction. Simplifying from four reactive timing conditions to only providing the directional signal at landing eliminated the need to instrument the 30cm tall block and provided more of a worst-case difference between the timing condition implementations.

Participants performed five trials in each timing condition and in each jump direction, for a total of 20 recorded jumps. Order of testing was double-blind randomized by the Arduino microcontroller via a seeded Durstenfeld technique. The microcontroller also randomly injected three “catch” trials into the order of testing; in this condition no directional signal was illuminated. This allowed for verification that the participant was not attempting to predict the jump direction, and inflated the number of potential responses in order to maintain a similar requisite response time [3] to previous investigations [2].

**Figure 1:** Mean unilateral VGRF across percentage stance time for each timing condition while jumping right. Shaded area is  $\pm$  standard deviation range.

A total of 19 retroreflective markers placed on the right foot, leg, pelvis, and torso were recorded by 8 Vicon cameras through Nexus 1.8.2 (160Hz, Vicon Corp, Oxford, UK). Right knee flexion and valgus angles were calculated for the performance; initial values at the first instant of force platform contact and peak values from the first 100ms of contact [4] were extracted. Similarly, peak unilateral vertical ground reaction forces during the same time window were identified and scaled to participant bodyweight. A repeated-measures ANOVA was calculated to determine the differences between jump direction and timing of the directional signal on dependent variables.

## RESULTS AND DISCUSSION

A significant main effect for timing condition was identified for each VGRF ( $p = 0.042$ ) and ST ( $p=0.001$ ), but no other variables ( $p > 0.15$ ). False discovery rate-corrected (*a priori* 0.05) pairwise t-tests did not identify any significant differences for the VGRF between the timing conditions. Significant differences were identified for ST relative to timing condition, and are presented in Table 1.

Similar to previous reports, ST increased in a reactive performance compared to a planned [2]. The grand mean change in ST of 175ms between these conditions is slightly less than theorized by the implications of Hick's Law [3], but similar to previous research [5].

In contrast to previous research [1,2,5], no significant kinematic or kinetic changes were identified between the timing conditions or jump directions. Given that the largest changes in similar variables were previously identified between these two timing conditions, these results are surprising. It is possible that the change in jump direction was not dramatic enough to alter landing techniques during initial contact with the force platform or during the first 100ms of landing. This is not entirely consistent with previous findings, however.

## CONCLUSION

Due to the lack of significant differences in kinematics and kinetics during landing between the timing conditions, caution is suggested if implementing a similarly simplified task. It is possible that the currently presented task does not exacerbate variables associated with ACL load adequately to be a valuable testing paradigm. It is also possible that the unchanged ACL load variables are related to an inflated ST. The potential relationships between ST and ACL load variables are being further studied by the current researchers.

## INTRODUCTION

Anterior cruciate ligament (ACL) injuries often cause significant limitations in both activities of daily living and sports. Patients demonstrate altered gait patterns up to 2 years after ACLR, with knee excursion asymmetries in both weight acceptance and mid-stance during gait. Additionally, altered kinetics and kinematics may contribute to the development of joint degeneration and premature osteoarthritis due to the change in load-bearing position[1].

Previous research has investigated the relationship between gait asymmetries and functional exams[2], and self-report outcomes and return to sport[3]. However, there is currently no evidence that investigates the difference between gait asymmetries and self-report outcomes at 1 year after ACLR. We hypothesized that male athletes with asymmetrical knee excursion patterns during gait would have lower self-reported outcomes scores.

## METHODS

Thirty-eight male athletes (age  $24.4 \pm 7.5$  years) completed biomechanical gait assessment 1 year after ACL reconstruction. Inclusion criteria included: age 13-55, >80% quadriceps strength index (QI), and participation in jumping, cutting, and pivoting sports >50 hours per year. All participated in a secondary prevention program[4]. We analyzed participants' walking patterns using an eight-camera motion capture (VICON, Oxford, UK) at 120 Hz and an embedded force platform (Bertec Corp., Columbus, OH) at 1080 Hz. We used 39 retroreflective markers on the bilateral lower extremities and pelvis for motion analysis testing. Participants walked over-ground at a self-selected gait speed maintained to  $\pm 5\%$  across trials. Data were processed using commercial software (Visual3D; C-Motion, Germantown, MD).

We dichotomized asymmetric (Asym) and symmetric (Sym) as a difference in sagittal plane knee excursion between the surgical limb and non-surgical limb that met or exceeded the minimal clinically important difference (MCID) of 3 degrees[5]. We did this at both weight acceptance (WA) and mid-stance (MS) and compared each excursion group separately.

Participants also completed self-report outcome measures: International Knee Documentation Committee Subjective Knee Evaluation Form (IKDC) and Knee Injury and Osteoarthritis Outcome Score (KOOS).

We used independent t-tests to compare outcome measures between groups. Alpha was set to 0.05 a priori.

## RESULTS

The mean difference between limbs (involved – uninvolved) for knee excursion was  $-3.6 \pm 3.5^\circ$  at WA and  $-4.6 \pm 4.5^\circ$  at MS.

There were no statistically significant differences between self-reported outcomes in men who walked symmetrically versus asymmetrically (Table 1). The mean differences between the groups were smaller than the MDC for the self-reported outcomes scores.

## DISCUSSION

The purpose of this study was to compare self-reported outcomes in male athletes who walked symmetrically vs asymmetrically 1 year after ACLR. We found no statistically significant or clinically meaningful difference among men who walked with knee excursion symmetry vs asymmetry on any self-reported outcomes measure.

A lack of difference between groups may be in part due to the stringent criteria all participants passed prior to enrollment. With these standards for

inclusion, we are not able to compare participants with lower baseline function and possible asymmetry during gait.

As part of a larger study, these men also completed an additional secondary prevention program and were required to meet stringent criteria prior to returning to sport. Most participants had full participation in activities of daily living (KOOS ADL score 99.0±2.8) and higher level activities (KOOS Sport/Rec 93.7±9.5) with little pain (KOOS Pain 96.3±4.5). This additional rehab and high functional level may have reduced the impact of gait asymmetries on self-reported outcomes.

We are the first to assess differences in self-reported outcomes in male athletes with and without gait asymmetries 1 year after ACLR. A study in total knee arthroplasty (TKA) patients found that 1 year after TKA, participants had improved self-reported outcomes from prior to surgery to one year after surgery, but these self-reported outcomes did not differentiate between those with and without gait asymmetries[6]. Additionally, Boonstra et al[7] found that post-TKA, patient-based scales were largely influenced by pain. This may suggest that once post-surgical pain is resolved, participants overestimate function[6]. Most participants in our study reported very little pain and high ADL participation regardless of detectable gait asymmetries. This may suggest similar influences of pain on perceived function in the ACLR population.

Additionally, our participants were men who participated in high level activities prior to injury and

completed an additional secondary prevention program after ACLR. High functional level and additional rehab may diminish the impact of gait asymmetries on self-reported outcomes, although further research is necessary.

## CONCLUSION

We found no statistically significant or clinically meaningful difference between male athletes who walked with knee excursion asymmetry and those who did not on any self-reported outcomes measure 1 year after ACLR.

## INTRODUCTION

Landing is considered one of the “high-risk” sporting movements that can lead to ACL injury [1]. Because of this, much attention has been placed on kinematic and kinetic variables associated with landing and how they relate to ACL injury risk. One such variable is foot progression angle (FPA).

Previous research has found landing with a “toe-in” position of 30° increases peak hip adduction, knee internal rotation angles and moments, as well as peak knee abduction angles, and decreases peak hip flexion angles [2]. Landing with a “toe-out” position has been shown to decrease these ACL injury variables [2]. However, participant FPA in the previous study was assessed using three different conditions: 1) neutral FPA of 0°, 2) toe-in FPA of 30°, and 3) toe-out FPA of 30°. No study thus far has assessed changes in FPA relative to a person’s natural FPA (self-selected) and the influences this would have on ACL injury risk variables. Currently, it is also unknown if smaller changes of FPA (i.e. 15° of toe-in or toe-out) also influence ACL injury risk variables the same as a more aggressive FPA (i.e. 30° of toe-in or toe-out).

Therefore, the purpose of this study was to assess the effects of changes in FPA from self-selected in 15° intervals on ACL injury risk variables during drop landings in healthy, recreationally active, males and females.

## METHODS

Ten healthy, active participants (five females, five males) volunteered for the current study and provided written informed consent. Participants also completed the Lower Extremity Functional Scale to ensure they qualified to participate.

At the start of their testing session, participants were fitted with a standardized lab shoe (Adidas Noveto)

and asked to complete a five-minute warm-up. After completing the warm-up, anatomical markers and tracking marker clusters were placed on the right leg of the participants (despite leg dominance). A three-second static calibration trial was collected, and data collection began.

An overhead hang bar was adjusted so that participants’ feet were 40cm above the force plate. Five drop landing trials from the hang bar were collected at the participant’s self-selected FPA. An average self-selected FPA was taken from the five self-selected trials and used to determine the 15° toe-in, 30° toe-in, 15° toe-out, and 30° toe-out FPAs. Drop landing tasks after the self-selected condition were counterbalanced and five trials of each condition were collected. A customized MATLAB code (MathWorks, Natick, MA) was used to provide real-time feedback of drop landing FPA during the toe-in and toe-out conditions to eliminate a targeting effect.

A 12-camera motion capture system (200Hz, Vicon, Centennial, CO, USA) and a force platform (2000Hz, AMTI, Inc., Watertown, MA) were used to collect marker coordinate and GRF data, respectively. Visual3D biomechanical software (C-Motion, Germantown, MD, USA) was used to process and analyze all data. Marker coordinate and GRF data were filtered using fourth-order Butterworth low-pass filters with cut-off frequency of 10Hz. 3D joint kinematics were calculated using a joint coordinate system approach. 3D internal joint moments were calculated using standard inverse dynamics techniques and expressed in the joint coordinate system. Joint moments were normalized to body mass.

A 2x5 (gender x task) repeated measures ANOVA was used to compare dependent kinematic and kinetic variables (v23.0, SPSS Inc., Chicago, IL). Significant interactions and main effects were examined with *post hoc* pairwise comparisons with

Bonferroni adjustments. Significance was set at  $p < 0.05$ .

## RESULTS AND DISCUSSION

Initial contact hip internal rotation, knee abduction, and knee external rotation angles as well as peak knee internal rotation moment were all significant between drop landing tasks ( $p < 0.05$ ). Initial contact knee flexion angle, as well as peak hip external rotation, knee extensor, and knee adduction moments were not significant for any task or gender difference ( $p > 0.05$ ). Peak knee adduction moment displayed a trend toward significance ( $p = 0.057$ ).

Our data supports previous studies that suggest landing with a “toe-in” FPA increases ACL injury risk kinematic variables [2]. Specifically, hip internal rotation, and knee abduction angles at initial contact increased as toe-in FPA increased, indicating greater medial knee collapse. Females experienced greater peak knee extensor, adduction, and internal rotation moments compared to males regardless of FPA. However, our kinematic and kinetic magnitudes are not consistent with that of previous research [2]. This is most likely due to the changes in FPA based on the participants self-selected FPA and not a neutral or 0° position. On average, self-selected FPA for the current study’s participants was 20° of toe-out.

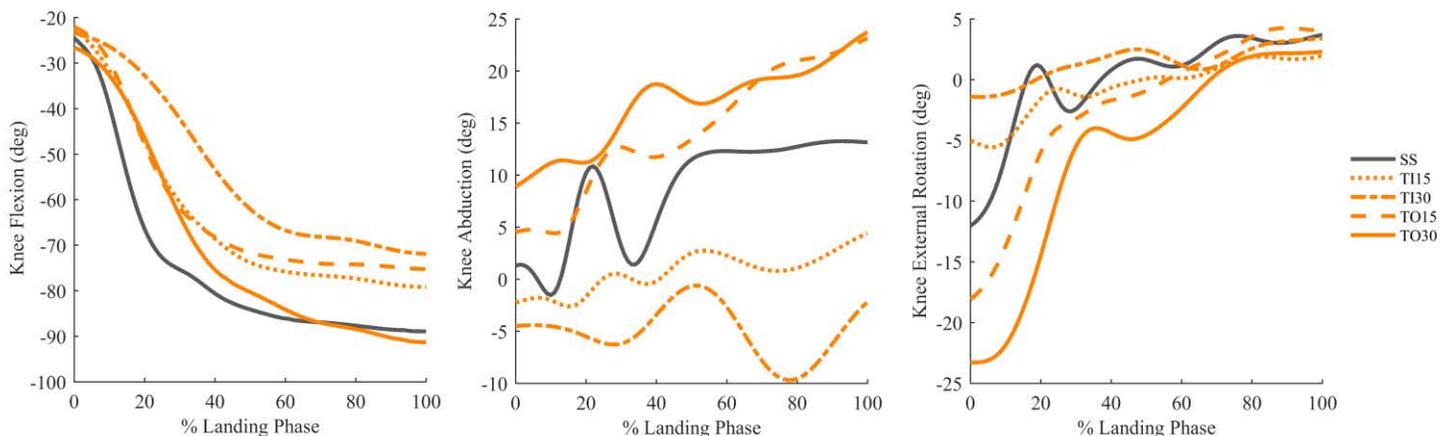

Therefore, our 30° toe-in from self-selected condition would only result in approximately 10° of toe-in. Differences in landing task (i.e. drop landing vs. jump landing) may also play a role in magnitude differences.

## CONCLUSIONS

Our results suggest that landing with a toe-in FPA will increase the magnitude of ACL injury risk variables of the hip and knee. Females demonstrate a greater magnitude of these variables with toe-in FPA of 15° and 30° compared to males. However, while hip and knee ACL injury risk variable magnitudes increase, they may not reach a high enough magnitude that would put athletes at a “high-risk” of an ACL injury as seen in previous ACL injury risk studies [3].

<sup>1</sup> Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

<sup>2</sup> Umeå University, Sweden

email: sdivyal@vt.edu

## INTRODUCTION

One of the most common tests used in rehabilitation for clinical assessments of functional performance following ACL injury is the one-leg hop forward where the jump distance is measured<sup>1</sup>. The standard way to evaluate the performance in this test is by using the limb symmetry index (LSI), which is the ratio of the jump distance for each of the two legs<sup>1</sup>. However, LSIs of similar magnitude could be achieved by very different limb kinematics, and merely reporting the LSI for jump length does not provide any information about the movement quality and the associated kinematic alterations that may prevail post-injury.

In this context, movement variability has now been accepted in both sports and clinical biomechanics to play a functional role in neuromuscular adaptations. This role includes facilitating adaptations of the individual motor system to processes such as learning, aging, and changing constraints such as pain, fatigue and injury e.g. 2-3. There are reports of different movement variability patterns in the short-term after ACL injury, but to the best of our knowledge, no study has assessed whether the intra-individual variability of joint kinematic patterns is still altered in ACL injured patients in the very long term. The aim of this study was to determine whether coordination variability of the hip-knee joint couplings during the one-leg hop was altered about 20 years after ACL injury compared to healthy knee controls.

## METHODS

This study is part of a large cross-sectional study of >100 individuals. Specifically in this study, 33 individuals who had undergone ACL injury and subsequent treatment using reconstruction surgery were compared with 33 age and gender matched

healthy controls. After warm-up and practice, all participants performed one-leg hops for maximal distance starting on one leg in an upright position from a force-plate, jumping forward as far as possible and landing on the same leg while maintaining balance on the ground. Hops were performed until 3 successful hops could be performed on each leg.

A 3-D motion capture system (Qualisys) was used to movement kinematics, from which knee and hip angles were computed. Force plate and marker data were used to compute take-off and landing instants for each jump, and a 100ms duration prior to take-off and 100ms duration following landing were defined as take-off and landing phases respectively. All the hip and knee joint angles were extracted during the take-off and landing phases for each of the three jump for further analysis. The following intra-limb couplings were investigated: knee abduction-adduction/hip abduction-adduction, knee abduction-adduction/hip rotation and knee abduction-adduction/hip flexion-extension. Angle-angle plots were created for each coupling, and joint coordination was quantified using a vector coding technique<sup>4</sup>. Briefly, coupling angles were calculated using the orientation of the resultant vector of each angle-angle plot to the right horizontal between every two successive data points of each trial. The standard deviation of the coupling angles across the three trials was then calculated for each time point, and then pooled across the whole trial by computing the overall root mean square. Thus this yielded a measure of between-trial, within-subject variability. This procedure was repeated separately for the take-off phase and the landing phase and for each lower extremity coupling using the 3 successful hops. Data from the injured legs of the ACL group were compared with the dominant leg of the non-injured controls.

## RESULTS AND DISCUSSION

Figure 1 shows the coordination variability of the injured side of the ACL group in comparison with the coordination variability exhibited by healthy controls during the take-off and landing phases.

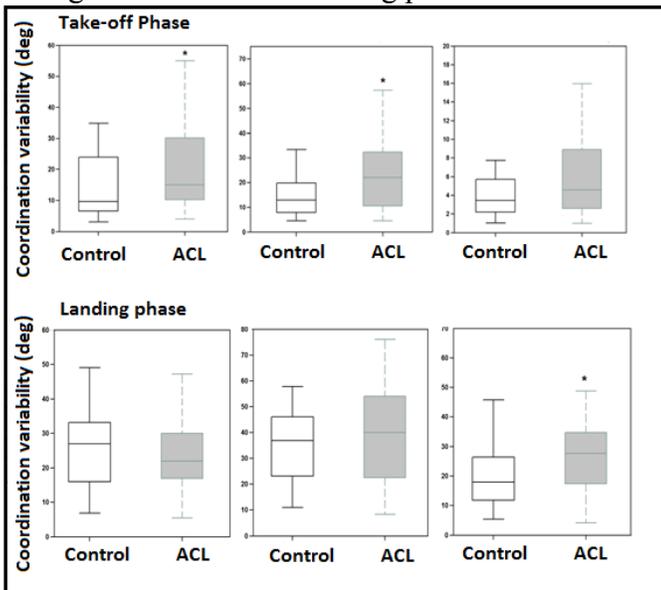

Fig. 1: Coordination variability (SD of vector coupling in degrees) of knee abduction/adduction coupled with hip abduction/adduction (left), hip rotation (center) and hip flexion/extension (right) during the take-off and landing phases of one-leg hops. Box plots show median values, 25th and 75th percentiles, and minimum and maximum values of each variable across all subjects in the group. Asterisk indicates a significant difference ( $p < 0.05$ ) in Mann Whitney U test between the control and ACL groups.

On average, the ACL group exhibited ~50% more variability in knee-hip abduction/adduction than the control group and nearly 60% more variability in knee abduction/adduction-hip rotation than the control group during the take-off phase. The ACL group exhibited ~ 50% more variability in knee abduction/adduction-hip flexion/extension coupling than the control group during the landing phase.

Our results of greater variability in hip-knee coordination in ACL group compared to healthy controls is in agreement with earlier studies <sup>e.g.,5</sup> who have investigated these couplings in the short-term after injury. Such increased variability has been suggested to be due to the absence of proper neural feedback mechanisms due to altered proprioception, despite the regaining of mechanical stability in individuals undergoing ACL reconstruction. For the first time, we have shown that such an effect is present even 20 or so years after injury. Furthermore, in our study, the injured and control groups were not significantly different in terms of hop length as

normalized to body length during the one-leg hop test. However, the injured groups showed significantly lower knee function (worse Lysholm knee scores and Knee injury and Osteoarthritis Outcome Scores). There were also significantly higher limb asymmetries (i.e. worse LSI scores) reported in the injured group than the control group, although the LSI of both groups were above 90% and hence classified as normal. Thus, although both groups showed similar performance in the one-leg hop test and had sufficiently “normal” limb symmetry, the injured group showed different joint coordination variability than the control group. This greater variability correlated with worse scores on tests of self-reported knee function.

## CONCLUSIONS

Improving our understanding of coordination variability and applying methods assessing intra-individual movement variability may provide more insight into mechanisms governing adaptations of neuromuscular control following injury, also in the very long term.

## INTRODUCTION

Asymmetries of the lower extremity functions have been identified in individuals following anterior cruciate ligament reconstruction (ACL-R) [1-3] which could contribute to recurrent anterior cruciate ligament (ACL) injury. Deficits in the ability to absorb forces through the lower extremity increases strain in the ACL, which could potentially lead to ACL re-injury. There are no studies examining energy absorption (EA) strategy between the ACL-R and contralateral (CON) limbs in adolescent males and females at a time of return to sports (RTS) following ACL-R. The purpose of this study was to examine the differences of EA pattern in the lower extremity in the ACL-R limb and contralateral limbs in adolescent males and females

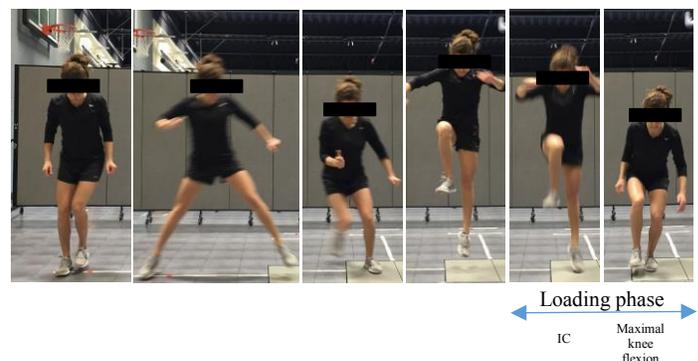

## METHODS

Cross-sectional descriptive study design was used. A total of fifty-three participants with ipsilateral ACL-R who were at a time of RTS following ACL-R volunteered (Male = 21: Age =  $15.67 \pm 1.20$  years, Ht =  $176.80 \pm 7.85$ cm, Mass =  $75.97 \pm 16.0$ Kg; Female = 32: Ht =  $164.35 \pm 6.89$ cm, Mass =  $66.41 \pm 6.89$ Kg).

Joint net power (J) was assessed using an eight-camera motion capture system and two forceplates while participants performed three separate lateral-vertical jump (LVJ) tasks (Figure 1). They stood lateral to the forceplate, located at 50% of their height. Participants then pushed off the ground with their non-testing limb, hopped onto the forceplate with their testing-limb followed by immediate

maximal vertical jump, and landed on the forceplate with their testing-limb. Immediately after landing back onto the forceplate, they were required to balance for approximately 2 seconds. Isokinetic strength of the quadriceps (QUADS) and hamstrings (HAMS) at 60 deg/sec was collected using an isokinetic dynamometer. Maximal voluntary isometric strength of the hip abductor (HAB), hip external rotators (HER), and hip extensors (HEXT) were assessed using a handheld dynamometer. All data were assessed bilaterally in order of uninvolved limb, followed by involved limb. Energy absorption of the hip, knee, and ankle joints were calculated by integrating the negative part of the power curve during the loading phase of the second landing of the LVJ and normalized to the product of height and weight (Ht\*BW) and averaged across three trials. Total EA was calculated as a sum of EA of each joint. Isokinetic strength of the QUADS and HAMS was normalized to body weight (BW) and averaged across 5 trials. Peak MVICs of the HAB, HER, and HEXT was normalized to the BW and averaged across 2 trials. Separate paired t-test were performed to examine the difference between the ACL-R and contralateral limbs in each group (male and female).

**Figure 1. Lateral-hop vertical jump (LVJ)**

## RESULTS AND DISCUSSION

During the loading phase of the LVJ, total EA was significantly decreased in both males ( $p=0.006$ ) and females ( $p=0.047$ ) in the ACL-R limb compared to the CON limb. Adolescent males demonstrated decreased EA at the knee ( $p<0.001$ ) and ankle ( $p<0.001$ ) joints in the ACL-R limb while adolescent females demonstrated increased hip EA ( $p=0.009$ ), and decreased knee ( $p<0.001$ ) and ankle ( $p=0.008$ ) EAs compared to the CON limbs (Table1).

For muscle strength, both groups had significantly decreased QUADS (Male:  $p<0.001$ ; Female:  $p<0.001$ ) and HAMS (Male:  $p=0.038$ ; Female:  $p=0.029$ ) strength, compared to the CON limbs. No significant differences were observed in the gluteal muscle strength (Table 2).

Following ACL-R, adolescent males and females demonstrated altered EA strategies in the ACL-R limb compared to the CON limb during the LVJ. In the ACL-R limb, adolescent males avoided the usage of knee and ankle joints to absorb forces while adolescent females relied more on the hip joint and avoided use of the knee and ankle joints,

in relation to the CON limb. These results suggest that adolescent males and female adopted different strategies to absorb forces during the LVJ. Since both groups displayed decreased QUADS and HAMS strength, these muscles may play an important role in absorbing forces through the lower extremity.

## CONCLUSIONS

Both male and female adolescents displayed different EA absorption strategies during the LVJ at a time of RTS following ACL-R. Increasing QUADS and HAMS strength may improve the EA pattern in the ACL-R limb, which could help develop a more symmetrical landing pattern.

## INTRODUCTION

The anterior cruciate ligament (ACL), along with preventing anterior translation of the tibia, provides important sensory information regarding the knee joint. ACL injury disrupts this information, leading to altered neuromuscular control of the lower extremity. Following ACL reconstruction (ACLR) it has been suggested that, if not addressed properly, neuromuscular deficits may occur [1]. Segment coordination is a measure of neuromuscular control that provides information about how adjacent segments move in relation to each other and should be relearned during rehabilitation. Using segment coordination variability as an indicator of poor neuromuscular control may lead to a better understanding of ACL injury risk and missing components of rehabilitation. Some authors suggest that there is an optimal level of variability for motor tasks with anything above or below this level leading to injury [2]. This range has yet to be identified but may prove to be an important factor in ACL injury and rehabilitation.

The current study aims to contribute to the existing literature by investigating lower extremity coordination differences between ACLR patients and control subjects during a jump-landing task. It was hypothesized that ACLR patients would exhibit altered lower extremity segment coordination patterns when compared to the control group.

## METHODS

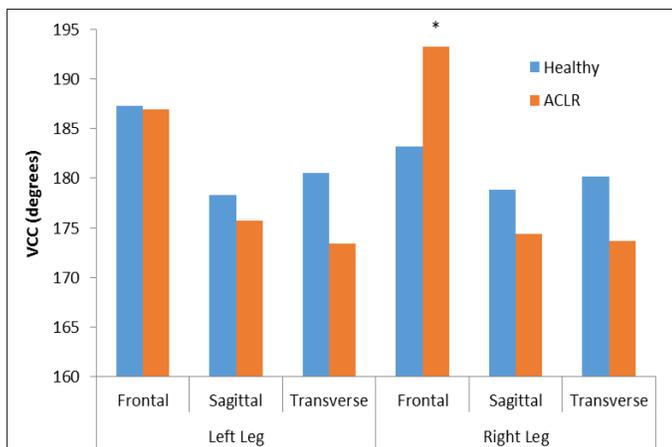

Thirty-five young females participated in the current study. Ten (age =  $15.7 \pm 0.95$  yrs, mass =  $65.81 \pm 13.37$  kg, height =  $163.83 \pm 8.84$  cm) were released from physical therapy for return-to-sport following ACLR of the right leg. Twenty-five (age

=  $15.24 \pm 1.2$  yrs, mass =  $58.05 \pm 8.83$  kg, height =  $164.57 \pm 5.66$  cm) had no previous lower extremity injury. All subjects were right-leg dominant. Subjects completed three trials of a jump-landing task from a 30 in box placed 50% of the subject's height behind two ATMI force plates (Advanced Mechanical Technology, Inc., Watertown, MA). Subjects jumped from the box, landed on the force plates, and immediately completed a maximal vertical jump. Kinematic data were collected using a 10-camera Qualisys Motion Capture System (Qualisys AB, Göteborg, Sweden) and were filtered using a fourth-order Butterworth filter and 12 Hz cut-off frequency. Joint couplings were created from the kinematic data and then used to create relative motion (angle-angle) plots as a function of anatomical plane. Statistical calculations from relative motion plots were adopted from a modified vector-coding technique [3] and included two measures: (1) relative motion area and (2) vector-coding that calculated an angle, with respect to the right horizontal, of the vector formed between two consecutive data points on the relative motion plot. Statistical analyses included separate repeated-measures ANOVAs conducted on dependent variables with leg, joint coupling, and anatomical plane as the repeated, within subject factors, and injury group as the between subject factor. An alpha value of 0.05 was used to define statistical significance.

## RESULTS AND DISCUSSION

The results of the vector coding analysis revealed significant main effects of coupling ( $p < 0.0001$ ) and plane ( $p < 0.0001$ ). The main effect of leg was found to be non-significant ( $p = 0.847$ ), but a significant triple interaction was found between leg, plane, and

test group. Specifically, in the frontal plane the coordination pattern of the right leg differed for the ACLR subjects compared to the control group ( $p = 0.008$ ). Additionally, a trend toward significance was found between groups for the coordination pattern of the left leg in the transverse plane ( $p = 0.076$ ). The mean vector coding angle was higher for the ACLR group for the right leg in the frontal plane, but was lower for the left leg in the transverse plane compared to the mean coordination of the control group (Fig. 1).

**Figure 1:** A comparison of mean coordination in the control group and ACLR group across all planes for each leg. \*indicates a statistically significant difference in coordination pattern between injury groups in the frontal plane ( $p = 0.008$ ).

The significant main effect of coupling shows that the lower extremity segments use varying coordination patterns during the dynamic task of drop landing to vertical jump performance. Additionally, the plane effect further illustrates the multi-dimensional aspect of the drop landing movement that is not typically addressed in most injury risk models.

The finding of an altered coordination pattern for the injured limb following ACLR compared to healthy controls suggests that athletes may be returning to competition while using movement patterns that place them at risk for further injury. The coordination differences suggest that a neuromuscular control component to ACL recovery may need additional attention during the rehabilitation process.

The findings also suggest that a compensatory strategy may be used in the uninjured limb of ACLR individuals. This result was highlighted by the trend toward significance of the coordination pattern, primarily in the transverse plane. As patients return-to-sport, it is likely that they will exhibit a disinclination to use their injured leg, leading to improper movement patterns. This may also lead to altered coordination patterns of the uninvolved leg as they attempt to correct for movement of the involved leg, potentially increasing the risk of injury. Lastly, many rehabilitation exercises focus on actions in the frontal and sagittal planes, such as controlling medial displacement of the knee and absorbing force during landing by increasing knee flexion, but observing motion in the transverse plane is a greater challenge. This may lead to a lack of feedback regarding transverse plane motion and a decreased ability to correct for movement pattern alterations when completing a dynamic task outside of a controlled setting.

## CONCLUSIONS

The significant triple interaction of leg, group, and plane confirmed the hypothesis that ACLR patients would exhibit altered coordination patterns when compared to control subjects. Additionally, coordination patterns of the injured leg may affect the uninjured leg and contribute to re-injury rates on the contralateral, as well as ipsilateral, side. Coordination changes can reveal how underlying tissues are deformed during motor tasks, and a better understanding of lower extremity coordination deficits following ACLR is needed to establish effective rehabilitation protocols to prevent secondary ACL injury. Overall, further investigation is needed to fully understand the implications of altered coordination patterns following ACLR.

# INDIVIDUALS FOLLOWING ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION ADJUST CENTER OF PRESSURE LOCATION TO REDISTRIBUTE EXTENSOR LOADING

<sup>1</sup>Ming-Sheng M. Chan, <sup>1</sup>Paige E. Lin, <sup>1</sup>Susan M. Sigward

<sup>1</sup>Human Performance Laboratory, University of Southern California, Los Angeles, CA, USA  
email: mingshec@usc.edu, web: <http://pt.usc.edu/mingshec/>

## INTRODUCTION

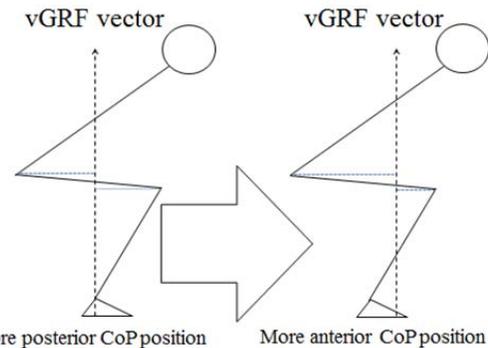

Individuals following anterior cruciate ligament reconstruction (ACLR) adopt loading strategies that shift the mechanical demands away from the surgical knee during bilateral tasks [1]. A strategy that shifts demands within the limb away from the knee and toward the hip extensors has been described during squatting [1]. Individuals 7 months post-ACLR exhibited a 25.5% lower knee extensor moment along with a 49.1% higher hip extensor moment, resulting in almost a two-times greater hip to knee extensor moment ratio in the surgical limb compared to the non-surgical limb (surgical: 163% vs. non-surgical: 87.5%) [1]. These data highlight between-limb differences in the distribution of extensor moments during squatting.

Distribution of extensor demands within the limb can be accomplished by altering joint kinematics, adjusting the position of center of pressure (CoP), or a combination of the two [2]. Theoretically, an anterior position of the CoP shifts the vertical ground reaction force vector closer to the knee joint and further from the hip joint, decreasing the demand on the knee extensors and increasing the demand on the hip extensors (Figure 1). However, it is not known if the distribution of sagittal plane extensor demands during squatting is accomplished by altering CoP position in individuals following ACLR.

The purpose of this study was to determine the relationships between CoP position and sagittal plane moments distributions both within- and between-limbs.

## METHODS

Eleven individuals (7 females,  $25.3 \pm 10.7$  yrs) 5 months ( $148.8 \pm 9.2$  days) following ACLR were enrolled in this study. They performed 2 sets of 5

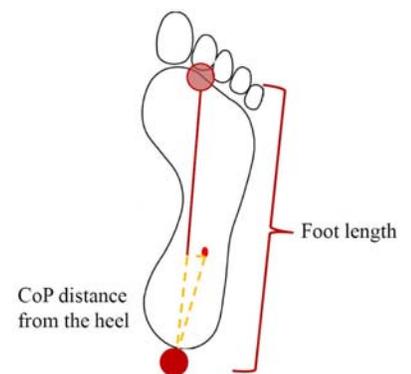

**Figure 1:** Conceptual diagram of the relationship between CoP position and joint moment distributions in the sagittal plane.

consecutive bilateral squats with bodyweight resistance.

Kinematics (250 Hz) were collected using a 11-camera motion capture system (Qualisys, Göteborg, Sweden). Ground reaction forces (1500Hz) were quantified using AMTI force platforms (AMTI, MA, USA). Three dimensional joint kinematics, ground reactions forces and anthropometrics were used to calculate net joint moments using standard inverse dynamics equations (Visual3D, C-Motion Inc., MD, USA). Kinetic data were normalized to body mass. Peak knee extensor moment (kEXT), peak hip extensor moment (hEXT), and CoP position were identified during the deceleration phase ( $0^\circ$  to maximum knee flexion angle).

Foot length was defined as the distance between markers placed on the second toe and the heel (Figure 2). CoP position ( $CoP_{pos}$ ) was calculated as distance from the heel and

**Figure 2:**  $CoP_{pos}$  (the yellow dash line). 2<sup>nd</sup> toe and the heel markers

normalized to the individual's foot length (Figure 2).  $CoP_{pos}$  at kEXT was identified. A greater number indicates a more anterior  $CoP_{pos}$ .

To reflect the relative extensor moment distribution between the hip and the knee within the limb, a hip to knee ratio (hEXT/kEXT) was calculated for each limb. A hEXT/kEXT > 1 indicates a more hip dominant strategy with a greater extensor moment in the hip relative to the knee.

Between-limb ratios (surgical limb / non-surgical limb) were calculated for  $CoP_{pos}$  and (hEXT/kEXT) to reflect the relative differences between limbs in extensor moment distribution and COP position. Between-limb ratios > 1 indicate that the surgical limb has a more anterior  $CoP_{pos}$  and a greater relative hip extensor moment contribution in the surgical limb. A total of 6 squats (the middle 3 squats of each trial) were chosen for data analysis.

Separate univariate linear regressions were used to determine if the  $CoP_{pos}$  was predictive of the extensor moment distribution for each limb and if the relative difference between limbs in  $CoP_{pos}$  predicted of the relative difference between limbs in extensor moment distribution ( $\alpha = .05$ ).

## RESULTS AND DISCUSSION

When considering each limb,  $CoP_{pos}$  was a significant predictor of the hEXT/kEXT (surgical:  $R^2 = .62$ ,  $p = .004$ ; non-surgical:  $R^2 = .38$ ,  $p = .042$ ; Figure 3, a and b). A greater hEXT/kEXT ratio was related to a more anterior  $CoP_{pos}$ .

When considering differences between limbs in extensor moment distribution and COP position, the between-limb  $CoP_{pos}$  ratio was a significant predictor of the between-limb hEXT/kEXT ratio ( $R^2 = .49$ ,  $p = .017$ ; figure 3, c). A larger between-limb hEXT/kEXT ratio was related to a larger  $CoP_{pos}$  ratio.

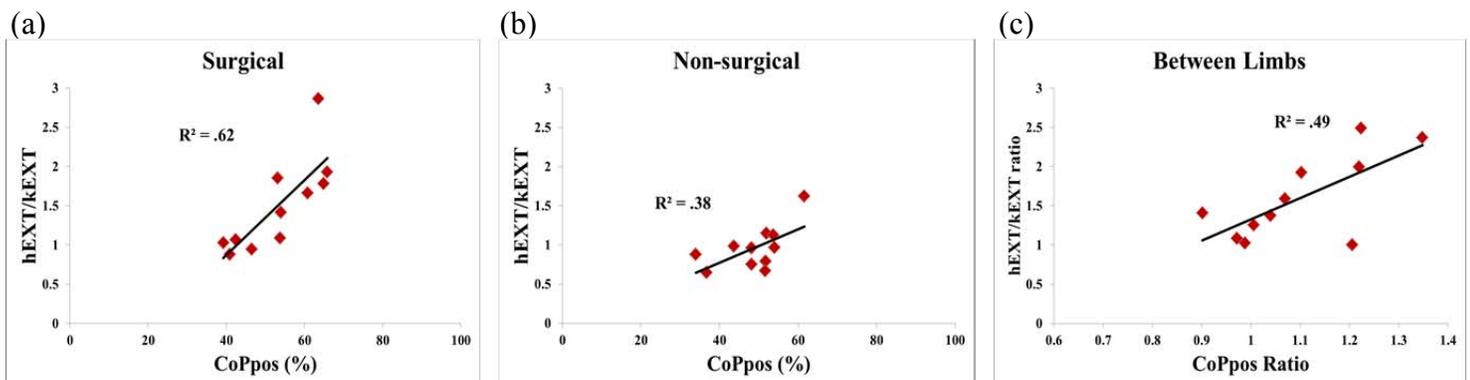

## CONCLUSIONS

At 5 months post-surgery,  $CoP_{pos}$  explained 62% and 38% of the variance in the hEXT/kEXT in the surgical and non-surgical limbs, respectively. A more anterior  $CoP_{pos}$  was related to a more hip dominant strategy. As the  $CoP_{pos}$  was positioned more anteriorly, the extensor demand at the knee decreased while the demand at the hip increased.

When considering between-limb differences, those who exhibited a more hip dominant strategy in their surgical limb compared to their non-surgical limb also positioned their COP more anteriorly in the surgical limb. This suggests that individuals following ACLr may adopt a strategy that positions the CoP more anteriorly to reduce the demands on the knee extensors in the surgical limb.

# SEX AND LEG DIFFERENCES IN ACL STRESS DURING DROP LANDING

Joshua T. Weinhandl, Ashley N. Grillo, and Onyebuchi N. Okereke

University of Tennessee, Knoxville  
email: jweinhan@utk.edu

## INTRODUCTION

The prevalence of anterior cruciate ligament (ACL) injuries in athletic populations is well documented [1], and a majority of these injuries are caused by noncontact mechanisms [2]. Furthermore, recent epidemiological evidence indicates that females are more than twice as likely to have a first-time noncontact ACL injury compared to males [3].

Epidemiological evidence also suggests leg dominance may serve as an etiological factor with regard to ACL injuries [4,5]. Negrete et al. [4] reported a possible association between leg dominance and ACL injury in females but not in males. Likewise, females appear more likely to injure the ACL in their supporting leg, whereas males tend to injure their kicking leg ACL [5].

Therefore, the purpose of this study was to determine if there is an interaction between gender and leg side on ACL stress during unilateral landings. We hypothesized that females would experience increased ACL stress compared to males, and a concurrent increase in related ACL injury risk variables. We also hypothesized that ACL stress and related ACL injury risk variables would be greater in the non-dominant leg compared to the dominant leg (preferred kicking leg).

## METHODS

Twenty-one recreationally active women (60.3±9.3 kg, 1.65±0.07 m) and twenty-two recreationally active men (82.3±18.3 kg, 1.79±0.09 m) volunteered to perform unilateral landings from 40 cm on their dominant and non-dominant legs. Dominant leg was defined as the preferred kicking leg. Prior to data collection, participants were informed of study procedures and provided written informed consent in accordance with institutional guidelines. Marker coordinate data (200 Hz, Vicon) and ground reaction force data (2000 Hz, Bertec) were collected simultaneously for all trials.

OpenSim (v3.3 <http://simtk.org>) was used to simulate all right and left leg landing trials [6]. An 8 segment, 23 degrees-of-freedom (*dof*) musculoskeletal model, with 92 Hill-type muscle actuators (modified from Gait2392), was scaled to match each participant's anthropometry based on experimentally measured anatomical landmarks. The knees were modified to be 3-*dof* joints (i.e., flexion-extension, adduction-abduction, internal-external rotation). Knee adduction-abduction and internal-external rotation *dof* were modeled as universal joints, with the same center of rotation as the flexion-extension *dof*, which was modeled as a planar joint, allowing the tibia to translate relative to the femur as a function of knee flexion angle. Static optimization was used to calculate the muscle forces required to reproduce the joint moments of each trial. The optimization minimized the sum of muscle activations to distribute muscle forces. Simulated knee joint reaction forces and moments, along with hamstrings, quadriceps and gastrocnemius muscle force estimates were input into a three-dimensional knee model to estimate ACL loading [7]. ACL stress was then estimated using average, gender specific measurements of ACL mid-substance area (females: 58.29 mm<sup>2</sup>; males: 83.54 mm<sup>2</sup>) [8].

A 2×2 repeated measures ANOVA was used to assess sex and landing leg differences in peak ACL stress. Other variables of interest included initial contact knee angles, maximum knee angles, and maximum knee moments of the landing leg. Landing phase was defined as initial contact to maximum knee flexion of the landing leg. ACL stress and knee moments were normalized to body mass. Significance for all tests was set at  $p < 0.05$ .

## RESULTS AND DISCUSSION

There were no significant sex×leg interactions for any of the variables examined. However, the interaction for peak ACL stress approached significance ( $p=0.077$ ). A significant main effect of

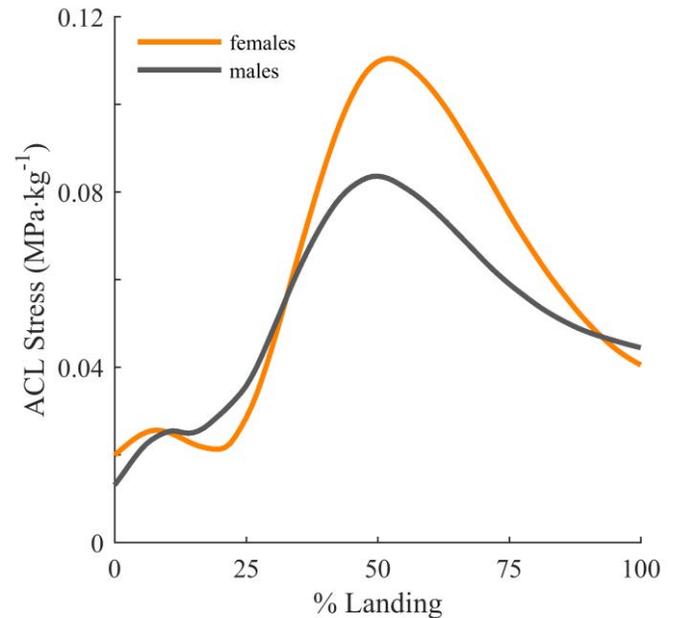

sex was identified for only peak ACL stress ( $p < 0.001$ ). The main effect of leg was significant for maximum knee internal rotation angle ( $p = 0.009$ ), maximum knee adduction moment ( $p < 0.001$ ), and maximum knee internal rotation moment ( $p < 0.001$ ).

Our first hypothesis that females would experience increased ACL stress compared to males, and a concurrent increase in related ACL injury risk variables was partially supported. Females experienced a peak ACL stress of  $0.15 \pm 0.03$  MPa·kg<sup>-1</sup>, compared to the  $0.12 \pm 0.03$  MPa·kg<sup>-1</sup> peak ACL stress experienced by males, regardless of landing leg. This finding is consistent with the increased rates of noncontact ACL ruptures in females [1]. However, there were no other sex differences observed, suggesting that factors contributed to the increased ACL stress in females besides knee mechanics. Examining hip and ankle mechanics may help explain the sex differences in peak ACL stress observed in the current study.

Our second hypothesis that ACL stress and related ACL injury risk variables would be greater in the non-dominant leg was also partially supported. While the sex×leg interactions for peak ACL stress was not significant ( $p = 0.077$ ), females seemed to show increased stress in the non-dominant ACL. Furthermore, there were alterations in knee mechanics. Specifically, non-dominant leg landings were characterized by a 2.2° increase in maximum knee internal rotation angle, as well as 67% and 125% increases increase in maximum knee adduction and maximum knee internal rotation moments, respectively. These variables are commonly associated with ACL injury risk [2], but their relationship to ACL stress remains unclear.

## CONCLUSIONS

Females experienced greater ACL stress during unilateral landings even though there were no other sex differences observed. This finding suggests females may be more susceptible to ACL injury when presented with unexpected perturbations that increase the load applied to the ACL. Our results also indicate that frontal and transverse plane knee loading is increased during non-dominant leg landings, even though ACL stress is unchanged.

**Figure 1.** ACL stress (MPa·kg<sup>-1</sup>) during unilateral landings for females (orange) and males (gray).

## INTRODUCTION

Individuals with anterior cruciate ligament reconstruction (ACLR) are at greater risk for knee osteoarthritis due to alterations in walking biomechanics [1]. For instance, individuals with ACLR have lesser knee flexion angles (KFA) and external moments (KFM) [1], partially due to quadriceps dysfunction [2]. However, hamstrings co-activation is also elevated in individuals with ACLR [2, 3], which may influence sagittal plane knee mechanics during gait, and confound the interpretation of reduced KFA and KFM. Therefore, the purpose of this study was (1) to compare knee mechanics (KFA and KFM), and quadriceps and hamstring activation between the injured and uninjured limbs of individuals with unilateral ACLR during gait, and (2) to examine the association between KFA and KFM, and quadriceps and hamstrings activation in the injured limb. We hypothesized that the injured limbs would have lesser KFA and KFM, lesser quadriceps activity, and greater hamstrings activity compared to the uninjured limb. We also hypothesized that greater quadriceps activity would be associated with greater KFA and KFM, and that greater hamstrings activity would be associated with lesser KFA and KFM.

## METHODS

Twenty-three individuals with primary unilateral ACLR volunteered to participate in this study (83% Female; Age =  $22.1 \pm 2.5$  years; Height =  $1.67 \pm 0.07$  m; Mass =  $69.2 \pm 13.5$  kg; Time Since ACLR =  $50.3 \pm 22.6$  months; International Knee Documentation Committee Score =  $85.3 \pm 10.3$ ; Graft Type: Patellar Tendon Autograft = 14, Hamstrings Autograft = 4, Allograft = 5).

Static markers were placed bilaterally on the iliac crest, greater trochanter, medial and lateral femoral

epicondyles, medial and lateral malleoli, and the first and fifth metatarsal heads. Rigid clusters of 4 markers were affixed to the pelvis, and bilaterally to the foot, shank, and thigh. Static markers were removed after a standing calibration trial. Surface EMG sensors were placed bilaterally on the vastus lateralis, vastus medialis, biceps femoris, and medial hamstrings. Ground reaction force, marker position, and EMG data were sampled while participants walked in laboratory standard neutral cushion footwear at a self-selected speed that was maintained within  $\pm 5\%$  across 5 trials. Participants walked across a 10m runway and made contact with consecutive force plates in the center of the runway.

Data were exported to Visual 3D for model construction, and further processed using a custom LabVIEW program. Kinematic and kinetic variables included the peak KFA and KFM during the first 50% of the stance phase. Raw EMG data were band-pass filtered from 20-350Hz, full-wave rectified, and low-pass filtered at 20Hz to create a linear envelope [2]. The processed signals were normalized to the EMG signal from maximal voluntary isometric contractions that were obtained prior to the gait trials, and the integral from 100ms prior to heel contact to peak knee flexion during the first 50% of stance phase was extracted [2]. Integrals for the vastus lateralis and vastus medialis, and biceps femoris and medial hamstrings, were averaged to create composite values of quadriceps and hamstrings EMG activity, respectively.

KFA, KFM, quadriceps activity, and hamstrings activity were compared between limbs using paired samples-tests. Pearson correlations were used to evaluate associations between the KFA and KFM, and quadriceps and hamstrings activity. Exploratory multiple linear regression analyses were used to predict KFA and KFM using quadriceps and hamstring activity as predictors.

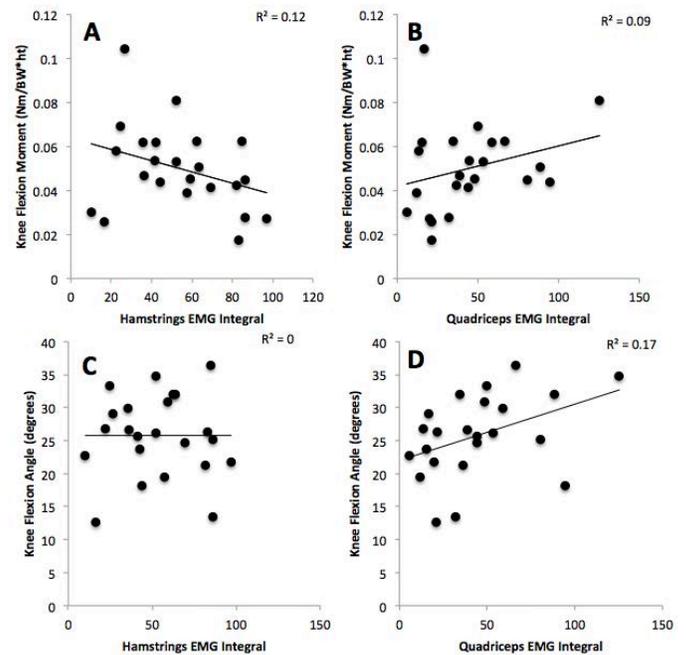

## RESULTS AND DISCUSSION

Gait speed was not associated with KFA ( $r = 0.14$ ,  $p = 0.31$ ), KFM ( $r = 0.23$ ,  $p = 0.28$ ), quadriceps activity ( $r = 0.20$ ,  $p = 0.35$ ), or hamstrings activity ( $r = 0.25$ ,  $p = 0.17$ ) in this sample; and therefore, was not accounted for in statistical analyses.

Hamstrings activity ( $53.7 \pm 25.1$  vs.  $35.8 \pm 20.4$ ,  $p < 0.01$ ) and peak KFM ( $0.06 \pm 0.02$  vs.  $0.04 \pm 0.02$  Nm/BW\*ht,  $p = 0.02$ ) were greater in the injured compared to uninjured limb. No difference was found between the injured and uninjured limbs in quadriceps activity ( $44.4 \pm 30.3$  vs.  $51.6 \pm 30.7$ ,  $p = 0.13$ ) or KFA ( $25.7 \pm 6.2$  vs.  $26.1 \pm 7.8^\circ$ ,  $p = 0.31$ ). Greater quadriceps activity was associated with a larger KFA (Fig. 1,  $r = 0.42$ ,  $p = 0.02$ ), and greater hamstrings activity was associated with a smaller KFM (Fig. 1,  $r = -0.35$ ,  $p = 0.05$ ). The association between quadriceps activity and KFM (Fig. 1,  $r = 0.29$ ,  $p = 0.09$ ), and hamstrings activity and KFA (Fig. 1  $r = -0.13$ ,  $p = 0.29$ ) were not significant.

Multiple linear regression indicated that hamstrings and quadriceps activity explained 24% of the variance in KFM and approached significance ( $F_{2,20} = 3.2$ ,  $p = 0.06$ ). Hamstrings activity ( $\beta = -0.41$ ,  $p = 0.05$ ), but not quadriceps activity ( $\beta = 0.37$ ,  $p = 0.07$ ) predicted KFM. Secondly, hamstrings and quadriceps activity explained 18% of the variance in peak knee flexion angle, but this model was not significant ( $F_{2,20} = 2.2$ ,  $p = 0.14$ ). The variable inflation factor due to any correlation between hamstrings and quadriceps activity was 1.04, confirming the absence of multicollinearity.

Previous studies indicate that individuals with ACLR have lower KFA and KFM in their injured compared to uninjured limb [1, 2]. These gait alterations are often attributed to a reduction in quadriceps function (i.e. quadriceps avoidance gait) that is common following ACLR [2, 4, 5]. However, many of these studies [1, 6] have failed to account for the contribution of increased hamstring activity, which is also common following ACLR [2, 3]. Hamstrings activity influences net knee joint moments, and future studies should account for hamstrings activity during gait analyses in individuals with knee pathology.

**Figure 1:** Associations between (A) KFM and hamstrings activity; (B) KFM and quadriceps activity; (C) KFA and hamstrings activity; (D) KFA and quadriceps activity

## CONCLUSIONS

These findings suggest that both hamstrings and quadriceps activity contribute to sagittal plane knee mechanics during the stance phase of gait in individuals with ACLR. Future longitudinal studies should examine the influence of elevated hamstrings activity on long-term knee joint health.

email: tmoffit@fullerton.edu

## INTRODUCTION

Quadriceps dysfunction is common following anterior cruciate ligament reconstruction (ACLR), and contributes to post-traumatic knee osteoarthritis (KOA) (4). Achieving >90% symmetry has been established as adequate for return to physical activity following rehabilitation (3, 4). Despite rehabilitation, quadriceps strength in the injured limb commonly fails to reach the strength of the uninjured limb (1). During walking, the quadriceps attenuate ground reaction force (GRF). In individuals with ACLR, decreased quadriceps function contributes to aberrant walking mechanics that may contribute to KOA (2). Moreover, quadriceps asymmetry predicts self-reported physical function (5). However, it is unclear if strength asymmetry is associated with asymmetry in functional tasks, such as gait.

The purpose of this study was to (1) examine the association between quadriceps strength asymmetry and gait asymmetry in individuals with ACLR, and (2) to compare gait biomechanics between individuals with high and low quadriceps strength symmetry between limbs. Dependent variables included the peak ground reaction force (GRF), peak knee flexion angle (KFA), and peak knee flexion moment (KFM). We hypothesized that strength symmetry would be associated with symmetry in KFA, KFM, and GRF during gait. We also hypothesized that individuals with high asymmetry would have greater GRF, and lesser KFA and KFM in their injured compared to uninjured limbs during gait.

## METHODS

Quadriceps function and gait biomechanics were assessed in 20 individuals with primary unilateral ACLR (Table 1).

**Table 1:** Participant Demographics

Demographics	
Sex (% female)	85%
Age (years)	21.9 ± 2.5
Height (m)	1.67 ± .07
Mass (kg)	68.8 ± 13.5
Time since ACLR (months)	49.5 ± 22.6
IKDC score	84.5 ± 10.3
<i>Graft type</i>	
Patellar tendon (n)	13
Hamstring tendon (n)	2
Allograft (n)	5

Peak torque (PT) was assessed using maximal voluntary isometric contractions (MVIC) at 45° of knee flexion. Each subject performed 3 MVICs on the injured and uninjured limb in a random order. The highest trials were normalized to body mass for analysis, and used to establish the symmetry index (SI). SI was derived by dividing the PT of the injured limb by the uninjured limb (3).

$$SI\% = \left( \frac{\text{Injured limb}}{\text{Uninjured limb}} \right) * 100$$

The SI was used to determine the percent asymmetry between limbs. A mean split of 84% SI was used to dichotomize the group into high SI (>84% symmetry; n=7, mean SI=94%) group (HIS), and low SI (<84% symmetry; n=8, mean SI=76%) group (LSI). The mean SI was near the range of previously established values (90%) (3), and deemed adequate to divide the sample.

Marker position and force plate data were sampled during 5 walking trials in neutral cushion footwear, at a self-selected speed that was maintained within ±5% across 5 trials. Participants walked over 2 consecutive force plates, striking the first plate with their right foot and the second with their left. Position and force data were exported to Visual 3D

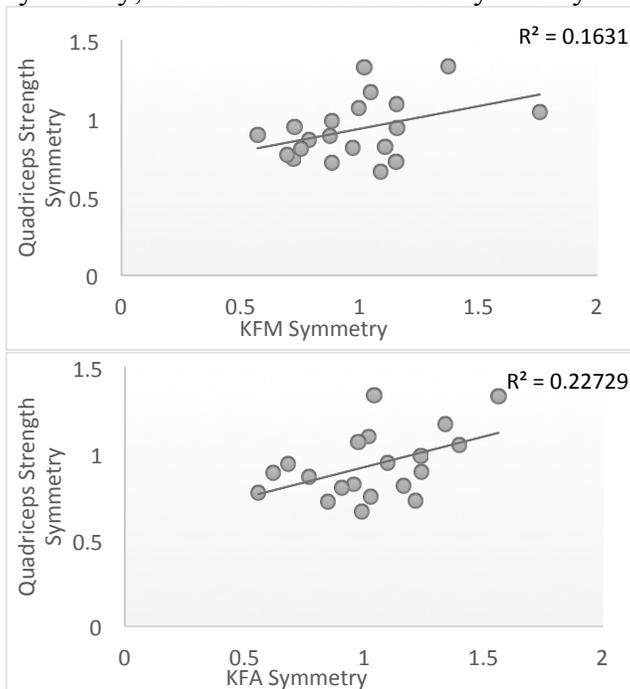

for model construction, and further analyzed using a custom LabVIEW program. Peak KFA and external KFM was calculated during the first 50% of the stance phase for each trial, and the average of all trials was used for analysis. The SI equation was also used to calculate GRF, KFA, and KFM symmetry.

Independent samples t-tests were used to compare GRF, KFA, and KFM between the HSI and LSI groups in the injured limb. Pearson correlations were used to examine the association between quadriceps strength SI and gait SI (KFA, KFM, and GRF) among all participants.

## RESULTS AND DISCUSSION

A trend was observed ( $P = 0.12$ ,  $d = 0.63$ ,  $LSI = 1.15 \pm 0.10$ ,  $HSI = 1.08 \pm 0.18$ ), indicating a higher peak GRF in the injured limb in the LSI compared to the HSI group. No differences were found in KFA ( $P = 0.27$ ,  $LSI = -26.55 \pm 6.02$ ,  $HSI = -29.05 \pm 9.13$ ) or KFM ( $P = 0.23$ ,  $LSI = 0.067 \pm 0.03$ ,  $HSI = 0.06 \pm 0.02$ ) between groups. Quadriceps Strength symmetry was associated with KFA symmetry ( $R = 0.48$ ,  $P = 0.02$ , Fig 1) and KFM symmetry ( $R = 0.40$ ,  $P = 0.04$ , Fig 1).

**Fig 1:** Associations between: Top – KFM PT symmetry; Bottom – KFA sand PT symmetry

Asymmetrical quadriceps strength is associated with asymmetrical gait characteristics (KFA and KFM) in individuals with ACLR. As such, strength asymmetries may contribute to asymmetry in movement patterns that may preferentially load the injured or uninjured limb. Furthermore, greater GRF in the injured limb of the LQI group may contribute to post-traumatic KOA. Therefore, rehabilitation protocols should consider restoring quadriceps strength symmetry, rather than bilateral quadriceps strengthening.

## CONCLUSIONS

Individuals with ACLR have quadriceps strength asymmetry that influences walking asymmetry (KFA and KFM). We observed some evidence that those with low quadriceps strength symmetry (i.e. a weaker injured compared to uninjured limb) experience greater GRF during walking compared to those with high quadriceps strength symmetry. Rehabilitation strategies should consider restoring strength symmetry between limbs to assist in improving long term joint health.

## INTRODUCTION

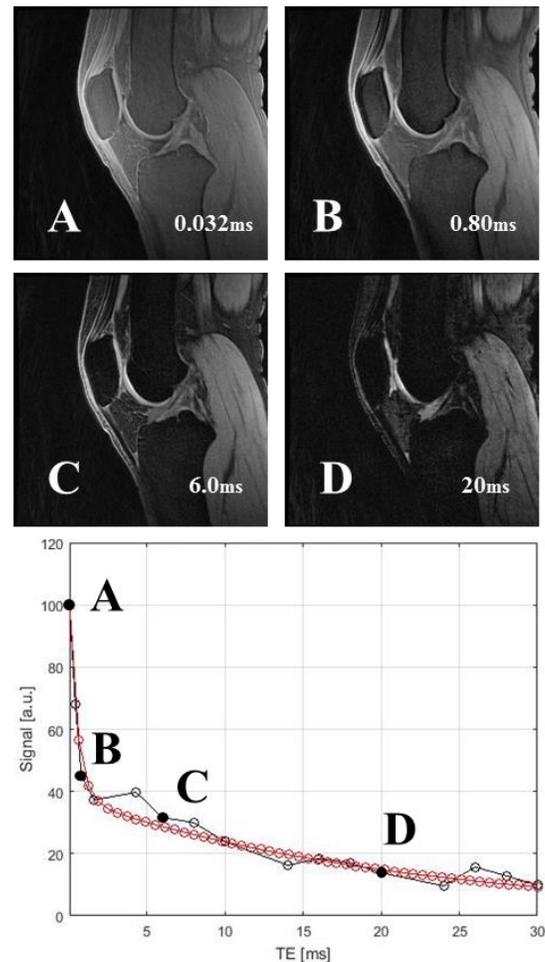

Rates of graft rupture following anterior cruciate ligament reconstruction (ACLR) have been reported at 6% [1]. Post-surgical vascularization and graft remodeling are critical to maintain long-term health and strength of the tissue. Prior studies have explored the potential of using magnetic resonance (MR) imaging to track ACL graft remodeling. Indeed, these studies have found that grayscale values of contrast-enhanced [2] and  $T_2^*$  weighted [3] MR images correlate to mechanical strength. However, tendons and ligaments are generally difficult to visualize with MRI, appearing dark due to rapid signal decay.

Recently developed technologies have allowed for implementation of faster echo times, better to image these tissues with higher contrast. Ultrashort echo time (UTE) sequences allow for collection of multiple echoes that can then be used to calculate  $T_2^*$  relaxation parameters with an exponential fit [4]. More recent studies have explored the use of a bicomponent exponential fit of  $T_2^*$  signal decay, which is believed to provide a quantitative measure of the tightly bound and free water in the tissue [5]. The ratio of bound and free water has been linked to localized tissue damage in tendon [6]. In this pilot study, we explore the potential for bicomponent UTE imaging as an *in vivo*, non-invasive diagnostic assessment of ACL graft health.

## METHODS

Four subjects with a primary unilateral, isolated ACLR were tested (2 hamstring and 2 patellar tendon grafts). Both knees were scanned in a 3T MR scanner (Discovery MR750, GE Healthcare, Waukesha, WI) with a padded knee extremity coil (InVivo, Orlando, FL). High resolution sagittal plane images at 16 different TEs from 0.032 to 30 ms

were collected. We segmented the ACL in the UTE images, and then co-registered the UTE images to locally align the ACL in each image set. Bicomponent exponential fitting of the signal intensity through time was conducted on each voxel in the segmented ACLs to get measures of the short and long  $T_2^*$  relaxation times [5]. We also computed the percentage of the signal due to the short  $T_2^*$  relaxation component (i.e.  $T_2^*$  fraction) as a measure of the fraction of bound water in the tissue (Fig. 1).

**Figure 1:** A-D) Sample image data collected with different echo times. Lower plot shows the bicomponent exponential fit of the signal intensity over the full range of the sampled echo times.

## RESULTS AND DISCUSSION

Short and long  $T_2^*$  measures averaged 4.3 and 36.6 ms, respectively, in the native ACLs (Table 1). The average  $T_2^*$  fraction was 50%, which is low relative to typical ligaments and tendons [6]. For each of the subjects, the short and long  $T_2^*$  measures were longer in the ACL graft than the native, contralateral ACL (Fig 2). The fraction of bound water was also increased in the reconstructed knee, averaging 57% across the four subjects (Table 1). Some subjects exhibited a substantial amount of heterogeneity of the quantitative MR metrics over the native and

reconstructed ACL, such that further tuning of the UTE sequence may be needed to enhance consistency and quality of the quantitative maps.

**Table 1.** Average  $T_2^*$  relaxation times in a slice of segmented ACL or graft.

	Native	Reconstructed
<b>Short <math>T_2^*</math> (ms)</b>	4.31±0.38	4.95±0.67
<b>Long <math>T_2^*</math> (ms)</b>	36.6±3.8	40.3±4.4
<b><math>T_2^*</math> Fraction</b>	0.503±0.057	0.567±0.047

## CONCLUSION

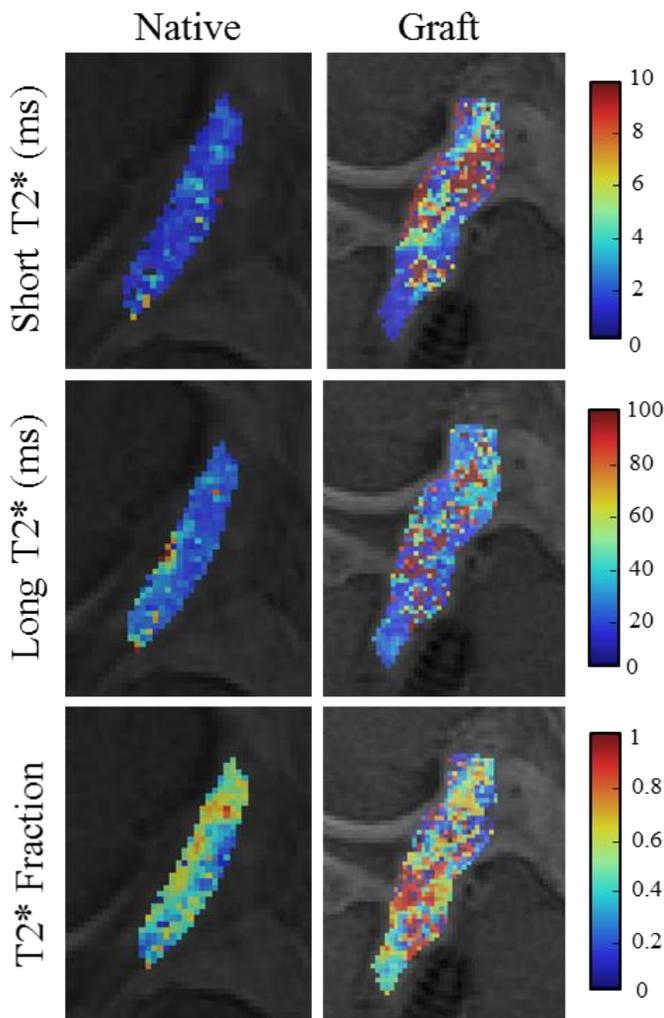

This study shows that it is feasible to perform ultrashort TE imaging of reconstructed ACLs and provides some evidence that quantitative MR metrics are not normalized in reconstructed ligaments. Further study is needed to assess whether the metrics reflect the health and strength of the tissue, which would support the use of UTE imaging to track tissue recovery following reconstructive surgery.

## INTRODUCTION

Approximately 75% of anterior cruciate ligament (ACL) ruptures occur in non-contact scenarios [1]. Often, this is the result of an impulse force within the first 50 ms of initial ground contact created from a rapid deceleration or change of direction [2]. Subsequently, it is important to understand the underlying mechanisms of ACL injury to determine the factors that increase risk of ACL injury. Improved knowledge of knee mechanics will enhance injury prevention, rehabilitation, and return to sport (RTS) criteria.

This current study was designed to mimic the mechanisms of a drop vertical jump (DVJ) *in vitro*. The DVJ is a motion used to determine athletes with a higher risk of ACL failure [3]. The goal of this study was to determine if magnitude of external moments and timing post-impact effected ACL strain and joint kinematics. We hypothesized that higher torque would generate greater anterior tibial translation, internal rotation, and ligament strain at 33 and 66 ms post-impact.

## METHODS

A novel cadaveric impactor was utilized to simulate a DVJ in lower extremities of 12 specimens (7 right, 5 left). Specimens ranged from 24 to 52 years of age. Specimens had no evidence of significant trauma/surgery to lower extremity and no evidence of extended chemotherapy. Specimens were dissected and prepared according to specifications outlined in Bates et al, 2017.

*In vitro* kinetics and kinematics were calculated from DVJ's of 70 subjects. Data was used to determine the mechanisms of risk in three degrees of knee forces/moments [i.e. knee abduction

moment (KAM), anterior tibial shear (ATS), and internal tibial rotation (ITR)]. Pneumatic cylinders applied the designated knee forces/moments (Table 1) to the tibia calculated from the *in vivo* subjects. A gravity-driven drop sled of 333 N was released from a height of 31 cm with quadriceps and hamstrings co-contracted with a 1:1 ratio. 3D markers were placed on the tibia and femur to determine joint kinematics (Northern Digital, Ontario, Canada). A differential variable reluctance transducers (DVRT) was implemented into the ACL to measure change in ligament strain during loading. Kinematic data is presented as the mean change in tibial position with respect to the femur. Knee abduction was not reported due to unresolved marker error.

**Table 1** *In vitro* Knee Forces and Moments Applied during Impact

Population Percentage	KAM (Nm)	ITR (Nm)	ATS (N)
0%	1.7	1	47
67%	26.8	18.6	80
120%	68.8	64.4	235

Statistical analyses was performed with JMP 10 (SAS Institute Inc., Cary, NC) with utilization of matched pairs and one-way ANOVAs with an alpha level < 0.05.

## RESULTS AND DISCUSSION

Results from this study indicate that magnitude of external forces and timing post-impact affects joint kinematics and ACL strain. Internal rotation and anterior tibial translation were significantly greater in the 120% condition then at the 67% at initial

contact (IC), 33 ms, 66 ms, and 100 ms after impact (Table 2). At 33ms after contact, internal rotation was  $14.94 \pm 17.14$  mm in the 120% condition and  $-1.42 \pm 15.03$  mm in the 67% ( $p < 0.05$ ). 120% condition generated  $3.99 \pm 5.09$  mm of medial translation and 67% applied  $-2.67 \pm 2.71$  mm at IC ( $p < 0.05$ ). Though kinematics changed with higher impact, the mean ACL strain did not. Lack of statistical significance in ACL strain is due to the physiological variations of ligament laxity between specimens.

Results from the timing test indicate that kinematics and strain significantly change post-impact under lower torque. In the 67% condition, 33ms post-impact, the knee experienced significantly high compression ( $0.62 \pm 1.15$  mm) flexion ( $-2.79 \pm 1.30$  mm), and lateral translation ( $-5.45 \pm 7.82$  mm). Knee anterior tibial translation ( $8.85 \pm 5.15$ ) also significantly increased at 33ms. At 66ms after impact, the knee experienced maximum ACL strain ( $6.93 \pm 7.71\%$ ) and increased internal rotation ( $4.51 \pm 9.96$  mm). The knee also returned to neutral flexion/extension and medial/lateral alignment. The higher torque load test did not result in significantly different joint kinematics or ACL strain at IC, 33 ms, 66 ms, or 100 ms post-impact.

Limitations in this test included physiological differences in ligament laxity and bone geometry, as well as innate error in the DVRT's.

## CONCLUSIONS

We hypothesized that higher external joint force would generate greater anterior tibial translation, internal rotation, and ligament strain at 33 and 66 ms post-impact. Results verify that increased torque during a simulated DVJ effects change in tibiofemoral kinematics but not ACL strain. Externally applied loads change a knee's kinematic response. At lower loads the 33 ms and 66 ms time points following impact generated the larger tibial translations, rotations, and ligament strain. Thus, these should be a time point of focus for ACL injury prevention. Future studies should focus on applying *in vitro* combinations external torque i.e. KAM, ATS, and ITR magnitudes during impact to further understand mechanisms of ACL injury.

# RELIABILITY OF A DEVICE TO MEASURE TORSIONAL STIFFNESS OF RUNNING FOOTWEAR

Rebecca Zifchock, Michaela Sulley, Gary Helton, Gregory Freisinger,  
Frank Blackmon, Roderick Wilson, and Donald Goss

United States Military Academy, West Point, NY, USA  
email: rebecca.zifchock@usma.edu

## INTRODUCTION

Load-bearing exercises such as running and marching account for up to 78% of injuries during Army basic training [1]. Previous literature suggests that there are intrinsic risk factors associated with running, such as high tibial shock values and extreme foot pronation/supination [2, 3]. However, there is also evidence to show that extrinsic factors, such as footwear, may influence injury risk. Butler et al. [4] showed that a cushioning shoe is particularly effective for attenuating shock, while a motion control shoe can reduce rearfoot motion. Therefore, it is important to understand footwear structure, so that its relationship injury susceptibility in runners may be studied more closely.

Torsional shoe stiffness has been previously quantified to assess the shoe's cushioning and support in a single metric [5]. It measures the resistance of the shoe to twisting about its long axis between the heel and the toe box. Assessment of shoe torsional stiffness has previously been conducted using expensive devices that cannot be easily transported for use in most laboratories and clinics. Therefore, the purpose of this study was to present and validate the reliability of a novel device designed to quantify torsional shoe stiffness, as well as heel thickness. This device was intended to be portable, lightweight, and inexpensive, without sacrificing accuracy and validity.

## METHODS

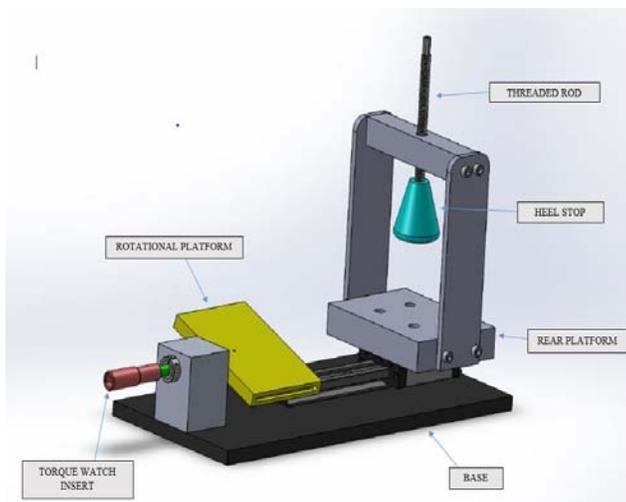

The Shoe Stiffness in Torsion Measurement (SySTM) device was designed specifically to be portable, inexpensive, and reliable for rapid measurement of torsional stiffness, as well as heel

thickness, for running footwear. Torsional stiffness was calculated by the following equation:

$$(L * T) / \phi$$

Where **L** is the length of the shoe, **T** is the torque, and  $\phi$  is the angle of displacement between the toe box and the heel counter of the shoe. An additional measure of heel thickness was also of importance for shoe structure characterization.

The SySTM device is shown in Figure 1. The entire device is 44 x 23 x 18cm (approximately 0.02 m<sup>3</sup>), and has a mass of 6kg. The *rotational platform* is attached to the *torque watch insert* and allowed to swivel with low friction through a stationary block, against which the front toe of the shoe is meant to rest. A “hook and loop” strap is threaded through the *rotational platform* to secure the toe box. The *rear platform* can slide with low friction along the *base* to accommodate a shoe ranging from women's size 4 to men's size 16. The *heel stop* can be rotated along the *threaded rod* to make contact with the insole of the shoe, as far against the posterior heel counter as possible. Not shown in this illustration are the four commercial items that provide the required measurements and standardization: (1) Powered hand drill which imparts approximately 1 N-m of torque to rotate the *heel stop* down into the heel counter until the clutch slips. (2) Set of calipers is used to measure the heel thickness by measuring the length of *threaded rod* remaining above the cross bar of the *rear platform* once the *heel stop* is engaged. (3) Metric scale used to measure the total length, **L**, of the shoe. (4) Torque watch used to record the peak torque, **T**, at the standardized rotation,  $\phi$ , of 30 degrees from horizontal.

**Figure 1:** The SySTM device as designed

Six individuals were trained on how to use the SySTM device. They each measured six different types and sizes of shoes (right side only). Each rater measured each shoe, in a randomized order, three times, the first was removed and considered a familiarization trial. For each independent measurement, heel thickness, length of the shoe, and torque required to achieve 30 degrees of rotational displacement in the medial and lateral directions were recorded in order to calculate the torsional stiffness in both directions.

The inter-rater and intra-rater reliability of the heel thickness, medial torsional stiffness, and lateral torsional stiffness were assessed through the calculation of interclass correlation coefficients (ICCs). A (2,1) model was reported upon such that these results could be generalized to any group of raters who would take a single measurement to characterize a shoe. In order to assess inter-rater reliability, only the second trial was entered into the model to calculate the reliability between testers. In order to assess intra-rater reliability, the data from the first and second trials were assessed against each other for each of the raters.

## RESULTS AND DISCUSSION

Table 1 shows the ICC values for inter-rater and intra-rater reliability of the device for quantifying medial and lateral torsional stiffness, as well as heel thickness, all of which fell into an excellent range of clinical reliability [6]. The mean medial torsional

stiffness deviation was 1.64 N-m<sup>2</sup>, which is 15% of the mean of that variable for all devices. The mean lateral torsional stiffness deviation was 1.33 N-m<sup>2</sup>, which is 13% of the mean of that variable for all devices. The mean heel thickness deviation was 0.65 mm, which is 1% of the mean of that variable for all devices.

**Table 1:** ICC Values

	<b>Medial Torsional Stiffness</b>	<b>Lateral Torsional Stiffness</b>	<b>Heel Thickness</b>
Inter-Rater ICC (2,1)	0.90	0.86	0.96
Intra-Rater ICC (2,1)	0.91	0.92	0.99

Heel thickness was a particularly reliable measure, as it is derived from a single measure of the threaded rod after it is lowered. Conversely, torsional stiffness is derived from measures of shoe length and torque (at a standardized angle). The combination of any small errors in these three measures likely contribute the variability.

## CONCLUSIONS

The results of this study suggest that the SySTM device is a reliable device for the measurement of shoe torsional stiffness and heel thickness. It is also significantly more portable and less expensive than the industry standards which typically use custom jig in an Instron testing machine (Instron; Norwood, MA). This makes it a feasible option for laboratories and clinics that may require a table-top device that can be stored when not in use.

## INTRODUCTION

Military personnel are consistently exposed to occupation related workloads, which have demonstrated an increased risk of musculoskeletal injuries [1]. Falls account for 18.4% of all cause injuries among military service personal [2]. Intrinsic human factors such as muscular fatigue, especially of the lower extremity and extrinsic environmental factors such as footwear, impact the ability to maintain balance. In order to react to balance perturbations, co-contraction of agonist-antagonist pairs of the lower extremity muscles increases to create stability around a joint, by generating stiffness in the agonist and antagonistic muscles pairs [3]. Moreover both footwear characteristics and lower extremity muscular fatigue have been shown to alter co-contraction [4,5]. Human-environment physical interaction is primarily mediated through footwear, thus usage and access to occupationally appropriate footwear is critical in balance performance. Although, there is considerable amount of literature discussing balance performance in various types of footwear, there remains a dearth in the literature concerning how a minimalist style military boot affects balance characteristics in a trained population. The purpose of the study is to assess the level of lower extremity agonist-antagonist muscular co-contraction during unilateral balance tasks before and after a military style physiological workload, in two different military approved footwear, Belleville 310ST hot weather standard tactical boot (STD) and Belleville TR101 MiniMil ultra-light minimalist style military boot (MIN).

## METHODS

The study was conducted in a repeated measures pre-test-post-test design with twenty-two healthy

male adults (age:  $22.2 \pm 2.7$  years; height:  $177 \pm 6.8$  cm; mass:  $79.8 \pm 9.7$  kg) with no history of musculoskeletal, orthopedic, neurological, cardiovascular, and vestibular abnormalities. Data collection procedures included an initial familiarization of the balance and workload protocols. The experimental testing involved participants tested on two separate days separated by at least 48 hours on two of the military footwear (STD, MIN) with a counter balanced footwear assignment. Participants performed dominant leg unilateral static balance trails (1L), prior (PRE) to and after (POST) a military type workload. The workload included an increasing speed and grade on a treadmill while donning a 16 kg backpack. Muscle activity was collected on medial gastrocnemius (Plantar Flexor-PF), tibialis anterior (Dorsi Flexor-DF), peroneus longus (Evertor- EV), and tibialis posterior (Invertor-IN) using BIOPAC EMG system. Balance was assessed in three sensory conditions: eyes-open (EO), eyes-closed (EC), and eyes-open foam (EOF). Co-contraction between the muscle pairs were calculated using the Co-Contraction Index (CCI) for the agonist-antagonist pairs of DF & PF and IN & EV using mean muscle activity the following equation [6]:

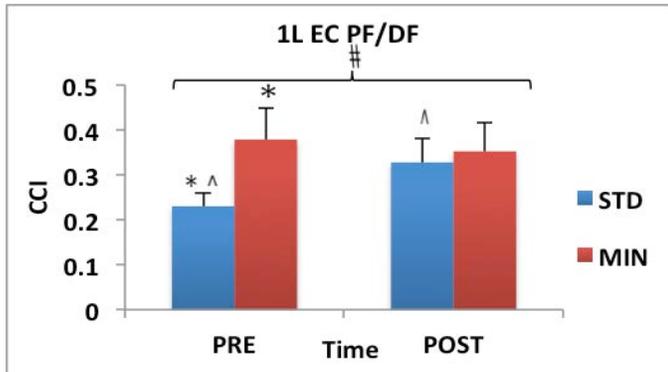

$$(EMG_{Least} + EMG_{Most}) \times EMG_{Least} / EMG_{Most}$$

A 2 (Footwear - STD x MIN) x 2 (Workload - PRE x POST) repeated measures ANOVA was used to analyze CCI at an alpha level of 0.05 using SPSS21.

## RESULTS AND DISCUSSION

Significant interaction was found for PF-DF CCI [F (1, 21) = 5.899,  $p = 0.024$ ,  $\eta^2 = 0.219$ ] in EC sensory condition (Fig. 1). Pairwise comparisons for simple main effects for interaction revealed significant differences for PRE with higher in CCI MIN

compared to STD and for STD with higher CCI in POST compared to PRE significant at  $p = 0.019$  and  $p = 0.031$  respectively. No significant footwear x time interaction or significant differences for main effect footwear or time was found in IN-EV muscle pairs across sensory condions.

**Figure 1:** Muscle co-contraction index for eyes-closed unilateral balance medial gastrocnemius (PF) and tibialis anterior (DF). # denotes significant interaction; \* denotes significant differences for footwear across time and ^ denotes significant differences for time across footwear.

MIN demonstrated a higher CCI in the PF-DF pair before the military workload. The minimalist boot features a thin insubstantial shaft in comparison to the standard footwear, which features a stiff thick boot shaft suggesting that in acute conditions the thick boot shaft decreases muscular exersion of the muscles around the ankle. Moreover, thin, less stiff boot-shafts may allow for greater range of motion (ROM) at the ankle in dorsiflexion and plantarflexion [5]. However, after workload in order to compentsate for fatigue an increase in CCI was needed to stabilize the ankle joint while donning STD. Thus after workload, the surrounding ankle musculature is similarly effected by the boot shafts. Additionally, CCI increased in the post workload condition while donning STD. Previous literature has displayed increase in the rate of energy expindature and muscular fatigue when a greater mass is placed on a footwear [7,8]. STD is 300 g heavier than MIN footwear, suggesting that the increase in CCI after the occupational workload, may be result of the increased STD mass, while the lighter MIN maintained a similar CCI to its PRE workload condtion.

Our results displayed greater co-contraction in the eyes-closed condition which supports previous literature that reported greater co-contraciton in altered visual information [9]. Once visual feedback was altered, increased co-contraction of PF-DF pair was needed to maintain balance. Greater co-contraction of this agonist-antagonist muscle pairs was exhibited in MIN pre workload in eyes closed condition. However post workload, a similar CCI is found between footwear suggesting that while wearing STD an increase reliance is placed on proprioceptive infomration from the muscles around the ankle joint in order to compensate for the lack of visual information and muscular fatgiue.

## CONCLUSION

In conclusion, CCI for plantarflexor and dorsiflexor pairs was significantly higher in the acute testing condition for the minilmist footwear, suggesting the specific design characteristic of an insubstantial boot shaft increased co-contraction of agonist-antagonist muscle pairs. However, both types of footwear did not differ in CCI after workload suggesting that other footwear design characteristics such as footwear mass, influence muscular cocontraction after an occupational related workload.

## INTRODUCTION

The United States Army Annual Injury Report identified that acute sprains/strains accounted for 9.3% and 51.0% of military hospitalizations and outpatient visits [1]. Of these injuries, lateral ankle sprains (LAS) resulted in 36% of days limited on duty due to injury. Military personnel are frequently exposed to environmental hazards such as irregular and/or uneven terrain, which may increase the susceptibility for lower extremity injuries. Although the specific mechanism of LAS injuries in military occupations is unknown, high incidence rates in athletics have been reported when landing on uneven surfaces, resulting in excessive inversion of the foot/ankle complex [2].

Augmented ground reaction forces (GRF) upon landing can increase the risk of injury, especially when the ankle is forced into inversion. [3]. Contradicting evidence regarding high and low-shaft athletic footwear suggests other mechanical design characteristics such as shaft stiffness, which reduces inversion range of motion (ROM), and mass of the footwear may influence the rate and amount of inversion when the foot/ankle is forced into inversion [4-5]. Therefore, selection of improper footwear, specifically in military populations that perform daily, occupational, and training tasks on uneven terrain, could increase the risk of LAS injuries.

Service members are provided with standard issue military footwear they are required to wear during active duty. Recently, minimalist footwear designs have been incorporated into military footwear, which feature a lighter mass, more flexible shaft, and a thin midsole in comparison to the standard issue footwear. Providing alternative footwear selections for service members may reduce the risk

of injury. However, the effectiveness of a minimalist boot design on ankle stability in military populations is unknown. Thus, this study examined the influence of a standard and minimalist military boot on GRFs during an inversion perturbation following a simulated military workload.

## METHODS

Twelve healthy adult males (age:  $22.0 \pm 2.0$  y; height:  $178.0 \pm 7.1$  cm; mass:  $81.1 \pm 10.6$  kg) who were moderately active with no self-reported history of musculoskeletal injuries completed the study. Participants completed two testing sessions, separated by at least 72 hours, with a crossover counterbalanced footwear assignment. Footwear used in the study was a standard boot (Belleville 310T hot weather standard tactical boot (STN); mass:  $801.13 \pm 40.4$  g) and a minimalist boot (Belleville TR101 MiniMil ultra-light minimalist tactical boot (MIN); mass:  $500.13 \pm 24.1$  g). Ankle stability was assessed before and after a simulated military workload using an outer sole with fulcrum, which created an inversion perturbation of 25 degrees upon landing [6]. A fulcrum (FUL) or a flat (FLT) outer sole was attached to the bottom of the participants' footwear without the participant having knowledge of the type of outer sole. After the outer sole was attached, participants stepped down from a 27 cm box onto an AMTI (Watertown, MA, USA) AccuGait force platform. A total of 10 successful trials, 5 with FUL and 5 with FLT were completed. Following completion of the ankle stability protocol, participants completed a simulated military workload on a treadmill wearing a 16-kg rucksack that has previously been utilized by DeMaio et al. [7]. After completion of the simulated workload, a post-workload ankle stability protocol was completed.

Data from the force platform was acquired and values of the maximum vertical ( $F_z$ ), anterior/posterior ( $F_y$ ), and medial/lateral ( $F_x$ ) GRFs were obtained and normalized to multiples of body weight for each footwear condition. Time to peak  $F_z$  was also obtained. Separate 2 (footwear) x 2 (time) RM-ANOVAs were computed for FUL and FLT conditions ( $p \leq 0.05$ ).

## RESULTS AND DISCUSSION

Cumulative means  $\pm$  SD are reported in Table 1. For the FUL condition, a significant footwear main effect for the  $F_x$  variable ( $p = 0.010$ ) was identified. In the FLT condition, analyses showed a significant footwear main effect for the  $F_y$  variable ( $p = 0.024$ ). For both footwear main effects, the MIN boot resulted in significantly less max force than the STN footwear. No other significant interactions or main effects were identified.

The primary purpose of this study was to examine ground reaction forces during a dynamic inversion perturbation following a simulated workload in two types of military footwear. In the current study, the main findings were that MIN demonstrated a significantly less peak  $F_x$  during the FUL condition and a significantly less peak  $F_y$  during the FLT condition (Table 1). These findings may be attributed to the differences in mechanical design characteristics of the boots. Although increased  $F_x$  during the FUL condition could be due to the greater STN boot mass, greater shaft stiffness in the STN boot could potentially limit ROM that might influence  $F_x$  during an inversion perturbation.

Moreover, increased shaft flexibility featured in the MIN boot might allow for greater ROM that could also impact the GRF during an inversion perturbation. Although this interpretation is difficult without ankle kinematics, allowing for greater inversion ROM in the MIN boot may have negative implications for risk of injury when the foot/ankle complex is unexpectedly forced into inversion.

Inadequate military footwear may help explain the high incidence of lower extremity injuries. Although results showed reduced  $F_x$  during FUL in MIN boots, mechanical design characteristics such as mass and shaft stiffness may potentially influence other parameters of ankle stability during an inversion perturbation. Future research should examine kinematic parameters of ankle stability to determine the impact of various mechanical design characteristics of military boots on ankle stability.

## INTRODUCTION

The field of exercise science is rampant with research on minimal footwear in runners. Minimal footwear, in attempts to mimic barefoot conditions, prioritizes lighter and more flexible shoe materials and a smaller heel-to-toe drop than standard sport footwear [1]. Studies focused on comparing performance variables among footwear types during non-running sport tasks are scarce, however. Greater soleus muscle activity while wearing standard training footwear compared to minimal footwear has been observed during maximal vertical jumping [2]. However no changes in maximal vertical jump performance were observed between footwear [2]. Although muscle activity measures provide important insight into muscular control during vertical jumps, joint power contributions indicate the net muscular contributions of involved musculature during jumping. Joint power contributions during jumping between different types of footwear have not yet been studied.

The purpose of this study was to compare lower limb joint power contributions and maximal jump height in athletes while wearing standard training shoes and minimal shoes. We hypothesized that minimal footwear would yield higher peak ankle joint power contributions but lower peak knee or hip power than standard footwear. Consequently, we also expected no differences in maximal vertical jump height between footwear conditions.

## METHODS

To date, six athletes (2 women; 22±1 years; 1.59±0.0 m; 57.8±10.0 kg, 4 men; 25±4 years; 1.78±0.10 m; 77.1±8.9 kg) who played in jumping sports or performed squats or weightlifting movements three or more times each week participated in the study. Before testing, participants completed a five-minute stationary bike warm-up followed by three 12-touch dot drills. Reflective

markers were placed on the pelvis, thighs, shanks and feet. A 9-camera motion capture system (240Hz, Qualisys AB) and a force platform (1200Hz, AMTI, Inc.) were used to collect kinematic and GRF data, respectively. Each athlete performed three practice jumps at less than maximal effort and three maximal countermovement vertical jumps (CMVJ) in both minimal and standard shoes from a self-selected stance width. Participants were instructed to jump maximally using a Vertec™ apparatus for external motivation. Participants were allowed to jump with their preferred technique (i.e., unrestricted). Standing reach height was measured at the start of jumping trial in both shoes to standardize jumping height. Unilateral limb (self-reported dominant) data from the maximal CMVJ were recorded.

Visual3D biomechanical software (C-Motion, USA) was used to process and analyze all data. Sagittal plane joint kinetics were calculated using Newtonian inverse dynamics equations and joint powers were calculated as the product of joint moments and angular velocities. Peak joint angular powers, joint moments and ranges of motion (ROM) during the concentric phase of the jump were analyzed. The average of each variable during the three CMVJ per footwear condition was used for analysis. A repeated-measures ANOVA with footwear condition as the within-subject factor was used to evaluate all variables ( $p < 0.05$ ). Cohen's  $d$  effect sizes were calculated to assess effect magnitudes.

## RESULTS AND DISCUSSION

As expected, vertical jump height was not different between footwear (**Table 1**). This finding is congruent with reports of no differences in vertical jump height between minimal and standard footwear [2]. Contrary to our hypothesis, ankle joint plantarflexor power was not larger for minimal

compared to standard footwear. Although ankle ( $p=.43$ ;  $d=.32$ ) and hip power ( $p=.78$ ;  $d=.11$ ) were not different between footwear, peak knee extensor power was smaller in the minimal compared to the standard shoe ( $p=0.05$ ;  $d=.18$ ). (Figure 1). There were no differences in sagittal peak joint moments, or joint ROM between footwear conditions ( $p>0.05$ ; Table 1). Although it has been shown that jumping in minimal footwear increases propulsive activation of the soleus [2], this could be a result of an increased proprioceptive load. Minimal footwear have much thinner soles than traditional, which has previously been associated with greater sensory input [3], and could have manifested as increased soleus activity [2]. This increased soleus activity could be a natural strategy that occurs in minimal footwear to account for the lack of stabilizing structures within the shoe when compared to standard shoes. While we expected greater ankle joint powers to manifest similar to what is observed in minimal footwear with runners [4], the vertical jump movement does not necessitate the same stretch-shortening cycle demand at the ankle that running does.

Considering that vertical jump heights were unchanged between footwear but that peak knee power was slightly greater in minimal footwear, our participants may have adopted a different jumping strategy in the novel footwear condition (i.e., participants had no jumping experience in minimal footwear). Since sagittal plane joint ROMs were unchanged between footwear conditions (Table 1), participants may have adopted a kinematic trunk or arm strategy to achieve similar jump heights in minimal footwear. Although we observed a small difference in knee joint power production in minimal compared to standard footwear, the small

effect size suggests that this difference is not meaningful.

## CONCLUSIONS

Our preliminary findings with a small sample size suggest that there are no meaningful differences in ankle, knee and hip power production during vertical jumping between minimal and standard footwear conditions. We are in the process of collecting more data from more male and female participants to better understand these footwear differences and, to assess any sex differences in joint power contributions during CMVJ.

# INFLUENCE OF MINIMALIST, NEUTRAL, AND ULTRA-CUSHIONING SHOES ON JOINT COORDINATION DURING RUNNING

Brianne Borgia<sup>1</sup> and James Becker<sup>2</sup>

<sup>1</sup>California State University, Long Beach, CA, USA

<sup>2</sup>Montana State University, Bozeman, MT, USA

email: james.becker4@montana.edu

## INTRODUCTION

Due to the synchronous movements of the lower extremity during the stance phase of gait, abnormal or excess motion of the foot can cause a disruption in joint actions [1]. Joints such as the knee may be especially sensitive to disruptions in timing [2] which may explain why knee injuries account for up to 25% of all running injuries [3]. Changing the footwear a runner uses is one mechanism which might potentially influence both foot function and the relative timing of joint movements. Changing footwear might also effect coordination and coordination variability between adjacent segments or joints, and thereby impact stresses placed on the joint [4].

In regards to the influence of footwear on joint coordination, it been previously shown that during the stance phase of running, peak eversion occurs significantly earlier when running in a shoe with a softer midsole compared to a harder midsole [3]. Additionally, when running barefoot verse shod appears to change both the amount and relative timing of knee joint flexion and extension [5].

Maximalist, ultra-cushioning shoes are rapidly growing in popularity. However, currently there is no data in the literature regarding how these shoes impact joint coordination. Therefore, the purpose of the study was to examine differences in inter-joint coordination and coordination variability when running in minimalist (MIN), neutral cushioning (NEUT) and ultra-cushioning (ULTRA) shoes.

## METHODS

Sixteen recreational runners (age:  $23.5 \pm 2.2$  years; height:  $1.68 \pm 0.19$  m.; body mass:  $76.5 \pm 4.5$  kg) participated in this study. All subjects were injury

free 6-months prior to and at the time of testing. Subjects were provided 3 pairs of shoes in their self-reported size. (Min shoe: New Balance 1400v3, Neut shoe: Nike Air Zoom Pegasus 32, Ultra shoe: Hoka OneOne Bondi 4).

Running kinematics were recorded using a 12-camera motion capture system (Qualisys, Inc., Gothenburg, Sweden) sampling at 200 Hz while participant ran on an instrumented treadmill (Bertec Corp., Columbus OH) at 3.0 m/s. Participants ran for 10 minutes in each shoe condition, with the first 9 minutes allowing familiarization to the footwear and data collected during the last minute. Marker trajectories were recorded for thirty seconds during the last minute of the 10-minute trial, from which ten consecutive steps were selected for analysis.

Raw marker trajectories were exported to Visual 3D (C-Motion, Inc., Rockville MD) where they were filtered using a 4<sup>th</sup> order, zero lag, low-pass Butterworth filter with a cutoff frequency of 6 Hz. Joint angles for the knee and segment angles describing the orientation of the rearfoot and tibia segments relative to the laboratory coordinate system were calculated. Angles were normalized to 100% of stance phase and exported to a custom LabView Program (National Instruments, Austin TX) where the following dependent variables were calculated: the position at initial contact, peak position during stance phase, and range of motion.

A modified vector coding approach [6] was used to determine the segment couplings between rearfoot and tibia, tibia and knee, and rearfoot and knee. Coupling angles were calculated at each point during stance phase and categorized into one of four patterns: proximal phase, in-phase, distal phase, or anti-phase. The frequency of each pattern were specifically quantified during early (ES: 0-33%),

mid (MS: 34-66%), and late stance phase (LS: 67 – 100%).

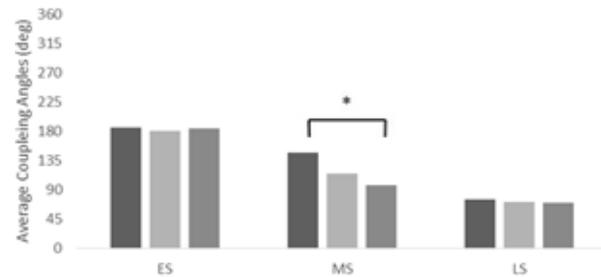

Differences in segment and joint kinematics were evaluated using a one way repeated measures ANOVA. Differences in average coordination patterns were evaluated using a two way (period of stance x shoe condition) repeated measures ANOVA. All statistical analyses were performed with an alpha of  $p < .05$ .

## RESULTS AND DISCUSSION

There was a significant period of stance by shoe interaction for average tibia-knee coupling angles ( $F_{4,60} = 3.507$ ,  $p = 0.012$ , Figure 1). Pairwise comparison revealed that during MS average coupling angles were larger in the MIN shoe ( $146.9 \pm 94.9$ ) compared to the ULTRA shoe ( $96.6 \pm 78.35$ ) condition ( $p = .029$ ). During MS in ULTRA conditions tibia-knee coordination was primarily in the distal phase, dominated by tibia motion. However, in the MIN condition tibia-knee coordination during MS was dominated by antiphase motion. No differences in coupling angles were observed for rearfoot-tibia or rearfoot-knee coordination at any of the three phases of stance. There were no statistically significant difference between shoe conditions for any of the segment or joint angle variables (Table 1).

The main finding from this study was higher amount of antiphase motion during MS in the MIN shoe condition. This coordination pattern means the tibia was internally rotating while the knee was extending. Previous research has suggested that this

type of motion may increase torsional stress on the knee joint [7]. While the results of this study provide insight into the role of footwear on joint coordination, additional studies are necessary to determine if these coordination patterns relate to injury incidence when using ultra-cushioning shoes.

**Figure 1.** Average period of stance x shoe interaction coupling angles of tibia I/R –knee F/E during early stance (ES), mid stance (MS) and late stance (LS) \* indicates significant difference at  $p < 0.05$  level.

## INTRODUCTION

Footwear science aims to advance comfort, safety, and economy of motion. Prior research has studied the effects of footwear design on impact loading, energy return, comfort, and movement control [1]. However, biomechanical studies examining the effects of military boot design on performance and injury prevention are limited [2].

Injury prevention is a priority within the military health system. Musculoskeletal injuries are prevalent and largely occur due to overuse and joint disorders [3]. In-shoe interventions may be beneficial, and using prescription orthotics as a preventative measure has been shown to reduce injury development in military recruits [4]. An energy storage and return orthosis (ESRO) was developed for this study to improve the biomechanical performance of Service Members. The purpose of this study was to determine how the ESRO integrated within military boots impacts performance in Service Members.

## METHODS

13 active duty Service Members (age:  $30 \pm 10$  yrs, height:  $1.77 \pm 0.06$  m, mass:  $86.12 \pm 10.35$  kg, 12 male 1 female) with no recent injuries underwent two sessions of gait analysis in a motion laboratory. Kinematic (120 Hz, Motion Analysis Corp), force plate (1200 Hz, AMTI, Inc.), EMG (1200 Hz, Motion Laboratory Systems, Inc.), and metabolic (Parvo Medics) data were recorded as subjects walked at a set speed (4mph). EMG and metabolic data were collected on a treadmill and joint kinematic and ground reaction force data were collected overground. A standard issue military boot and a boot with an integrated ESRO orthotic were tested in a randomized order (Figure 1). The

ESRO boots were, on average, 234g (0.52lbs) lighter than the standard boots.

**Figure 1:** Top: Image of the standard boot (left) and test ESRO boot (right). Bottom: Image of the ESRO (left) and full assembly (right).

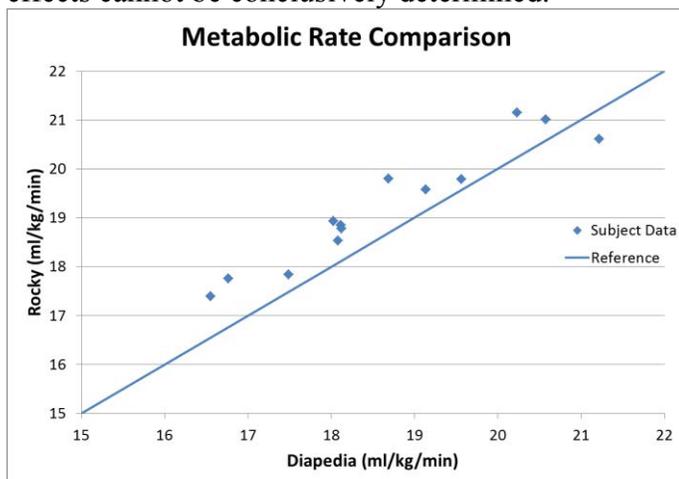

Five strides of kinematic/kinetic data and 10 strides of EMG data were analyzed. Lower extremity joint angle, moment, and power data were calculated and peak values during key points of stance and swing were identified. Integrated EMG activity from the gluteus maximus, gluteus medius, rectus femoris, vastus medialis, biceps femoris, lateral gastrocnemius, medial gastrocnemius, soleus, and tibialis anterior was analyzed during 6 phases: 0-10%, 10-30%, 30-50%, 50-60%, 60-80%, and 80-100% of the gait cycle. Metabolic rate was calculated as the average rate during 2 minutes of steady state walking.

A 2-way repeated measures ANOVA (boot x phase of gait) and post-hoc paired t-tests with Bonferroni-Holm corrections identified significant differences in the EMG data. Paired t-tests with Bonferroni-Holm corrections identified significant differences

between boots for the kinematic, kinetic and metabolic data ( $\alpha = 0.05$ ).

## RESULTS AND DISCUSSION

The ESRO boot produced a small (2.8%) but significant and consistent reduction in metabolic rate ( $p < 0.001$ ) (Fig 2). The reduction in mass of the ESRO boots likely contributed to part of the improved metabolic performance. The ESRO may have also contributed. Prior literature indicates that for every 100g added to the ankle, the metabolic rate increases by 0.8% at 4mph [5]. Therefore a 234g decrease in footwear mass would equate to an expected 1.9% decrease in metabolic rate. The ESRO may have contributed to the remaining reduction in metabolic rate but its independent effects cannot be conclusively determined.

**Figure 2:** Metabolic rate comparison between the standard boot and ESRO boot.

The internal knee extensor moment and knee power absorption in late stance both significantly decreased in the ESRO boot ( $p < 0.014$ ). The difference was 0.05 Nm/kg for the extensor moment and 0.37 for power absorption. The lack of other significant biomechanical changes suggests the ESRO boot may not increase the risk of musculoskeletal injuries.

EMG remained largely unchanged between conditions. However, there was a significant interaction effect between the boot type and phase of gait for the tibialis anterior ( $p = 0.047$ ) and the biceps femoris ( $p = 0.001$ ). The tibialis anterior had a significant 6% reduction in activity in the ESRO

boot during late stance ( $p < 0.001$ ) and a 17% reduction in early swing ( $p = 0.006$ ). It is possible that these reductions may have played a small role in reducing the metabolic rate of walking, but the tibialis anterior is not a large muscle and accounts for only a minor portion of the overall energy expenditure.

There were several limitations. First, the 4mph speed may not highlight the aspects of the boots at different speeds (running). In addition, there was no accommodation time for the boots, which often require a “break-in” period for comfortable use. Finally this abstract does not report all the variables that may be associated with overuse injuries.

## CONCLUSIONS

The novel boot with the ESRO demonstrated reduced metabolic cost with few altered biomechanics. The reduced mass of the ESRO boot likely drove the significant decrease in metabolic activity, and the ESRO integrated within the boot may have also contributed. The reduction was small, but may have important performance implications over time. Overall, the reductions in cost occurred without largely impacting overall gait mechanics and muscle activity.

## INTRODUCTION

Falls in the work place are a major economic burden. The Bureau of Labor Statistics reported a total of 4,679 workplace fatalities, and a total of 316,650 non-fatal workplace injuries that were due to falls in 2014. Moreover, the leading event or exposure for occupational injuries and illness were workload overexertion [1]. Previous literature has suggested that occupational footwear can cause balance decrements [2,3,4], as can occupational workloads [3,4]. Occupational footwear, while designed primarily for safety, may not provide proper ankle and foot support and predispose the body to postural control decrements, particularly when exposed to extended durations of an occupational workload. Thus, the purpose of this study was to examine differences in muscle activation levels of the lower extremities while wearing different types of occupational footwear during a simulated extended duration occupational workload. The current footwear are standard footwear of the construction and manufacturing industry, and include the Work Boot (WB) (mass:  $0.39 \pm 0.06$  kg; boot shaft height: 18.5 cm), Tactical Boot (TB) (mass  $0.53 \pm 0.08$  kg; boot shaft height: 16.5 cm) and Low Top Shoes (LT) (mass:  $0.89 \pm 0.05$  kg; boot shaft height: 9.5 cm).

## METHODS

Fifteen healthy male adults (aged  $23.6 \pm 1.2$  years; height of  $181 \pm 5.3$  cm; weight of  $89.2 \pm 14.6$  kg), with no history of orthopedic, musculoskeletal, cardiovascular, neurological, or vestibular

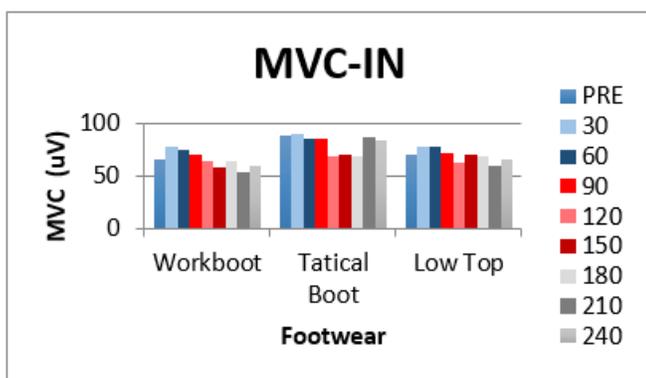

abnormalities participated in this study. For the purposes of this abstract, 8 subjects are considered. Participants were tested on three separate days while wearing a randomly assigned occupational footwear, separated by a minimum of 72 hours. The experimental session included an extended duration of a simulated occupational workload which included walking for 4 hours with muscle activation measured every 30 minutes (Pre, 30, 60, 90, 120, 150, 180, 210 & 240 min). Participants were instructed to walk at a self-selected pace and a self-selected path on a hard firm surface until every 30 minute interval to complete muscle activity testing. Muscle activation testing was performed using maximal voluntary contractions (MVCs) of six lower extremity muscles, the quadriceps, hamstrings, plantarflexors, dorsiflexors, ankle inverters, and everters. Surface electromyography signals were recorded from the right leg musculature: tibialis anterior (TA), medial gastrocnemius (MG), semitendinosus (H) and vastus medialis (Q), soleus (IN) and peroneus longus (EV). The EMG signals were recorded using silver/silver chloride monopolar surface electrodes. The ground electrode was placed on the tibial tuberosity. The EMG was recorded using Noraxon® MyoResearch software (Noraxon U.S.A. Inc. Scottsdale, AZ.). Raw EMG data were collected at 1,500 Hz, band-pass filtered (20-250Hz) and rectified prior to analysis. Three maximal voluntary contractions, five seconds in duration were performed for each muscle. Quadriceps and hamstring MVCs were performed while seated on a weight bench, plantarflexion, and dorsiflexion MVCs were performed in the standing position. The mean muscle activity for each MVC were obtained

and averaged together across the three trials for analysis. Mean muscle activity during the MVCs were analyzed using a 3 x 9 (Footwear [WB, TB, LT] x time [Pre, 30, 60, 90, 120, 150, 180, 210, 240]) repeated measures ANOVA. If main effects or interaction differences were observed, simple effects were calculated while applying a Bonferroni correction factor for multiple comparisons. All statistical analyses were performed in SPSS version 22 with an a priori alpha level of 0.05

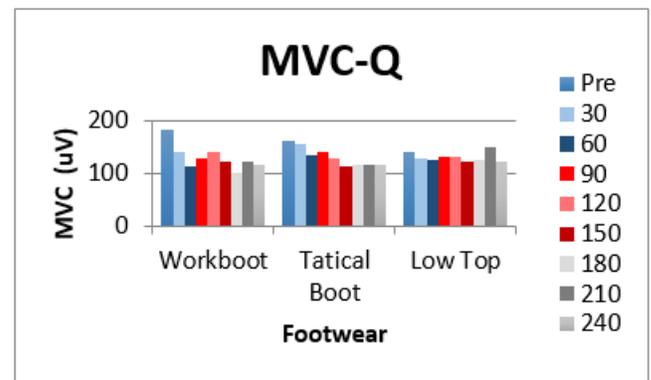

## RESULTS AND DISCUSSION

A significant main effect for time was found for IN MVC ( $F(8,56) = 2.819, p=0.011$ ). Pairwise comparisons for main effects revealed significant differences with higher MVC at minute 30 than minute 120 and a higher MVC at minute 60 than minute 120 at  $p=0.042$  and  $p=0.028$  respectively. A significant main effect for time was found for Q MVC ( $F(8,56) = 4.909, p > .001$ ). Pairwise comparisons for main effects revealed significant differences with higher MVC at minute 30 than minute 240 at  $p=0.024$ . No significant differences were observed between the footwear conditions.

The significant main effects for time in the IN and Q MVCs may suggest that fatigue affected the most distal part of the lower extremity (IN) after 120 minutes, earlier than the more proximal and larger muscle (Q) at the 240 minute time point. The results agree with the literature, which shows that MVC's should decrease due to the lack of motor unit recruitment with the increase in strenuous workloads [2,4,5].

**Figure 1:** Mean MVC's of the inverter muscle (IN) at nine time points.

**Figure 2:** Mean MVC's of the vastus medialis muscle (Q) at nine time points.

A decline in the capacity to recruit muscle fibers may indicate tiredness, discomfort, and injuries associated with long duration walking and standing, [6,7]. This may become dangerous, especially in occupational settings, due to the elevated stress placed on the postural control system by hazardous environmental factors [8].

## CONCLUSIONS

Although the footwear analyzed in the current study may not significantly influence on MVC's, we cannot dismiss the possibility that footwear with different physical characteristics may alter the MVC's. It is also possible that footwear specially designed for the occupational work environment may influence muscle activity during a period longer than 4 hours. Therefore, future research should utilize a similar protocol over a longer duration.

## INTRODUCTION

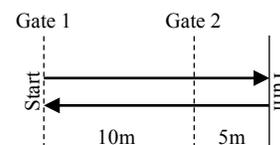

Basketball is a game of multiple, high intensity sprints covering an average of 15m [1]. Sustaining sprint performance over the course of a game is challenging: speed and distance traveled significantly decrease in the second half of games.

Recent work has shown the negative effect of footwear with increased longitudinal bending stiffness on the ability to accelerate, demonstrating that greater stiffness is related to slower acceleration over short distances [2]. It remains unknown if flexible footwear helps with sprinting performance over time as is the case in basketball. Therefore, the purpose of this work was to determine if shoes with different bending stiffness influence initial sprint performance and the overall performance decrement throughout a repeated sprint test.

## METHODS

Nine male basketball players (30.2± 4.2 yrs., 1.88 ± 0.04 m, 93.9 ± 7.6 kg) participated in this study. Three different shoes were compared which differed only in their bending stiffness. During three separate visits to the laboratory, athletes performed the repeated sprint ability test (RSA) once per visit and wore a different shoe each time. The RSA is a fatiguing performance drill that tests an athlete's anaerobic capacity [3]. The test consists of ten repeated shuttle sprints that are 30 meters in length (15m + 15m) with thirty seconds of rest between each sprint. If the athlete exerts maximal effort on each sprint, their speed will decrease with each repetition as the effects of fatigue increase. From this decay in performance, the rate of fatigue can be calculated [3]. Previous work has identified that initial performance and the rate of fatigue are positively correlated and have been shown to differentiate endurance athletes from athletes who participate in team sports. [4].

Faster initial sprint times are associated with greater decay in performance over the course of the drill [5]. Conversely, slower initial times are associated with smaller decay rates. Performance was assessed by using wireless timing gates placed ten meters apart. One set of gates was placed at the start/finish line, while the second timing gate allowed for the change of direction speed to be measured (Fig. 1).

**Figure 1:** Placement of timing gates with respect to the 15m shuttle course allowed for linear sprint and change of direction performance to be measured.

Dependent variables included performance decrement ( $S_{dec}$ ), best lap time, fastest turn, total test time and average lap time. Performance decrement was calculated as:

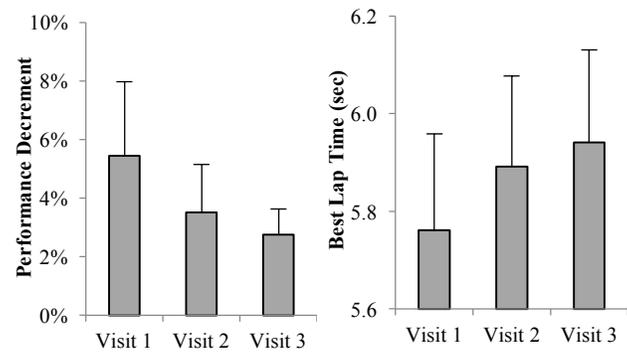

$$S_{dec}(\%) = \left\{ 1 - \frac{(S_{avg})}{S_{best}} \right\} \times 100$$

A one-way repeated measures ANOVA was used to test for the effect of visit order followed by a separate analysis comparing footwear conditions if an order effect didn't exist.

## RESULTS AND DISCUSSION

In general, sprint times were slower throughout the progression of RSA for all athletes on all visits. A significant order effect was found for performance decrement ( $P < 0.01$ ) and best lap time ( $P < 0.01$ ). Initial sprint times were fastest in the first visit of the study. Additionally, performance decrement was the greatest in the first visit of the study and decreased on each subsequent visit (Fig. 2). There was no order

effect for the total test time and average lap time (Table 1).

**Figure 2:** Performance decrement (left) decreased from visit to visit, while best lap time increased (right).

Total time to complete the drill was similar across all three shoe conditions. Specifically, the total times for the flexible, medium and stiff conditions were  $58.37 \pm 3.76$ ,  $57.96 \pm 3.25$  and  $58.12 \pm 2.89$  seconds, respectively ( $P = 0.76$ ). Additionally, the average lap time was the same across all three shoe conditions which were  $6.11 \pm 0.23$ ,  $6.06 \pm 0.14$  and  $6.08 \pm 0.20$ , for the flexible, medium and stiff shoes ( $P = 0.70$ ).

The original purpose of the study was to determine the effect of bending stiffness over the course of repeated sprints. As there were no differences in total time to complete the test across shoes, it appears that the range of stiffness tested in this experiment are not great enough to cause a change in performance.

Interestingly, a systematic strategy across study visit was observed in the results. It appears that athletes may have elected to run slower on the initial sprints in visits two and three. This order effect may have been to reduce the discomfort/fatigue associated with the test, based on the experience from the first visit. Additionally, using a different strategy from visit to

visit caused a lot of variability across shoe conditions, potentially overshadowing any footwear effects.

## CONCLUSIONS

Increasing bending stiffness did not affect the total time of the RSA. The range of stiffness tested in this study may be different from previous work.

It was found that athletes self-optimize their performance of the RSA test to produce the same average work load yet with slower initial sprint times. This strategy may have been employed as a way to reduce the discomfort associated with high intensity exercise. The strong order effect observed prevents confirmation of the original purpose to see if initial sprint performance is improved in flexible footwear.

These findings suggest that future work should consider how to measure maximal effort exercise across multiple sessions. One way to mitigate these findings may be through real-time motivational feedback to the athlete.

## INTRODUCTION

Lower extremity injuries are common to runners, including - but not limited to - stress fractures from repeated impact and loading. Though there are many contributors to such injuries, loading rate (LR), which is the rate of vertical ground reaction force development, has been implicated in particular [1].

Some kinematic parameters of foot strike may be tied to helping reduce LR. Among these are potentially foot strike index (SI) and running cadence (RC). SI is a measure of how far forward on the sole of the foot initial impact with the ground occurs (measured as a percentage of foot length). Running cadence is measured in steps (foot strikes) per minute. It is possible that further forward SI and increased RC may help reduce LR [2,3].

Zero-drop (ZD) shoes (Altra Running, Logan, UT) have no difference between forefoot and rearfoot midsole stack heights. The makers of the shoe suggest that this encourages less overstriding, leading to increased RC and a more forward SI. However, the effect of this footwear on these variables is not fully understood.

The purpose of this study was to compare SI, RC, and LR for runners when running in the ZD shoe to running in three other shoes: traditional (TR), stability (ST), and maximalist (MX).

## METHODS

All study procedures were reviewed and approved by the University IRB, and all subjects provided informed consent. Thirty runners (15 M, 15 F) ran for three-minute bouts at a time on a treadmill at their preferred, self-selected pace. They ran in each of the four shoes in counterbalanced order. After the

three-minute bout on the treadmill, subjects ran across a force platform at the same pace.

The right lower extremity was marked with retro-reflective markers and the last 30 seconds of treadmill running, as well as the force plate run, were recorded using a multi-camera 3D system. High speed video (300 Hz) and digitization were used to measure SI [4]. Custom software was used to make subsequent calculations for SI, RC, and LR during initial impact. Paired t-tests ( $\alpha = 0.05$ ) were made to identify any differences between shoes among these variables.

## RESULTS AND DISCUSSION

Descriptive statistics for all variables are presented in Table 1. Several differences are noted in response to the study purpose.

First, SI was further forward for the ZD shoe than for TR shoes ( $p=0.002$ ), ST shoes ( $p<0.001$ ), and MX shoes ( $p=0.004$ ). Next, RC was increased in the ZD shoe over the TR ( $p<0.001$ ) and MX shoes ( $p=0.012$ ), but not the ST shoe. Last, LR was reduced in the ZD shoe compared to the TR shoe ( $p=0.009$ ) and MX shoe ( $p=0.019$ ), but not the ST shoe. A secondary analysis did not reveal direct correlations between SI and LR, or between RC and LR.

Taken together, these findings underscore the complexity of the leg spring, and the importance of considering it as a complete mechanism., rather than focusing on any one characteristic of impact mechanics. In this sample, LR was reduced in the ZD shoe compared to two others. However, even though this was seen concurrently with an increased cadence and a more forward foot strike overall, the variability in LR was not directly explained by either of these variables. This suggests that it is a combination of factors that predicts LR (rather than

any single one), and that different runners experienced different combinations of factors.

However, the current results suggest that the ZD design does have an effect on running mechanics somehow, and that some of these effects occur immediately. For example, there was an overall more-forward SI in the ZD shoe. The majority of this result came from a large effect for a handful of subjects who dramatically changed their SI in the ZD shoe but not in the other shoes (see Figure 1). In previous studies, such a big change typically resulted from instruction and/or the removal of shoes altogether [5]. The current subjects received no instructions other than to run at their preferred pace on the treadmill for three minutes.

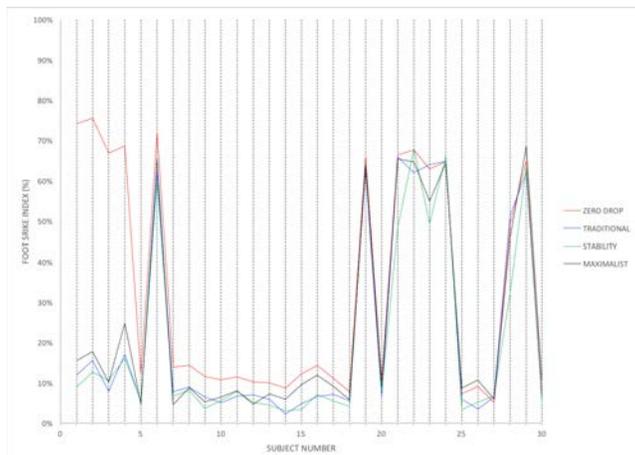

Figure 1: Foot strike index for each subject by shoe. 100% is toe, 0% is heel.

Additionally, increased cadence naturally occurred overall in the ZD shoe. Because speed was held constant, this is tied to reduced stride length, implying a probable overstride reduction. This was likely a contributor to reduced LR as well. Further analysis revealed an attendant increase in knee flexion excursion during weight acceptance in the ZD shoes compared to the TR shoe ( $p = 0.002$ ).

It is evident that runners experienced mechanical changes during impact that taken together likely contributed to the reduced LR, which they would experience as a softer landing. While no one factor may have done this directly, the combination of factors possibly related to the ZD design seems to have changed the leg spring for many of the runners.

## CONCLUSIONS

Overall, there was a reduced loading rate in runners who tried the zero-drop shoe design when compared to loading rates in traditional and maximalist shoes. A combination of factors probably led to this result, but among them may be increased cadence and a more forward foot strike, as well as an associated increase in knee flexion during landing. More research is needed on the long-term effects that adapting to these changes may have for the runners over time, but those who wish to increase cadence and/or land more forward on the foot when running should consider the zero-drop design.

## INTRODUCTION

Running shoes design and construction is ever changing and has resulted in a wide variety of shoes available for commercial purchase including the Hoka One One to Vibram FiveFingers. Arguments both for and against the benefits of cushioning in running shoes have been made; in particular, whether cushioning has a protective or detrimental effect on running related overuse injuries. Recently, a new paradigm has been proposed which argues that the cushioning of the shoe is not as important as the perceived comfort of the shoe and ease of preferred movement path the shoe allows [1]. This hypothesis is possible given that runners tend to normalize joint stiffness and impact force characteristics and tibial shock in response to varying shoe and surface conditions [e.g. 2]. The result that impact forces increase as cushioning increases is counterintuitive. It would be expected that greater midsole cushioning would create a softer landing, similar to the effect of bending the knees when landing from a jump. It has yet to be investigated whether the timing between peak vertical impact force and peak tibial acceleration are changed with varying midsole thicknesses. Although impact forces increase with greater cushioning, a delay in the timing between peak impact force and peak tibial acceleration may indicate that more shock is attenuated by the shoe rather than the tissues of the foot and leg.

The purpose of this study was to examine the effects of an increase of 3 mm and 6 mm in shoe midsole thickness on the timing and magnitude of peak vertical impact force and peak tibial acceleration. It was hypothesized that the delay between the timing peak impact and peak tibial acceleration would increase as midsole thickness increases.

## METHODS

To date, seven healthy, male rearfoot runners between the ages of 18 and 40 volunteered to participate in this study. All participants read and agreed to IRB documents before participating. Participants were outfitted with retroreflective markers secured to anatomical points on their right foot, right leg, and pelvis. The three models of shoes were tested which were identical in all aspects except their midsole thickness (18 mm, 21 mm, and 24 mm). Participants ran in all three shrouded shoe models at  $3.5 \text{ m/s} \pm 5\%$  across a force platform (1200 Hz) imbedded in an 18m runway. Nine infrared Qualisys motion capture cameras recorded the position of the retroreflective markers (240 Hz). A triaxial accelerometer secured to the anteromedial aspect of the distal right tibia was used to measure tibial shock during the stance phase (1200 Hz). Camera, force platform, and accelerometer data were time synchronized. Impact-related variables were assessed from the vertical ground reaction force (vGRF) using previously established methods [3]. A repeated measures ANOVA ( $\alpha=0.05$ ) with Tukey's post hoc comparisons was used to compare the kinetic and kinematic variables between the three midsole thickness conditions. Given the small sample size, Cohen's  $d$  was also used to determine if the none statistically significant differences displayed meaningful trends.

## RESULTS AND DISCUSSION

There was a significant decrease in average vertical loading rate, a significant decrease in instantaneous vertical loading rate, and a significant decrease in peak tibial acceleration as midsole thickness increased (Table 1). Time to peak vGRF impact increased as midsole thickness increased but was not statistically significant ( $p>0.05$ , Table 1). Time to

peak tibial acceleration increased with increased thickness for 18 mm to 21 mm ( $d = 0.37$ ), did not differ between 18 mm thickness and 24 mm ( $d = 0.09$ ), and decreased with increased thickness from 21 mm to 24 mm ( $d = 0.78$ ). No change in the magnitude of the vGRF impact peak was detected between midsole conditions ( $p > 0.05$ , Table 1). No differences in joint kinematics were observed ( $p > 0.05$ ).

The decreases in the average and instantaneous vertical loading rates of the vGRF were consistent with previous studies and may be attributed to an increase in the time to peak impact rather than a significant decrease in the impact peak magnitude [4, 5]. The lack of difference in the kinematic variables might be explained by the identical heel-toe drop between the three shoe thickness models tested [6]. Previous research that showed kinematic differences with differing shoe thicknesses had differences in heel-toe drop between shoe conditions [7]. The lack of kinematic difference could also be explained by the preferred movement path paradigm [1].

The 24 mm thickness condition resulted in the longest delay between the vGRF impact peak and peak tibial acceleration. The smallest difference in timing between peaks occurred with the 21 mm thickness condition (Table 1). The 21 mm condition also resulted in the greatest vGRF impact peak magnitude and longest time to peak tibial acceleration.

## CONCLUSIONS

Increasing the midsole thickness of running shoes from 18 mm to 21 mm to 24 mm reduced ground impact characteristics without changing gait kinematics. The increased delay between peak vGRF impact and peak tibial acceleration may suggest a greater role of the shoe in modulating the tibial shock as midsole thickness increases from 18 mm to 24 mm. Further analysis and more subjects may be needed to explain the inconsistent results with the intermediate, 21 mm thickness condition. The data may indicate an “optimal” midsole thickness for creating less injurious impact conditions.

## INTRODUCTION

Ballet requires a unique balance of athleticism and artistry. Several jumping and landing skills, such as ballonné and grand jeté, will be performed frequently. Grand jeté is a big leap in the form of splits, and the lower extremity would bear substantial impacts during the landing. Two potential contributing factors of ballet dancer's injuries are excessive ground reaction forces and shoe type [1]. The jumping/landing tasks usually have large impacts on the lower extremities, but neither the flat shoes nor pointe shoes could provide significant shock absorption for dancers. Landing on extreme plantar-flexed postures after a grand leap are the frequent circumstances that cause injuries in ballet dancers. The most common injury is ankle inversion sprains, which also have high rate of recurrence and subsequent disability and residual symptoms [2]. These observations lead to a result that impacts at landing have to attenuate by good rolling-down mechanism at the ankle-foot region and also coordinated movements in the lower extremities. However, previous literature seldom reported the descriptions of joint mechanics in lower extremities during the jumping/landing tasks. Therefore, the aim of this study is to investigate the joint mechanics in lower limbs during the landing of grand jeté with flexible ballet (or soft) shoes and pointe shoes in young female ballet dancers.

## METHODS

Nineteen healthy collegiate ballet female dancers were recruited for detailed biomechanical analysis.

Each participant was asked to warm-up first, and then perform grand jeté at least for five times wearing first with soft shoes and then pointe shoes in our motion analysis laboratory equipped with six infrared camera (Vicon MX, Oxford Metrics, UK) and three mounted force platforms (AMTI Inc., Watertown, MA, USA) to collect the kinematic and kinetic simultaneously. Several events during a grand jeté were determined by the currencies of the maximal knee flexion angle, highest body center of mass, foot touch-down on the ground, foot rolling-down to maximal ankle dorsi-flexion angle, and the lift-off from the ground (Fig. 1). The joint angles, moments in the lower extremity starting from the landing to the rolling-down phase in a grand jeté on the force platform were concentrated and the peak values were obtained and used for further analysis. All the dependent variables will be analyzed using SPSS statistical software to determine the differences between shoe types.

## RESULTS AND DISCUSSION

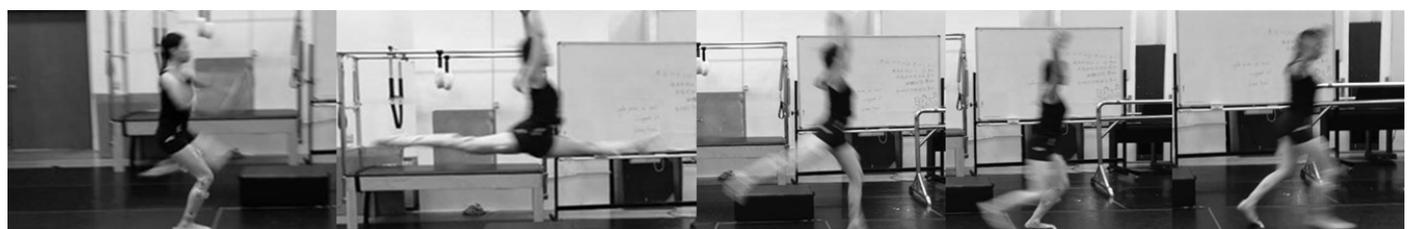

The results showed the significant differences between shoe types occurred mainly in hip and ankle-foot region (Table 1). In the sagittal plane, significant larger hip flexion angle, more forefoot plantar-flexion angle and smaller hip flexor moment at the touch-down were found in the pointe shoe condition. Then, the larger hip flexed angles and ankle plantar-flexion angle were also found in the rolling-down phase. In the frontal plane, smaller midfoot eversion at the touch-down but larger ankle eversion angle during the rolling-down phase were demonstrated in the pointe shoe condition. In the

transverse plane, the larger forefoot internal rotation angle and larger external rotator moment at the knee joint but smaller at the ankle joint were found.

Different landing mechanism would affect the magnitude of the ground reaction force [3]. When wearing different shoe types, the ballet dancers learned to adapt themselves with different landing mechanisms. With the restriction at the toe-box of the pointe shoes, the dancers would land with less forefoot dorsi-flexion but with more flexed hip joint. While wearing the soft shoes, the mid-foot could land with a more everted position, which indicated a flexible foot structure that benefits the shock absorption. Therefore, another strategy occurred during the rolling-down phase with larger knee internal rotator moment.

## CONCLUSIONS

This study aimed to investigate the different landing mechanisms when performing a grand jeté with soft and pointe shoes in young ballet dancers. It has

**Figure 1:** Events during a grand jeté.

**Table 1:** Selected joint angles and moments at touch-down and peak values during the rolling-down phase in the landing of grand jeté wearing flat or pointe shoes in the healthy young female ballet dances.

# LIGAMENT STRAIN RESPONSE BETWEEN CONTRALATERAL PAIRS OF LOWER EXTREMITIES DURING *IN VIVO* LANDING SIMULATION

<sup>1</sup>April L. McPherson, <sup>1</sup>Nathaniel A. Bates, <sup>1</sup>Nathan D. Schilaty, <sup>1</sup>Christopher V. Nagelli, <sup>1</sup>Aaron J. Krych, and <sup>1</sup>Timothy E. Hewett

## INTRODUCTION

Biomechanical measures of limb asymmetries during *in vivo* investigations have been identified as a risk factor for primary and secondary anterior cruciate ligament (ACL) injury.[1,2] Recent methodological developments have applied *in vivo* knee kinetics to exert physiologically relevant landing forces on cadaveric lower extremities to mimic ACL injury risk.[3] It is unknown whether contralateral ACLs respond and subsequently fail in a consistent manner during simulator testing. Thus, the objective of the study was to determine if contralateral pairs exhibit different ligament strain responses during simulated *in vitro* landing. It was hypothesized that contralateral lower extremities would exhibit similar ligament strain responses.

## METHODS

A novel mechanical impact simulator was used to simulate the impulse ground reaction force generated during an *in vivo* landing task.[3] External knee abduction moment (KAM), anterior shear (ATS), and internal tibial rotation (ITR) were applied to the specimen in a randomized order of pre-determined magnitudes. External load magnitudes were determined from a previous *in vivo* study of a healthy athlete cohort who performed a drop vertical jump (DVJ) task. Ligament strains were recorded by differential variable reluctance transducers (DVRT) implanted on the ACL and medial collateral ligament (MCL). Eleven pairs of cadaveric lower extremities were obtained from an anatomical donations program (n = 5 female, n = 6 male; age = 42.4 ± 8.6 years; mass = 87.7 ± 21.6 kg; BMI = 29.1 ± 6.6). Analyses of ligament strains were performed between dominant and non-dominant sides. Paired *t*-tests were used to

analyze the data for significant differences ( $p < 0.05$ ) between contralateral pairs.

## RESULTS AND DISCUSSION

Prior to failure, contralateral pairs exhibited no significant differences in maximum ACL strain ( $p = 0.07$ ) or maximum MCL strain ( $p = 0.38$ ) during a simulated DVJ landing (**Table 1**). These findings are consistent with a previous investigation of contralateral differences using *in vivo* kinematics to drive a robotic simulation, which similarly reported no differences in peak ligament strain between contralateral limbs.[4] Whereas previous ligament strain testing studies isolated ligaments by removing the surrounding tissues and used a uniaxial testing device, the current study is a novel way to investigate ligament strain response with all surrounding structures intact in a physiologically relevant manner.

**Table 1:** Maximum ligament linear strain percentage values recorded prior to specimen failure

	Dominant	Non-dominant
ACL	12.05 ± 3.84%	19.18 ± 12.19%
MCL	4.21 ± 7.60%	8.04 ± 9.85%

\*No statistically significant difference between sides ( $p < 0.05$ )

Contralateral pairs tended to fail at similar externally applied loads and with similar pathologies (**Table 2**). Fourteen of the 22 specimens survived to the complete high-risk loading condition (i.e. 100\_100\_100). Interestingly, 12 of these 14 specimens represent 6 contralateral pairs that both reached the complete high-risk trial. For those specimens that survived the complete high-risk trial, the impulse force was adjusted to half the body weight and KAM, ATS, ITR were each increased 20% until the specimen failed.[3]

Findings from this study indicate that limb dominance does not affect the failure threshold of the ligament, since no differences in ligament strain were observed between dominant and non-dominant sides. This may indicate that limb asymmetry is not solely determined by the structure of the ligament, but rather by the product of multiple extrinsic factors and loading mechanisms that influence ACL response. Previous research has demonstrated limb asymmetries observed *in vivo* that increase ACL injury risk can be corrected with neuromuscular training.

The current study is not without limitations. DVRTs are known to have large variability when implanted in soft tissue structures. It also should be noted that failure of three specimens was not due to ACL rupture, but rather femoral fracture or MCL rupture. These three specimens exhibited intact ACL structures in post-testing orthopedic examinations. The remaining nineteen specimens exhibited clinically representative ACL failures, most commonly femoral avulsions. The three non-ACL failure specimens were included in the data analysis in order to represent ligament strain response between contralateral pairs for the comprehensive set of failure mechanisms observed during the landing simulation test. Ligament strains from the trial that induced the failure for each specimen were included in the analysis.

## CONCLUSIONS

There were no significant differences in ACL or MCL strain values between limb sides during *in vitro* simulation testing. This finding indicates that limb dominance does not influence the failure threshold of the ACL, since there was no significant difference in failure strains. As such, it is likely that the mechanical and structural properties of the ACL are comparable between contralateral pairs from the same, healthy specimen. In addition, this study clarifies that observed limb asymmetries *in vivo* are likely more attributable to factors external to the ACL such as neuromuscular control, loading pattern, intra-articular geometry, and lower extremity kinematics.

## INTRODUCTION

Patellar tendinopathy is a common condition in athletes who perform repetitive jumping and landing movements. The incidence rate of patellar tendinopathy has been reported to be as high as 45% and 30% among elite volleyball and basketball players, respectively [1].

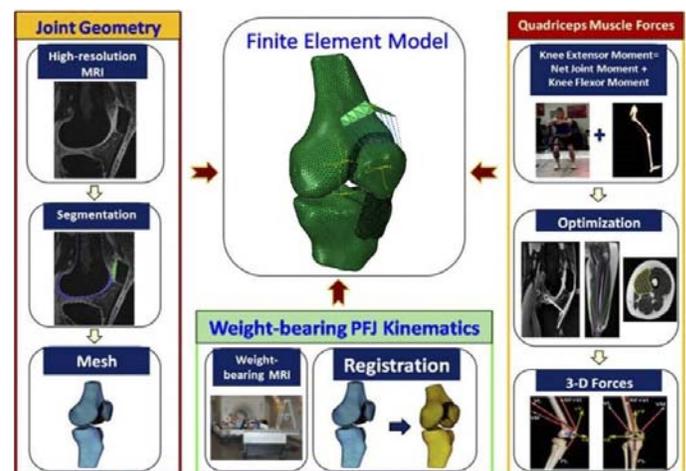

Excessive patellar tendon loading is considered to be the primary cause of patellar tendinopathy [2-3]. It has been proposed that abnormal lower extremity kinematics can contribute to increased patellar tendon loading. In particular, a previous study has reported greater knee internal rotation and hip abduction in persons with patellar tendon abnormality compared to controls [2]. Although altered lower extremity kinematics in the frontal and transverse planes may be a risk factor for patellar tendinopathy, a comprehensive analysis in the context of patellar tendon loading has not been performed.

The purpose of this study was to determine the influence of femur and tibia rotations in the frontal and transverse planes on peak patellar tendon stress and strain using three-dimensional (3D) subject-specific finite element (FE) modeling. We hypothesized that increased rotations of the femur and tibia in the frontal and transverse planes would result in increased peak patellar tendon stress and strain.

## METHODS

A 3D FE model of the knee joint was developed from a healthy female participant (28 years of age). Subject-specific input parameters included 1) patellofemoral joint (PFJ) geometry, 2) weight bearing PFJ kinematics, and 3) quadriceps muscle forces (Fig. 1). Subject-specific PFJ geometry and morphology, weight-bearing PFJ alignment, and

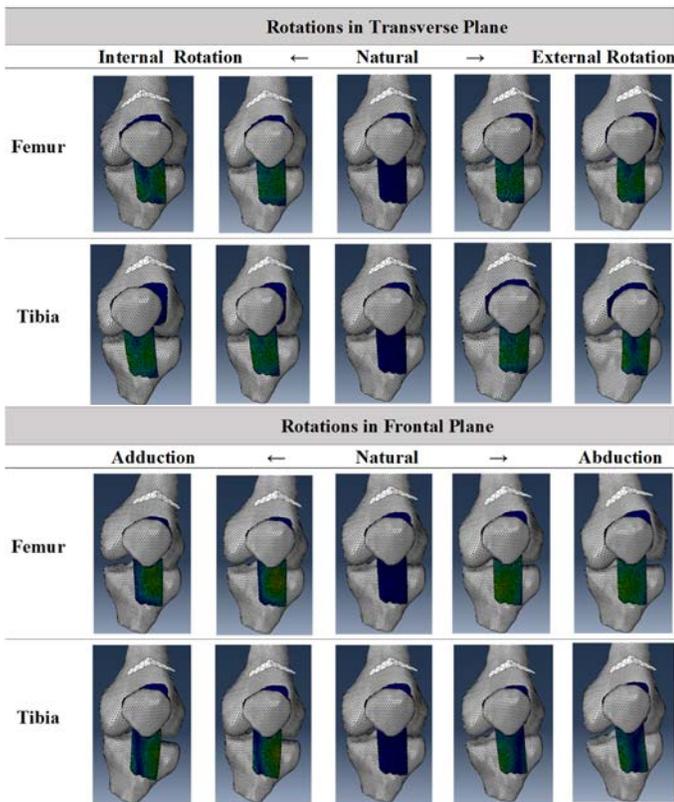

quadriceps muscle morphology were obtained from magnetic resonance (MR) imaging. Lower extremity biomechanics data (kinematics, kinetics, and EMG) were collected during a squatting task (45° of knee flexion).

**Figure 1:** 3D subject-specific finite element model framework.

Detailed descriptions of subject-specific inputs for the FE model have been described in previous publications [4-5]. The patellar tendon was modeled as homogeneous elastic and transversely isotropic using tetrahedral continuum elements. Elastic constants for patellar tendon were determined based on the data obtained by Rawson et al [6].

To examine the influence of femur and tibia orientation on patellar tendon stress and strain, the femur and tibia were rotated about their respective axes from the natural weight-bearing position to 10° (2° increments). The process was repeated for the transverse plane (internal and external rotation) and frontal plane (abduction and adduction) (Fig. 2). Quasi-static loading simulations were performed using a nonlinear FE solver in ABAQUS.

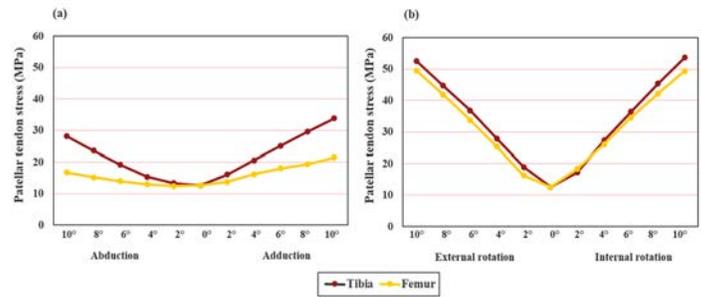

**Figure 2:** Finite element model simulation for femur and tibia rotations in transverse and frontal

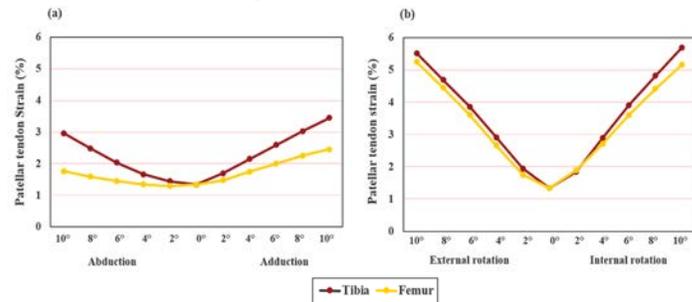

Patellar tendon stress and strain were quantified in terms of maximum principal stress and strain, respectively. The peak values of patellar tendon stress and strain were calculated as the mean of the top 5% of elemental stress and strain values, and was used for statistical analysis.

## RESULTS AND DISCUSSION

Both femur and tibia motions demonstrated a linear increase in patellar tendon stress and strain values during both frontal and transverse rotations in either direction (Fig. 3 & 4). In general, transverse plane motions had a greater influence on patellar tendon stress and strain than frontal plane motions. In the frontal plane, tibia rotations had a greater influence on peak patellar tendon stress (Fig. 3a) and strain (Fig. 4a) compared to femur rotations. In the transverse plane, femur and tibia rotations influenced patellar tendon stress (Fig. 3b) and strain similarly (Fig. 4b).

**Figure 3:** Peak patellar tendon principal stress resulting from femur and tibia rotations in frontal (a) and transverse (b) planes.

**Figure 4:** Peak patellar tendon principal strain resulting from femur and tibia rotations in frontal (a) and transverse (b) planes.

## CONCLUSIONS

Femur and tibia rotations in frontal and transverse planes result in increased peak patellar tendon stress and strain. In particular, patellar tendon stress and strain appear to be more sensitive to transverse plane motions as opposed to frontal plane motions. The findings of this study suggest that altered lower extremity kinematics in the frontal and transverse planes may contribute to patellar tendinopathy.

# ANTHROPOMETRIC SCALING OF MUSCULOSKELETAL MODELS

<sup>1</sup> Paulien E. Roos, and <sup>1</sup> Xianlian Zhou\*

<sup>1</sup> CFD Research Corporation, Huntsville, AL, USA

\*email: alex.zhou@cfdr.com, web: <http://www.cfdr.com/>

## INTRODUCTION

There is a need for anthropometrically scaled musculoskeletal (MSK) models in research areas such as ergonomics, medical and military applications. Such scaled models should take into account gender and the shape of the human body and adjust muscle strength accordingly. Here we introduce a method that takes body measurements as input to estimate anthropometry and scale MSK models.

## METHODS

For the development of our scaling method we have gained access to 3D body models of the ANSUR II database [1]. Among a larger survey of military personnel, 4,802 male and 1,986 female were selected and their 3D whole body scans were used to generate digital 3D body shapes. Two sets of data were provided to us (one male and one female), including a mean surface model,  $\pm 3SD$  (standard deviation from the mean surface) principal shapes for selected principal component or Eigen vectors, and variances for each vector, all derived from principal component analysis (PCA) of the 3D body scans. The male dataset includes 34 principal component (PC) vectors, covering about 98% of total variance, and the female dataset 40 PCs covering about 98% of the total variance.

We developed an Anthropometry Model Generating (AMG) GUI software that reads in a mean surface model, PCA variances, and PCs and link them to anthropometry features (or virtual measurements) derived from 3D body shapes [2]. These features include, but are not limited to, height, weight, torso, neck and head width, depth, length and circumference. They are mostly calculated with assistance from body landmarks identified on the 3D body shape. Within the software, the values of

these features can be adjusted and the corresponding body shape will be generated accordingly. Body weight is a special feature calculated as the multiplication of body volume and density, and we chose densities for the male and female ( $1014\text{kg/m}^3$ ;  $973\text{kg/m}^3$ ) such that the mean male and female calculated weights are equal to the measured mean weights exactly. The 3D body model was voxelized and segmented into different body parts, mass and inertia properties of each segment are calculated [2]. In general, voxelized geometry will slightly overestimate the volume. We compensate for this by scaling mass and inertia with a volume ratio between the real volume (calculated based on closed triangular surface) and the voxelized volume.

Joint center locations and axes were calculated using the body (skin) landmarks and the plug-in-gait method with some adjustments. Given an MSK model fitted within skin, its joints and body segments were linked to these calculated locations and axes. Its segment inertia properties were linked to voxelized body segmentations and muscle path is scaled according to segment scaling factors.

To obtain an MSK model with appropriate muscle strength, we first scaled an MSK model to 50<sup>th</sup> percentile male dimensions and tuned muscle maximum isometric force (via optimization) such that the model's moment generating capacity agrees with that reported for 50<sup>th</sup> percentile males in literature. This model is used as a template in the AMG software for scaling with 3D body shape. A template 50<sup>th</sup> percentile female model is created similarly using literature available.

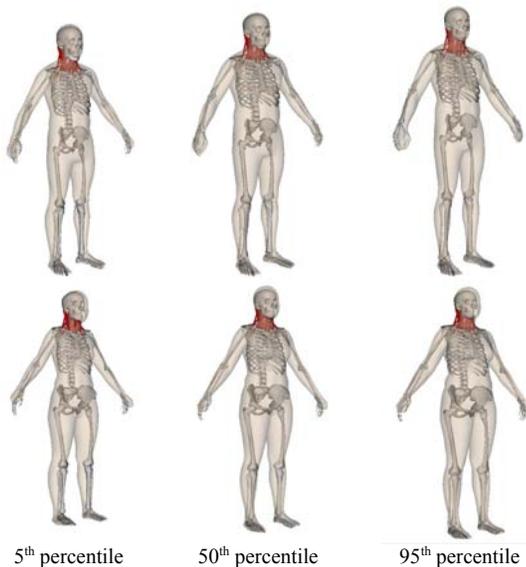

## RESULTS AND DISCUSSION

To demonstrate capabilities of our software, we present the results of male and female neck models derived from the neck model by Vasavada et al. [3].

Four anthropometric models were created based on body height, mass, and neck circumference specifications corresponding to a 5<sup>th</sup> and 95<sup>th</sup> percentile male and female from the ANSUR II database (Table 1; Fig. 1).

**Table 1:** Parameters used for anthropometric models.

	Height (m)	Mass (kg)	Neck circum. (m)
5 <sup>th</sup> M	1.65	64.4	0.40
5 <sup>th</sup> F	1.53	51.3	0.34
50 <sup>th</sup> M	1.76	84.6	0.43
50 <sup>th</sup> F	1.63	66.8	0.37
95 <sup>th</sup> M	1.97	110.7	0.48
95 <sup>th</sup> F	1.74	97.1	0.41

**Figure 1:** Scaled male and female models.

During scaling, muscle maximum isometric force is scaled with mass. Fig. 2 presents moment generating capacity of the scaled male and female models. As expected, the 95<sup>th</sup> percentile model is strongest in all directions and the 5<sup>th</sup> percentile model the weakest. It can be seen that male and female strength has been scaled differently; the 5<sup>th</sup> percentile male has similar extensor strength as the 50<sup>th</sup> percentile female, but is stronger in flexion, lateral bending and axial rotation, for which it is more similar to the 95<sup>th</sup> percentile female. This is because the 50<sup>th</sup> percentile male model was tuned to male strength data and the female model to female strength data.

In conclusion, we successfully created a GUI based software to scale MSK models based on anthropometry and gender that only requires simple body measurements as input. The software also provides tools to further optimize the strength of generated anthropometric MSK models. Similar approach was also utilized to generate lumbar and shoulder MSK anthropometric models.

# AUTOMATION OF VOLUMETRIC MESH GENERATION, MESH ASSEMBLY AND MODEL INPUT FROM SURFACE REPRESENTATIONS OF TISSUE STRUCTURES

Ben Landis, Ahmet Erdemir, PhD

Computational Biomodeling (CoBi) Core and Department of Biomedical Engineering, Lerner Research Institute, Cleveland Clinic, Cleveland, OH, USA

email: [landisb@ccf.org](mailto:landisb@ccf.org) website: <https://simtk.org/projects/openknee>

## INTRODUCTION

Finite element analysis has become an increasingly routine and essential component of biomechanics research [1]. However the development of quality virtual representations for finite element analysis is a laborious task, even after image segmentation is completed and surface representations of tissue structures are available. The volumes of geometries need be individually meshed. Then the user interactively selects mesh regions, specifically node, element and surface sets, to facilitate defining the model. Finally meshes of different tissues are combined and the mesh sets are utilized to define constraints and interactions between tissue components and to apply the appropriate boundary conditions. The resultant model then needs to be stored in a markup compatible with the simulation software of preference, e.g. Abaqus (Simulia, Johnston, RI) and FEBio [2], common solvers in biomechanics [3]. The goal of this study is automate all these processes in order to provide an unsupervised workflow for volumetric mesh generation, mesh assembly and model input file generation starting with surface representations of tissue structures.

## METHODS

A Python script was designed, using free and open source Salome [4], to streamline the process of meshing and model assembly through automation. An input XML document contains the hierarchy of the anatomy of interest, that is the tissue components, pointer to tissue surface geometry, and connectivity and interactions, e.g., ties and contacts (Figure 1). The hierarchical structure of this format is general and flexible enough to be applicable to a wide variety of biomedical areas. Upon execution of

the script, the surfaces are loaded and Salome generates volumetric finite element meshes. In following, groups of nodes, faces and elements are automatically defined based on connectivity description provided in the XML document, the characteristic length of the input geometry segments, and the inter-part proximity, e.g. euclidean norm between nodal positions of different tissues. Thresholds for proximity can be adjusted by the user by setting a multiplier. The script provides a warning to the user should they introduce non-reciprocated conditions for contact and ties.

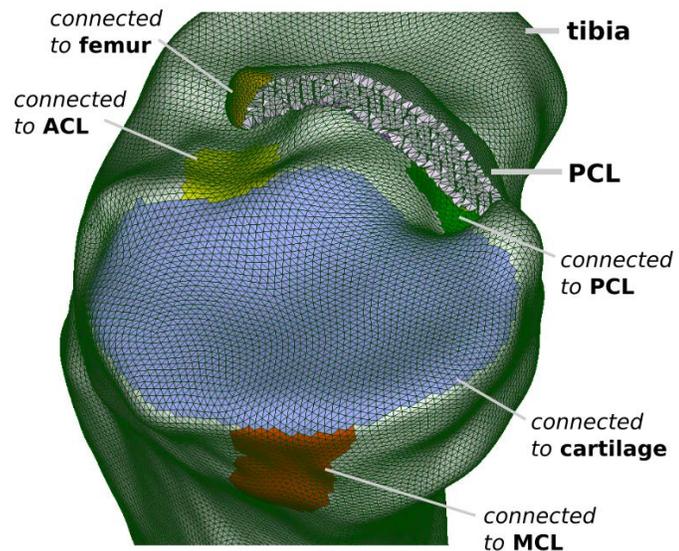

```
<Tibia multiplier = "0.9">
  <file> oks001_MRC_TBB_LVTIT_10.stl</file>
  <material> rigid </material>
  <Contact>
    <MCL multiplier = "0.7"/>
    <PatellarLigament/>
  </Contact>
  <Tie>
    <MCL multiplier = "0.5"/>
    <ACL/>
    <PCL/>
    <PatellarLigament/>
    <MedialMeniscus/>
    <LateralMeniscus/>
    <TibialMedialCartilage/>
    <TibialLateralCartilage/>
    <Fibula multiplier = "1.5"/>
  </Tie>
</Tibia>
```

**Figure 1:** An sample connectivity file for the tibia. The proximity calculation can be adjusted by the multiplier parameter.

The script then creates assemblies of the these parts, specifying ties and contacts in the specific language of the simulation software packages. The currently available options these include specific formatting for Abaqus (Simulia, Johnston, RI),

Febio[2], and the SOFA Framework [5], and could be extended to other formats with only moderate effort.

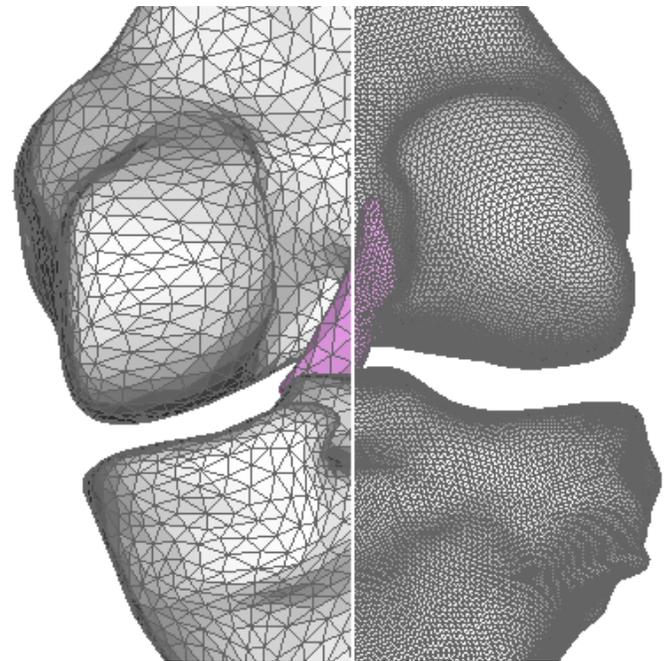

The script was tested on a set of geometries from the Open Knee(s) [6]. Various models were assembled for the knee, incrementally increasing the fidelity of the simulation by adding/removing parts to the assembly such as the menisci. To test of changing the geometric parts of the assembly, simplified models of the knee (femur-anterior cruciate ligament-tibia) were generated with coarse and fine meshes.

**Figure 2:** A completed mesh of the tibia, showing the color identified locations of the ligaments and cartilage groups that were automatically created to utilize for connectivity constraints.

## RESULTS AND DISCUSSION

Figure 2 shows the sets created on the tibia when using the ligaments, cartilage and bones as input to connectivity file. The automated assembly makes studies of mesh refinement easily accomplished by replacing the pointers to the files associated with each part and re-running the script (Figure 3). This same feature can also be used for swapping healthy tissue representation with a diseased or artificial part, with the limitation that both parts geometries need to have been defined in the same coordinate system. Additionally the generation of model input for different solvers can facilitate simulations in a alternative software packages to compare or confirm results.

**Figure 3:** The automated model assembly allows for rapid mesh refinement studies by providing the means to quickly replace geometry. Healthy representations of the tissue can be interchanged easily with diseased or artificial parts.

## CONCLUSIONS

This paper presented an automated workflow for combining tissue parts for finite element analysis and feeding the outcome to model input formats of simulation software packages. This high throughput approach removes the model assembly bottleneck of finite element analysis.

## INTRODUCTION

The use of commercial and open-source interactive musculoskeletal modeling software has allowed for greater understanding into the function muscles play in locomotion; for example, the role of the gluteus maximus. Early and current models make simplified assumptions, such as utilizing single line segments from origin to insertion or line-independent wrapping techniques. In 2005, Blemker, et al. [1] developed a highly sophisticated finite-element model of the gluteus maximus [2, 3]. It is considered a gold-standard by the authors.

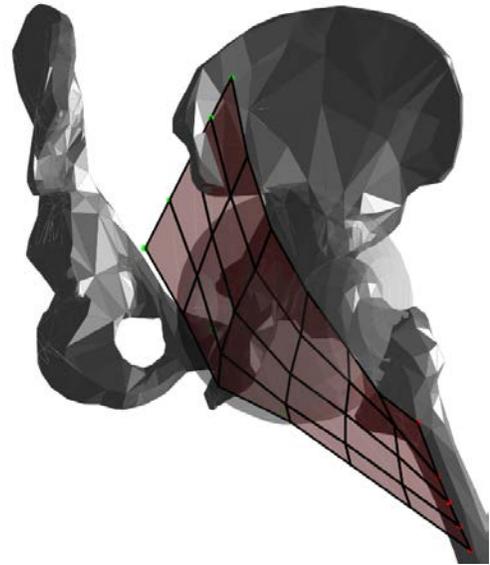

Although Blemker & Delp's model has demonstrated accuracy, it requires substantial resources and computational energy to create. In addition, it is not compatible with any musculoskeletal modeling programs, such as OpenSim. Therefore, there is a need for an intermediate model, wherein not only are its moment arm (MA) estimates accurate, but it can also be used clinically, in programs like OpenSim.

The objectives of this work were to: 1) describe our mesh wrapping approach to modeling the gluteus maximus muscle and 2) compare hip extension MA to the wrapping model in OpenSim [2], and a reference model [1] over a 90° range of hip flexion.

## METHODS

Our approach introduces muscle fiber lines of action connected both longitudinally and transversely, effectively creating a 2D rectangular grid or mesh of 1D line elements (Figure 1). The origin and insertion points of the gluteus maximus were taken from Arnold, et al. [2] and were linearly interpolated to five longitudinal lines of action rather than three. Five transverse lines were used between origin and insertion. Also, a wrapping sphere, unlike an ellipsoid in Arnold's model, was used. In addition, a

sacrospinous ligament was modeled to help anchor the gluteus maximus.

**Figure 1.** 3D surface plot of the gluteus maximus mesh model (red). Black lines are longitudinal and transverse elements. Wrapping object is the semi-transparent sphere.

Each element was modeled as a linear elastic spring with a stiffness and slack length. Two stiffness values were used:  $k_{\text{long}} = 3 \times 10^6 \text{ N} \cdot \text{m}^{-1}$  and  $k_{\text{trans}} = k_{\text{lig}} = 4 \times 10^6 \text{ N} \cdot \text{m}^{-1}$ . Slack lengths were calculated as 75% of the average muscle length over a 0° to 30° flexion range, using the stiffness parameters only. The mesh node coordinates were calculated by minimizing mesh elastic energy and constrained so as not to penetrate the sphere. The mesh was solved from 0° to 90° hip flexion in 2° increments. All calculations were performed in MATLAB.

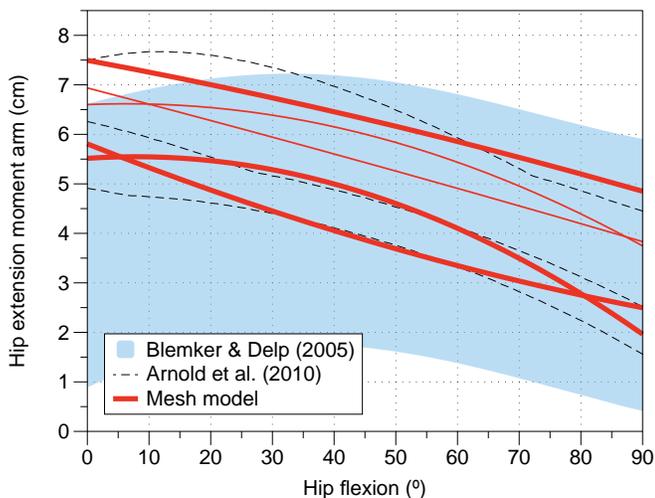

Muscle length versus flexion angle were extracted and a cubic regression was fit to each line,  $\ell_i(\theta)$ . Instantaneous MA lengths were calculated analytically [5]:

$$MA_i(\theta) = \frac{d\ell_i}{d\theta}$$

MAs from Arnold, et al. [2] were exported from OpenSim. In addition, MA ranges reported by Blemker, et al. [1] were obtained using cubic regressions of the reported values. The MA results of Blemker & Delp's finite-element model were presumed to be the most accurate and used as reference [1]. Average root mean square errors (RMSE) were calculated for Arnold's model and our mesh model against Blemker's data for the entire hip flexion range.

## RESULTS AND DISCUSSION

The mesh muscle length cubic regression fits were excellent, where for any line,  $R_i^2 > 0.999$ . The MA results of our model, compared with those of Blemker, et al. [1] and Arnold, et al. [2], can be seen in Figure 2. The total RMSE for our model and Arnold's model relative to Blemker's model can be found in Table 1.

**Figure 2.** Hip extension moment arms of the gluteus maximus of the mesh model compared to the current OpenSim model [2] and Blemker, et al. [1]'s finite-element model. Bold red lines correspond to Arnold's original three lines of actions.

Based on RMSE values, the interdependent line wrapping model is superior to the independent line wrapping algorithms currently utilized by a standard OpenSim model. As computational power of standard workstations increases, so does the ability to utilize more accurate, higher resolution models. Although finite-element models are still out of reach for routine subject-specific and dynamic modeling,

the mesh wrapping approach may be an appropriate stepping-stone for muscles with complex geometries, such as the gluteus maximus.

	RMSE (cm)	$\Delta$
<b>Arnold et al. (2010)</b>	0.211	
<b>Mesh model (3 lines)</b>	0.129	-38.83%
<b>Mesh model (5 lines)</b>	0.103	-51.47%

**Table 1.** RMSE relative to Blemker's model. Mesh model (3 lines) refers to the original three lines utilized by Arnold's model.  $\Delta$  represents change relative to Arnold's RMSE.

## CONCLUSIONS

We have presented a new mesh model for use in musculoskeletal modeling. This gluteus maximus model has decreased the MA error found in a standard OpenSim model by ~40–50% throughout hip flexion. There remains room for improvement and further verification and validation in other planes of motion. The mesh model requires less computational power and resources than finite-element models. By further parameterizing and optimizing our model, it may prove to be an accurate alternative to standard independent line-wrapping models. Future work will explore their utility in dynamic simulations.

## INTRODUCTION

Musculoskeletal models and simulations have become a valuable platform on which it is possible to investigate the intricacies of human movement in great detail. Recent studies have shown that incorporating subject specific data into these models, rather than the traditional method of scaling a generic model [1], may greatly affect their output [2]. This level of specificity in musculoskeletal models potentially increases their utility for various research or clinical tasks, such as tailoring rehabilitation from musculoskeletal injuries or simulating orthopaedic surgical procedures. However, for a model to be considered truly subject specific, it should include the muscle architecture (muscle force generating properties) data of the subject upon which the model is based. Recent studies have shown that diffusion tensor magnetic resonance imaging (DTI) can be used to reconstruct muscle fiber trajectories in skeletal muscle [3], which, when combined with other anatomical MRI sequences (i.e. T1), allows muscle architectural characteristics such as mass, fiber lengths and pennation angles to be gathered from live subjects non-destructively. As yet there is no standardized method of tracking muscle fibers, and furthermore there has been no comprehensive validation of the precision with which this method can reconstruct muscle fibers and estimate muscle force generating properties for use in musculoskeletal models.

Here we aim to perform a novel validation of the DTI technique to measure muscle architecture data, by directly comparing MRI-based data to those gathered from dissections of human cadaveric lower limbs. Once rigorously validated, the ability to gather muscle architecture data from live human subjects has the potential to greatly improve the accuracy of

musculoskeletal models by making them truly subject-specific.

## METHODS

MR images of one cadaveric right lower limb (hemipelvectomy, Female, 22 y/o) were acquired (3T Siemens Biograph mMR) using T1 turbo spin echo (TSE; voxel size  $0.47 \times 0.47 \times 6.5 \text{mm}^3$ , repetition time [TR] 650ms, echo time [TE] 23ms) and diffusion weighted echo planar sequences (voxel size  $2.96 \times 2.96 \times 6.5 \text{mm}^3$ , TR/TE 7900/65ms, 12 direction diffusion gradients, b value- 0 &  $400 \text{s/mm}^2$ , spectral attenuated inversion recovery). The images were acquired in axial slice orientation and repeated for a total five beds, in order to image from the iliac crest to the ankle joint. The fibers of 21 muscles of the lower limb were tracked with the DTI images using Camino software (Fig. 1) [4]. A custom Matlab script was used to estimate the length of each fiber, and pennation angle was measured using ImageJ (U.S. National Institutes of Health, Bethesda, MD, USA). Muscle masses were calculated from the volume of 3D muscle meshes created through digital segmentation of T1 anatomical images. All these architecture data were used to calculate physiological cross sectional area (PCSA,  $\text{mm}^2$ ), a major determinant of muscle force generation, using the equation:

$$\text{PCSA} = (M_m * \cos\theta) / (L_f * \rho),$$

where  $M_m$  is muscle (belly) mass (g),  $L_f$  is muscle fiber length (mm),  $\theta$  is muscle fiber pennation angle and  $\rho$  is the density of mammalian skeletal muscle ( $0.001056 \text{gmm}^{-3}$ ).

These data were then manually measured from the same 21 muscles from the same cadaver through dissections. Here, each muscle was dissected out and cleaned of fat and fascia before measurement.

**Figure 1.** The fibers of the Vastus medialis (A) and Tibialis anterior (B) muscles, tracked from diffusion tensor magnetic resonance images (DTI) and Camino software.

Muscle mass was measured using a digital scale (accurate to 1g), and fiber lengths were measured using 12" precision dial calipers (accurate to 1mm). Photographs were taken of each muscle, and fiber pennation angle was measured from these using ImageJ. For fiber length and pennation angles, five measurements were taken at different areas of each muscle, and the mean value calculated.

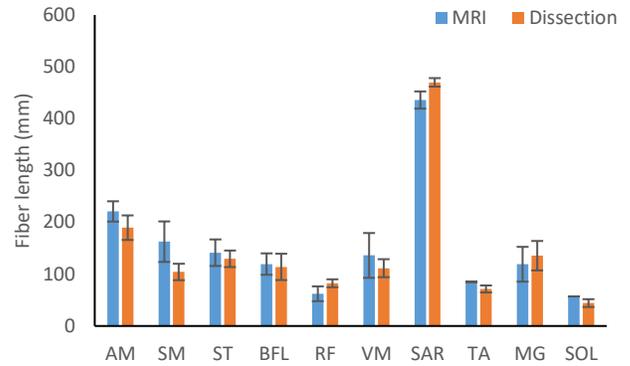

## RESULTS

Across the 21 muscles analyzed, mean fiber lengths measured using DTI were on average 7.96mm longer than those measured using dissections (5.8% of mean fiber length from dissections; Fig. 2). However, both mass and PCSA were estimated by MRI to be lower than when measured through dissections, with differences of 15g (7.9% of mean mass) and 225mm<sup>2</sup> (14.86% of mean PCSA) respectively. Measured pennation angles were more variable, with a mean difference of 3.78° (28.4% of mean value) found.

## DISCUSSION

The muscle architecture data measured from both MR images and manual dissections match well in terms of muscle mass, fiber lengths and PCSA across most of the muscles analyzed here. The tendency for the DTI fiber tracking to slightly over-estimate fiber lengths, and for the T1 anatomical segmentation to slightly underestimate muscle mass, compound to underestimate PCSA, and by extension muscle force output.

Fiber pennation angle was the most variable measurement between the MRI and dissection

**Figure 2.** Select mean muscle fiber lengths, as estimated from diffusion tensor magnetic resonance images (DTI) and measured from dissections. Error bars= ±1S.D.

measurements. However, this factor is heavily influenced by the level of stretch in the muscle, although fortunately musculoskeletal model sensitivity analyses have shown that pennation angle has little effect on muscle output [5].

## CONCLUSIONS

Overall, based on novel validation from one cadaveric limb, we can be tentatively confident that the method of using diffusion tensor and T1 anatomical MRI to gather muscle architecture data from live subjects is a promising technique to improve the accuracy of subject specific musculoskeletal models and simulations of human movement. To bolster this confidence, we plan to use these methods to gather these same data from additional cadaver specimens, to further investigate the accuracy of this technique in representing muscle architecture.

email: pariserk1@udayton.edu

## INTRODUCTION

A reverse total shoulder arthroplasty (RTSA) is a common treatment used to stabilize the shoulder and improve range of motion in patients with rotator cuff muscle tears or severe arthritis. The RTSA implant is designed to enable the deltoid muscle to become the primary stabilizer thereby increasing the stability of the joint [1]. To improve stability, RTSAs increase the deltoid muscle moment arm and decrease the required deltoid force to achieve the required torque about the glenohumeral joint for shoulder movement. Previous research suggests that a more medial and inferior placement of the center of rotation for the RTSA implant is ideal, however, implant placement is complex given the multiple degrees of freedom of the shoulder joint [2]. In addition, there is no standardized, objective way for a surgeon to position an implant on a specific patient.

Simulation and optimization methods have been used to understand moment arms and their effect on muscle function, to predict muscle forces, and to analyze how surgeries affect the muscle moment arms with general models [3]. However, the effect of patient-specific muscle parameters on modeling realistic muscle function in this population is unknown. Calibration of patient-specific parameters via optimization is feasible, but can be time consuming. Due to the fast workplace environment, surgeons cannot afford to wait a long time for optimizations to converge. In order to decrease convergence time and apply these tools clinically, muscle parameter optimizations must be provided a realistic initial guess that is representative of the patient's muscle function. To our knowledge, previous studies have not established guidelines for adjusting muscle parameter values from literature, especially across a group of subjects. Reduction of

passive force produced by muscles may be a mechanism for adjusting parameters values. Therefore, the purpose of this study is to investigate how much deviation from the literature muscle parameter values is necessary in order to reduce passive force and produce more realistic muscle activations for patient-specific cases.

## METHODS

Eight subjects with two different RTSA implants participated in this study (age:  $73 \pm 6$  years, height:  $65.63 \pm 2.85$  in, mass:  $77.28 \pm 9.62$  kg). EMG, motion capture, and fluoroscopic data were collected previously [4-5]. Fluoroscopic and motion capture data defined the motion in patient-specific shoulder models scaled using the subjects' heights. Muscle moment arms, joint moments, and musculotendon lengths were calculated in OpenSim [6].

The optimal fiber length and tendon slack length values of the three deltoid muscles were modified from the literature values [7] using scaling factors. Scaling factors were chosen manually with the goal of determining common factors for each deltoid muscle across all of the subjects so that the muscle tendon length (IMtilda) values were within the active force range, 0.5-1.0, on the force length curve.

MATLAB was used to generate plots of the IMtilda values, predicted muscle activation as compared to the experimental EMG data, and force contribution from each of the three deltoid muscles before and after the literature parameter values were modified.

## RESULTS AND DISCUSSION

For all eight subjects, reduction of passive force produced more realistic muscle forces and

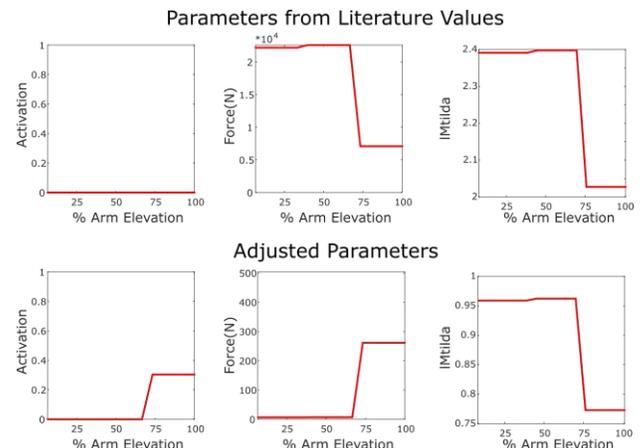

activations. Common scaling factors were found for the medial (DELTA2) and posterior (DELTA3) deltoids, but not for the anterior (DELTA1) deltoid. The DELTA1 scaling factor for six of the eight subjects was 1.5, but was 1.79 and 2.22 for the other two subjects. DELTA2 and DELTA3 had scaling factors of 1.13 and 1.25 respectively. The ranges for the average IMtilda values across all eight subjects for each of the deltoid muscles prior to adjusting the parameters were: DELTA1: 1.4-3.05, DELTA2: 0.85-1.05, and DELTA3: 0.84-1.08. After adjusting the parameters, the IMtilda ranges were: DELTA1: 0.7-0.91, DELTA2: 0.625-0.82, DELTA3 0.675-0.84. Some of the subjects had IMtilda values for one or more deltoids within the desired range prior to adjustment, but others, as depicted by the ranges, produced large passive forces. There was an inconsistency amongst the subjects as to which deltoid required the most parameter adjustment, thus emphasizing the importance of patient-specific muscle parameter adjustment.

Using the literature parameter values, many subjects displayed a trend in which the muscle activation was minimal, but the predicted muscle force was very high. Once the parameters were adjusted, however, the muscle activation and force contribution became more realistic for all three deltoid muscles for all eight subjects. For example, Figure 1 shows the influence of adjusted parameter values for a representative subject's DELTA1 muscle. With the literature values, DELTA1 produced purely passive force during the motion, requiring no activation from the muscle. By adjusting the parameters to reduce passive force production, the muscle activation and force are more realistic. In addition, the resulting muscle activation mimics the trend observed in the experimental EMG data.

## CONCLUSIONS

RTSA patients have varying height, weight, and muscle function. Therefore, it is important that RTSA implants be placed in patient-specific locations to have optimal deltoid muscle function after surgery. To determine patient-specific implant placement, patient-specific models are needed. It is not adequate to scale the models in terms of the subjects' heights only. This study illustrates the need

for adjustment to the commonly used literature muscle parameter values to generate patient-specific models that more accurately reflect a patient's muscle activation and muscle force contribution. Reduction of passive force appears to be a feasible process to adjust muscle model parameter values and improve patient-specific calibration of models. Future work should focus on automating the calibration process and continuing to test passive force reduction as mechanism for producing realistic results in a larger patient population.

# KNEE CONTACT FORCE PREDICTIONS ALTERED BY OBJECTIVE FUNCTIONS DURING OPTIMIZATION

<sup>1</sup> Elijah C. Kuska and <sup>1</sup> Allison L. Kinney

<sup>1</sup> University of Dayton, Dayton, OH, USA  
email: kuskae1@udayton.edu

## INTRODUCTION

Persons with musculoskeletal disorders may have mobility limitations. The level of impairment experienced is patient-specific. Because of this, the rehabilitation the individual needs should also be unique. However, current rehabilitation techniques are generalized for the many rather than the few. The knowledge of patient-specific muscle forces may help to create individual rehabilitation techniques.

Muscle forces must be computationally predicted because they are difficult to measure experimentally. In order to predict these forces, optimization is needed because the musculoskeletal system is under-constrained (# muscles >> # degrees of freedom). Optimizations are reliant on objective functions to converge to a unique solution. Previous studies have examined objective functions and their influence on muscle force predictions [1]. Validation of these predictions are limited because of the *in vivo* nature of muscle forces. Validation may be improved by the use of *in vivo* knee contact force data [2]. The purpose of this study was to investigate how knee contact force predictions are altered by objective function choice during optimizations of self-selected speed and modified walking gait.

## METHODS

Optimizations of 8 different complete walking gait cycles (5 self-selected speed, 3 modified) were generated using data from the 3<sup>rd</sup> Grand Challenge Competition to Predict In Vivo Knee Contact Loads. Data were collected from a single female subject with a force measuring knee implant (left knee, age 68 years, mass 79 kg, height 1.3 m) [2]. Data used in this study includes left leg CT images, motion capture data, ground reaction force data, and *in vivo* knee contact data (forces and torques along all three

axes). The knee contact data were gathered from the subject's force measuring knee implant.

A full leg model containing the patient's bones and implant components was created in OpenSim [3] from the CT images. Muscle geometry and parameters were obtained from a generic model for the 44 Hill-type muscles [4]. Joint kinematics and joint torques were calculated in OpenSim. All optimizations incorporated inverse skeletal dynamics and forward activation and contraction dynamics.

Optimizations were conducted in MATLAB using software designed for direct collocation optimal control: GPOPS-II [5] and ADiGator [6]. All optimizations were performed with constraints such that the sum of the muscle force contributions to the inverse dynamics torques matched the experimental inverse dynamics torques. Muscle forces were optimized while minimizing objective functions over the simulation time  $T$  with the generic form:

$$J = \int_0^T \sum_{i=1}^m u_i^p dt$$

where  $u$  represents the category of muscular effort (excitation, activation, force, or stress) for the number of muscles  $m$  and  $p$  represents the exponent (1, 2, 3, or 4). This resulted in a total of 16 objective functions to be run for each of the 8 gait cycles. Optimizations were performed on a 3.3 GHz Intel Xeon processor with 16 GB RAM. Convergence time and experimental data replication accuracy were analyzed across all optimizations for all gait cycles.

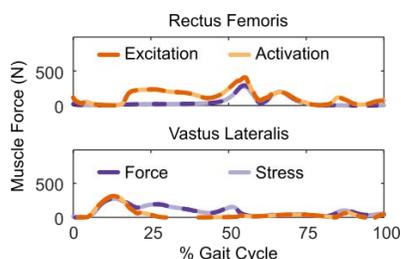

## RESULTS AND DISCUSSION

For all gait cycles, all 16 objective functions matched the inverse dynamic data and converged. Thus, they can be deemed valid and feasible. All of the objective functions averaged a convergence time of less than 8

minutes across all gait cycles. The fastest converging category of muscular effort was activation and the fastest converging power was the 2<sup>nd</sup>. Excitation to the second was the fastest converging objective function (1.49 minutes).

All 16 objective functions had relatively accurate total knee contact force replication. The best replicating category of muscular effort was activation and the best power was the 3<sup>rd</sup>. Stress to the third was the best replicating overall with an average (across all gait cycles) R<sup>2</sup> value of 0.860. This value surpasses previous studies that predicted knee contact forces [7].

Muscular force predictions across all objective functions per trial were similar and some trends were noticed. The first trend noticed was between categories of muscle effort during the self-selected walking trials. Non-force containing objective functions (excitation/activation) favored bi-articular muscles while force containing objective functions (force/stress) favored muscle with larger maximum isometric forces and cross-sectional areas (Figure 1). The trend was similar but not exact during the modified gait trials. During the modified gait trials the force and stress objective functions still favored the larger and more powerful muscles, but the excitation and activation objective functions did not favor the bi-articular muscles as much. This differences between the self-selected gait trials and the modified gait trials may reflect altered muscle control when performing a more demanding task.

**Figure 1.** Optimized muscle forces from objective functions across categories of muscular effort.

Another trend that occurred was based on the power the objective function was raised to: higher powers favored more shared muscular effort. This meant that as the exponents increased the predictions became more fatigue-like [1]. In addition, as the objective function's power increased, they better predicted the

*in vivo* knee contact data. This may indicate that as the objective functions became more fatigue-like they better represent muscle coordination strategies used by humans.

## CONCLUSIONS

Results of this study provide insight into the muscle coordination strategies used by humans during self-selected and modified walking gaits. Continuation of this study will need to look at other subjects and other non-walking motions. This would assist with determining if our methods are patient or walking-gait specific. If proven, this could create a quantitative tool to assess movement impairments in individuals and allow clinicians to design effective patient specific rehabilitation techniques.

For future use, a best objective function needs to be identified. Though time efficiency is important for clinicians, we believe that differences in time between functions is not considerable enough to justify using excitation squared. We believe the objective function that best replicates the data should be used: stress cubed. The stress cubed objective function should be used in clinical applications to create effective rehabilitation techniques.

email: sabickmb@slu.edu, web: <http://parks.slu.edu/departments/bme/>

## INTRODUCTION

Due to the complexity and lack of bony stability in the shoulder, 1.7% of the population will suffer from shoulder instability [1]. Multiple factors including the individual shoulder geometry, weakness in the rotator cuff muscles, subluxed glenohumeral ligaments, or a reduced intrarticular pressure can lead to instability. Upper extremity musculoskeletal models would provide an excellent tool for examining the individual contributions of these factors to instability, but most existing musculoskeletal models only allow three rotational degrees of freedom (DOF) of the glenohumeral joint [2]. Therefore, realistic six DOF glenohumeral kinematics cannot be studied.

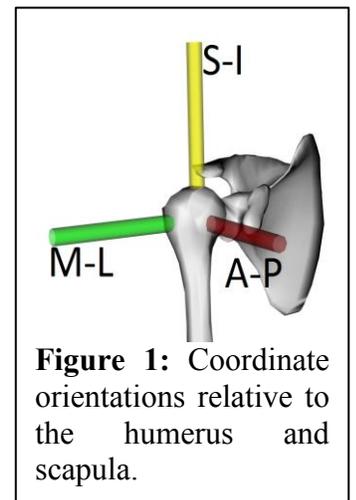

Updating computational shoulder models to include translational degrees of freedom requires including realistic ligament models to provide joint stability, especially in the extreme ranges of motion. However, modeling ligaments requires making informed decisions regarding appropriate material properties and attachment point locations that make sense anatomically and provide convergent solutions in simulations. Understanding how sensitive the model is to these parameters helps guide appropriate choices and assess the robustness of model predictions. The purpose of this study is to quantitatively analyze the sensitivity of an existing upper extremity model to changes in locations of the origin and insertion of two simulated ligaments.

## METHODS

The open-sourced Open-Sim (version 3.3, Stanford University, Stanford, CA USA) model, MoBL\_ARMS [2], was updated to include three translational DOF at the shoulder in addition to the rotational DOF. Ligament representations of the coracohumeral ligament (CHL), superior

glenohumeral ligament (SGHL), and the middle and inferior glenohumeral ligaments and the posterior capsule were modeled as nonlinear elastic bands with attachment points at their anatomical locations as described in Boulet et. al. [3]

The CHL and SGHL were then disabled one at a time while the other ligament attachment points were adjusted in 1 mm increments from 1-3 mm. On the scapula, adjustments were made in the anterior/posterior and superior/inferior directions, while adjustments on the humerus were made in the lateral/medial and superior/inferior directions (Fig. 1). All muscle elements were disabled, and only the translational degrees of freedom were allowed. Forward dynamics simulations were then completed under the influence of gravity, allowing the solution to stabilize over a simulation period of 6 seconds. Overall humeral displacement relative to the glenoid in each simulation was obtained and linear regression analysis was performed to quantify the sensitivity of displacement to ligament attachment location.

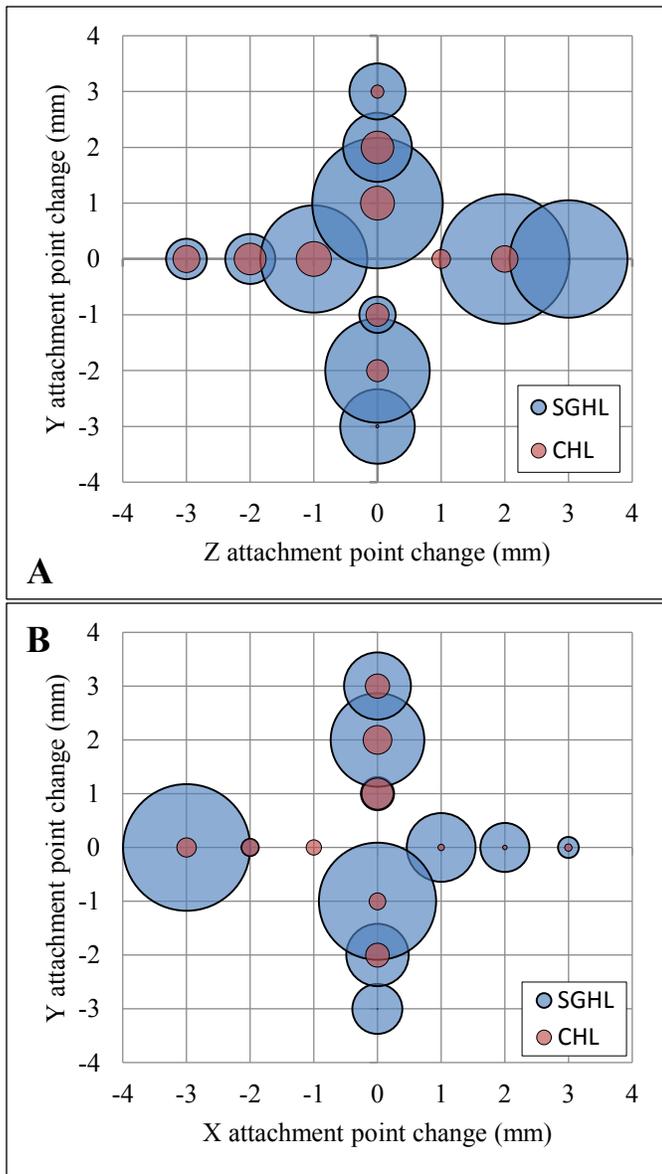

**Figure 1:** Coordinate orientations relative to the humerus and scapula.

## RESULTS AND DISCUSSION

A linear relationship exists between a change in attachment point location and the humeral displacement for each ligament and direction, though the magnitude of that change varies depending on the ligament. Additionally, an inferior attachment point change on the scapula provided the same results as superior change on the humerus for both ligaments (Table. 2). The linear relationship is

understandable as the ligaments are acting in the linear range of their force-length curves.

**Figure 2:** Change in displacement of the glenohumeral joint relative to attachment point change on the humerus (A) and on the scapula (B).

The differences in displacement are related to the shape of the wrapping surface of the ligaments on the humerus. These slight deviations can be seen with the SGHL A-P attachment point change on the scapula (Fig. 2B). The differences in magnitudes of the insertion/displacement relationship between the ligaments are due to the relative contribution of the CHL and the SGHL to stability. With a change in the SGHL attachment point, the model responded

with a greater change of glenohumeral displacement than when the CHL attachment point was implemented (Fig. 2). At its neutral attachment point, the CHL allows a displacement of 29.0 mm, whereas the SGHL will only allow the system to displace 22.3mm.

**Table 1:** Displacement of the glenohumeral joint at each attachment point location change (mm).

	CHL				SGHL

## CONCLUSIONS

Understanding the sensitivity of the model's outputs relative to the attachment point of the ligaments is an important step in beginning to accurately model ligaments in OpenSim, and eventually understanding the stability of the shoulder. The elasticity of the ligaments will have a large effect on the magnitude of the insertion/displacement relationship, but without the ligament's resting length properly modeled, the elastic properties will not accurately represent the ligament. Regardless, attachment point placement can alter a model output greatly: a few millimeters change on either bone can cause a large change to the overall force applied on the system. Great consideration must be taken when choosing where to place the ligaments on the model.

## INTRODUCTION

Upright birthing positions such as squatting are associated with clinical benefits, such as shorter labor and fewer assisted deliveries [1], and have demonstrated a widening of transverse pelvic dimensions [2]. The mechanics of various birthing positions are still poorly understood and most women still deliver lying on their backs (in the lithotomy position), which may be attributed to caregiver preference and constraints imposed by medical procedures, rather than comfort of the mother. Further insight into the mechanics of upright birthing positions may promote natural delivery under complicated circumstances for which medical interventions, such as forceps or Caesarean delivery, have traditionally been recommended. Our objective was to use a computational model to determine the effects of joint loading in the squat position on pelvic alignment.

## METHODS

Two female subjects, one 32-weeks pregnant (mass = 78.9 kg) and an age- and height-matched non-pregnant control subject (mass = 44.5 kg), were recruited for this study. The non-pregnant subject was positioned in supine in a 3.0-T magnetic resonance imaging (MRI) scanner (Magnetom TrioTim, Siemens, Erlangen, Germany) with legs raised to resemble the lithotomy position. A pelvic region coronal scan was acquired from which pelvic bones were segmented using Mimics™ segmentation software (Materialise, Belgium).

A three-dimensional model of the pelvic region, including bones and major ligaments as shown in Figure 1, was constructed and then imported into a multibody dynamic simulation package (RecurDyn™, FunctionBay Inc., Seoul, Korea).

**Figure 1:** Anterior (A) and Posterior (B) views of pelvic model (with orientation of coordinate system) generated from MRI. Bones include L5 vertebra, left and right innominate bones, sacrum, coccyx, and proximal segments of left and right femurs. Ligaments include sacroiliac ventral, short posterior, long posterior, and interosseous, sacrotuberous and sacrospinous ligaments, and superior, inferior, anterior, and posterior pubic ligaments.

The L5 vertebra was fixed, while the femurs were permitted linear translation along the global x-axis; this permitted the hip joints to diverge or converge as needed. Sacroiliac and pubic symphysis joints were left unconstrained.

Torques used to actuate the simulation at the lumbosacral and hip joints were determined using standard motion analysis techniques during five squatting trials for each subject. Two force platforms (Bertec, Columbus, OH) and 13 optical cameras (Oqus 300+, Qualisys, Gothenburg, Sweden) captured data at 120 Hz that were analyzed using an inverse dynamics approach in Visual3D (C-Motion Inc., Germantown, MD). Ligaments were modeled as springs with piecewise linear stiffness approximations; material properties were determined from the literature [3].

The simulation was validated by comparing model measurements against those calculated from a second MRI scan acquired with the non-pregnant subject in a kneeling-squat position (Figure 2) and values from the literature [2].

**Figure 2:** The KneelSquat posture adopted by the non-pregnant subject in the MRI scanner. This was also the position used by subjects in the study conducted by Reitter *et al.* and represented the most upright position possible within the confines of the bore.

## RESULTS AND DISCUSSION

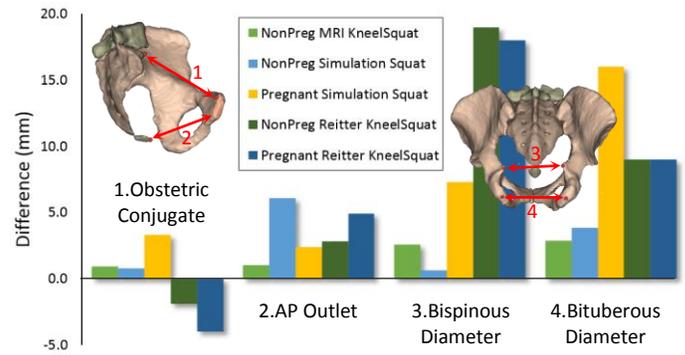

Mean joint reaction moments calculated for the pregnant and non-pregnant subjects in the squat position are listed in Table 1. Moments were determined about the pelvic axes shown in Figure 1. Though most of the difference between pregnant and non-pregnant joint moments may be attributed to subject mass, posture may also be a factor since the pregnant subject adopted a wider squatting stance.

When applied to the computational model, these joint moments increased all pelvic measurements and primarily opened the pelvic outlet in the anterior-posterior (AP) and transverse directions (Figure 3). This trend matched the measurements in the KneelSquat MRI posture; however, the increase in AP Outlet diameter determined from the non-pregnant simulation squat was substantially larger than the KneelSquat MRI measurement.

The differences in measurements between both pregnant and non-pregnant simulation squats and non-pregnant MRI results were within the range of difference between our non-pregnant subject's measurements and the mean values from the non-pregnant subject group in the study by Reitter *et al.* [2]. Results should be interpreted with caution due to model simplifications.

**Table 1:** Moments [Nm] calculated at hip and lumbosacral joints in the resting squat position. Hip moment magnitudes were averaged between left and right sides and are reported using the sign for the right hip.

	Hip			L5-S1
	X	Y	Z	X
Non-Pregnant	-20.5	14.1	-0.6	-53.7
Pregnant	-35.1	43.9	2.9	-77.7

**Figure 3:** The difference in pelvimetry measurements as compared to the supine MRI position. Mean group differences from Reitter *et al.* [2] are also included.

## CONCLUSIONS

In this study, a computational model was developed to simulate the effects of hip and lumbosacral joint moments during squatting on pelvic kinematics and was validated against MRI measurements in a single subject. Joint moments estimated in both pregnant and non-pregnant subjects during squatting produced an increase in anterior-posterior and transverse pelvic outlet measurements comparable to results in the literature.

Results suggest that benefits of squatting likely extend beyond gravity acting on the fetus to advantageous maternal joint loading that could open the outlet of the birth canal and potentially facilitate delivery. The substantial increase in ligament laxity experienced during pregnancy would furthermore enhance this effect. Such evidence may improve medical intervention during childbirth; for example, maneuvers used to assist delivery may be performed more effectively or eliminated altogether by having the mother adopt an upright position and making the most of these biomechanical advantages.

## INTRODUCTION

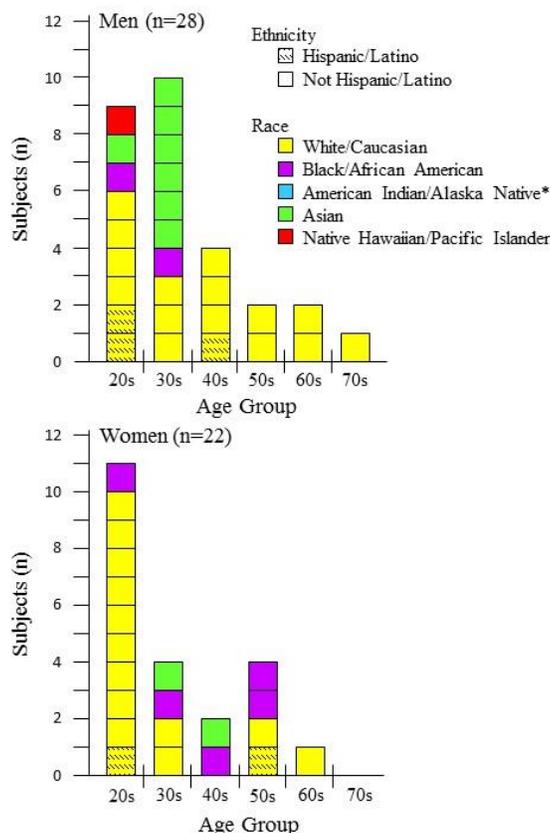

Anthropometry data provides useful information regarding health status, disease risk, and body composition [1], but is also used to develop or refine anatomical representation in computer models for biomechanics. Most studies collecting anthropometric data of the arms and legs record only one circumference location along each segment, generally at the midpoint or at the maximal girth of the segment [1].

The data reported for this study is part of a larger study to acquire anatomical and mechanical data for creating computer models of multi-layer tissue architecture of the musculoskeletal extremities. The purpose of this portion of the study was to acquire anthropometric measurements (length and circumference) of the arms and legs. While other studies have collected similar anthropometric data, albeit in a restricted number of locations on the segment, our data, in combination with the acquisition of tissue thickness data [2], will allow for the development of multi-layer tissue models based on data from the same subject.

## METHODS

Fifty adult subjects were recruited to participate in this study, which was approved by the Cleveland Clinic Institutional Review Board and the Human Research Protection Office of the U.S. Army (USAMRMC ORP HRPO). Subject specific information including age, mass, height, gender, race, ethnicity, and activity level were obtained. Specific regions for anthropometric data collection included right upper and lower arms and legs. With subjects lying supine, reference marks were made on

landmarks of the extremities using a washable marker. The length of each segment was measured between the following landmarks: the lateral acromion and the humeral lateral epicondyle (upper arm), the humeral lateral epicondyle and the ulnar styloid process (lower arm), the greater trochanter and the lateral tibial plateau (upper leg), and the lateral tibial plateau and the lateral malleolus (lower leg). Three circumference measurements at the distal, central, and proximal sections were recorded. For the arm, circumferences were drawn at the distal

**Figure 1:** Age, gender, ethnic, and racial distribution of participants. \*None of the participants were part of the American Indian/Alaska Native racial group.

axillary, the distal shaft of the humerus, and the midpoint between these locations, as well as at the level of the proximal shaft, the distal shaft of the ulna-radius, and the midpoint between these locations. For the leg, circumferences were drawn at the top of the inner thigh, the distal shaft of the femur and the midpoint between these locations, as well as at the distal tibial tuberosity, the distal shaft of the tibia, and the midpoint between these locations. Circumference measurements were taken along with the distance of the measurement location from the nearest superior landmark. All measurements were recorded to the nearest millimeter by the same investigator, using a cloth tape measure.

## RESULTS AND DISCUSSION

The demographics of current subject sample population are reported in Figure 1. The mean ( $\pm$ SD) age, height, mass, and body mass index were  $26.8 \pm 13.6$  years,  $170 \pm 8.7$  cm,  $78 \pm 17.6$  kg, and  $26.8 \pm 5.6$  kg/m<sup>2</sup>, respectively. Mean ( $\pm$ SD) and range of segment length and circumferences were grouped according to gender (Table 1). Following data dissemination of the database, individualized data can be extracted for further analysis.

As can be seen from the results (Table 1), circumference values change throughout the length of the extremity. In contrast to having a single circumference measurement, having circumferences from multiple locations with a segment increases the

detail in shape descriptors and therefore will improve the fidelity of anatomical and inertial representation, e.g., in musculoskeletal models [3]. The geometry of external volume of segments, when supported by individual tissue thicknesses [2], will allow for detailed volumetric representation of tissue composition, i.e., that of skin, fat, and muscle.

## CONCLUSIONS

This database, which will be publicly accessible, provides anthropometric data from a group of subjects with a variety of demographic parameters. Variations in the circumference measurements within an individual segment indicate the need for data to elaborate on gross shape descriptors of the segment and enhance individualized models of anthropometry.

## INTRODUCTION

The wealth of research into the human musculoskeletal system using biomechanical modeling has mainly relied upon generic models, built upon the muscle architecture (which determine muscle force generating properties) and musculoskeletal geometry (bone morphology and muscle attachment points) of cadaveric specimens. These parameters are then often scaled by various anthropometric measures to match individual subjects [1]. However, the accuracy of these scaled generic models in various functional analyses has been questioned, with several studies showing that incorporating subject specific musculoskeletal geometry into these models has a potentially large impact on their output [2]. The effects of adding subject specific muscle architecture to musculoskeletal models have yet to be investigated in detail.

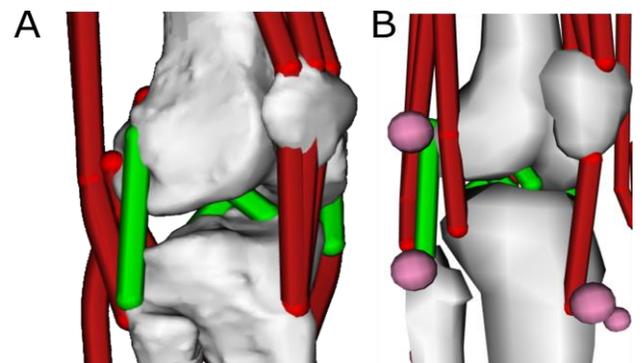

One possible use for musculoskeletal models, and particularly models incorporating subject specific musculoskeletal properties, is predicting the functional outcomes from surgical procedures, which could potentially allow clinicians to tailor rehabilitation programs to individual patients. Knee ligament reconstructions, for example, are commonly performed on athletes, and require lengthy periods of rehabilitation before normal sporting activity can resume. Using subject specific musculoskeletal models, which include detailed knee joint bone geometries, muscle force generating properties, as well as muscle and ligament attachment points, to predict how individuals might respond to these surgeries has the potential to speed up the rehabilitation process or even improve functional outcome, particularly by reducing the risk of secondary injuries or osteoarthritis [3].

Here we propose to create subject specific musculoskeletal models and simulations of the lower limb (with a specific focus on the knee joint), and

compare the functional outputs to those from scaled generic musculoskeletal models, during both walking and running. This analysis will give valuable insight into the necessity of incorporating such detailed subject specific muscle properties and bone geometry into musculoskeletal models, and potentially increase the utility of biomechanical models to both researchers and clinicians.

## METHODS

One 13 musculotendon unit actuated right lower limb musculoskeletal model was created in OpenSim software [1], based on the musculoskeletal geometry and muscle architecture of a healthy subject (Male, 24y/o. Fig. 1). These data were gathered from three magnetic resonance imaging (MRI) sequences. A T1 turbo spin echo (TSE; axial, voxel size  $0.47 \times 0.47 \times 6.5 \text{mm}^3$ , repetition time [TR] 650ms, echo time [TE] 23ms) sequence was used scan the entire lower limb, from hip to foot. This scan was used to create 3D meshes of bones and muscles and to determine muscle attachment sites. A T2 (sagittal,  $0.29 \times 0.29 \times 0.59 \text{mm}^3$ , TR/TE 29/16) sequence was used to scan the knee joint ( $\pm 7.5$  cm from the joint line). This scan was used create detailed 3D meshes of the distal femur, the proximal tibia and fibula,

**Figure 1.** Subject specific musculoskeletal model (A), with subject-specific muscle force generating properties, attachment sites and bone geometries, compared to a generic, scaled musculoskeletal model [4] (B).

knee ligaments, menisci and associated cartilage. Finally, diffusion weighted echo planar sequences (voxel size  $2.96 \times 2.96 \times 6.5 \text{ mm}^3$ , TR/TE 7900/65ms, 12 direction diffusion gradients, b value- 0 &  $400 \text{ s/mm}^2$ , spectral attenuated inversion recovery) were used to gather muscle architecture data through the tracking of muscle fibers [4]. These data define the force generating properties of the muscles within the musculoskeletal model. A second, generic lower limb musculoskeletal model [5] was scaled to approximately match the anthropometry of the same subject (Fig. 1).

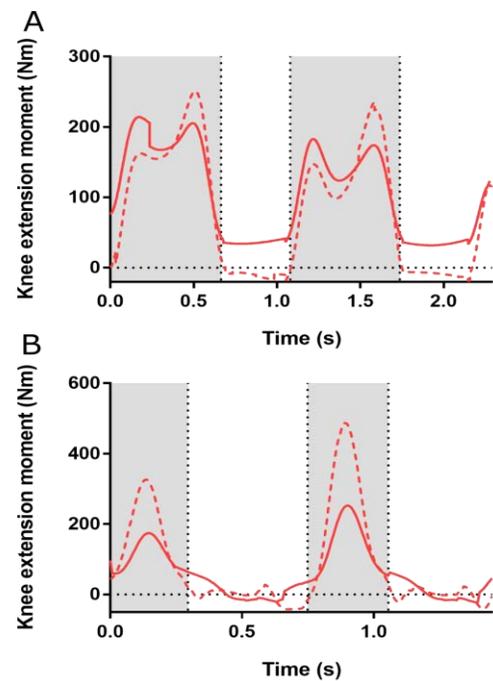

To simulate motion within both models, kinematic data for treadmill walking and running were gathered using a combination of marker based motion capture (Vicon; 100Hz walking, 150Hz running) and biplane radiography system (100Hz/150Hz). Ground reaction force data (GRF) were recorded with a dual belt instrumented treadmill (Bertec, 1000Hz).

The inverse kinematics tool within OpenSim was used to generate motions for two walking and running gait cycles for the both the subject specific lower limb model and the scaled generic model. The residual reduction algorithm (RRA) tool was applied to both models to reduce residuals, and to adjust the models to make them more dynamically consistent with the applied ground reaction forces. Inverse dynamics analyses were then used to predict the net (flexor-extensor, adduction-abduction, internal-external rotation) moments (Nm) around each lower limb joint during both walking and running.

## RESULTS AND DISCUSSION

The inverse dynamics analyses predicted smaller peak knee extension moments during both walking and running in the subject specific model, relative to the generic model (Fig. 2).

These initial results from inverse dynamics analyses give considerable credence to the notion that incorporating subject specific musculoskeletal geometry and muscle force generating properties into biomechanical models greatly affects their output, although the degree of this effect depends on the movement analyzed. The difference in knee extension moment between the subject specific model and the scaled generic model suggests that using biomechanical modeling techniques for clinical purposes, such as informing patient

**Figure 2.** Net knee extension moments in the subject specific (solid line) and the scaled generic (dashed line) models, during walking (A) and running (B). Shaded areas indicate stance phase.

rehabilitation or simulating orthopaedic surgical procedures, may greatly benefit from the addition of subject specific data. To bolster the confidence of this claim, we plan to perform more in depth analyses, such as Computed Muscle Control (CMC) and Joint Reaction Analysis, to test for any differences in muscle forces or activations, as well as joint contact forces, between the subject specific or scaled generic models.

Further development of these models may also improve the comparisons made here. Detailed knee joint kinematics from biplane radiography will be incorporated into the models to more accurately represent the motion of the femur and tibia during walking and running.

## INTRODUCTION

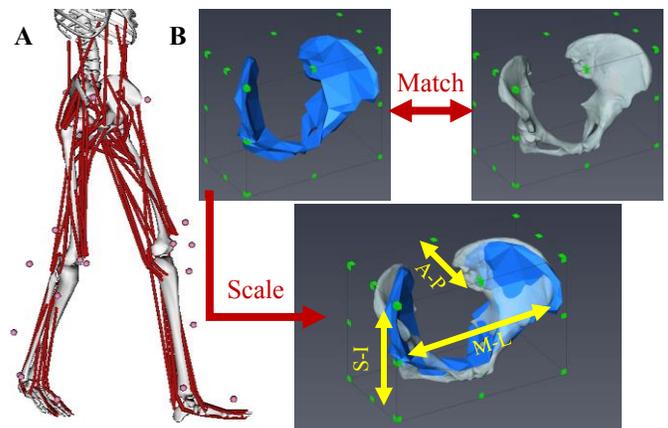

Subject-specific musculoskeletal modeling relies on accurate estimation of joint center locations and proper scaling of model geometry. Sensitivity studies of model estimates, such as hip joint reaction forces (JRFs) and muscle function, have generally reported low to moderate differences between models with subject-specific versus generic geometry, but cautioned the effects may depend on the population and variables being studied [1, 2]. Indeed, models incorporating abnormal proximal femur geometry have shown significant differences in hip joint forces with increased deformity [3, 4]. Model sensitivity for hips with abnormal pelvic geometry, as in cases of hip dysplasia, is unknown but potentially important because altered hip joint geometry and loads may contribute to soft tissue damage in the joint [5]. Also, while models can be refined by incorporating more details, it is usually beneficial to find a balance between specificity and feasibility to facilitate large-scale musculoskeletal modeling research. Thus, the objective of this study was to compare hip joint center (HJC) location, JRFs and muscle forces between musculoskeletal models scaled using 3D reconstructions from computed tomography (CT) images and models scaled solely with skin markers, for individuals with and without hip dysplasia. We hypothesized intra-subject, inter-model differences to be more prominent for subjects with hip dysplasia.

## METHODS

Eighteen subjects participated after informed consent and IRB approval. Nine subjects had symptomatic hip dysplasia (DYSP; 3M, 6F, 26±7 y/o, 22.7±3.1 BMI) while the other 9 were healthy controls (CONT; 3M, 6F, 26±4 y/o, 23.8±4.5 BMI). Subject-specific pelvis geometries were reconstructed from CT images; kinematic and kinetic gait data were also collected and processed for OpenSim, as described previously [6]. A 23 degree-of-freedom model with

pelvis, lower limbs, torso, head segments and 96 muscle-tendon actuators (**Fig. 1A**) was scaled to each subject via two methods (as described below):

*Method 1. Marker-based uniform pelvis scaling – “Generic model”:* All segments were scaled based on anthropometric measurements derived from skin markers at bony landmarks. Pelvis geometry was scaled uniformly based on differences between virtual and experimental markers placed on anterior and posterior superior iliac splines (ASIS, PSIS).

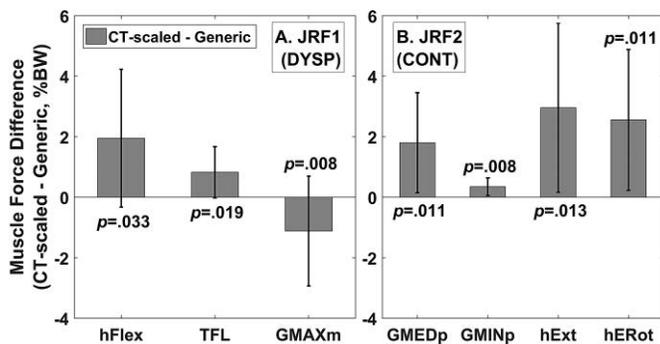

**Figure 1:** (A) OpenSim baseline model; (B) for CT-scaled model, dimensions of generic pelvis geometry (blue) were measured and scaled to match CT 3D reconstruction (gray).

*Method 2. CT-based non-uniform pelvis scaling – “CT-scaled model”:* The baseline OpenSim model pelvis was aligned in Amira with 3D-reconstructed pelvis geometry of each subject. The dimensions of the pelvises were measured as: horizontal distance between ASIS and PSIS, vertical distance between top of iliac crest and lower border of ischial tuberosity, and lateral distance between left and right iliac crests (**Fig. 1B**). The baseline pelvis was then scaled non-uniformly in OpenSim using the three dimensional ratios between baseline and CT geometries. The other segments were scaled with virtual and experimental markers.

For both models, hip joint angles were calculated by inverse kinematics and joint moments by inverse dynamics. After a residual reduction algorithm, individual and grouped (e.g. hip flexors) muscle forces were calculated by static optimization; JRFs were then computed. Data for a representative trial of each subject were interpolated to 0-100% of gait. For each trial, the peak JRFs in early stance (JRF1) and mid-stance (JRF2) were determined. Hip joint angles, moments, JRFs, and muscle forces at these two time points, and HJC location were statistically ( $\alpha=0.05$ ) analyzed between CT-scaled and Generic models, using paired *t*-tests or Wilcoxon signed-rank tests as appropriate. Inter-model comparisons were made for CONT and DYSP subjects separately.

## RESULTS

For DYSP subjects, HJC location in CT-scaled models was more posterior ( $-73\pm 7$  vs.  $-67\pm 4$  mm), inferior ( $-65\pm 4$  vs.  $-63\pm 3$  mm) and lateral ( $82\pm 6$  vs.  $80\pm 4$  mm) versus Generic models, but significant only posteriorly ( $p=0.03$ ). For CONT, HJC location in CT-scaled models was equally posterior ( $-73\pm 4$  vs.  $-73\pm 5$  mm), more superior ( $-66\pm 5$  vs.  $-68\pm 5$  mm) and more lateral ( $87\pm 5$  vs.  $86\pm 6$  mm) versus Generic, but differences were not significant. Hip JRFs, angles and moments were not different between CT-scaled and Generic models at JRF1 or JRF2 for either group.

**Figure 2:** Inter-model muscle force differences at (A) JRF1 and (B) JRF2. Error bar =  $\pm 1$  SD of difference.

At JRF1 (**Fig. 2A**): for DYSP, CT-scaled models estimated larger forces for hip flexor group (*hFlex*) and tensor fasciae latae (*TFL*), and smaller force for gluteus maximus middle fibers (*GMAXm*) compared to Generic. No inter-model differences were found for CONT. At JRF2 (**Fig. 2B**): for CONT, CT-scaled models estimated larger forces for gluteus medius posterior fibers (*GMEDp*), gluteus minimus posterior fibers (*GMINp*), hip extensor group (*hExt*) and hip

external rotator group (*hERot*) compared to Generic. No inter-model differences were found for DYSP.

## DISCUSSION & CONCLUSIONS

Despite producing more accurate pelvis sizes by directly scaling to the skeletal dimensions of each subject and bypassing marker placement errors, the CT-scaled models did not estimate different hip JRFs, angles or moments compared to Generic models. The insensitivity of JRFs between subject-specific and generic models is supported by some past studies [1, 2] and may suggest that either method is suitable to estimate resultant joint forces. However, pelvis geometry for both CT-scaled and Generic models was derived from a single baseline. Since neither model incorporated true subject-specific pelvic geometry, both methods may have omitted important traits such as unique muscle paths and HJC locations. Differences in muscle forces seen here (**Fig. 2**) may stem not only from pelvis scaling, but also from muscle activation estimated by static optimization to equilibrate model torques. Without accessing true subject-specific geometry of the hip or experimental muscle activation data, it cannot be verified that muscle paths and forces from CT-scaled models are more accurate than Generic. We showed recently that highly subject-specific pelvis models can delineate JRF differences between dysplastic and healthy hips, but those models required full access to subject-specific bony geometry and HJC location [6]. The current study lays groundwork for future work to determine the level of model specificity required to reliably estimate joint mechanics, yet also feasible for most research projects. In conclusion, musculoskeletal models with pelvis geometry non-uniformly scaled from CT images were not different versus models uniformly scaled with skin markers, and both methods may underestimate differences in subjects with hip deformity compared to controls.

# ASSESSMENT OF SPASTICITY BY A NOVEL STRETCH REFLEX ACTIVATION MODEL

<sup>1</sup>Moon Jeong Kang, <sup>1</sup>Young Nam Jo, and <sup>1</sup>Hong Hee Yoo

<sup>1</sup>Hanyang University, Seoul, Republic of Korea  
email: hhyoo@hanyang.ac.kr

## INTRODUCTION

Spasticity is a motor disorder characterized by a velocity-dependent increase in the tonic stretch reflex [1]. The diagnosis and assessment of spasticity requires a neurologic assessment of patient, including reflexes, muscle tone. Despite of much effort to understand and improve treatments for patients, there are only a limited number of studies on spasticity.

The pendulum test models are one of a method to measure spasticity. During the test, the leg is fully extended, and then allowed to swing freely. For patients with spasticity, specific swing pattern is observed. There are some mathematical model to evaluate the swing pattern of patients with spasticity. He et al. developed the model including time delay, threshold, and gain [2].

In this study, we developed the stretch reflex activation model, and assess the spasticity by the model. Proposed model considered muscle type.

## METHODS

We simulated the pendulum test of patients with spasticity and assessed spasticity with parameters used in simulation. First, the equation of motion was derived considering muscle force induced by stretch reflex model. We assumed the pendulum motion of a leg as a sagittal motion. The knee joint is modeled as a revolute joint (Fig. 1). Equation of motion of the pendulum motion is as follows.

$$I\dot{u} + cu + MLg \sin q - F_m D = 0 \quad (1)$$

Where  $I$  is moment of inertia of a leg,  $c$  is damping coefficient,  $M$  is mass of a leg,  $L$  is a length of a leg,  $F_m$  is muscle force,  $D$  is moment arm of  $F_Q$ , and  $q, u, \dot{u}$  are joint angle, angular velocity, and angular

acceleration. Joint angle could be calculated by simulation. Optimization method which minimized difference of joint angle from simulation and experiment was used.

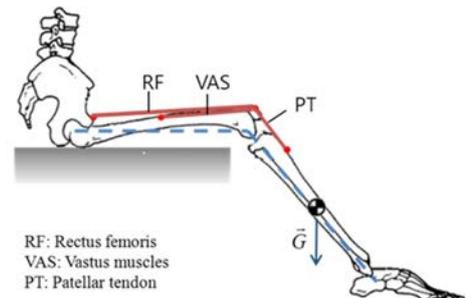

Muscle force induced by stretch reflex could be calculated with Hill-type muscle model as follows [3].

$$\begin{aligned} \tilde{F}^m &= \{f_a(a, \tilde{l}^m, \tilde{v}^m) + f_p(\tilde{l}^m)\} \cos \phi(\tilde{l}^m) \\ \tilde{F}^m &= F^m / F_o^m, \quad \tilde{l}^m = l^m / l_o^m \end{aligned} \quad (2)$$

where  $a$  is muscle activation,  $\phi$  is pennation angle,  $F_o^m$  is optimal muscle force, and  $l_o^m$  is optimal muscle length. During the test, muscle force by stretch reflex is only generated. Therefore we considered muscle force induced by the stretch reflex with suggested stretch reflex activation model. We developed the stretch reflex activation model considering muscle type. The model was based on the study of He et al. [2]. The model consists of threshold, and gain as

$$\begin{aligned} a(t) &= \sigma \left[ \frac{w_1}{T_L} (L_F - T_L) + \frac{w_2}{T_V} (\dot{L}_F - T_V) \right] \\ \text{where, } T_L &= \lambda_1 L_o^m, \quad T_V = \lambda_2 V_{\max} \end{aligned} \quad (3)$$

where  $u$  is muscle activation,  $w_1, w_2$  are the ratio of

**Figure 1:** Musculoskeletal model.

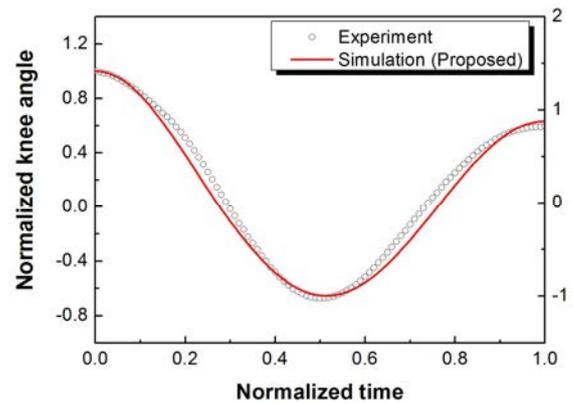

the slow twitch fiber and fast twitch fiber,  $L_F, \dot{L}_F$  is muscle length and velocity,  $L_o^m$  is optimal muscle length,  $V_{max}$  is maximum muscle contraction velocity, and  $\lambda_1, \lambda_2$  are subject dependent parameters. As the muscle length and stretch velocity exceed the each threshold, muscle is activated as equation (3). It is assumed that the former is related with muscle length, and the latter is related with muscle stretch velocity. If a muscle has same portion of muscle type,  $w_1 = w_2 = 0.5$ . For validating the model, we did pendulum test with healthy adults. For the experimental data of spasticity, results in study of Fowler were used [4].

## RESULTS AND DISCUSSION

For the validation, we compared the knee joint angle and the muscle activation with experiment results of joint angle and EMG signal (Fig. 2). Different with healthy subjects, the knee joint angle has small range of motion. There are 5 parameters in the model. We focused on variation of the parameters as increasing level of spasticity. Muscle activation and knee joint angle were calculated from simulation.  $\lambda_2$  and  $w_2$  were varied with the level of spasticity (Table 1). For the results of spasticity,  $\lambda_2$  decreased. It means that velocity threshold decreased for spasticity. In other word, stretch reflex can be easily induced and is sensitive to muscle stretch velocity for spasticity. However,  $w_2$  increased for simulation of pendulum motion of spasticity. It seems that ratio of muscle type also affects the motion of patient with spasticity.

## CONCLUSIONS

In this study, we developed the stretch reflex activation model, and simulate the pendulum motion of patients with spasticity. For the patients with spasticity, the parameters related with muscle stretch velocity and muscle type were different from that of healthy adults. It seems that muscle stretch

**Figure 2:** Knee angle trajectories of experiment and simulation.

velocity and muscle type affect the level of spasticity.

# JOINT CONTACT IS SENSITIVE TO GEOMETRY COARSENESS AND STIFFNESS IN OPENSIM

<sup>1</sup> Michelle R. Krach, <sup>1</sup> Michael W. Hast, and <sup>1</sup> Josh R. Baxter

<sup>1</sup> University of Pennsylvania, Philadelphia, PA, USA

## INTRODUCTION

End-stage joint arthritis is commonly treated with total joint replacement, which was performed on more than 1 million Americans in 2011. Patient outcomes are influenced by surgical and implant factors, but testing this multi-factorial space in clinical studies is not always practical. Finite element modeling allows researchers to isolate the biomechanical effects of modifiable parameters; however, many commercially available software packages are costly, require a great deal of expertise to use effectively, and require substantial amounts of time to create simulations.

OpenSim is a free and open-source musculoskeletal platform that is well accepted in the biomechanics community [1]. While joints of the body are traditionally represented with prescribed kinematic mechanisms in OpenSim, they can also be modeled by relying upon articulating joint contact. To date, the OpenSim contact modeling paradigms are not fully documented and the implications of geometry mesh size and material properties on computation time and fidelity are not clearly defined.

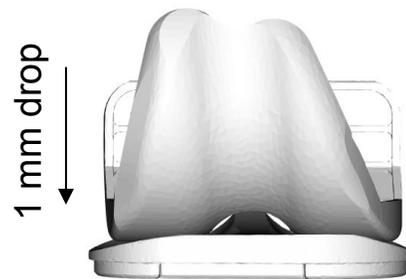

The purpose of this study was to characterize the effects of simulation contact parameters – stiffness and geometry coarseness – on computation time and component penetration. This was achieved by simulating contact between the tibial and femoral components of a total knee replacement.

## METHODS

Tibiofemoral contact was simulated with a forward dynamic model in OpenSim to quantify the relationships between computation time, implant penetration, material stiffness, and geometry coarseness. Briefly, the femoral component was placed 1 mm above the tibial component and ‘drop and settle’ motions were simulated for 1 second. (Fig 1) High-resolution CAD files of a cruciate-retaining

total knee replacement (eTibia) were used in the model and the number of faces used to represent the tibial component was resampled to 100, 500, 1,000, 2,500, and 5,000 faces using MeshLab. The femoral component mesh remained constant at 10,000 faces across all simulations. Additionally, seven stiffness values (ranging between  $10^9$  to  $10^{15}$  N/m), and 3 femoral component masses (1, 10, and 100kg) were used in the simulations. The simulation was repeated 105 times to explore all possible combinations of the aforementioned variables of interest.

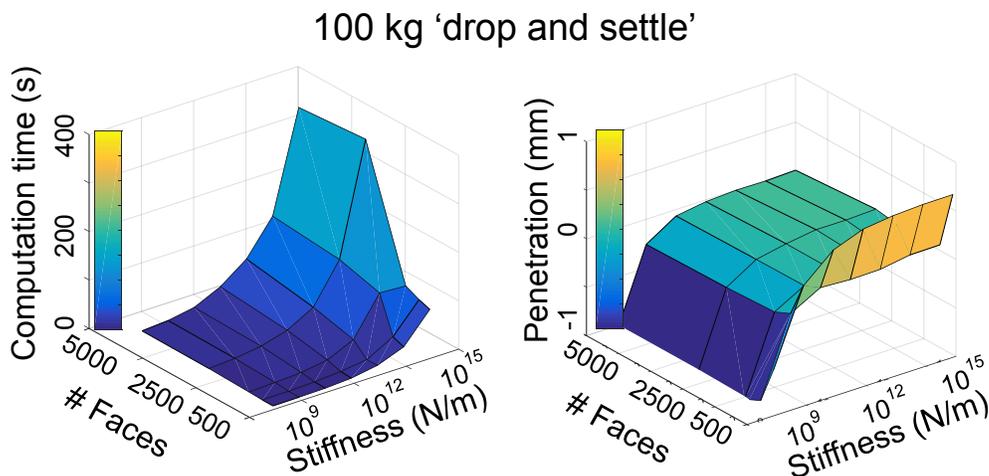

Simulation performance was quantified as computation time and component penetration. Component penetration was calculated as the vertical change in position of the femoral component center of mass from the point of initial component contact to the final settling position.

**Fig. 1.** Tibiofemoral contact was simulated by dropping the femoral component from a height of 1 mm above the tibial component. Tibial mesh size and stiffness were changed and tested at 3 femoral masses to characterize the effects of these model parameters on computation time and component penetration.

## RESULTS AND DISCUSSION

Simulated implant penetration was most physiologic ( $< 0.3$  mm) and computation time was minimized ( $< 25$  s) when stiffness was set at  $10^{10}$  N/m and a finer mesh geometry (1000 or greater faces) was utilized (Fig. 2). Computation time was sensitive to both stiffness and loading magnitude but independent of the contact mesh coarseness (Figure 2).

**Fig. 1.** Material stiffness and mesh density both affected computation time and component penetration during all ‘drop and settle’ simulations. Increasing the material stiffness parameter resulted in computation times 20-30 times greater than models with a stiffness of  $10^{10}$  N/m. Component penetration was affected mostly by low stiffness values and coarse meshes.

The expected penetration for weight bearing simulations (100 kg) was assumed to be between 0.1-0.3mm. This was based on an implant retrieval study indicating this degree of permanent deformation after years of loading [2]. Lack of penetration (negative values) can be explained by two phenomena: 1) incomplete settling of the femoral component caused by overly stiff components, or 2) unrealistic protrusions of contact geometry caused by coarse meshing.

Stiffness values outside of the bounds of this experiment (less than  $10^{10}$  and greater than  $10^{12}$  N/m) caused undesirable simulation behavior. For example, overly compliant models resulted in implant penetration approaching 1 mm while overly stiff models resulted in unsettled simulations consisting of very small integrator time-steps. Initial simulations included stiffness values of  $10^7$  and  $10^8$  N/m, but were excluded as the femoral component fell through the tibia at higher loading magnitudes. Stiffer models took much shorter time steps (up to 34 times smaller) than the best performing models, which explains both the increased computation time and oscillating reaction loads in stiffer simulations.

This simple sensitivity analysis of the elastic foundation contact algorithm within OpenSim has several limitations. The results have not been validated with a physical experiment. We are actively pursuing a validation study where we test the identical component geometry under computational

and benchtop testing conditions. Additionally, the loading profile was derived from a constant mass being acted upon by gravity rather than the dynamic loads that drive human motion. The preliminary findings of this study will be used to optimize more rigorous musculoskeletal models to test the effects of implant geometry on knee biomechanics during clinically relevant activities like walking, rising from a chair, and navigating stairs.

## CONCLUSIONS

Finite element models provide unparalleled amounts of information about contact mechanics within a joint, but they require considerable amounts of time and expertise to execute. In comparison, simulating joint contact using the native elastic foundation paradigm within OpenSim is relatively quick and easy. Depending on the application, this approach may provide enough information for testing clinically relevant parameters with regards to implant selection, placement, and performance. To this end, the current study has provided rudimentary guidelines for utilizing this tool in a quick and effective manner.

# USING MUSCULOSKELETAL MODELS TO ESTIMATE THE PASSIVE JOINT STIFFNESS

<sup>1</sup> Andrea Zonnino, <sup>1</sup> Fabrizio Sergi

<sup>1</sup>Department of Biomedical Engineering, University of Delaware, Newark DE

## INTRODUCTION

Joint stiffness is actively modulated by healthy humans during tasks requiring interaction with the environment [1]. For individuals with neuromotor dysfunctions, however, the response of the neuromuscular system to exogenous perturbations is compromised [2]. As such, analysis of joint stiffness during manipulation could be important both for basic research in motor neuroscience, and for clinical assessment purposes.

Joint stiffness can be described by two different components: active and passive. The active component is related to the force generating capability of muscles; the passive component is an intrinsic property that depends on the passive elastic behavior of the muscles.

Although experimental approaches to the computation of the passive joint stiffness have been presented [3], the complexity and the length of the experiments limit the number of postures in which joint stiffness can be computed. Musculoskeletal models (MSMs) could extend the results of human subject experiments, and estimate the stiffness of different joints across their entire workspace. However, MSMs have not been developed for joint stiffness analysis; even the simplest models can be characterized by unstable values of stiffness that are not physiologically accurate [4].

This work develops a framework to analyze joint stiffness in MSMs and presents a procedure to minimally modify some of the muscles parameters of a MSM to obtain stable and physiologically accurate values of passive joint stiffness.

## METHODS

In static conditions, joint stiffness ( $K_\theta$ ) is the derivative of the multivariate torque ( $\tau$ ) vs. angle ( $\theta$ ) relationship:

$$K_\theta = \frac{\partial \tau}{\partial \theta} \quad (1)$$

where  $\tau$  is a function of the musculotendinous forces ( $f^{MT}$ ) and the muscle Jacobian ( $J$ ) (i.e.  $\tau = J^T f^{MT}$ ).

Assuming that muscles are modeled with a Hill-type model, and considering only the muscle's passive component, it is possible to express  $f^{MT}$  as:

$$f^{MT} = f^T = f^M = f^{PE} (l^{PE}) \cos(\alpha) \quad (2)$$

where  $f^T$  and  $f^M$  are the forces along the tendon and muscle respectively;  $\alpha$  is the pennation angle.

It is possible to show that:

$$K_\theta = J^T \frac{1}{c} \frac{K^{PE} K^T}{K^{PE} + K^T} J - \frac{\partial J^T}{\partial \theta} f \cos(\alpha) + J^T f \sin(\alpha) \frac{\partial \alpha}{\partial \theta} \quad (3)$$

where  $c = \left(1 + \frac{l^{PE}}{\partial l^{PE}} \frac{\partial \cos(\alpha)}{\cos(\alpha)}\right)$ . We consider a joint unstable if at least one of the eigenvalues of  $K_\theta$  is negative.

Since the first term of (3) is always positive, negative (i.e. unstable) values of stiffness can only be introduced by the second and third terms. The parameters that influence stability are then the moment arm ( $J$ ), its derivative ( $\frac{\partial J}{\partial \theta}$ ), the muscle force ( $f^{PE}$ ), the pennation angle ( $\alpha$ ) and its derivative ( $\frac{\partial \alpha}{\partial \theta}$ ). Preliminary analysis shows that the third term of (3) influences the final value of stiffness by only 0.1%. As such, we consider the moment arm and the muscle force as the only relevant parameters.

We applied the described analysis to study the stiffness of the wrist joint implemented in the upper limb model proposed by Holzbaur et al. [5]. We used a simplified version of the model where only five muscles (ECRL, ECRB, ECU, FCR, FCU) were considered. We calculated stiffness in a 2D workspace defined by two wrist rotations, flexion/extension (FE) with a range of  $-50^\circ$  (extension) to  $50^\circ$  (flexion), and radial/ulnar deviation (RUD), ranging from  $-25^\circ$  (radial deviation) to  $10^\circ$  (ulnar deviation).

Since the model is unstable in certain regions of the workspace (see results), we developed a framework to determine how to minimally modify the model to obtain stability. As both the moment arm [6] and the tendon slack length [7] are highly variable between individuals and cannot be measured

accurately, we hypothesized that that small modifications to these parameters could yield equally accurate MSMs, which are also stable and suitable for the analysis of dynamic interaction with the environment.

We conducted an exhaustive search on the space defined by each muscle attachment point and tendon slack length, and used optimization to find a set of parameters that achieves stability in all workspace postures while minimally changing model behavior. Our analysis seeks to minimize the following function:

$$\Phi = a_1 \frac{A_{unst}}{A_{tot}} + a_2 \frac{\Delta L_{ts}}{\Delta L_{ts_{MAX}}} + a_3 \frac{\Delta \rho_{IP}}{\Delta \rho_{IP_{MAX}}} + a_4 \frac{A_{sl} - A_{sl_0}}{A_{tot}},$$

where  $A_{unst}$  and  $A_{sl}$  are the area of the unstable portion and of the slack portion of the workspace, respectively;  $\Delta L_{ts}$  is the tendon slack length variation;  $\Delta \rho_{IP}$  is the insertion point displacement. A preliminary analysis showed that, by keeping the flexors unloaded in the entire workspace, as proposed by [5] and shown in Fig. 1A, the model presents a partial area where all the muscles are slack. Considering this a non-physiological condition, we forced to the FCR and FCU to decrease the slack area by 20% (i.e. the same amount of modification required to stabilize the ECRL and ECRB).

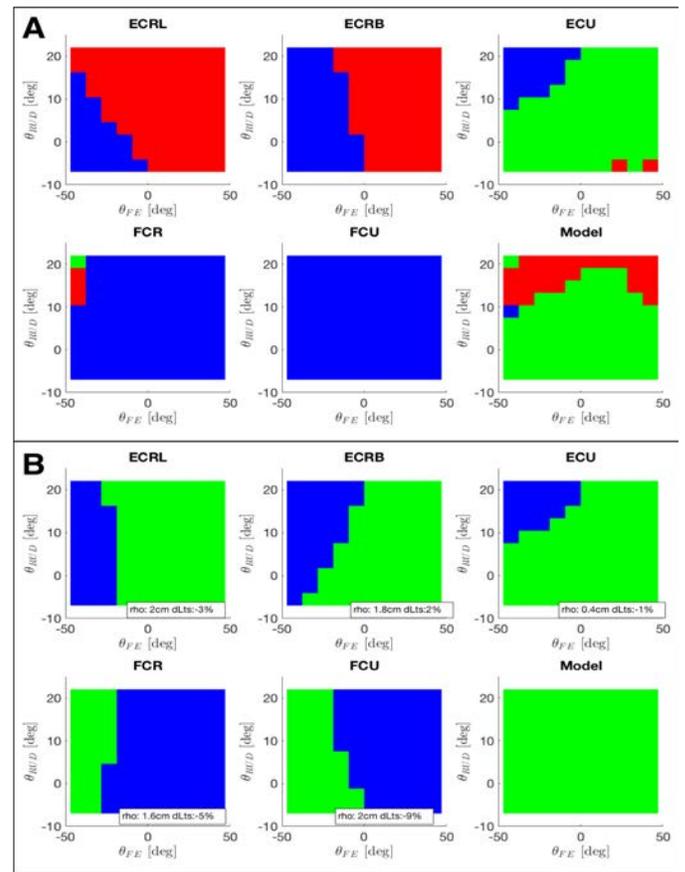

## RESULTS

### Model stability analysis:

We analyzed joint stability separately for each muscle of the model, and created the stability maps reported in Fig. 1A, which demonstrated the presence of a large unstable region in the workspace. The instability was caused by two muscles (ECRL and ECRB) that, if stretched, are always unstable.

### Stabilization of unstable muscles:

With the optimization procedure, the attachment points and tendon slack length of the unstable muscles were modified to achieve stability throughout the workspace for each muscle and for the entire model (Fig. 1B). Muscle moment arms for the stabilized muscles were changed substantially only for ECRB in the RUD axis, for which the average change in moment arm required for model stabilization was 280%.

**Figure 1:** Stability maps for each muscle individually and for the entire model: (A) original model based on [5], (B) optimized model. In each map the green area is the stable area, the red area is the unstable area and the blue area is the slack area.

## CONCLUSIONS

Using a musculoskeletal model to investigate the joint stiffness is valuable, as it may allow for the exhaustive analysis of the joint stiffness properties.

Even though MSMs have not been developed to analyze the joint stiffness and can show unstable behavior, we developed a novel method that allows stability to be achieved through minimal parameter changes of the MSM. With proper experimental validation, this method may allow to use current MSMs to study joint stiffness to optimize human-robot interaction and/or to quantify the evolution of disease in neuromotor disorders.

# Investigating Uncertainty in Constitutive Modeling of Components of the Human Head

Patrick Brewick and Kirubel Teferra

US Naval Research Laboratory, Washington, DC, USA  
email: patrick.brewick@nrl.navy.mil; kirubel.teferra@nrl.navy.mil

## INTRODUCTION

Detailed finite element (FE) modeling of the human head provides an invaluable resource for quantifying the mechanical response within the brain during a blast loading event. The exact connections between loading patterns, tissue mechanical response, and injury/physiological effects are still quite unknown; however, the exceedance of specified threshold values based on direct and derived measures of stress, strain, pressure, and acceleration within the brain have been shown to be useful injury criteria. The utility of these thresholds is somewhat mitigated by the fact that preliminary parametric studies have shown significant variation in the predicted injury response, indicating that the exact relationship between model geometry, material properties, and mechanics-based injury response metrics has not yet been established.

The use of stress and strain measurements as indicators of or criteria for injury necessitates accurate material models for the many constitutive components of an FE model of the human head. Identifying an appropriate constitutive model form and optimal parameter values for biological tissues is an enormous challenge hindered by large epistemic uncertainties. This work lies within a larger effort to quantify the uncertainty encountered during modeling of the human head.

## METHODS

The biomaterial components within the human head model, *e.g.*, white matter, gray matter, skin, and bone, were primarily described with the constitutive model forms for hyperelastic, viscoelastic, and hyper-viscoelastic materials. This study was primarily concerned with fitting parameters for the Ogden model of hyperelasticity and the Maxwell model for viscoelasticity. The strain energy density function for an Ogden model is given by Eq. (1)

$$W = \sum_{i=1}^N \frac{2\mu_i}{\alpha_i^2} (\lambda_1^{\alpha_i} + \lambda_2^{\alpha_i} + \lambda_3^{\alpha_i} - 3) \quad (1)$$

where  $N$  is the model order,  $\lambda$  is the principal stretch, and  $\alpha$  and  $\mu$  are model-specific parameters.

Each model form contains parameters that must be estimated by fitting to experimental data. Available data sets are often limited due to the many vagaries associated with testing biomaterials, but sophisticated models must be calibrated and validated based on these narrow data sets. For some materials data must be aggregated from a series of unrelated studies in order to create a complete data set, but combining disparate data sets typically requires numerous assumptions about experiments performed under different conditions and using different equipment.

Typically the experimental data was provided in the form of stress-strain curves; stress may be easily derived for the Ogden model in Eq. (1) and strain is directly relatable to  $\lambda$ . The actual fitting may be performed through an optimization process, but the nonlinearity of the model forms and the necessary constraints on the model parameters meant that the result from a single optimization trial would not necessarily capture the ideal result. For instance, one crucial but complex constraint was Drucker stability [1], a physics-based requirement relating changes in stress to changes in strain. Therefore, an emphasis was placed on the posterior distributions for each parameter instead of individual parameter estimates.

The posterior distributions were based on adopting a Bayesian approach, using the familiar form of Eq. (2)

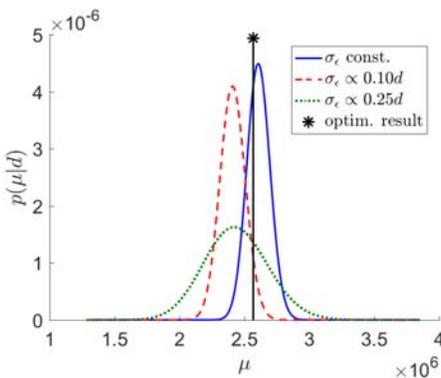

$$p(\theta|d) = \frac{p(d|\theta)p(\theta)}{\int_{\Theta} p(d,\theta)d\theta} \quad (2)$$

where  $\theta$  represents the unknown model parameters, *e.g.*,  $\alpha$  and  $\mu$ , and  $d$  represents the experimental data.

$p(\theta|d)$  is the desired posterior distribution and  $p(d|\theta)$  may be considered the likelihood function, which models the error between the model predictions and experimental data.  $p(\theta)$  is simply the prior distribution for the unknown parameters. Given the complex form of the models, the posterior distribution cannot be easily solved analytically, especially for larger models. Thus, Markov Chain Monte Carlo methods [2] were employed as they allowed for heuristic parameter bounds, inequality constraints on certain parameter sets, as well as nonlinear functional constraints on the constitutive model forms, such as that for Drucker stability.

## RESULTS AND DISCUSSION

The advantage of this Bayesian approach is that the posterior distributions provide an estimated density for the region of optimal values, as opposed to the maximum likelihood estimate provided during optimization. This becomes important when addressing the inherent uncertainty in experimental data. When calibrating a purely hyperelastic model for the pia mater with a simple, single-term Ogden model ( $N = 1$ ), the posterior distributions showed a marked dependence on the assumed variance in the error between the model prediction and experimental data,  $\sigma_\varepsilon$ . This may be easily seen in Fig. 1.

**Figure 1:** Comparison of posterior distributions for  $\mu$  from a single-term Ogden model for pia mater.

The different distributions for  $\mu$  in Fig. 1 are generated by simply changing how  $\sigma_\varepsilon$  is treated. Assuming the variance is constant across all measurements results in a relatively narrow

distribution whose mean lies near the optimal result. However, assuming that the error variance at a given measurement point is directly proportional to its measurement value, *e.g.*, by 10% or 25%, results in much different distributions with shifted mean values. A similar plot may be generated for  $\alpha$ .

The results shown in Fig. 1 are merely for the simplest model class and one of the simplest biomaterials in terms of data sets. More complex materials, such as brain matter, bone, and skin, require significantly more detailed models with greater numbers of parameters (and thus greater dimensionality) and comprise much larger data sets that often span orders-of-magnitude in both stress and strain. Thus, these materials will ultimately produce more complex distributions.

## CONCLUSIONS

This study emphasizes the important role uncertainty plays in biomechanics modeling. It was shown that even small changes to the assumed degree of error in the model can lead to much broader uncertainty in the parameter estimates. However, the degree of uncertainty varies from parameter to parameter.

The uncertainty within the parameters represents only the beginning of this investigation as the main goal of this long-term study is to investigate how these parameter uncertainties propagate through the greater FE model. Future work will focus on analyzing the influence and correlation of parametric uncertainties with TBI prediction.

## INTRODUCTION

Altered biomechanical loading in the lumbar spine has been suggested as a contributing factor to the greater prevalence of low back pain in certain populations, such as people with a transtibial amputation (TTA) [1]. Musculoskeletal modeling and simulation techniques allow for estimation of muscle and joint contact forces that are difficult or impossible to measure *in vivo*. Reliable estimates of *in vivo* spinal loading from musculoskeletal models can provide insight into potential mechanisms for low back pain development without the need for invasive measurements. However, when developing musculoskeletal models and simulations, validation of the metrics of interest is critical. Thus, the purpose of this study was to develop and validate a whole-body musculoskeletal model with detail of the lumbar spine during planar trunk-pelvis movements for people with and without TTA.

## METHODS

A musculoskeletal model of the trunk and lower limbs with detail of the lumbar spine was developed in OpenSim 3.3. This model included the lower body from [2], the lumbar spine and torso from [3], muscle strengths from [4], and body mass distributions from [5]. The model included 294 Hill-type musculotendon actuators, five lumbar vertebrae and eight additional body segments. The model had 23 degrees of freedom as in [2], with the motion of the five lumbar intervertebral joints defined with a linear function based on overall trunk-pelvis motion. The model was adapted to represent a person with TTA by removing twelve muscles crossing the affected leg ankle joint, reducing the residual shank mass, and shifting residual shank center-of-mass location proximally.

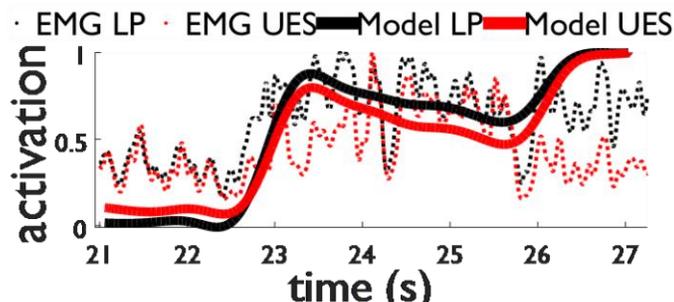

Four male participants (mean(SD): 35(15 yrs, 1.82(0.05) m, 85.4(2.9) kg, one with a left unilateral transtibial amputation), and two female participants (21-25 yrs, 1.64 m, 58.9-79.2 kg, no amputations) were analyzed during four trunk-pelvis range of motion (ROM) trials. Participants began the trials from a neutral standing posture. Sagittal plane flexion, sagittal plane extension, frontal plane lateral bending to the right, and transverse plane axial rotation to the left were completed. Kinematics were collected at 120 Hz with a 20-camera motion capture system and a full-body marker set including markers placed at C7, T8, xyphoid process, and bilaterally at the acromion, PSIS, ASIS, iliac crest, and greater trochanter. Electromyography (EMG) sensors were placed bilaterally on the upper erector spinae and lumbar paraspinal muscles. Ground reaction force and EMG data were collected at 1200 Hz.

Kinematics and GRFs were low-pass filtered with a 4<sup>th</sup>-order Butterworth filter with cutoff frequencies of 6 Hz and 10 Hz, respectively. EMG data were band pass filtered between 6 and 20 Hz. An eight-segment Visual3D model was used to determine the inverse kinematics solution, and to scaled models to each participant. Each analysis began with a static, standing posture of at least 0.5s. Then, a static optimization algorithm solved the muscle recruitment problem at each time step by minimizing an objective function of the sum of muscle activations squared. Estimated back muscle forces from static optimization were compared with the timing of collected EMG data. Net joint contact loads were calculated at L4-L5, low-pass filtered at 1 Hz and converted to intradiscal pressure based on [4] and average L4-L5 intervertebral disc cross-sectional areas (CSA) from [6,7]:

$$\text{Disc Pressure} = \frac{\text{Compressive Force}}{\text{CSA} \times 0.66}$$

## RESULTS AND DISCUSSION

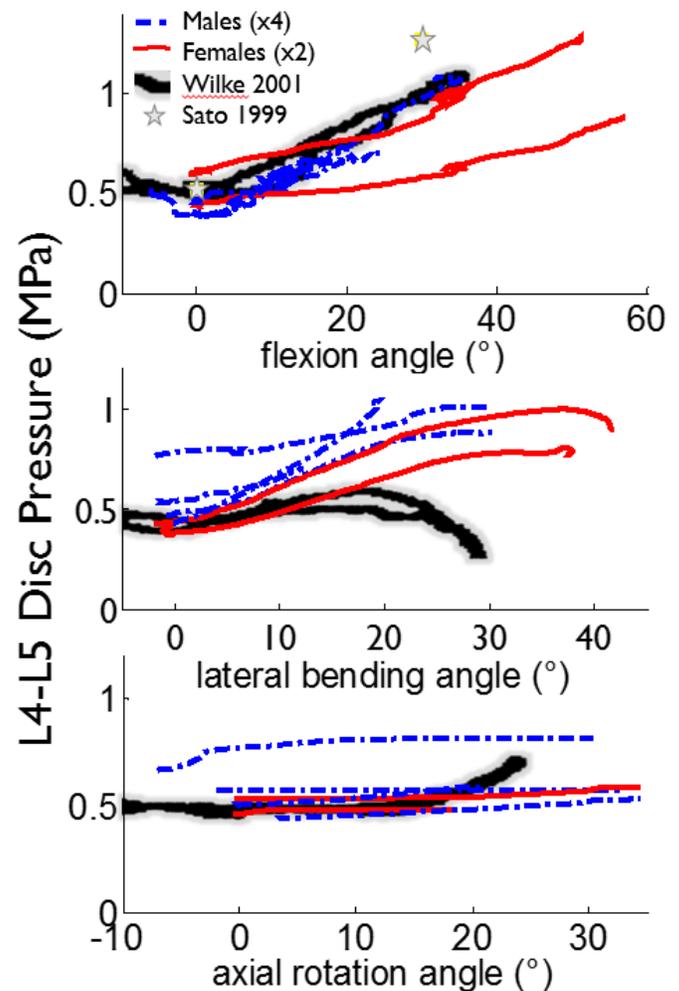

Timing of model muscle activations corresponded well with measured EMG data (example flexion trial, Fig. 1). Disc pressures calculated in the model also generally agreed with those found in [6] and [7] (no significant difference between standing pressures, Fig. 2). The two female participants had the largest ROM of the six participants in flexion, lateral bending (Fig. 2) and extension (not pictured). Greater ROM from females may be attributed to effects of anatomy on trunk and pelvis tracking. Notably, the data from [6] and [7] are from male participants, and thus may be less relevant to females. The decrease in disc pressure at 20-30° of lateral bending was attributed to muscle deactivation in [6], but our loading estimates were higher at these positions. Higher loading from the model relative to [6] may also suggest greater spinal loading in the facet joints. In the model, facet and disc loading are both included in the net contact force, while facet joint loading was unknown in [6].

**Figure 1:** Summed model muscle activation estimates (solid) for lumbar paraspinals (LP: multifidus, quadratus lumborum, longissimus pars lumborum, iliocostalis pars lumborum) and upper erector spinae (UES: longissimus pars thoracis, iliocostalis pars thoracis) compared with processed LP and UES EMG signals (dashed) during trunk flexion. Model activations and EMG signals were normalized to their peak filtered value.

## CONCLUSIONS

Estimates of lumbar spine loads during trunk ROM trials in this study were consistent with prior *in vivo* measurements. Future work will further investigate loading differences between males and females and in people with low back pain.

**Figure 2:** Calculated intradiscal pressures during ROM trials for all participants, intradiscal pressures from [6] (black solid line), and average pressures from [7] (gray stars, 8 participants). Data were scaled to body mass in [6].

## INTRODUCTION

Low back pain (LBP) is a common problem in the general population [1] and has many potential causes. Abnormal whole-body kinematics may lead to increased and/or asymmetric lumbar spine loading, both of which are potential causes of pain. Although LBP is a multifactorial condition, abnormal biomechanics may be an important cause of pain at the tissue-level in locations such as the intervertebral discs or facet joint capsules [2].

Computational modeling techniques can be used to obtain estimates of biomechanical parameters related to LBP that are difficult or impossible to measure *in vivo*. Dynamic rigid-body simulations of human movement can be performed with musculoskeletal models to estimate muscle forces and joint loading. Finite element (FE) models can be used to simulate certain regions of the body and estimate tissue-level mechanics. Separately, both techniques have certain limitations such as lack of constitutive detail in musculoskeletal models and computational expense in FE models. To our knowledge, no previous study has combined the benefits of these two modeling techniques to investigate tissue-level metrics commonly associated with LBP during dynamic movements. The purpose of this study was to develop a multiscale model of the human lumbar spine, including the whole-body-level and tissue-level (lumbar spine L1-L5), and evaluate the model with a case study focused on a sit-to-stand motion.

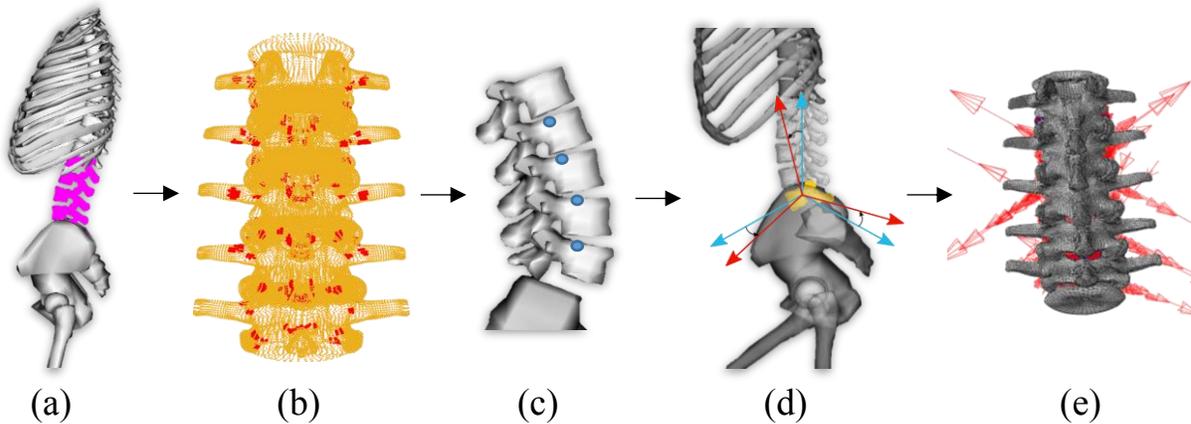

## METHODS

A whole-body musculoskeletal model with lumbar spine fidelity was created using OpenSim 3.3 (OS). A detailed model of the lumbar spine and torso [3]

was combined with a lower extremity model [4]. A validated FE model of the lumbar spine created in Abaqus/Standard [5] was used to replace the L1-L5 geometry of the OS model and was adapted to match the OS model's global reference frame (Fig. 1a). Lumbar spine muscle attachment locations were obtained using a plugin developed for OS [6] and were transferred from OS to the FE model (Fig. 1b). The fixed centers-of-rotation for each OS model intervertebral joint were implemented in the FE model to constrain the motion of the joints to 3 rotational degrees of freedom (DOF) (Fig. 1c).

One participant was recruited for the case study to test the multiscale model during a sit-to-stand motion (male, 27 yrs, 69.88 kg, 1.75m). The participant was initially positioned in a backless chair with knees and hips at 90° flexion and ankles hip-width apart in a neutral position. The participant's arms were folded across his chest as he progressed to upright standing. Ground reaction forces were collected on two force plates at 1200 Hz and kinematics were collected at 120 Hz using a 20-camera motion capture system.

An inverse kinematics solution was determined using least-squares optimization algorithm with an eight-segment model in Visual3D and used as an input to the OS model. The orientation of the L5 vertebra at each increment of the motion was determined from the OS model and applied to the FE model (Fig. 1d). Using optimization that minimized the sum of muscle activations squared, the force developed by each lumbar spine muscle was estimated at each time increment of the motion and applied to the FE model. Joint contact forces and moments were also determined for the joint between the torso and L1 in the OS model and applied to the FE model for dynamic consistency (Fig. 1e). To evaluate the

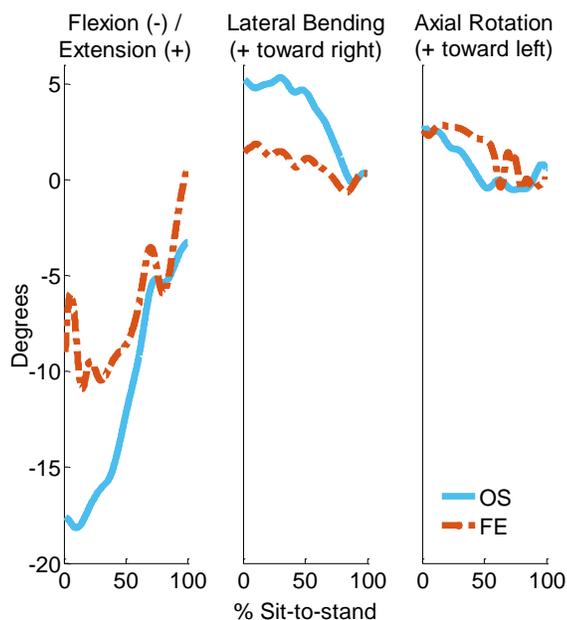

**Figure 1:** Workflow of the multiscale model development (specific step details described in the text).

transfer of muscle forces and consistency of the models at the two length scales, FE output kinematics were compared to the OS input kinematics.

## RESULTS AND DISCUSSION

Total lumbar spine motion (L1-L5) was compared for the 3 rotational DOF (Fig. 2). Flexion exhibited the greatest difference in kinematics ( $8.6^\circ$ ) near the initiation of the sit-to-stand motion.

**Figure 2:** Multiscale lumbar spine kinematic evaluation between the OS input and FE output kinematics.

In this multiscale framework, the FE model played the role of sensor to deliver tissue-level metrics (disc stress, facet contact pressure, etc) not represented by the OS model. The validated FE model [5] had sagittally symmetric geometry (Fig. 1b) and generalized material properties for all soft tissues (annulus, nucleus, ligaments, facet cartilage) to represent an average male lumbar spine. This generality in size, shape, and lumbar mechanics was consistent with the OS model (Fig. 1a). Nevertheless, the whole-body OS model (including lumbar joints) was displacement-controlled, whereas the tissue-level FE model was force-controlled. In light of this mechanical difference between the model scales, it can be argued that the kinematic agreement demonstrated in Fig. 2 is quite good, and the FE model is reasonably able to represent variations in tissue-level metrics that are driven by biomechanical abnormalities measurable at the whole-body-level. The broader aim of this research to use the multiscale framework for this purpose – to help clarify how changes in whole-body biomechanics may relate to tissue-level sources of LBP.

## INTRODUCTION

Musculoskeletal models of the cervical spine commonly represent neck muscles with straight paths. However, the curvature of neck muscles affects biomechanical predictions. In this study, we calculated the moment arms of neck muscles *in vivo*, when their paths are constrained naturally by underlying and overlying soft tissues.

The purpose of this study was to compare moment arms of curved and straight neck muscle paths for head and neck flexion and extension, and to compare moment arm calculation methods (tendon excursion, geometric and effective torque methods). We hypothesize that (1) moment arms of curved muscle paths will be significantly different from straight paths; and (2) the three methods will produce significantly different moment arm estimates for curved muscle paths, but not straight.

## METHODS

Magnetic resonance images (MRI) were acquired for two 50th percentile males in 5 sagittal plane postures: 30° and 15° flexion, neutral, 15° and 30° extension. Subjects provided informed consent, and the protocol was approved by the ethics board at the University of British Columbia. Fifteen neck muscle pairs were examined from the MRI data.

The curved path of each muscle was determined from the centroids on each MRI slice, and the straight path was defined between the first and last point (Fig. 1A&B). The muscle paths were also modeled in SIMM (Musculographics, Santa Rosa, CA) using moving muscle points that moved relative to each vertebral body (Fig. 1C) [1]. MRI paths were defined in the five imaged postures, whereas model paths were defined over the range of motion.

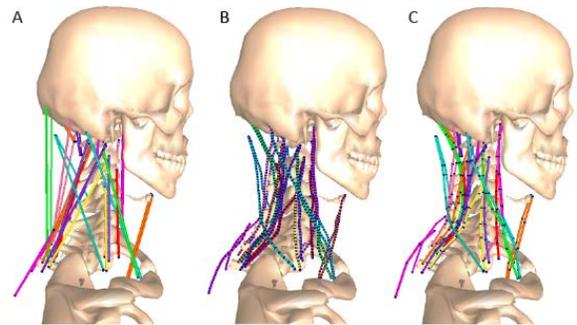

Figure 1: Subject-specific model in the neutral posture. A: Straight muscle paths. B: Curved paths from MRI centroid points. C: Curved paths with moving muscle points.

Five moment arm estimates were determined for each of the straight and curved paths: geometric method for MRI and model paths, tendon excursion for MRI and model, and effective torque for the model. **Geometric (Geo):** The center of rotation (COR) of the head with respect to the sternal notch was calculated using the Rouleaux method [2]. Geometric moment arm was defined as the perpendicular distance from the COR to the straight path; or to a tangent vector through the muscle point closest to the COR in the curved path [3]. **Tendon excursion (TE):** Muscle length was fit with a cubic polynomial, and moment arms were calculated as the derivative of muscle length with respect to joint angle. **Effective torque (ET):** Moment arms were estimated in SIMM as the effective torque: the torque that would produce the same motion as an applied force. Moment arm is the effective torque for a unit muscle force [4].

Moment arm estimates were compared using a two-way ANOVA with repeated measures comparing two factors: muscle path (straight and curved), and moment arm method (model geometric, model tendon excursion, MRI tendon excursion and model effective torque). Root mean square (RMS)

## INTRODUCTION

Scaling a musculoskeletal model to the properties of an individual can be time consuming if the strength at each joint must be assessed, but the model can be inaccurate if default parameters are used. We sought a compromise that adequately estimated the strength the muscles need to produce torques at selected joints in the lower extremity, and was not time consuming in the data collection process. Therefore, the purpose of this research was to test a procedure that adjusted the scaling factor for maximal static muscle forces to ensuring adequate muscle strength. This method was compared to a method that used a set scaling factor to estimate muscle strength.

## METHODS

Seven young adult recreational runners (3 males, age: 21.3±2.1 yr; body mass: 68.9±6.7 kg; height: 1.84±0.07 m and 4 females, age: 25.3±5.2 yr; body mass: 56.6±11.3 kg; height: 1.64±0.08 m) participated in this study. The runners ran across a force platform (1000 Hz) at 3.5 m/s while 8 cameras recorded the kinematic data (200 Hz). Inverse dynamics and rigid body assumptions were used to estimate 3D joint moments at the hip, knee and ankle. A musculoskeletal model [1] estimated the maximal dynamic muscle forces and moment arms for each of 44 lower extremity muscles. The maximum isometric muscle forces were first scaled by body mass and then increased by a factor of 1.5. This scaling factor is the suggested value to get the model to walk with adequate strength using OpenSIM software [2]. The isometric forces were adjusted by length and velocity during each frame of the activity to obtain maximal dynamic muscle forces. These were then used as input to an optimization procedure that estimated the actual muscle forces during the running. The optimization procedure selected muscle forces that minimized the sum of the squared muscle stresses while constraining the solution such that the

muscles produced torques estimated from the inverse dynamics, if possible. The selected constraints were the sagittal plane hip, knee, and ankle torques as well as the frontal and transverse plane hip torques. The optimization was run a second time, and instead of a scaling factor of 1.5, a variable scaling factor was used. This value was estimated such that the muscles had enough strength to produce the joint torques of the given running trial. During each frame of data, the maximum dynamic muscle forces were multiplied by the muscle moment arms and the resulting torques were compared to the inverse dynamic forces during the trial. If they were not adequate, the muscle forces were increased to a level that insured the actual joint torques could be matched.

## RESULTS AND DISCUSSION

The set max force condition with a scaling factor of 1.5 did not create muscle forces that could produce the inverse dynamics torques during running (Figure 1). The average variable scaling factor was 2.5±0.27. Each joint had a statistically significant reduction in the RMSE for the variable scaling factor condition (Table 1).

Table 1: RMSE for the set and variable factors (\* indicates significance).

Joint Torque	RMSE SF (N)	RMSE VF (N)
Sagittal Hip Torque	7.7±3.3	3.3±1.1*
Frontal Hip Torque	18.3±7.5	4.3±1.5*
Transverse Hip Torque	2.2±1.2	1.4±0.7*
Sagittal Knee Torque	19.5±9.8	3.5±1.1*
Sagittal Ankle Torque	26.2±7.7	3.1±2.1*

It should be noted that the RMSE for the variable factor condition was not reduced to zero. This is likely because co-contractions can reduce the ability of the muscles to produce their maximum joint

torque. This may need to be taken into account when estimating the scaling factor in future research. Further refinement of this method might include a separate scaling factor for each joint, with biarticular muscles taking the larger scaling factor of the two joints. It might be argued that all that is needed is to increase the set scaling factor from 1.5 to 2.5. This may work but it reduces the advantage of selecting a scaling factor based on individual strength.

### CONCLUSIONS

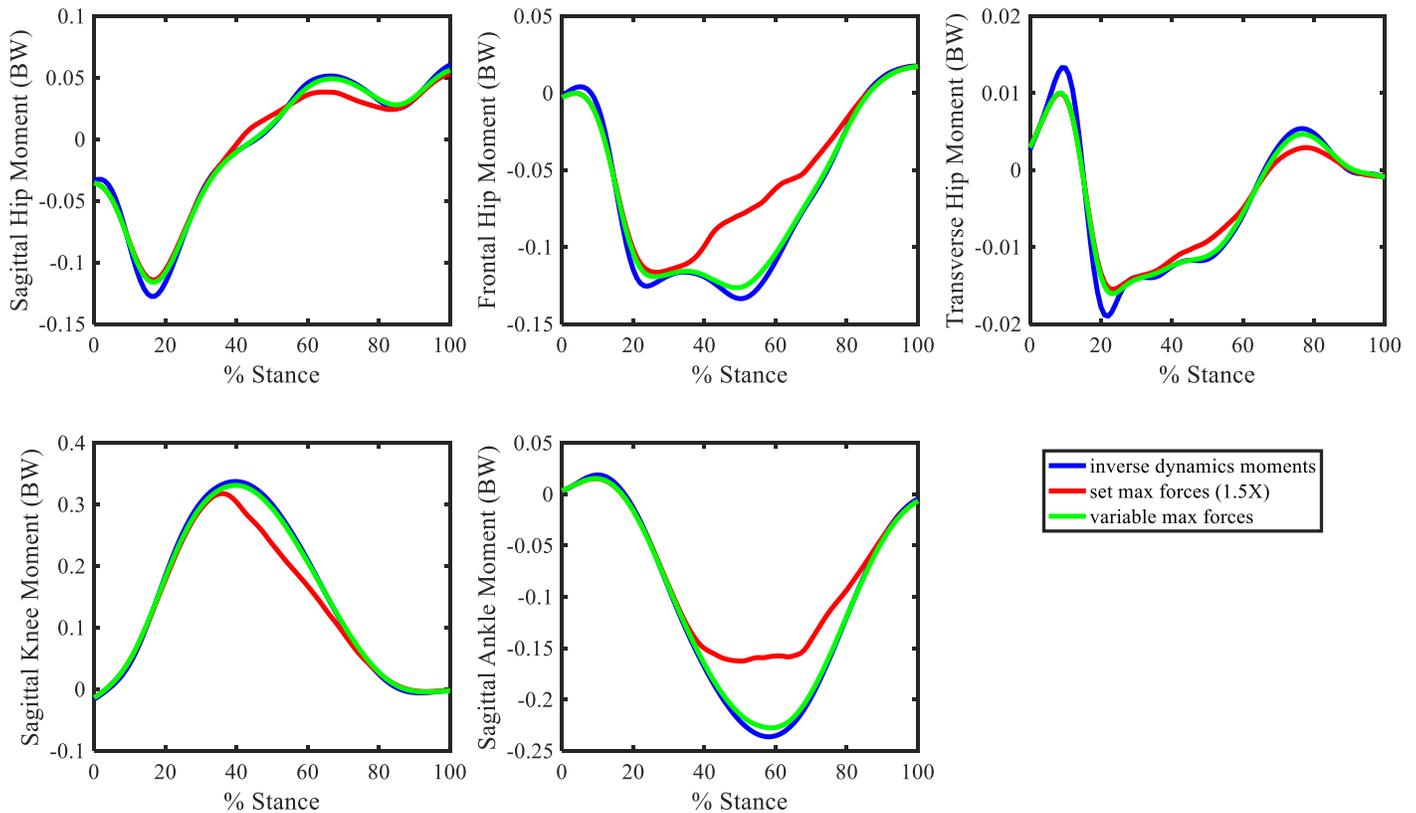

The variable scaling factor technique successfully ensured that the muscles adequately produced the inverse dynamics torques for a particular activity.

This may be a better technique than applying a set scaling factor to all of the subjects. At the very least it ensures that muscle torques are not underestimated by the optimization process.

## INTRODUCTION

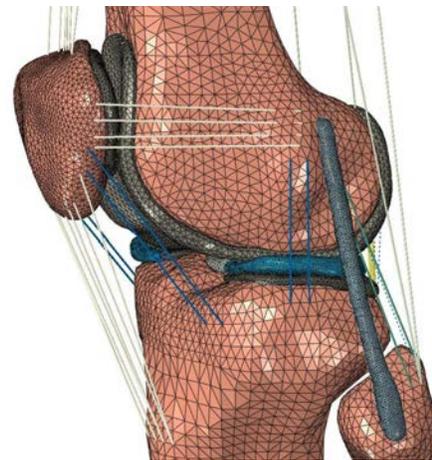

The menisci play an important role with respect to knee kinematics and loading, but to date, many finite element (FE) knee models omit the menisci [1]. The purpose of this study was to simulate knee joint loading scenarios during bipedal landing from a jump associated with anterior cruciate ligament (ACL) injury using finite element models with and without menisci to investigate the contribution of the menisci to resulting knee kinematic, cartilage pressure and ACL strain.

## METHODS

MR images from one, healthy, 21 year old male were converted to 3D models of bone and soft tissue using Mimics (Materialise, Leuven, Belgium). Meshes of C3D4 elements were constructed in Hypermesh (Altair, MI, USA) before final assembly in Abaqus/Explicit 6.14-5 (Simulia, RI, USA). Cruciate and collateral ligaments were modeled as Holzapfel-Gasser-Ogden hyperelastic materials. The remaining joint capsule was modeled with uniaxial connector elements. Bone and cartilage were modeled as linear elastic materials. Menisci were modeled as transversely isotropic. The meniscal horns were modeled as nonlinear axial connector elements with an effective stiffness of 2000 N/mm [2].

Surface to surface contacts between the menisci and opposing cartilage surfaces were defined. The contacts were frictionless with a “hard contact” pressure overclosure relationship to prevent penetration of the master surface into the slave. The menisci were removed from the model for simulations without menisci.

Simulations were done at 25° flexion with 1200 N quadriceps and 800 N hamstrings loads. Four loading scenarios were considered: 268 N anterior shear force (ASF), 60 Nm internal tibial rotation moment (ITM), 75 Nm knee abduction moment, and all three loads combined. All load cases were followed by an impact step representative of a bipedal landing (half body-weight) from a height of 30 cm.

**Figure 1:** Finite element knee model with intact menisci shown in light blue.

## RESULTS AND DISCUSSION

Internal tibial rotation and knee valgus angle tended to increase in simulations without the menisci, most notably in the isolated loading conditions. Little difference was seen for ACL strain and anterior tibial translation with and without menisci cases. Although the data for both with and without menisci were similar, the data for simulations with menisci were in better agreement with the mean values reported by Kiapour et al [3] for cadaveric assessment of ACL injury mechanisms.

Maximum contact pressure on the lateral (LTC) and medial (MTC) tibial cartilages were computed, Table 1. Peak contact pressure increased for all loading cases after the menisci were removed from the models. In ASF and ITM loadings the maximum contact pressure was observed on the medial tibial cartilage while in KAM and combined loading maximum contact pressure was on the lateral tibial cartilage. Figure 2 shows the contact pressure contours for pure ATS loading condition.

## CONCLUSIONS

The emphasis of this study was on the impact that modelling the menisci in FE models of the knee joint has in predicting ACL strain and resulting kinematics and contact pressures. The results presented herein showed a moderate impact on the kinematics at the knee joint under loads and impact representative of bipedal landing. Results showed increased contact pressure on the tibial cartilages in all cases.

Future efforts, including a more robust sample size, expanded loading conditions over larger ranges of

flexion, and varied material properties of the menisci (representative of pathology and variation inherent in the population) are warranted to further study the impact of the menisci on the knee joint as well as the relevance of their inclusion in finite element models of the knee. A total of three models were developed over the course of this study and will be included in future works. Our data suggest that due to decrease in cartilage pressure in the presence of menisci, healthy menisci in athletes may be helpful in preventing/delaying the onset of OA.

## INTRODUCTION

The quality of magnetic resonance- and ultrasound-based three-dimensional (3D) models in biomechanics research relies heavily on the ability to accurately represent muscle architecture in these models. It is important to investigate the accuracy, usefulness/functionality and validity of these biomedical image-based models, to ensure that they parallel biological conditions, since conclusions made from these models are often used to inform medical treatments and surgeries. Simple models are an excellent means by which to conduct preliminary research, as they allow for method refinement before investing resources into further MRI and ultrasound image acquisition, processing and complex model building.

The aim of this study was to demonstrate how a simple 3D computer aided drawing (CAD) muscle model can be created to match available architectural data of an *ex vivo* specimen. This method will be demonstrated with human medial gastrocnemius (MG) data measured *ex vivo* by anatomical inspection and ultrasound [1-3].

## METHODS

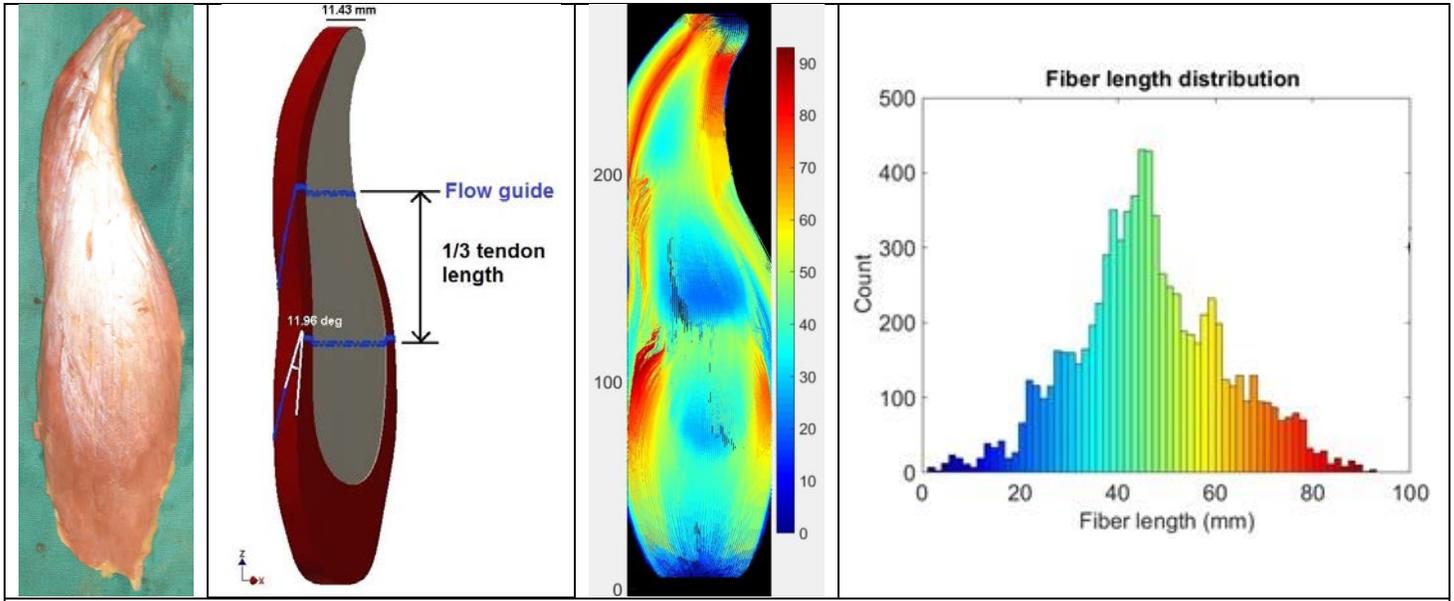

Lower limb muscle architecture data was collected from the cadaver of a 52 y-o, male subject (ht = 170.18 cm, wt = 74.84 kg) during a previous study [1]. At the time of data collection, photographs were taken of each muscle with tendons intact. A photograph of the medial gastrocnemius (MG) was imported into Autodesk Inventor (Autodesk Inc., San Rafael, CA) and a 2D outline of the muscle was made using interpolated splines, to obtain the frontal shape of the muscle. The drawing was scaled according to the muscle and tendon lengths in Table 1 (below). The 2D drawing was extruded to create an 11.43 mm thick 3D object. This thickness was selected based on the mean thickness

of an *ex vivo* MG from a 62 y-o male, measured by anatomical inspection [3]. The model was divided into 3 parts (proximal, central and distal) by two 0.5 mm cuts that a) ran from one-third the length of the proximal to one-third the length of the distal tendon and b) ran parallel to the first, and halved the remaining 2/3<sup>rds</sup> of both tendons (Figure 1B).

**Table 1:** *Ex vivo* medial gastrocnemius architectural data used to create the simple model.  $L_M$  = muscle length,  $L_{TIP}$  = length internal proximal tendon,  $L_{TID}$  = length internal distal tendon

Architectural Property	Measurement
Mass <sub>NoTendon</sub> (g)	175.73
$L_M$ (mm)	276.73
$L_{TIP}$ (mm)	210.80
$L_{TID}$ (mm)	211.35

These planes served as “flow guides” when the volume was exported to Simulation CFD (Autodesk Inc., San Rafael, CA), a computational fluid dynamics (CFD) software used as a Laplacian approach for defining muscle fiber tractography [4]. CFD material parameters were set to incompressible with fluid density and viscosity set to: 1 g/cm<sup>3</sup> and 1000 Pa-s, respectively, to ensure laminar flow. To simulate muscle fascicles running from tendon to tendon, inlet boundary conditions of 1 Pa pressure was set at proximal aponeurosis and an outlet condition of 0 Pa pressure at distal aponeurosis. All other surfaces were given a slip condition, which ensured laminar flow. The program’s automatic mesh function was used to generate a fine mesh for which fluid velocity vectors were obtained at each element upon completion of the flow simulation. Fiber tracts (lengths) were determined in MATLAB (Mathworks, MA) by calculating the lengths of streamlines generated from seed points set along the central YZ plane of the model (Figure 1C).

**Figure 1:** A) Photograph of *ex vivo* medial gastrocnemius (MG), B) 3D CAD model of MG, created using photograph and scaled to architectural measurements from same specimen, C) Fiber tracts throughout 3D MG model determined by computational fluid dynamics simulation, and D) fiber length distribution of all tracts in model

Fiber lengths were visually estimated from the simple model in three locations similar to those recorded in the *ex vivo* specimen [1]. The mass of the specimen was used to calculate its volume, assuming that density of muscle is  $1.056 \text{ g/cm}^3$ . The CSA of the coronal face of the model was used to find its volume. After model construction, pennation angle ( $\theta$ ) of the model was determined as the angle between the flow guides and the coronal face of the model. PCSA was calculated using the following formula [2], taking into account  $\theta$ :

$$PCSA (\text{cm}^2) = \frac{M (\text{g})}{\rho (\text{g/cm}^3)} \times \frac{\cos \theta}{Lf (\text{cm})}$$

## RESULTS AND DISCUSSION

The simple model captured the average fiber length and PCSA of the *ex vivo* specimen very well (Table 2). The average Lf was 52 mm for both the specimen and the model, thus the Lf/Lm ratio was the same at 0.19. The smaller volume of the model compared to the 52 y-o specimen volume was likely because the model's thickness measurement came from the more atrophied muscle of a 62 y-o specimen. The differences in pennation angles were attributed to the constraints of the CFD flow guides and the uniform thickness of the model. The model's angle is a function of its thickness, since the guides must dissect both the proximal and distal

tendons into thirds. Despite the model's smaller pennation angle, the PCSA of the model was  $29 \text{ cm}^2$  compared to  $31 \text{ cm}^2$  of the model, thus very similar.

**Table 2:** Comparison of the *ex vivo* medial gastrocnemius (MG) data and parameters of the simple model.  $Lf_{\text{ave}}$  = average fiber length of 3 different locations

Source	Volume ( $\text{g/cm}^3$ )	$Lf_{\text{ave}}$ (mm)	$\theta$ ( $^\circ$ )	PCSA ( $\text{cm}^2$ )
<i>Ex vivo</i> MG	166.41	51.86	18.33	30.52
Simple model	153.10	51.67	11.96	28.99

This study shows that a simple CAD model can recapitulate *ex vivo* architectural data very similarly and may be useful in the initial stages of image-based muscle modeling research for fine-tuning and sensitivity analyses of dynamic and finite element simulations, for example. Other muscles with different architectural arrangements should be modeled similarly to determine if this method is applicable to all muscles.

# STRAIN ANALYSIS ON THE FEMORAL NECK USING FINITE ELEMENT MODEL DURING STAIR NAVIGATION

<sup>1</sup>Chen Deng, <sup>1</sup>Jason C. Gillette, <sup>1</sup>Timothy R. Derrick

<sup>1</sup>Iowa State University, Ames, IA, USA

email: [chend@iastate.edu](mailto:chend@iastate.edu), web: [http:// www.kin.hs.iastate.edu/](http://www.kin.hs.iastate.edu/)

## INTRODUCTION

Femoral neck stress fractures are among the most serious of all types of stress fractures [1,2]. Understanding the loading environment is a crucial factor for reducing their incidence [3,4]. The loading at the femoral neck can be estimated by applying activity specific loading, (muscle forces and joint contact forces) to the finite element model of the femur. In this study, the purpose was to analyze both tensile and compressive strains at the femoral neck during stair ascent and descent.

## METHODS

17 older adults (7 males, age:  $60 \pm 6$  yr, body mass:  $75 \pm 14$  kg, height:  $1.73 \pm 0.05$  m; 10 females, age:  $57 \pm 5$  yr, body mass:  $67 \pm 8$  kg, height:  $1.67 \pm 0.05$  m) with no lower limb injuries volunteered to participate. All subjects performed 5 successful trials of stair ascent and the same number trials of descent with a 3-stair staircase. Motion capture data (120 Hz, Vicon MX, Vicon, Centennial, CO, USA) and force data (120 Hz, AMTI, Watertown, MA) were collected during each trial.

Raw force data and motion capture data were input into Matlab programs and low-pass filtered at 6 Hz. Inverse dynamics and rigid body assumptions were used to calculate 3-D joint moments and reaction forces at the hip, knee and ankle of the right leg. A musculoskeletal model was used to obtain maximal dynamic muscle forces, muscle moment arms and orientations for 44 lower limb muscles [5]. Static optimization was used to select a set of muscle forces that minimized the sum of the squared muscle stresses and balanced the sagittal plane hip, knee and ankle moments, frontal plane hip moment, and the transverse plane hip and ankle moments with the external moments for each frame of data. Muscle forces and joint reaction forces were summed to estimate the 3-D hip joint contact forces.

Hip joint contact forces and 27 muscle forces attaching on the femur were used in the Matlab program to write input model files for FEBio software, which ran the finite element analysis for the entire femur during peak resultant hip joint contact forces for both first and second half of the stance phase.

The maximum compressive and tensile strains during the two hip joint contact force peaks on the cross-section of femoral neck were identified. Differences in maximum tensile and compressive strains during hip joint contact force peaks between stair ascent and descent were assessed by paired t-tests with 2 tails ( $\alpha = 0.05$ ).

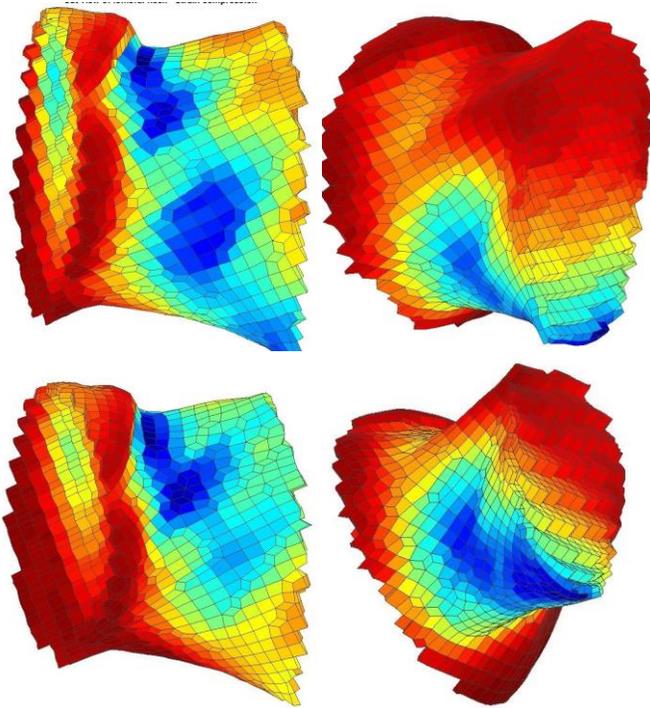

## RESULTS AND DISCUSSION

Both of the compressive and tensile maximum strains were reported at the time of peak hip joint contact force during stair ascent and descent.

For the compressive strains, stair descent produced greater maximum strains than stair ascent at peak 1 of the hip joint contact force (stair ascent:  $-853.2 \pm 381.2$   $\mu\text{s}$ , stair descent:  $-1133.6 \pm 883.0$   $\mu\text{s}$ ,  $p = .0079$ ) and peak 2 (stair ascent:  $-781.8 \pm 372.4$   $\mu\text{s}$ , stair descent:  $-1120.4 \pm 939.8$   $\mu\text{s}$ ,  $p < .001$ ).

The increased compressive strains during stair descent could be caused by the impact of the initial foot contact on the ground at peak 1, and greater acceleration during push off at peak 2.

In Figure 1.1, greater compressive strain was located at the superior-posterior side for stair ascent, while the inferior side had more compressive strains for stair descent.

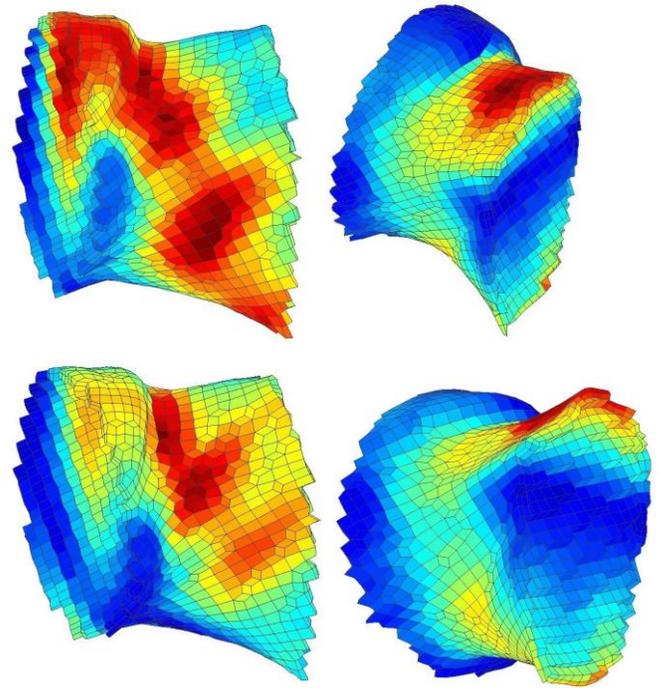

**Figure 1.1:** The compressive strain distribution for the femoral neck: top-left (peak 1 for stair ascent, posterior view), top-right (peak 1 for stair descent, posterior-lateral view), bottom-left (peak 2 for stair ascent, posterior view), bottom-right (peak 2 for stair descent, posterior-lateral-inferior view).

There was no statistical difference for the tensile strains at both peaks of the hip joint contact force between stair ascent and descent (peak 1:  $p = 0.374$ , peak 2:  $p = 0.967$ ). The tensile strains were similar between stair ascent and descent for both peak 1 (stair ascent:  $1769.2 \pm 810.9 \mu\text{s}$ , stair descent:  $1574.1 \pm 1476.9 \mu\text{s}$ ) and peak 2 (stair ascent:  $1544.4 \pm 713.6 \mu\text{s}$ , stair descent:  $1519.9 \pm 1568.3 \mu\text{s}$ ).

It is likely that stair ascent and descent did not produce tensile loading on the femoral neck differently. This may be due to the activities of the hip abductor muscles, which could counter the large adductor torque caused by the torso weight.

In Figure 1.2, greater tensile strain was located at the superior-posterior side for stair ascent, while the maximum tensile strains occurred at the superior side for stair descent.

**Figure 1.2:** The tensile strain distribution for the femoral neck: top-left (peak 1 for stair ascent, posterior view), top-right (peak 1 for stair descent, posterior-lateral-anterior view), bottom-left (peak 2 for stair ascent, posterior view), bottom-right (peak 2 for stair descent, posterior-lateral-inferior view).

## CONCLUSIONS

At the femoral neck, the compressive strains increased during stair descent compared to ascent, while the tensile strains did not change. Since the finite element (FE) model was based on only one cadaver, the FE model with more individualized bone geometry and material properties (CT or MRI) could improve estimates of bone strain.

# A Zero-Feedback and Stable Running Model Controlled by a Central Pattern Generator

Samuel Masters, Justin Wager, and John Challis

The Pennsylvania State University, University Park, PA, USA  
email: sem361@psu.edu

## INTRODUCTION

The trajectory of the whole-body center of mass (COM) during human running is similar to that of a spring-loaded inverted pendulum (SLIP). Humans passively store and release energy, and actively produce energy during running. The triceps surae are the main contributors to propulsion during running [1]. The gross motion of the center of mass during the stance phase is mostly due to knee and hip kinematics. Thus, a simple two-body SLIP model that represents the lower and upper bodies and has an active propulsive phase should be sufficient to capture many aspects of human running.

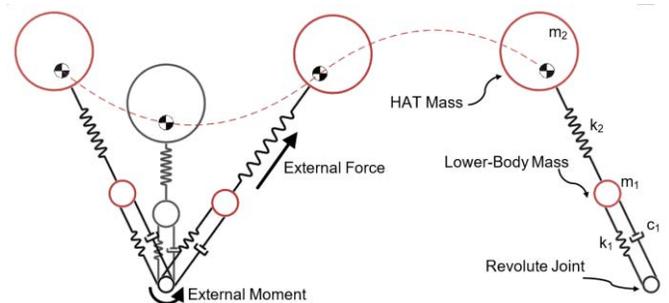

Stability has been studied in human locomotion. However, the majority of these studies center around human walking and their asymptotically stable robotic and model counterparts. Human running does not have an asymptotically stable model counterpart. We will propose and analyze an asymptotically stable running model that can be used to study the stability and energetics of human running.

## METHODS

The SLIP model contained two masses, a spring connecting the upper body to the lower body, and a spring-damper connecting the lower body to the ground (Fig. 1). The springs had a constant stiffness and nonlinear dampening. The dampening was a function of the dampening constant, spring compression, and spring compression velocity.

The SLIP model was powered by an external moment at the spring-ground interface and a propulsive force (PF) that accelerated the whole system COM. The moment was directly proportional to the PF. The propulsive phase of the gait cycle

started when the COM was past vertical and ended when the spring connecting the ground to the lower leg approached its resting length. A tanh function was utilized in order to enforce a zero PF and external moment before and after the propulsive phase.

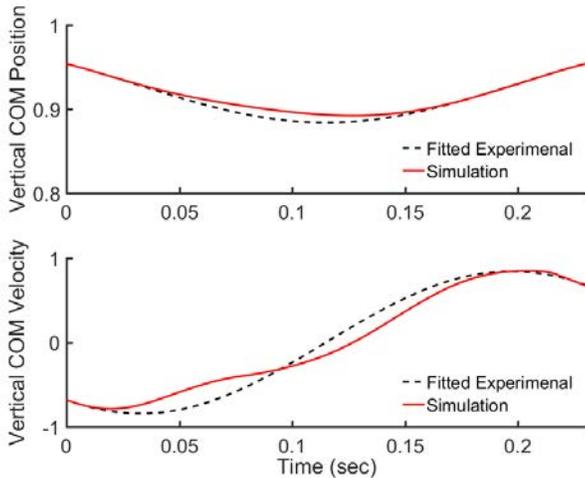

**Figure 1:** Two-mass SLIP model of running with a stance and flight phase.

Stance phase kinematics and vertical ground reaction forces (GRFs) from 10 college-aged male subjects were used to determine the parameters of the model. The COM vertical position and velocity were fitted with a sine wave to enforce smoothness and cyclical kinematics. A particle swarm optimization was utilized to determine the best set of parameters for matching the modeled fit for each subject's kinematics and the magnitude and timing of the impact and active force peaks of the vertical GRF. Following the optimization, the SLIP model was simulated until its step cycle converged to a period-one gait cycle.

The PF and initial ground-contact angle were tuned such that the horizontal velocity of the model match that of each subject during stance phase. The flight-phase kinematics were determined using constant acceleration equations of motion and the next stance cycle proceeded when the COM height was at the experimental COM height during foot-ground contact.

A simple measure of stability was utilized to assess the SLIP model's performance. The spring attaching the lower body to the ground was increased in stiffness by 100% for a single step cycle to simulate a local change in the stiffness in terrain. The number of steps that the model took until the COM velocity kinematics converged to within  $10^{-3} \text{ m}\cdot\text{s}^{-1}$  of the period-one gait cycle were counted (Fig. 3).

**Figure 2:** The stance phase vertical COM trajectory for a typical experimental trial (black, dotted line) and the SLIP model (red, solid line).

## RESULTS AND DISCUSSION

All units containing force were normalized with respect to subject body weight (BW). The mean spring stiffness for the lower and upper springs were  $309 \pm 27 \text{ BW}\cdot\text{m}^{-1}$  and  $224 \text{ BW}\cdot\text{m}^{-1}$ , respectively. The dampening constant was  $18.8 \pm 5.1 \text{ BW}\cdot\text{s}\cdot\text{m}^{-1}$ . The mean PF and PM were  $7.2 \pm 1.5 \text{ BW}$  and  $2.1 \pm 1.0 \text{ BW}\cdot\text{m}$ . The weight of the lower and upper bodies were 0.165 BW and 0.835 BWs.

The vertical COM position and velocity of the SLIP model matched that of the fitted experimental data

(Fig. 2). The vertical COM position of the SLIP model was always within 10% of the experimental data. The mean horizontal velocity was  $2.9 \text{ m}\cdot\text{s}^{-1}$  and vertical velocity at foot-ground contact was  $0.72 \text{ m}\cdot\text{s}^{-1}$ . On average, the magnitude of the impact and active peaks of the GRF were within 9.1% and 8.5% of the experimental vertical GRF.

None of the models failed to converge following a perturbation to the lower body spring stiffness. The mean number of steps that each model took before converging to the limit cycle was 31.4 steps (Fig. 3). Generally, the models with a higher spring stiffness took longer to converge.

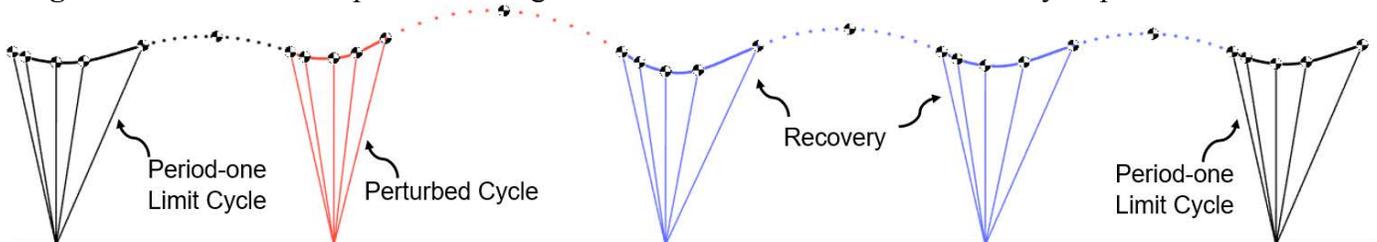

Due to the simplicity of the model and the exclusion of a feedback controller, it can be used to study many of the same aspects that we study in simple, bipedal walkers. Some of those aspects include local, orbital, and global stability measures (e.g., Lyapunov Exponents, Floquet multipliers, and the basin of attraction), the energetics of running (e.g., dissipation, storage, and return of energy), and the whole-body or segmented body COM trajectories during running (e.g. control strategies for locomotion).

We have introduced a model of running that expands on the SLIP model of running [2] to include a CPG. The model is asymptotically stable, requires no control feedback for sufficiently small perturbations, and can mimic the kinematics and dynamics of the COM during human running.

## INTRODUCTION

A ground contact model is essential for forward dynamic simulations because it determines the forces applied to the skeletal system to generate a movement. A previous strategy has been to model the ground contact of human walking with viscoelastic elements which generate force as the foot penetrates the surface in forward dynamic simulation [1]. The viscoelastic model is physically based upon the material properties of the shoe, ground surface and foot [2]. Although this model is able to produce accurate results, development and verification of the model has to be done within the context of forward dynamic simulations and errors can be masked by an array of other uncertainties within the simulation. Moreover, the previous model is for humans and cannot be applied to other animals. Thus, a ground contact model which is linked to the joint kinematics could be developed and verified more easily.

A focus of our research is to elucidate the mechanisms of extreme jumping performance in kangaroo rats. To perform forward dynamic simulations of vertical jumping, we need to develop a ground contact model. Ideally, there would be only one viscoelastic element that is linked to the joint kinematics, so that it could be developed and verified through experimental data. To this end, we defined a virtual displacement for foot segment based upon midfoot angle and then calculated force by applying this displacement to a viscoelastic element. We found model parameters from experimental data and assessed model accuracy using different experimental trials with a range of jump heights.

## METHODS

### *Experimental Data*

Kinematic and kinetic data of a kangaroo rat (weight 0.11 kg) were collected during 5 different vertical jumps over barriers 30 to 40 cm in height. A high

speed video system (250 Hz) recorded the kinematics of the jump, which was used to calculate joint angles. Ground reaction force data were collected simultaneously by using a force platform (600 Hz).

### *Ground Contact Model*

We chose to link the viscoelastic model to rotation of the metatarsal-phalangeal (MTP) segment for two reasons: empirically, the MTP kinematics was most closely correlated to the time-course of the ground reaction force; and theoretically, the MTP joint could act as a passive rotational spring due to the anatomy of the kangaroo rat foot. Contact force between the toe and the ground was generated by one viscoelastic element attached to the toe at a distance of  $r$  from MTP joint. The amount of virtual motion of the viscoelastic element has determined by rotation of the MTP joint minus the amount of vertical motion of the MTP joint (*i.e.*, movement away from the ground). This amount was calculated according to:

$$z = -(\cos(\theta))^2(r \cdot \sin(\theta) - z_{midfoot\ joint}) \quad (1)$$

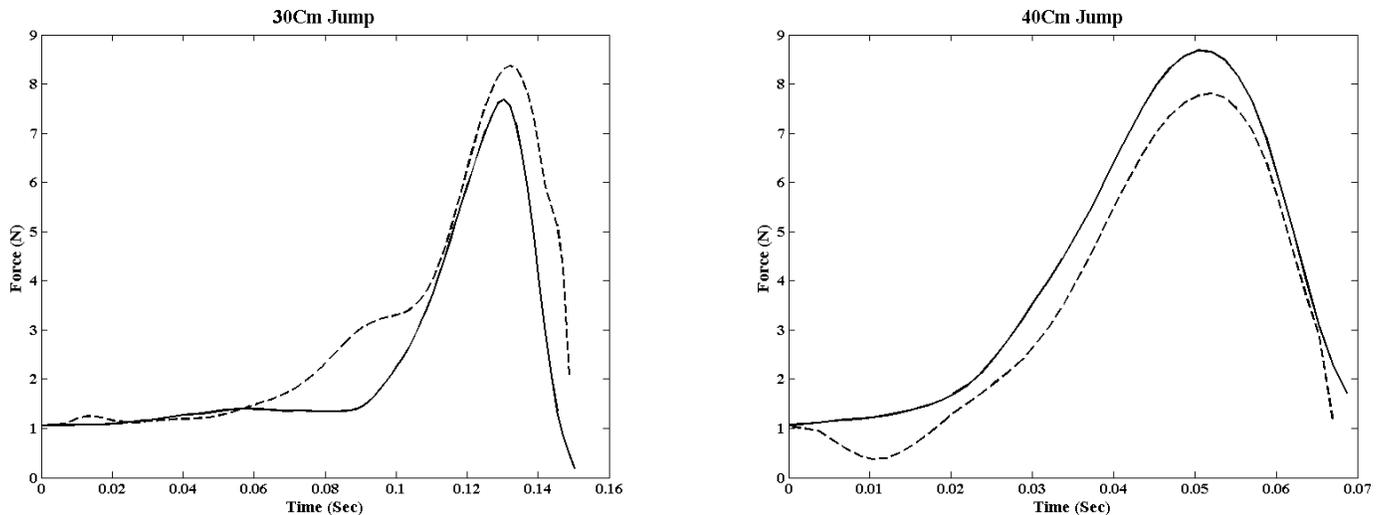

where  $r$  = distance of attachment point to MTP joint (15 mm),  $\theta$  = angle of MTP segment (relative to horizontal) minus the initial MTP angle (*i.e.*, the change in angle from the initial posture) and  $z_{midfoot\ joint}$  = MTP joint vertical coordinates. Note that the additional cosine term is to account for less contact area of toe segment on the ground (*i.e.*, less contact with the viscoelastic element).

Force produced by the viscoelastic element was calculated as:

$$F = C_f(c_1z + c_2\dot{z}) \quad (2)$$

where  $F$  = change in vertical force from the initial ground reaction force (equaling body weight) and  $c_1$  and  $c_2$  are foot specific parameters of the viscoelastic element.  $C_f$  is a correction factor that is based on initial posture:

$$C_f = 1 + \theta(t = 0) \quad (3)$$

**Figure 1.** Experiment (solid line) and simulation (dashed line) force for lowest and highest jump heights.

This correction factor was necessary because the model only used MTP rotation and vertical position, so more extended initial postures needed larger viscoelastic coefficients to maintain body weight. The correction factor ranged from 1.13 to 1.52. The model coefficients in equation (2) were optimized to fit the simulation force with experimental data according to least squared error, and they were kept constant for all trials.

## RESULTS AND DISCUSSION

Model coefficients were optimized as  $c_1 = -1200 \text{ N/m}$  and  $c_2 = -1.5 \text{ N.s/m}$ . Simulated and experimental force compared well across the range of jump heights (Fig. 1). To assess the accuracy of the simulation, we used temporal and amplitude metrics. For temporal accuracy, the average difference between the time of the simulated and experimental peak force was found to be 3.9 ms. For amplitude accuracy, the average difference in peak magnitude was 0.7 N (equivalent to 9.8% error compared to the experimental value). Overall, the simulations also showed the same shape over time as the experimental data.

The physical premise of the model was that the MTP joint acts like a rotational spring that generates the ground reaction force. Our results indicate that the rotational spring analogy might be a reasonable approximation of the mechanics of the kangaroo rat

foot, which has an anatomy distinctive to many bipedal hoppers.

## CONCLUSIONS

In this study, ground contact forces produced by vertical jumps of a kangaroo rat were predicted from the rotation and vertical displacement of the MTP segment. A disadvantage of this model was the need for a correction factor based upon initial posture. However, the correction factor could indicate a change in foot mechanics as the initial posture changes. In conclusion, this strategy would be useful in forward dynamic simulations because:

- The predictions are computationally efficient with only the MTP joint kinematics involved.
- It predicted the time of the peak ground reaction force accurately and provided a reasonable estimate of the magnitude of the peak ground reaction forces.

# VERBAL FEEDBACK DURING A SINGLE RUNNING RETRAINING SESSION: BIOMECHANICAL EVIDENCE OF A POSITIVE OUTCOME

Katherine Sharp, Julianne Stewart, Jenny Anne Maun, Kimberly Rowe, and Marilyn Wyatt  
Naval Medical Center San Diego, San Diego, CA USA  
email: katherine.sharp5.ctr@mail.mil

## INTRODUCTION

The Intrepid Dynamic Exoskeletal Orthosis (IDEO®) is a carbon fiber ankle-foot orthosis designed to return the wounded service member to a high level of functional activity. When a patient receives this custom-made orthosis, participation in the Return to Run (RTR) program is mandatory. This program teaches patients many skills which include running with a midfoot strike pattern to both maximize energy return from the brace and protect the knee from hyperextension [1]. The process of converting to a midfoot strike pattern can be challenging and time-consuming, and a majority of runners are natural heel strikers [2, 3]. Therefore, the purpose of this case study was to investigate the immediate impact of a single, brief running retraining session on foot strike pattern and kinematics of an IDEO user.

## METHODS

A portable motion capture system was used to capture overground running data on a male (age 40y/o; height 1.8m; weight 87.54kg) active-duty service member using the IDEO due to a pilon fracture secondary to a 60ft fall while repelling. The patient completed the RTR program before this biomechanical evaluation. A full-body six degrees of freedom marker set was used and 12 motion capture cameras (Motion Analysis Corp., Santa Rosa, CA, USA) collected kinematic data at 300 frames per second while the patient ran down a 50m runway at his self-selected speed. Data were post-processed using Visual 3D (C-Motion Inc., Germantown, MD, USA), and a fourth-order, low-pass Butterworth filter with a cutoff frequency of 8Hz was used.

Motion data were captured before (PRE) and after (POST) a retraining session. No form-related

instructions were given during the data capture sessions. Upon completion of the PRE session, it was apparent that the patient was landing with excessive knee extension at initial contact and maintaining this position throughout the stance phase (Fig. 1). This information was then used to structure the brief retraining session.

**Figure 1:** Patient exhibits excessive knee extension at initial contact and throughout the stance phase prior to gait retraining.

A verbal retraining session was performed on a standard treadmill without motion capture. This session consisted of the patient warming-up for five minutes at his self-selected speed followed by researchers and clinicians providing feedback for an additional five minutes. The feedback consisted of verbal cues to shorten step length (i.e. “take shorter steps”) and to increase step rate (i.e. “quicker turnover”). Both modifications were successfully accomplished during this period of time.

## RESULTS AND DISCUSSION

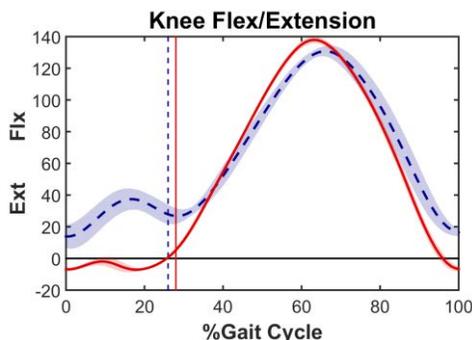

The patient ran at similar velocities during the PRE and POST testing sessions indicating differences were not due to a change in velocity (Table 1). He successfully increased his step rate by 3.3 steps/min and decreased his stride length by 0.2m in response to verbal feedback from PRE to POST.

Additionally, the patient's step length symmetry improved (Table 1).

This patient is similar to most runners in that the transition from a heel strike to a midfoot strike pattern while running presented difficulty. However, initiating a focused, long-term retraining program was not an option because the patient is active-duty military and stationed an hour from the biomechanics laboratory. The retraining technique used in this study was inspired by Wood & Kipp (2014) who successfully reduced tibial peak positive acceleration in runners after five minutes of audio biofeedback. Similarly, after the brief retraining session using verbal feedback, the patient successfully landed with a flexed knee at initial contact (Fig. 2), which drastically improved his knee kinematics throughout the gait cycle (Fig. 3).

**Figure 2:** Patient exhibits improved knee flexion at initial contact following a brief retraining session.

**Figure 3:** Average knee flexion/extension on the right (IDEO) side over 100% of the gait cycle during pre-training (red solid line) and post-training (blue dashed line). Vertical lines represent toe-off.

Considering the patient's reported daily use of the IDEO for work and recreation, maintenance of his increased knee flexion at initial contact, increased step rate, and decreased stride length should lower his risk for injury [3].

## CONCLUSIONS

The brief patient retraining session used verbal feedback that focused on stride length and step rate while the patient ran on a treadmill. Subsequently, during overground running, improvements were found in his foot strike pattern and knee kinematics. The patient was provided feedback on these positive outcomes and will participate in a future study to see if improvements have been maintained. Understanding the value of brief retraining sessions compared to longer, more involved retraining programs is a question for continued research.

# INFLUENCE OF ILIOTIBIAL BAND SYNDROME ON PELVIS – THIGH COUPLING AND COUPLING VARIABILITY DURING RUNNING

<sup>1</sup>Eric Foch, <sup>2</sup>David Ebaugh, and <sup>2</sup>Clare E. Milner

<sup>1</sup>Central Washington University, Ellensburg, WA, USA

<sup>2</sup>Drexel University, Philadelphia, PA, USA

email: [eric.foch@cwu.edu](mailto:eric.foch@cwu.edu)

## INTRODUCTION

Healthy running involves inter-segmental coupling variability. However, too much or too little variability may result in abnormal soft tissue strains resulting in overuse running injuries [1] such as iliotibial band syndrome (ITBS). Typically, iliotibial band mechanics during running are inferred from the peak hip adduction angle [2, 3]. Yet, discrete analysis does not indicate if contralateral pelvic drop or thigh adduction contributes more to hip adduction and how pelvis – thigh coupling varies during stance.

Vector coding provides a continuous measure of pelvis – thigh coupling angles. Coupling angles and coupling variability can be determined via two vector coding approaches [4, 5]. However, it is unknown if the two approaches yield similar results. Therefore, the purpose of this study was to determine if contralateral pelvis drop/elevation – thigh abduction/adduction coupling and coupling variability differed among female runners with current ITBS, previous ITBS, and controls according to the vector coding approach used. We hypothesized that contralateral pelvis drop/elevation – thigh abduction/adduction coupling would be similar among groups with both vector coding methods. Second, we hypothesized that runners with current ITBS would exhibit less variability than runners with previous ITBS and controls regardless of the vector coding approach.

## METHODS

The Institution's Human Subjects Review Board approved all procedures prior to beginning the study. Twenty-seven female runners between the ages of 18 and 45 provided written informed consent. Runners comprised three equal groups: current ITBS (age: 26.2 (7.9) yrs; height: 1.64 (0.04) m; mass: 53.3 (3.7) kg), previous ITBS (age: 24.7 (5.2) yrs; height: 1.68

(0.03) m; mass: 61.7 (9.9) kg), and controls (age: 25.3 (7.0) yrs; height: 1.71 (0.05) m; mass: 59.6 (5.2) kg) [3]. A secondary analysis of an existing running data set was performed [3]. The two vector coding approaches computed the coupling angle from 0° – 90° (VC90) [4] or 0° – 360° (VC360) [5]. The stance phase was normalized to 100%. Pelvis – thigh coupling angles were determined from relative motion plots. Relative motion plots were divided into four periods: Period 1 (0-20%), Period 2 (~20-50%), Period 3 (~50-75%), and Period 4 (75-100%). At each percent of stance for the five trials, the coupling angle was computed. Coupling angles were averaged across trials, and the mean coupling angle was determined for each period of stance. Coupling variability was computed as the standard deviation of the pelvis – thigh coupling angles for each percent of stance across the five trials [4, 5]. For VC90, a coupling angle <45° indicated greater pelvis motion relative to the thigh. Whereas a coupling angle >45° indicated greater thigh motion relative to the pelvis. In-phase coupling (pelvis and thigh move equal amounts) was exactly 45°. [4] VC360 defines pelvis phase (337°-22.5° and 157.5°-202.5°), thigh phase (67.5°-112.5° and 247.5°-292.5°), and in-phase couplings (22.5°-67.5° and 202.5°-247.5°) on the entire unit circle. Additionally, VC360 defines anti-phase coupling relationships (pelvis and thigh move in opposite directions; 112.5°-157.5° and 292.5°-337.5°), whereas VC90 cannot define this pattern. [5] Two multivariate analysis of variance (MANOVA) were performed: 1) coupling angles for each period of stance; 2) coupling variability for each period of stance. *Post hoc* Fisher's test was used when a main effect was found ( $\alpha = 0.05$ ).

## RESULTS AND DISCUSSION

Contralateral pelvis drop/elevation – thigh abduction/adduction coupling angles were similar among groups during each period of stance for VC90

and VC360 (Table 1). However, coupling variability was different among groups via the VC90 approach during initial loading (Period 1;  $P = 0.004$ ) and late stance (Period 4;  $P = 0.002$ ). During initial loading and late stance, runners with previous ITBS demonstrated greater coupling variability compared to the current ITBS ( $P = 0.002$  and  $P = 0.003$ , respectively) and control ( $P = 0.006$  and  $P = 0.001$ , respectively) groups. Coupling variability was similar among groups via the VC360 approach.

No pelvis – thigh coupling differences among groups suggests ITBS injury status does not affect frontal plane inter-segmental motion during stance. Similarly, hip adduction/abduction – hip internal/external rotation coupling angles did not differ between women with current ITBS and controls during stance via the VC90 approach [2]. Differences in frontal plane pelvis – thigh coupling and transverse – frontal plane hip coupling may not be associated with ITBS. However, the pelvis – thigh phase relationships differ between VC90 and VC360 approaches. The average coupling angle computed via VC90 indicated a pelvis phase throughout stance. Whereas all groups exhibited in-phase pelvis – thigh coupling from ~50-75% of stance via VC360. During late stance, the average coupling angle indicated anti-phase pelvis – thigh coupling among groups.

During initial loading and late stance, absolute mean variability differences across groups between VC90

and VC360 ranged from  $0.3^\circ$  to  $1.7^\circ$  and  $2.4^\circ$  to  $8.6^\circ$ , respectively. Thus, small mean differences may indicate the greater variability demonstrated by runners with previous ITBS via VC90 but not VC360 was due to chance. No previous ITBS study has reported VC360 coupling variability. However, the patellofemoral pain literature indicates VC360 knee – rearfoot coupling variability differences between women with and without patellofemoral pain is the exception rather than the norm [1].

## CONCLUSIONS

Contralateral pelvis drop/elevation – thigh abduction/adduction coupling angles were similar among runners via VC90 and VC360 approaches. However, VC360 provided additional detail compared to VC90 by classifying two additional phases: in-phase and anti-phase pelvis – thigh coupling. Greater pelvis – thigh coupling variability in the previous ITBS group identified via VC90 but not VC360 should be interpreted with caution.

# Changes in Limb Symmetry during a 2 Mile Outdoor Run

## INTRODUCTION

The presence of side-to-side asymmetry is known to increase injury risk during running and other dynamic activities. Additionally, fatigue has been shown to affect the body's loading patterns over the course of a high-endurance run<sup>1</sup>. Previous research has focused on the use of instrumented treadmills to collect running data during long distance runs with no previous work examining these changes during prolonged overground running<sup>2</sup>. Reports have proven that joint mechanics, loading, and temporal variables differ on a treadmill compared to an overground environment<sup>3</sup>, including the peak value of the ground reaction forces<sup>4</sup>.

Despite the various studies pertaining to asymmetry in runners, the impact that fatigue has on side-to-side asymmetry has never been assessed in an overground running study. Therefore, this study investigated the impact of fatigue on loading symmetry during a 2 mile run on an outdoor course. We hypothesize that the LSI will increase during the run as the subject begins to fatigue.

## METHODS

27 subjects (Table 1) completed a 2 mile overground run wearing single-sensor, load monitoring insoles (pedoped, Novel Electronics, St. Paul, MN). These measured the subjects' normal in-shoe ground reaction forces sampled at 100 Hz throughout the duration of the run. An iPod Touch (5<sup>th</sup> generation, Apple Inc, Cupertino, CA) was used to collect the vGRF data via Bluetooth connection while being secured to the runner in a running pouch worn on the waist in a position that was comfortable for each subject. Each subject ran the same 2 mile course.

Subjects were allowed to run in their own training shoes to decrease the influence of a novel shoe condition. The forces from twenty-step intervals were pulled for each limb at 25%, 50%, and 75% of the run to determine how limb symmetry changed

throughout the run. Using a custom Matlab script (Mathworks, Natick, MA), the overall peak and impact peak (when present) was identified for each step. For each subject, a limb symmetry index (LSI) was calculated for each step for both the impact peak and the overall peak using the equation below. The LSI values were then averaged at each time point (25%, 50%, and 75% of the run) for each subject.

$$LSI = \frac{|Left\ Peak - Right\ Peak|}{0.5 * (Left\ Peak + Right\ Peak)}$$

To analyze the results, the LSI values were first tested for normality using the Shapiro-Wilks test. Then either a 1x3 repeated measures ANOVA or a non-parametric Wilcoxon test was conducted to determine differences in symmetry across time (JMP, SAS, Cary, NC). Finally, a non-parametric Wilcoxon signed rank test was completed to determine differences between the LSI impact peak and the LSI overall peak at each time point individually. For all statistical tests, a type I error rate of  $\alpha=0.05$  was used to determine statistical significance. A gender comparison was not completed on this data as we would like to have a greater number of subjects, 20 males and 20 females, before analyzing the potential differences between male and female runners.

**Table 1:** Subject Demographics

	Male (n=16: 59.2%)	Females (n=11: 40.7%)
Age (years)	22.93 ± 2.93	21.92 ± 3.04
Height (m)	1.81 ± 0.07	1.66 ± 0.05
Weight (kg)	77.78 ± 9.54	59.73 ± 4.34
Weekly Mileage (miles)	10 ± 6	16 ± 9

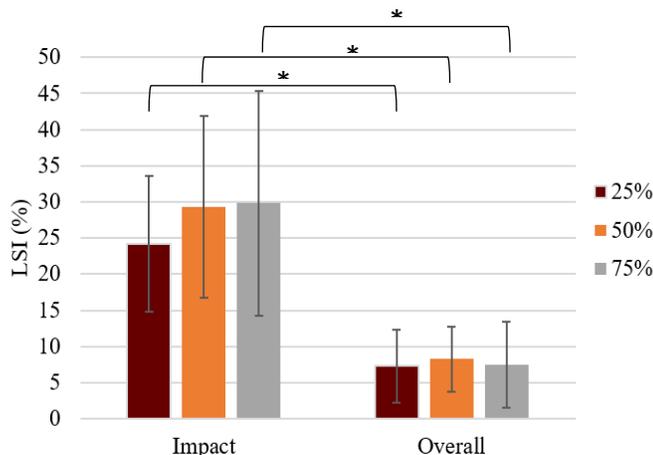

## RESULTS AND DISCUSSION

The mean time taken to complete the 2 mile run was 14:52 ± 1:51 minutes for men and 15:38 ± 1:26

minutes. Our limb symmetry indexes are reported in Figure 1. Previously reported symmetry indexes are 3.1% for the peak vertical GRF and 12.6% for the vertical impact peak for a short (25m) indoor run over force platforms<sup>5</sup>. While our LSI values are higher than what has been reported, the previous articles all considered indoor or treadmill running which provides a consistent and predictable running environment compared to outdoor overground running.

The LSI values calculated from the overall peak load were not normally distributed while the LSI values from the impact peak were normally distributed. Therefore, overall peak LSI analyses will be completed with non-parametric tests and the impact peak LSI analyses will use parametric tests. There was no difference in overall peak load LSI across time ( $p>0.229$ ) as determined through non-parametric statistics. In addition, no differences in impact load LSI existed across time ( $p=0.207$ ) (Figure 1).

When the LSI values calculated from the impact load were compared to the values calculated by the overall peak load, we found a significant difference between groups, with the impact peak LSI being greater ( $p<0.001$ ). While the impact peak LSI values are higher than those previously reported, the results of the current study are similar to previous work that indicated that the LSI was greater for the impact peak LSI than for the overall peak LSI<sup>5</sup>.

**Figure 1:** The mean LSI value and standard deviation for each time point (25%, 50% and 75%) of the run is shown above. The \* indicates a difference between the impact LSI and overall LSI values.

The lack of change in LSI across time does not support the study hypothesis. At the end of each run, we spoke to the participants about the difficulty of the run and their level of fatigue. During these discussions it was clear that most of the participants were experienced runners who were currently training for 10K, half marathons and full marathons races. Therefore, it is likely that the 2 mile course that was being completed was not challenging enough to result in changes in loading symmetry due to fatigue. In future studies that are designed to assess the impact of fatigue on loading symmetry might need to be completed on a more challenging course, require that the subjects complete the course in a pace that is similar to their race speed or have the subjects complete a longer run in order to increase the level of fatigue. In addition, future work could include the assessment of a rate of perceived excursion at the end of the run to be able to include this measure as a covariate in the statistical analysis.

## CONCLUSION

We did not see any difference in LSI across time using either the impact peak or the overall peak values. There was a difference between the LSI collected at the impact peak and the LSI determined from the overall peak value. These results indicate that the subjects use a portion of the stance phase after the impact peak to alter the loading pattern in order to improve their limb asymmetry by the time they reach the peak overall load during running.

## INTRODUCTION

Knee osteoarthritis (OA) is a common occupational hazard for members of the armed services. In fact, the incidence of knee OA in service members has recently increased [1]. Knee OA develops by repeatedly placing abnormal loads on the joint during weight-bearing activity, such as locomotion. Specifically, knee OA is associated with greater lateral knee motion (i.e., varus thrust) and subsequent loading of the medial knee joint compartment during weight-bearing activities [2, 3]. During weight-bearing, varus thrust (i.e., an abrupt increase in the knee adduction angle of 3° or more) increases the incidence, progression and severity of OA [2, 3]. During military activities, service members routinely run with body borne loads that exceed 30% of their body weight. These body borne loads produce significant adaptations in lower limb biomechanical profile, elevating the loads placed on the knee joint during locomotion [4]. The elevated loads may contribute to the increased incidence of OA by exaggerating lateral motion and medial compartment loading for service members that present varus thrust. With that in mind, the purpose of this study was to quantify how body borne load impacts knee biomechanics for participants who present varus thrust during running.

## METHODS

Eighteen male military personnel (age:  $20.2 \pm 3.3$  yrs, height:  $1.8 \pm 0.6$  m, weight  $19.0 \pm 10.8$  kg) had 3D knee joint biomechanical data recorded during an over-ground run task. Each participant performed the run task with three load conditions: light (NL), medium (ML) and heavy (HL). For the NL, participants wore equipment (helmet, boots and mock weapon) that weighs ~ 6 kg. For ML (15% of BW) and HL (30% of BW), participants wore a weighted vest (WeightVest.com Inc. Rexburg, ID, USA) that was adjusted to have the total load (vest plus NL equipment) equal either 15% or 30% of their

BW. With each load, participants performed three successful runs. Each run required participants run at 4.0 m/s down a 10-m walkway and contact a force plate (Optima, AMTI, Watertown, MA, USA) with their dominant limb.

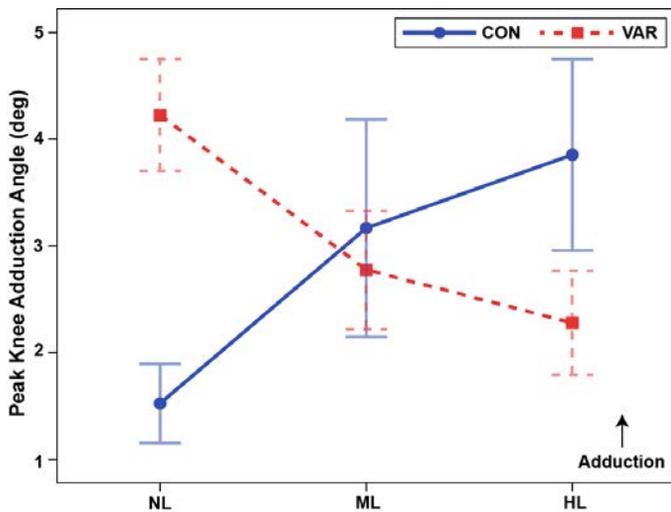

During each run, knee biomechanics were quantified from 3D trajectories of 36 reflective markers recorded with twelve high-speed (240 fps) optical cameras (Opus, Qualysis AB, Gothenburg, Sweden). After securing each marker on the participant, a stationary recording was taken to create a kinematic model with seven skeletal segments (bilateral foot, shank and thigh, and pelvis segments) and 24 DoF. During each run, synchronous GRF data and marker trajectories were low pass filtered with a fourth-order Butterworth filter (12 Hz). The filtered marker trajectories were processed to solve joint rotations at each time frame, and filtered kinematic and GRF data were processed to obtain knee joint moments using Visual 3D (C-Motion, Rockville, MD).

Each participant had varus thrust quantified as the range of knee adduction motion exhibited from heel strike to mid-stance (0% - 51%) during the NL run. Varus participants (VAR, N = 9) exhibited knee adduction equal to or greater than 3° [2, 4]; whereas, control participants (CON, N = 9) exhibited less than 3° of knee adduction motion.

For analysis, dominant limb peak knee adduction joint angle and moment exhibited during weight-bearing (0% - 51%) were quantified. Subject-based means for each measure were calculated and submitted to a RM ANOVA to test the main effects of and possible interactions between load (NL, ML and HL) and group (VAR vs CON). Where statistically significant ( $p < 0.05$ ) differences were observed, a modified Bonferroni procedure was used. Significant interactions were submitted to 1-way ANOVA stratified by group and followed by *t*-tests to test main effects.

## RESULTS AND DISCUSSION

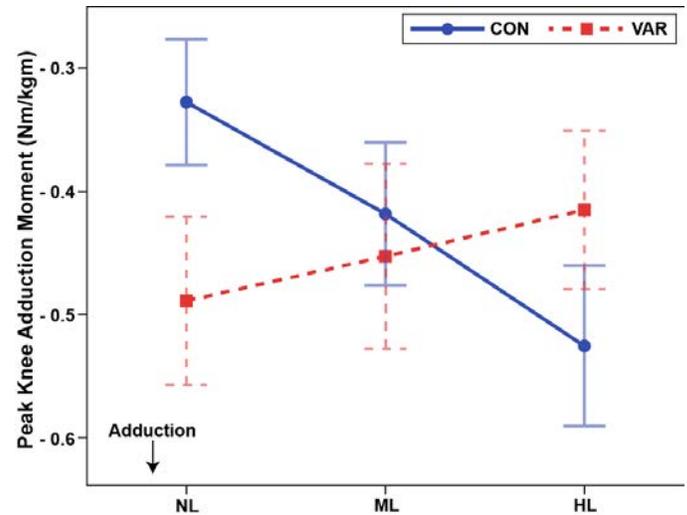

The ANOVA revealed a significant 2-way interaction for peak knee adduction angle ( $p = 0.001$ ) (Fig. 1). Specifically, VAR participants exhibited greater knee adduction compared to the CON participants with the NL ( $p = 0.001$ ) condition, but a significant difference in knee adduction was not evident between groups with either ML ( $p = 0.741$ ) or HL ( $p = 0.142$ ) conditions. Although VAR participants exhibited excessive knee adduction motion during the NL runs, the addition of body borne load did not further increase their use of knee biomechanics linked to OA. The VAR participants, in fact, exhibited a significant reduction in peak knee adduction with the addition of the HL ( $p = 0.023$ ). Conversely, the CON participants exhibited a significant increase in peak knee adduction during the HL runs ( $p = 0.037$ ). For the CON participants, the addition of a heavy borne load may increase their risk of developing knee OA during military service by causing them to rely upon greater knee adduction motion during locomotion.

**Figure 1:** Peak (mean  $\pm$  SE) knee adduction joint angle exhibited by the VAR and CON participants with each load condition.

A significant 2-way interaction was also evident for peak knee adduction moment ( $p < 0.001$ ) (Fig. 2). For CON participants, running with the heavy borne load increased the knee adduction moment and load placed on the medial knee joint compartment. Specifically, the CON participants exhibited a

significant increase in knee adduction moment with HL compared to NL ( $p = 0.006$ ) and ML ( $p = 0.031$ ), but no significant difference was evident between the ML and NL ( $p = 0.079$ ) conditions. The VAR participants, however, exhibited no significant difference in knee adduction moment between any load condition ( $p = 0.174$ ). Further work is need to determine why the CON, but not VAR participants exhibited significant increase in peak knee adduction moment with the addition of a heavy borne load.

**Figure 2:** Peak (mean  $\pm$  SE) knee adduction joint moment exhibited by the VAR and CON participants with each load condition.

## CONCLUSIONS

Participants that exhibit varus thrust when running with the lightest body borne load did not increase knee biomechanical patterns related to the incidence of knee OA with the addition of a heavy body borne load. Control participants, however, increased peak knee adduction joint angle and moment, biomechanical patterns related to the development of knee OA, with the addition of a heavy borne load. Further research is warranted to understand why certain individuals exhibit frontal plane knee instability with the addition of body borne load.

## INTRODUCTION

Studies relating running mechanics to running injuries are most often conducted in the laboratory environment. Further, due to space constraints and ease of analysis, many of these studies are performed on a treadmill. However, most distance and recreational runners complete the majority of their miles outdoors, not on a treadmill.

There has been a proliferation of wearable devices, such as inertial measurement units (IMUs) available to the running and research community. These IMUs allow the measurement of tibial shock (TS; also known as tibial acceleration) while running outdoors, TS has been linked to overuse running injuries in the laboratory setting [1]. However, it is unknown if TS is similar between laboratory treadmill running and running outside where the majority of runners complete their training. Stride length has been reported to be shorter, and cadence higher, during treadmill compared to over-ground running [2]. These differences in mechanics may result in higher tibial shock while running outdoors.

The purpose of this study was to determine if tibial shock is different between treadmill and outdoor running. We hypothesized that TS would be lower for treadmill running than for outdoor running.

## METHODS

254 runners participating in a marathon were recruited. Each subject wore a 3-axis accelerometer attached to their distal medial, right tibia collecting data at 1kHz while they ran on a treadmill and while running an outdoor road marathon (race).

Subjects ran on a treadmill one to three days prior to the marathon at 90% of target marathon speed. The

lower treadmill speed was chosen to avoid compromising race readiness. Subjects were given 3 minutes to warm up on the treadmill in their own way. Once the target speed was reached, 30 seconds of data were used for analysis.

Subjects also completed the same race wearing the accelerometer. Marks were placed on the participants' leg and accelerometer strap during the treadmill testing to assist participants in consistent location and attachment pressure on race morning. Data for approximately the entire seventh kilometer of the marathon were used as this was the earliest flat kilometer of the race. We chose this as the point of comparison as the runners were fresh and the terrain similar to that of the treadmill.

Subjects who reported pain >3/10 on a numeric rating scale prior to the seventh kilometer of the race or who were wearing different shoes between the treadmill and the race conditions were excluded. Additionally, we excluded subjects without complete race and treadmill data. The resulting 192 subjects were used in our analysis [105 males, 87 females; age=44.9±10.8yrs]. Foot strike patterns (determined during the treadmill running) and footwear varied widely within the population. 142 subjects were rearfoot strikers, 30 midfoot strikers and 20 forefoot strikers. Footwear was categorized based upon stack height. 19 wore maximally cushioned, 92 traditional and 54 wore partially minimal shoes, with 8 barefoot or in minimal shoes. 19 runners wore shoes that fell into categories in-between these.

Resultant acceleration was calculated as the root sum of squares of the acceleration from the three axes. Tibial shock (TS) was determined as the peak

resultant acceleration for each right foot fall, averaged for reach subject over the time periods described (Treadmill: 30 seconds after warmup; Race: entire 7<sup>th</sup> km of a marathon). Acceleration due to gravity [ $g=9.81\text{m/s}^2$ ], was subtracted from the resultant accelerations, and then used to normalize TS to units of gravity, g.

Correlation analyses and paired t-tests were used to evaluate differences in TS recorded during treadmill ( $TS_{TM}$ ) and race ( $TS_R$ ) running.

## RESULTS AND DISCUSSION

Treadmill TS ( $TS_{TM}$ ) was significantly correlated with race TS ( $TS_R$ ;  $r^2=0.35$ ,  $p<0.001$ , Fig1 left) but significantly lower than  $TS_R$  ( $p<0.001$ ; Fig1 right).

These results are not surprising, given that TS is strongly correlated with speed [3], and treadmill speeds were significantly lower than race speeds ( $p<0.001$ ; Fig1 middle & right). Using a previously determined association between speed and TS ( $5.26 \frac{g}{m/s}$ ),  $TS_{TM}$  were adjusted to account for their slower speeds. Speed-adjusted treadmill TS ( $TS_{SA-TM}$ ) were more strongly correlated to  $TS_R$  ( $r^2=0.40$ ,  $p<0.001$ ; Fig1 left) but were still significantly lower than  $TS_R$  ( $p<0.001$ ; Fig1 right).

Tibial shocks may be inherently different while running an outdoor race than while running on a treadmill, even when accounting for speed

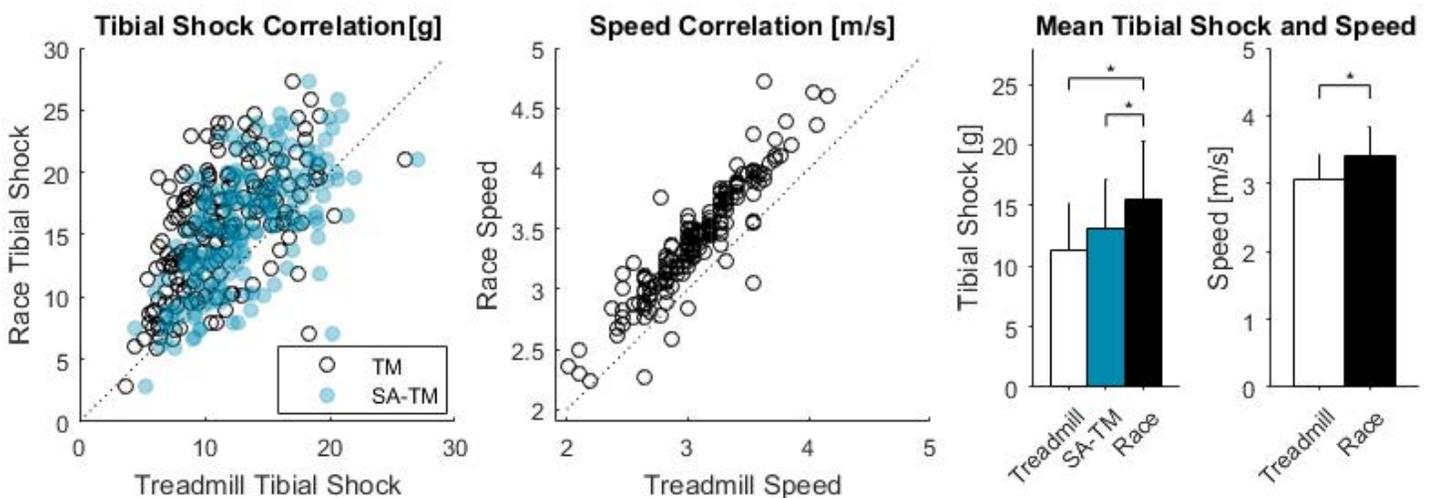

differences. Differences may also be a function of altered running mechanics (i.e. decreased cadence, increased stride length), device placement and attachment pressure, or surface compliance. We attempted to minimize device fixation variance by developing a method to verify correct placement and tension as described above. Still, strap tightness may have been altered for comfort before the race and the location could have differed slightly. The treadmill used is more compliant than asphalt, which could also contribute to TS differences. However, previous work has shown that stiffer foot-ground interfaces tend to reduce leg stiffness [4] and impact forces [5] rather than increase them.

## CONCLUSIONS

Tibial shocks appear to be significantly lower when running on a treadmill than when running in an outdoor race. Future studies should incorporate the measures of cadence and stride length in order to further understand the source of the higher impacts when running outdoors.

## INTRODUCTION

Previous studies have related the biomechanics and metabolic costs of running over level ground [1,2], but the link between biomechanics and metabolic costs for non-level running is less clear [3]. The metabolic cost of running has been explained by the mechanical work involved; rates of positive mechanical work and metabolic energy both increase linearly with speed [4]. However, this approach produces muscular efficiencies of 40-50%, which are much higher than physiologically possible (25%) [4]. Even greater efficiencies are obtained when including negative mechanical work. Applying the mechanical work model to non-level running would generate even more unreasonable efficiencies, as external work must be done to raise or lower the center of mass. The spring-mass model was created in part to explain the high efficiency values observed during running. It models the leg as a massless linear spring that stores and returns elastic energy, and thus performs mechanical work. However, elastic energy utilization of the leg spring is jeopardized during non-level running [5].

The metabolic cost of running on level ground is primarily due to generating force to support body weight [6]. The cost of generating force hypothesis posits that metabolic cost is inversely proportional to contact time during running [1]. [7] showed that active peak ground reaction forces (GRFs) applied perpendicular to the surface and contact times were not significantly different between level and downhill running at one speed. This suggests that metabolic cost remains constant regardless of slope when running at the same speed. However, metabolic cost decreases to a minimum on downhill slopes between  $-6^\circ$  and  $-9^\circ$  [8].

In addition to the metabolic cost of generating force to support body weight, there is a metabolic cost of

propelling body mass while running [9]. During level-ground running at a constant speed, the magnitudes of parallel braking and propulsive impulses are equal and opposite, resulting in a net zero parallel impulse [7]. Parallel impulses incur a metabolic cost but do not have a net effect of propelling the runner forward. Thus, the sum of the absolute values of the braking and propulsive impulses has been termed wasted impulse [3]. During non-level running, a component of the total parallel impulse is due to gravity; therefore, a portion of the parallel impulse is no longer considered “wasted” because it compensates for this gravitational impulse. [3] found that wasted impulse decreased exponentially ( $R^2=0.89$ ) when running uphill due to decreases in negative external work (braking), and that wasted impulse explains a portion of the metabolic cost of running. Here, we predict that wasted impulse will also decrease when running downhill, due to decreases in positive external work (propulsion). We hypothesize that changes in wasted impulse will be strongly correlated ( $r>0.70$ ) to changes in metabolic cost during downhill running at different speeds.

## METHODS

20 healthy runners (12 M, 8 F; mean±S.D. age: 26.6±6.2 yrs, mass: 68.7±8.4 kg, and height: 175.8±8.9 cm) participated and provided written informed consent according to a VAECHCS Human Subjects IRB approved protocol. Subjects reported no cardiovascular, pulmonary, or neurological disease or disorder, and no musculoskeletal injuries.

Subjects performed 12, 5-min trials on a 3D force-instrumented treadmill (Treadmetrix, USA) over two visits. Subjects ran at three speeds (2.25, 2.50, 3.00 m/s) on four slopes ( $0^\circ$ ,  $-2^\circ$ ,  $-4^\circ$ ,  $-6^\circ$ ). Each visit began with a 5-min standing trial, followed by 6 running trials in randomized order with at least 2

min rest between trials. We measured rates of oxygen consumption and carbon dioxide production throughout each trial using indirect calorimetry (ParvoMedics TrueOne2400, Sandy, UT, USA) and averaged these rates over the last 2 min of each trial. We ensured subjects utilized primarily oxidative metabolism from respiratory exchange ratios <1.0. We calculated metabolic power using a standard equation [10] and determined net metabolic power ( $P_{met}$ ) by subtracting the metabolic power during standing from each trial's metabolic power.

During a third visit, subjects performed all 12 running trials on the force treadmill (1000 Hz) for 30-sec each. We digitally filtered GRFs using a 4th-order low-pass Butterworth filter with a 30 Hz cutoff and analyzed 15 consecutive strides per trial. We used a 20N perpendicular GRF threshold to determine foot-ground contact.

Parallel impulses were computed by integrating all negative (braking) or positive (propelling) GRFs during each ground contact period. Wasted impulse per step ( $I_{wasted}$ ) was calculated from the sum of the absolute values of the parallel braking ( $I_{brake}$ ) and propulsive impulses ( $I_{prop}$ ) minus the parallel component of the gravitational impulse ( $I_{gravity}$ ):

$$I_{wasted} = |I_{brake}| + |I_{prop}| - |I_{gravity}|$$

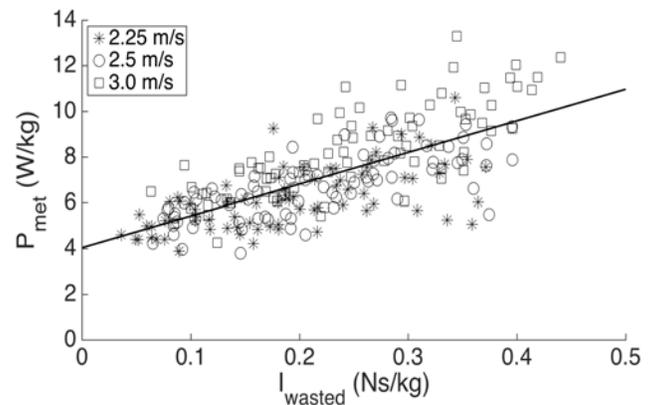

We calculated  $I_{gravity}$  using mass ( $m$ ), gravity ( $g$ ), treadmill slope ( $\theta$ ), and time between two consecutive foot strikes ( $t_{step}$ ):

$$I_{gravity} = m * g * \sin \theta * t_{step}$$

We divided  $I_{wasted}$  by body mass and calculated a mean value for each condition. We used Pearson's product-moment correlation ( $r$ ) to determine the relationship between  $I_{wasted}$  and  $P_{met}$  with a significance level of 0.05.

## RESULTS AND DISCUSSION

$I_{wasted}$  decreased when running downhill compared to level-ground. For 2.25, 2.50, and 3.00 m/s, respectively, at  $-2^\circ$   $I_{wasted}$  was 26%, 27%, and 25% lower, at  $-4^\circ$   $I_{wasted}$  was 82%, 78%, and 72% lower, and at  $-6^\circ$   $I_{wasted}$  was 271%, 223%, and 182% lower compared to level-ground running.

**Figure 1.** The relationship between  $I_{wasted}$  and  $P_{met}$  ( $R^2=0.52$ ).

There was a significant correlation between  $I_{wasted}$  and  $P_{met}$  ( $r(231)=0.72$ ;  $p<0.0001$ ) (Fig. 1).  $I_{wasted}$  alone explained 52% of the variance in  $P_{met}$ . [9] found that the metabolic cost of generating parallel propulsive forces accounts for about one-third of the total metabolic cost of running on level-ground, and when pulling forward on the runner, metabolic cost decreased despite an increase in braking forces. The greater proportion of metabolic energy consumption explained by  $I_{wasted}$  in the present study suggests that all three parallel impulses ( $I_{brake}$ ,  $I_{prop}$ , and  $I_{gravity}$ ) are important when evaluating the cost of braking and propelling body mass parallel to the surface during downhill running.

## CONCLUSIONS

$I_{wasted}$  is an important factor for predicting metabolic energy consumption during downhill running. Additionally, the cost of braking and propelling body mass parallel to the running surface may contribute more to total metabolic energy cost during downhill running than level-ground running.

# THE EFFECT OF GRADE ON THE BIOMECHANICS OF DOWNHILL RUNNING IN FEMALE DISTANCE RUNNERS

## INTRODUCTION

Vast numbers of people run because it provides a variety of health benefits and can be done anywhere. Long distance runners have an increased likelihood of running up and down hills during long runs, and hill training is a key technique used to build strength and speed. Despite the health benefits of long distance running, anywhere from 27 to 79 percent of distance runners will sustain an overuse injury over the course of a year [1].

Kinetic variables such as high vertical ground reaction forces (GRF), and high impact loading rates have been linked to overuse injuries in runners [2]. Some of the most common overuse running injuries are patellofemoral pain syndrome (PFPS) and stress fractures [3]. The most likely cause of stress fractures and PFPS are high GRFs [4,5].

Although numerous studies have been conducted on level running, there is limited research available regarding downhill running. No downhill running studies have been conducted looking at specifically females, yet females are at an increased risk of injury due to anatomical differences [6]. Therefore, the purpose of this study was to analyze the biomechanics of female distance runners at four different downhill grades compared to level with regards to the risk of injury. It was hypothesized that the steeper declines would show greater vertical GRFs, higher loading rates, and increased knee and hip extension at initial contact, leading to an increased risk for injury.

## METHODS

Fifteen healthy, female distance runners (Age: 23.5 ± 4.9 years, Ht: 1.7 ± .06m, Wt: 57.8 ± 6.8kg, weekly mileage: 35 ± 13 miles) participated in this

study. All participants signed an informed consent, and IRB approval was received. Participants were provided compression clothing and standardized athletic shoes. Anthropometric measurements were taken, and reflective markers were placed on anatomical landmarks following a modified plug-in-gait model.

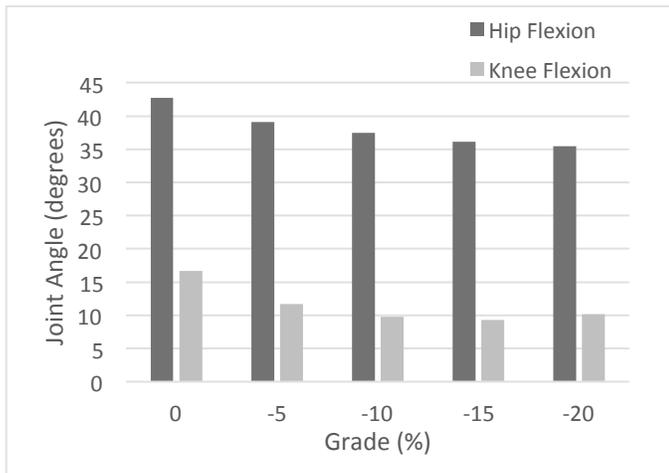

Participants warmed up for 5-10 minutes on a level surface before being fit with a harness attached to the ceiling as a safety precaution. Each participant ran on an AMTI force-instrumented treadmill (Advanced Mechanical Technology, Inc., Watertown, MA, USA) at 0%, -5%, -10%, -15%, and -20% grades for 1-2 minutes at 4.0 m/s in a randomized order. Participants were given 3-5 minutes of rest between each condition.

Kinematic data were collected using 15 VICON infrared cameras (Oxford Metrics, Oxford, UK), sampling at 200 Hz. Kinetic data was sampled at 2000 Hz. Vicon Nexus 2.5, Visual 3D, and Matlab were used to process the data and calibrate the treadmill. Statistical significance was determined using a repeated measure MANOVA in SPSS with an alpha level of .05.

## RESULTS AND DISCUSSION

The GRF at -15% and -20% were both significantly greater compared to each of the other grades ( $p < .001$ ). There was also a dose-response relationship in 10% increments. The -15% grade was greater than -5%, and -20% was greater than -10%. The average and peak loading rates were significantly greater in each of the downhill grades compared to the level condition, and there was a dose-response relationship seen ( $p < .001$ ). However, 0% and -5% were not significantly different from each other (Table 1).

Knee and hip flexion at initial contact decreased significantly in each of the downhill grades compared to the level condition ( $p < .001$ ) (Fig. 1).

**Figure 1:** Hip and knee joint angles at initial contact.

Musculoskeletal injuries occur due to forces being applied to a structure beyond the capabilities of that structure. Repetitive forces that are small in magnitude and high in number are likely to cause an overuse injury [7]. Distance runners are highly prone to stress fractures due to the repetitive loading of the lower extremity [8]. The risk of sustaining a stress fracture increases when the magnitude of the load being applied increases, as was seen in our results. Running down steep hills involves landing from a greater vertical height, which can lead to a greater vertical GRF, and decreased knee and hip flexion [9], as was illustrated in our results.

High GRFs and landing in greater knee extension have been found to increase the likelihood of sustaining PFPS [4,10]. Increased GRFs and a high rate of loading may also increase the risk of stress fractures. Therefore, the results from our study indicate that running downhill may increase the risk

of injury. Additionally, the steeper the grade is, the greater the risk of injury becomes.

## CONCLUSIONS

There is a chance that running downhill at steep grades for an extended period of time may increase the risk of sustaining a running related injury. It is important for runners and coaches to be aware of these potential risks when running downhill so that training may be modified to avoid injury.

# FOOTSTRIKE PATTERN EFFECTS ON LOADING IN RUNNERS WITH TRANSTIBIAL AMPUTATION: PRELIMINARY RESULTS

Tatiana Djafar, Katherine Sharp, Julianne Stewart, Jenny Anne Maun, Kimberly Rowe, and Marilyn Wyatt  
Naval Medical Center San Diego, San Diego, CA, USA  
email: tatiana.e.djafar.ctr@mail.mil

## INTRODUCTION

Runners with amputation have higher reported rates of injury than their able-bodied counterparts, with the most common injuries documented as overuse injuries in the intact limb [1]. Research has shown a positive relationship between greater vertical average loading rates (vALR), defined as how fast vertical ground reaction force (vGRF) rises to its first peak, and lower extremity injury rates in running [2]. Additionally, footstrike pattern has been reported to affect the magnitude of vALR, with a forefoot strike pattern (FFS) resulting in a lower vALR than a rearfoot strike pattern (RFS) [3]. However, there has been limited research examining these effects on persons with amputation. Therefore, the purpose of this pilot study was to compare the vertical loading of runners with amputation using FFS to those using RFS with their intact, unaffected limb. It was hypothesized that the vALR of the affected limb would show no differences between the groups due to the consistency of footstrike pattern in a running specific prosthesis while the vALR of the unaffected limb would be greater in the RFS group. Consequently, it was expected that the difference of vALR between the affected and unaffected limbs within groups would be greater in the RFS group as well.

## METHODS

Five subjects (age  $30 \pm 8$  years; height  $1.7 \pm 0.1$  m; weight  $79.3 \pm 13.9$  kg) with unilateral, transtibial amputation were studied using a mobile, overground motion capture system. All subjects had been cleared for high-level activity by their providers and were prescribed the same running specific prosthesis (Össur® Flex-Run™).

Data were collected with a set-up that included four portable force plates (Kistler Instrument Corp., Amherst, NY, USA) embedded within a portable

walkway, and frontal and sagittal high-speed videos (Nikon Corp., Tokyo, Japan) were taken for reference purposes. Analog data were sampled at 1800 Hz, and a fourth-order, low-pass Butterworth filter with a cut-off frequency of 50 Hz was subsequently applied.

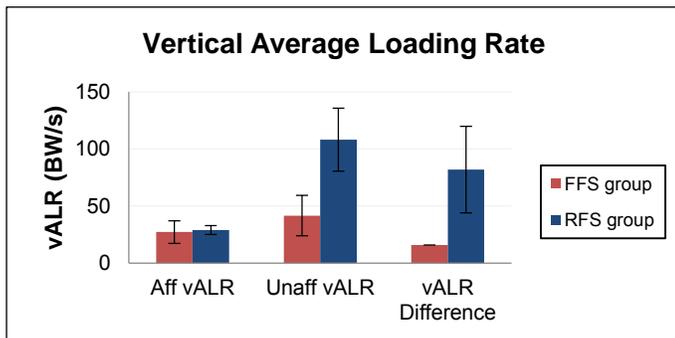

Subjects ran through the capture volume at  $3.5 \text{ m} \cdot \text{s}^{-1} \pm 5\%$  during data collection, which concluded after a minimum of three clean force plate strikes per leg were recorded within the specified velocity range. Strike index calculation of the intact limb determined group designation for four subjects (FFS  $> 33\%$ , RFS  $\leq 33\%$ ). Initial contact with the forefoot or midfoot was considered FFS while initial contact with the heel or hindfoot was considered RFS. Sagittal reference videos confirmed calculated footstrike patterns and were also used to solely determine the footstrike pattern of one subject for whom strike index was unavailable. Kinetic data were processed using Visual 3D software (C-Motion Inc., Germantown, MD, USA), and vALR was calculated as the first derivative of vGRF between 20% and 80% of the impact peak, defined as the first peak of vGRF.

## RESULTS AND DISCUSSION

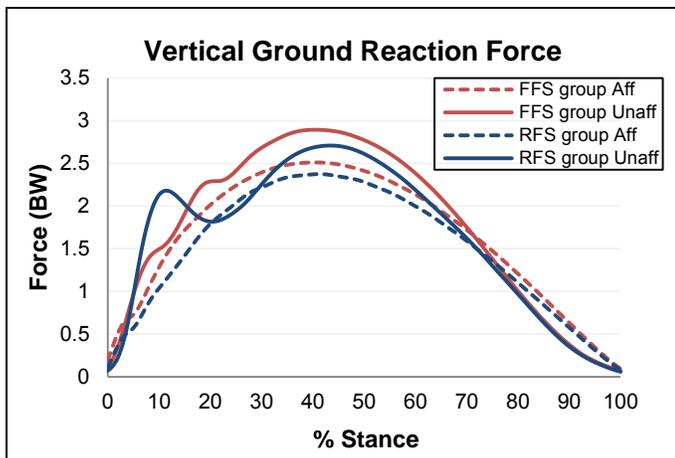

Two subjects were identified as using FFS, while the remaining three were found to be using RFS on their unaffected side. As expected, the vALR of the affected limbs were nearly identical between groups, while the unaffected limbs showed large differences compared to each other (Fig. 1, Table 1). When comparing the affected and unaffected limbs within groups, differences in vALR were found for both groups. However, differences with RFS were more than five times greater than differences with FFS (Fig. 1, Table 1). It is evident that loading in this subject group is asymmetric regardless of footstrike pattern, but limb-to-limb vALR differences within a runner are greatly

decreased when using FFS with the intact limb (Fig. 1, Fig. 2, Table 1).

As previously mentioned, vALR has been suggested as an important indicator of injury risk, with greater rates considered a possible cause of overuse running injuries [2]. While the results of this pilot study are preliminary in nature, there is evidence to consider footstrike pattern conversion as a clinical intervention to reduce vALR in the intact limb of runners with amputation. The injury risk may not be eliminated as vALR asymmetry was still observed with FFS, but it could potentially be reduced.

**Figure 1:** Mean  $\pm$  1 standard deviation vALR of the affected (Aff) limb, unaffected (Unaff) limb, and difference between limbs

**Figure 2:** Mean vGRF normalized to stance for the affected (Aff) and unaffected (Unaff) limbs between groups

Additionally, these preliminary results have implications for other studies investigating running mechanics of persons with amputation. Future research efforts may want to consider categorizing

subjects with unilateral amputation by footstrike pattern depending on their variables of interest due to the inherent differences in loading observed here.

Despite a large effect size of the vALR differences between limbs (2.47), the main limitation of this study is the sample size. The wide range of running experience among this small group may account for the variable vALR and, thus, the larger standard deviations. A post-hoc power analysis calculation determined that a sample size of eight, with four subjects in each group, would be necessary to achieve 80% power. In addition to increasing the sample size, future work will aim to determine where footstrike patterns may further influence asymmetries within kinematics and other kinetic parameters. It would be beneficial to incorporate able-bodied runners with both footstrike patterns for comparison as well.

## CONCLUSIONS

The limited research on the effects of footstrike pattern on loading in runners with amputation warrant the need for further study of the running mechanics of this population, and though preliminary, the results presented here support this need. Decreasing the loading rate of the intact limb can potentially reduce the risk of overuse injury, and clinicians and coaches may facilitate this goal by training these runners to adopt a FFS pattern.

# STEP FREQUENCY IN ELITE ULTRA-MARATHONERS DURING A 100-KM ROAD RACE

<sup>1</sup> Geoffrey T. Burns, <sup>1</sup> Jessica Deneweth Zender, and <sup>1</sup> Ronald F. Zernicke

<sup>1</sup> University of Michigan, Ann Arbor, MI, USA  
email: gtburns@umich.edu

## INTRODUCTION

The step frequency, or cadence, of a runner has been the subject of great interest in the context of both injury prevention and performance optimization [1-5]. While humans have been shown to self-optimize their step frequency to that which is the most energetically efficient [3,4], manipulating step frequency has been explored as a method to reduce peak impact forces [5-7]. Furthermore, experienced runners have been found to self-select higher step frequencies than novice runners [8], but varied results have been reported regarding the effect, if any, that fatigue has on self-selected step frequency [2,9].

Given the fundamental nature of this kinematic variable, there is a need for normative, field-based data on the characteristics of step frequency across individuals, ranges of paces, and levels of fatigue. The ultra-marathon has been proposed as model to study the consequences of muscular fatigue and prolonged stress in running [10], and studies on healthy, elite runners can provide insights into highly experienced individuals who have “self-optimized” their biomechanics. Therefore, examining step frequency during an elite road ultra-marathon over repeated, level-terrain could provide insight into the step frequencies of experienced runners across a range of speeds and levels of fatigue in a relatively controlled, yet field-based environment.

## METHODS

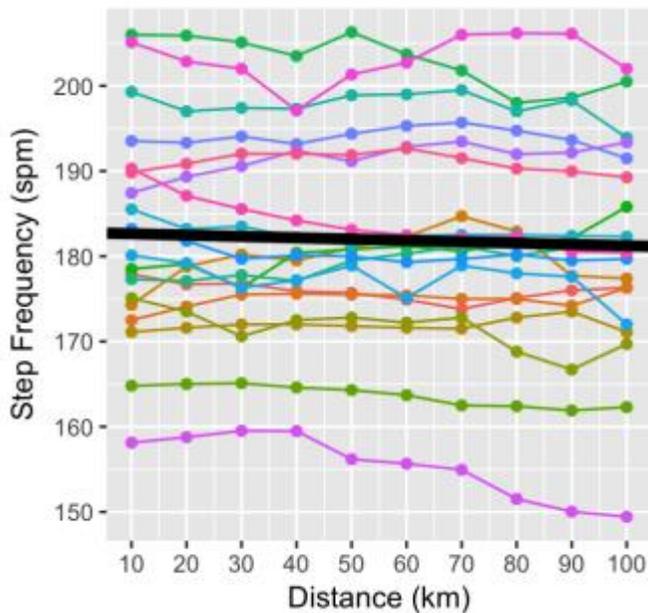

To characterize the step frequency in elite ultramarathon runners, wrist-based accelerometry data were collected from competitors in the 2016 IAU 100-kilometer World Championship in Los Alcazeres, Spain. The race consisted of 10 loops of a 10-km circuit on city roads with 5 m of elevation

gain and loss. Nineteen individuals (12 males and 7 females), all finishing in the top 25 places of the race, provided the researchers with the file recorded from his or her accelerometer-embedded wrist-based GPS device for the step frequency analysis. Speed and pace were recorded at 10-km intervals from the race’s official lap reports, and the average step frequency for each lap was calculated.

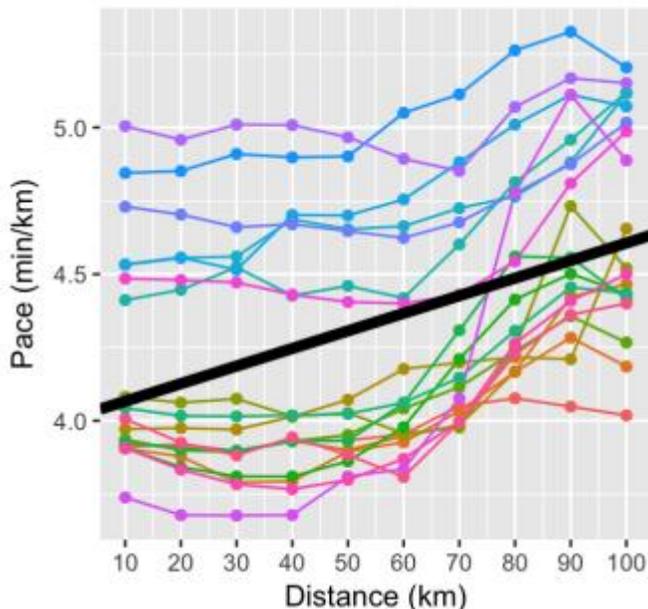

To analyze changes throughout the race in the runners’ step frequencies and paces and to explore the relations between the two variables, mixed-model linear regressions were performed on each variable. Distance into the race and sex were used as fixed predictors, and within-subject changes across distance were modeled treating subjects as random effects. Coefficients of the model were assessed for significance using t-tests at a p-value < 0.05. All data processing and statistical analysis were performed in R 3.2.2 (R Foundation for Statistical Computing, Austria).

## RESULTS AND DISCUSSION

The mean step frequency of all competitors during the race was  $182.0 \pm 12.4$  steps per minute (spm), corresponding to a stride frequency of 1.52 Hz. Female competitors had a significantly higher step frequency than male competitors: 189.5 spm vs. 177.6 spm ( $p < 0.001$ ). Within all competitors, step frequency did not significantly change over the course the 100-km race (Beta = -0.016 spm per km;  $p = 0.19$ ) (Fig. 1). However, pace significantly slowed over the course of the race (Beta = 0.01 min/km per km;  $p < 0.001$ ) (Fig. 2). Finally, there was no significant relation between step frequency and pace after controlling for the sex difference (-2.2 spm per min/km;  $p = 0.47$ ).

**Figure 1:** Step frequencies of individual runners over the course of a 100-km race with the regression line of step frequency across distance. Note that the slope of the line is not significantly different from zero.

**Figure 2:** Paces of individual runners over the course of a 100-km race with the regression line of pace across distance.

## CONCLUSIONS

In elite ultra-marathoners, step frequency did not change over the course of a 100-km race despite a significant slowing of pace. Significant gender differences existed, with women running 12 spm more than men. Furthermore, step frequency did not significantly change with pace. This study provides field-based evidence that step frequency is relatively independent of pace across varied levels of fatigue in highly experienced long-distance runners.

# KNEE JOINT STIFFNESS AS A NEUROMUSCULAR COMPONENT OF PREFERRED SPEED

Jacqueline Morgan, Bhushan Thakkar, Kathryn Harrison, Gregory Crosswell, Robert Tickes, D.S. Blaise Williams III

VCU RUN LAB, Virginia Commonwealth University, Richmond, VA, USA  
email: [morganj3@mymail.vcu.edu](mailto:morganj3@mymail.vcu.edu) web: <https://khs.vcu.edu/about/vcu-run-lab>

## INTRODUCTION

Preferred running speed is commonly utilized in clinical practice and research to best represent a runner's normal gait mechanics. A physiological reason for choosing a preferred speed is to create an energy-efficient stride (6). Preferred stride frequencies have been found to be economically similar to optimal stride frequencies during non-fatiguing running (3). Another important contributor to running performance is lower extremity stiffness. Torsional joint stiffness at the knee (KS) and ankle (AS) are associated with improved performance through the elastic energy storage and return theory (7).

Traditionally, KS and AS are calculated as the slope of the moment-angle plot during force absorption (2). Typically, changes in joint moments and angles are expressed as differences between peak values and initial contact. Peak values of the knee and ankle, however, do not occur simultaneously or during similar phases of stance. Hence, calculating joint stiffness from the linear component of the moment-angle curve may better estimate the forces absorbed by the lower extremity joints. Throughout the absorption phase, torsional stiffness changes relative to changes in force and displacement and thus this is not a strictly linear measurement.

Calculating torsional stiffness during the stance phase (instantaneous stiffness) may provide a unique method for examining the motor control parameters of preferred running and its relationship to joint stiffness. Therefore, the purpose of our study was to examine the relationship between preferred running speed and joint stiffness (KS, AS), along with the timing and magnitude of peak instantaneous stiffness at the knee (%K, KIS) and ankle (%A, AIS).

## METHODS

Thirty-three healthy female runners between 18 and 50 years old [mean age 29.8 (7.5) years, height 1.64 (0.06) m, weight 61.8 (9.6) kg] volunteered. Passive retroreflective markers were affixed to bilateral lower extremities using a modified Cleveland Clinic marker set.

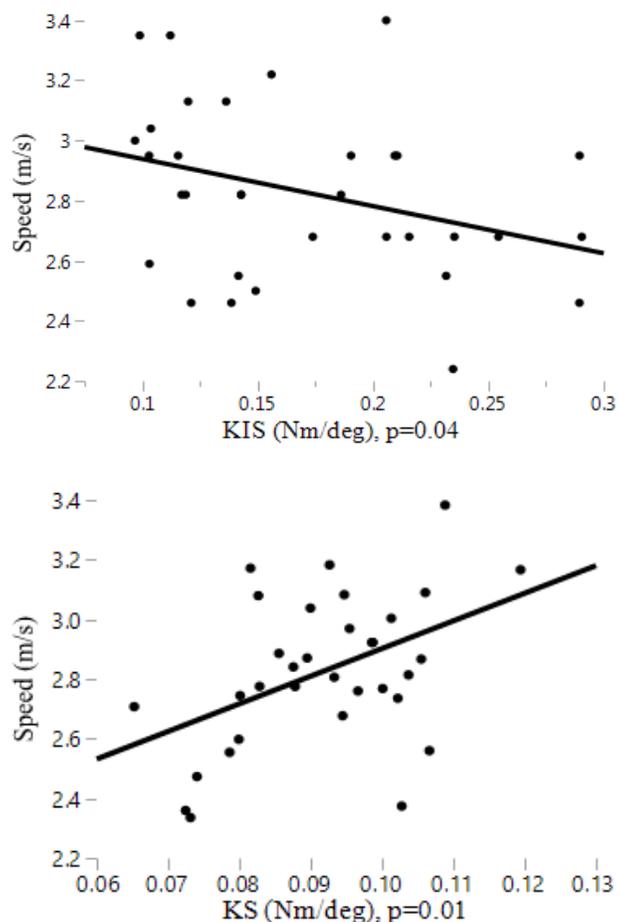

Gait analysis was performed on an instrumented treadmill (Treadmetrix, Park City, UT) using a 5-camera motion analysis system (Qualisys, Goteborg, Sweden). Static calibration was performed with the subject in a dual support, upright standing posture. Following calibration, joint markers were removed and each participant ran at a preferred speed [mean velocity 2.83 (0.287) m/s]. Analysis was collected for 30 seconds and the data analysis was performed.

Visual3D software (C-Motion, Germantown, MD) was used to compute kinematic and kinetic variables of joint angles and moments. KS and AS were calculated as a simple-spring model, during the linear component of the moment-angle curve. KIS and AIS were calculated as peak joint stiffness between 20% of stance and peak joint moment. %K and %A were assessed at the percent of stance associated with peak instantaneous stiffness.

A forward step-wise multiple linear regression analysis was employed to examine the association between preferred running speed and six potential independent variable gait measures. Variables of KS, AS, KIS, AIS, %K, %A were fit into a best-fit model utilizing the Akaike Information Criterion (AIC) selection criteria. Analysis was performed using JMP® Pro 12.2.0, SAS Institute Inc, 2015. Significance was set at  $\alpha < 0.05$ .

## RESULTS

Six covariates of gait stiffness variables were fit into a best-fit forward step-wise linear regression model. The AIC selection criteria resulted in a best fit model using covariates of KS, KIS, and %K. The results of the regression model found a significant positive association between preferred speed and both knee stiffness variables (Adj  $R^2 = 0.304$ ,  $p = 0.004$ ), with KS and KIS explaining 30.4% of the variance in preferred speed. Post hoc analysis showed KS was positively associated with preferred speed (slope = 9.26), while KIS was negatively associated with speed (slope = -1.77) (Figure 1a-b).

**Figure 1:** The correlation between preferred speed and KIS (1a), and KS (1b).

## DISCUSSION

Stiffness variables of the knee and ankle were examined for their relationship to preferred running speed. Only knee stiffness variables (KS, KIS) were found to be significantly correlated to preferred

speed. Previous research has found increases in speed to be significantly associated with increases in knee stiffness (1,4), when stiffness was assessed across previously determined speed. KIS was found to be inversely associated with faster self-selected speeds, suggesting that torsional stiffness parameters that are more consistent across stance with damped peaks may allow for greater control of movement during running and a faster more efficient gait.

The results of our finding are novel and suggest that knee stiffness may be a motor control parameter used to generate a neuromuscularly efficient gait. Implications from our findings suggest runners may have an optimal knee stiffness during preferred running to provide the runner with a “comfortable” gait (5). The runners recruited in our study were recreational runners. Therefore, improving neuromuscular performance through the generation of preferred stiffness may help to temper any reductions in maximal predictors of performance ( $VO_{2max}$ ).

Physiological measures were not collected for this study, however, future studies would benefit from examining the relationship between joint stiffness, running economy, and motor control to better understand the recreational runner. Investigations into the optimal joint stiffness may aid future researchers and clinicians when examining deficiencies in stiffness, injury risk, and potential intervention to address those impairments.

## INTRODUCTION

Running while carrying a load under different conditions such as slopes and speeds is a part of military training [1], trail running [2], commuting and conditioning exercises [3]. There have been different studies on effects of slope [4–6], speed [7,8] and load [3,9,10] on biomechanics of running. However, only a limited number of studies analyzed the effects of multiple parameters in interaction (e.g. [3]) and, to the best of our knowledge, there has been no study on the effects of slope and speed during jogging with a relevant military load at slow speeds that are likely to occur at such slope and load combinations. Knowledge about the effects of slope and speed on the joint kinetics can be useful for understanding the performance requirements of different types of terrain and for preparing accordingly. Our aim is to study the effects of slope and speed on joint kinetics during slow jogging with a military relevant backpack load. We hypothesize that uphill jogging will increase positive work (mostly at the hip and ankle) [5, 6] and reduce negative work and that faster jogging will increase both positive and negative work (mostly at the hip and ankle) [3,7,8].

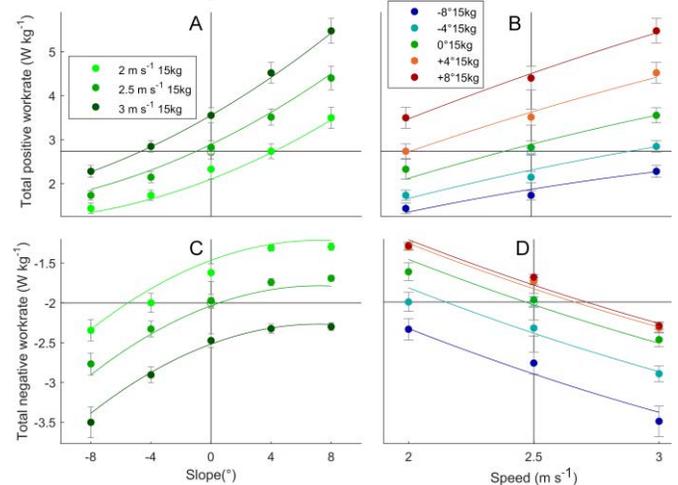

## METHODS

We tested 10 healthy male participants ( $29 \pm 2$  yrs;  $76 \pm 3$  kg;  $1.79 \pm 0.02$ m; mean  $\pm$  s.e.m.) during jogging on a treadmill (Bertec) at 15 combinations of slope ( $-8$ ,  $-4$ ,  $0$ ,  $+4$  and  $+8^\circ$ ) and speed (2, 2.5 and  $3 \text{ m s}^{-1}$ ) with a 15kg backpack. We measured joint kinetics using motion capture (Vicon). We calculated rates of positive and negative work for each joint by integrating positive and negative

power portions and dividing by stride time. Next, we evaluated the linear, second order and interaction effects of slope and speed on each metric using mixed-model ANOVA with stepwise elimination.

## RESULTS AND DISCUSSION

As hypothesized, we found that an increase in slope leads to an increase in positive work rate at the hip and ankle joint (similar to [5] and [6]) and to a decrease in negative work rate mostly at the knee joint and for the sum of all joints (Figure 1). Furthermore, we found that an increase in speed led to an increase in positive work rate at all joints, but at the knee this effect is very small. We also found that an increase in speed led to an increase in negative work rate for all joints. We found significant interactions for the effect of slope and speed in all joints for positive work rate but only in the knee for negative work rate (Table 1).

**Figure 1:** Effects of speed (a,c) and slope (b,d) on total positive (a,b) and negative (c,d) work from the hip knee and ankle. Dots and error bars are mean  $\pm$  s.e.m. Lines show curve fits from ANOVA.

## CONCLUSIONS

These results quantitatively show that fast uphill loaded jogging is strenuous, not only because positive joint work rate increases with slope and speed, but also because the interaction between slope and speed further magnifies these effects. Results also show that the combination of fast downhill jogging leads to high negative work at the knee because of the effect of slope, the effect of speed and that this is further magnified by interaction of slope and speed. Knowledge of these effects can be useful for choosing pacing strategies, course selection, estimating injury risk, optimizing training and rehabilitation and for selecting and developing orthotic or assistive devices. For example, an assistive exoskeleton for running [11] could be programmed to change its assistance magnitude based on the equations in table 1 to mimic human responses to changes in slope and speed.

# RELATIONSHIP BETWEEN RUNNING ECONOMY AND KINEMATICS OF THE UPPER EXTREMITY AND TRUNK

Grace Rhodehouse, Shane P. Murphy, Barbara J. Schornstein, Abbie E. Ferris,

email: grace.rhodehouse@unco.edu web: www.unco.edu/biomechanics

## INTRODUCTION

Variability in running economy has been reported in homogenous groups (based on maximal aerobic capacity or race performance) of trained distance runners. Lower extremity kinematics such as increased shank angle and increased knee flexion have been shown to improve steady state economy (i.e., lower  $\text{VO}_2$  consumption), but have not fully explained the variations seen in the homogenous groups [1].

Previous research has also suggested that upper extremity motions such as decreased trunk angle and decreased wrist excursion path lead to improved running economy [2], but it is unclear whether variability in upper extremity mechanics can provide further insights into the differences in running economy among similarly trained runners.

The purpose of this present study was to determine whether upper extremity and trunk kinematics were related to running economy. It was hypothesized that greater motion of the upper extremity and trunk, as well as increased variability of these measures within a participant would lead to increased steady state  $\text{VO}_2$  during running.

## METHODS

Eleven healthy, highly trained female runners ( $21 \pm 3$  years,  $1.69 \pm 0.05$  m,  $58.5 \pm 3.6$  kg) with 5k or 10k times between 19-24 or 40-45 minutes, respectively, and training at least 15 miles per week participated in the study. Participants visited the Biomechanics Lab on two separate occasions, completing a  $\text{VO}_{2\text{max}}$  test (Visit 1) and a steady state running protocol (Visit 2). During both visits, participants ran on an instrumented treadmill

(AMTI, Watertown, MA) while expired gases were collected using a metabolic cart (Parvo Medics, Sandy, UT). A ramped protocol was used for the  $\text{VO}_{2\text{max}}$  test, with participants running at  $3.1 \text{ m}\cdot\text{s}^{-1}$  for the entire test. Treadmill grade was increased by  $2^\circ$  every two minutes, until voluntary exhaustion [3]. During Visit 2, steady state  $\text{VO}_2$  was measured during a six-minute run at  $3.5 \text{ m}\cdot\text{s}^{-1}$ . Whole body and segmental anthropometrics were measured following guidelines of VICON's Plug-In-Gait Model. Retroreflective markers were positioned bilaterally on anatomical landmarks according to this model. Marker coordinate data (100 Hz) were captured during each running trial (VICON, Englewood, CO).

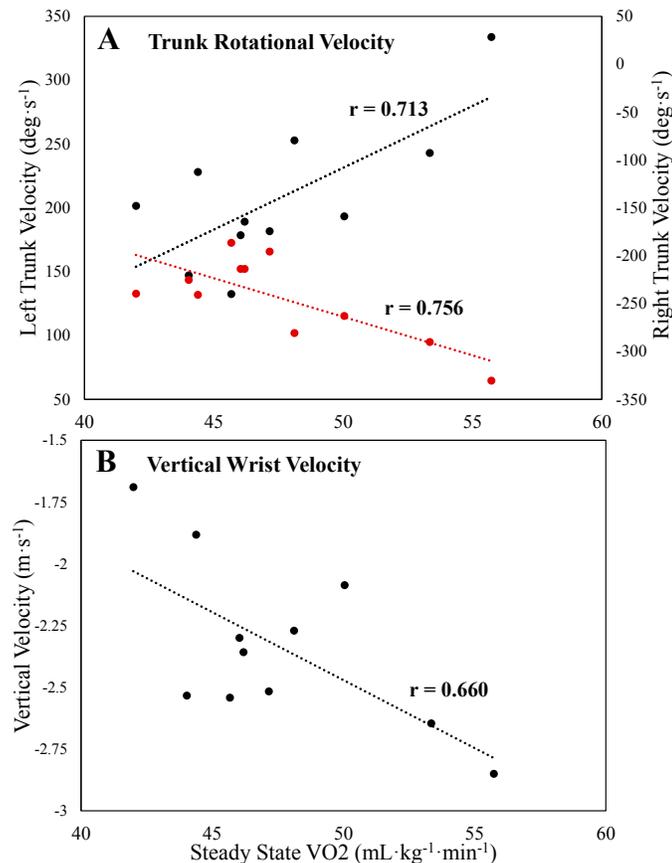

Metabolic data were averaged over the last 60 s of the six minute treadmill bout. Kinematic data were also identified during this last 60 s of the trial. Left arm kinematics of 10 strides during steady state running were analyzed. (Visual 3D, C-Motion, Germantown, MD). Resultant wrist excursion length, and range of motion (ROM) and angular velocities for the shoulder, elbow, and trunk were calculated in all three planes. Stride-to-stride variability during the 10 strides for each participant was also determined for each measure. A Pearson Product Moment Correlation analysis was used to determine relationships between steady state  $\text{VO}_2$  and upper body kinematics. Significant relationships were those with  $r > 0.602$ .

## RESULTS AND DISCUSSION

The  $\text{VO}_{2\text{max}}$  test was designed to have participants reach maximum effort, however the majority of subjects reached voluntary exhaustion before exceeding an RER value of 1.1. Therefore, we will refer to the max value from these tests as  $\text{VO}_{2\text{peak}}$ .

$VO_{2peak}$  ranged between 49.9 - 71.6  $mL \cdot kg^{-1} \cdot min^{-1}$ , with a group mean of  $60.9 \pm 6.6 mL \cdot kg^{-1} \cdot min^{-1}$  (time to exhaustion  $9.6 \pm 1.9$  minutes). The steady state protocol in Visit 2 was performed at a high intensity in comparison to measured  $VO_{2peak}$  for each participant ( $79 \pm 9\%$  of  $VO_{2peak}$ ). This relatively high intensity level reflects an effort expected of a highly trained runner in an intense workout or race setting.

No significant relationships were observed between any measures of stride-to-stride variability and  $VO_2$ . A significant correlation was observed between trunk rotational angular velocity and  $VO_2$  ( $r = 0.713$  and  $r = 0.756$  for rotation to the right and left, respectively). During the steady state run, less economical runners (i.e., higher  $VO_2$ ) had increased rotational trunk velocity (Fig. 1A). A significant correlation was also observed between wrist velocity in the vertical direction and  $VO_2$  ( $r = 0.660$ ). As downward wrist velocity increased,  $VO_2$  increased (Fig. 1B).

**Figure 1:** Relationships between steady  $VO_2$  and rotational trunk velocity (A) and vertical wrist velocity (B). Right trunk rotation (red) is plotted using the right vertical axis and left trunk rotation (black) is plotted using the left vertical axis of panel A.

Increased rotational trunk velocity and increased vertical wrist velocity may contribute to increased muscle actions of the trunk and elbow to slow down and speed up the segment's motion. This increased muscle action likely leads to increased metabolic energy expenditure during running.

Trunk flexibility has previously been shown to be related to running economy [4]. Greater trunk rotation flexibility is related to higher steady state  $VO_2$  during running. In the current study, trunk ROM, about the vertical axis, approached the critical value ( $r = 0.578$ ). Thus, during dynamic activity, increased rotational motion of the trunk also appears to increase  $VO_2$ . It is likely that the motion of the trunk is controlled significantly by active muscle rather than more passive mechanisms that might arise with each contact with the ground.

Left wrist excursion path length also approached the critical value ( $r^2 = 0.2965$ ). Runners displaying longer path lengths were less economical during steady state running. Although we were unable to determine a significant relationship between wrist excursion and  $VO_2$ , previous research has found longer wrist excursion path lengths among less economical runners, during steady state running [1], which is consistent with the trend we observed.

## CONCLUSIONS

Stride-to-stride variability of the upper extremity and trunk kinematics was not related to running economy. However, more economical runners (lower  $VO_2$ ) had lower rotational trunk velocities and slower vertical velocities of the wrist. Limiting trunk and wrist motions may lead to lower energy expenditures during steady state running.

# THE EFFECT OF TRANSITIONING FROM A REARFOOT STRIKE PATTERN TO A NON-REARFOOT STRIKE PATTERN ON RUNNING IMPULSES

Adam Reynolds, Erin Florkiewicz, Donald Goss, Gregory Freisinger

United States Military Academy, West Point, NY, USA

email: [gregory.freisinger@usma.edu](mailto:gregory.freisinger@usma.edu), web: <http://www.usma.edu/cme/SitePages/Home.aspx>

## INTRODUCTION

Annual running injury incidence has been reported between 19-79% with approximately 40% of all running-related injuries occurring at the knee [1]. Several popular strategies have been proposed to reduce lower extremity injury risk while running, to include minimalist footwear and alterations in running form [2].

Previous studies have shown a rearfoot strike pattern to be associated with a greater incidence of repetitive stress injuries when compared to a forefoot strike pattern [3]. Much of this research has focused on vertical loading rate and peak vertical load, but less has focused on the effects on the impulse, or time integral of applied force, which the individual experiences. The purpose of this study was to further investigate the changes in impulse when transitioning from a rearfoot strike (RFS) to a non-rearfoot strike (NRFS) running style.

Acceleration in running results from an imbalance of posterior and anterior impulses [4]. This study investigated running at a constant pace in which a balance must exist between these two impulses. We hypothesized that following the transition from RFS to NRFS, a decrease in the magnitude of the posterior and anterior impulses will be observed. We also hypothesized that vertical impulse will decrease, while medial and lateral impulses remain unchanged, following running style transition.

## METHODS

Nine patients were recruited from the Arvin Cadet Physical Therapy Clinic at West Point, NY for the 10-week transition program and provided IRB approved informed consent. Participants were cadets with previous running experience and their demographics are shown in Table 1. All participants met each of the 6 inclusion criteria: 1) previously a RFS runner; 2) recovering from a lower extremity

injury; 3) able to walk pain free for 2 miles; 4) dorsiflexion range of motion of at least 80% symmetry; 5) capable of performing 20 unassisted single leg heel raises; 6) able to perform a single leg hop for distance with at least 80% symmetry. These participants were clinically diagnosed and recovering from one of the following lower extremity injuries: patellofemoral pain syndrome (3), lower leg stress injury (2), lower leg fracture (1), plantar fasciitis (1), and anterior cruciate ligament reconstruction (2).

Sex	5 Male : 4 Female
Age, years	20.3 ± 2.2
Height, cm	170.7 ± 13.8
Mass, kg	71.7 ± 14.9
*All values are means ± standard deviations	

The running transition program began with a private 30 minute training session to encourage transition from a RFS to a NRFS running pattern. Training focused on soft landing off of the heel, a cadence of approximately 180 steps/minute, forward trunk lean and strict adherence to a gradual walk to run progression. Participants met with their study assigned medical provider once a week post-training for the first 4 weeks, then again at weeks 6, 8, and 10 upon which the training focuses were reinforced.

Prior to the training program and at week 10 post-training, each participant's running ground reaction force were assessed. Participants ran at a self-selected speed for 5 minutes on an instrumented treadmill [Bertec; Columbus, OH]. Speed was kept constant throughout the study. Foot-strike pattern was assessed utilizing a high speed digital camera [Casio EX-ZR200; Tokyo, Japan] recording at 240 frames per second. Ground reaction forces were sampled at 1000Hz, low-pass Butterworth filtered at 35Hz, and normalized as a percentage of each

participant's bodyweight (BW). This data was used to calculate impulse in the vertical (vImp), anterior (aImp), posterior (pImp), medial (mImp) and lateral (lImp) directions for each step. Ensemble averages were calculated from five left and right stance phases, then the left and right foot data were also averaged. Cadence was determined based on the vertical ground reaction force data. Subjective measures of running ability were assessed using the Patient Specific Functional Scale (PSFS) and Single Assessment Numeric Evaluation (SANE) averaged scores. PSFS measures functional running ability on a scale from 0 (unable to perform running) to 10 (able to perform running at the same level as before injury), whereas SANE assesses how normal their injured body part feels from 0% to 100%.

Paired t-tests were used to identify differences between the initial and 10 week assessments for the impulse calculations, cadence, and PSFS measures. A significance level of  $\alpha = 0.05$  was used.

## RESULTS AND DISCUSSION

All 9 subjects successfully transitioned to a NRFS running style as verified by high speed camera. Cadence increased from an average of  $170.2 \pm 10.1$  to  $179.8 \pm 6.4$  steps per minute ( $p < 0.05$ ). Average PSFS and SANE scores also increased by approximately 50% ( $p < 0.01$ ) and 25% ( $p < 0.01$ ) respectively, suggesting increased running ability and decreased discomfort (Table 1).

Contrary to our hypothesis, our results demonstrated a significant increase in the average pImp ( $p < 0.01$ ) and a matching increase in aImp ( $p < 0.01$ ). The average magnitude of change increased

approximately 10% bodyweight-seconds (BW-s) for each pImp and aImp. This suggests there is overall greater total impulse in the anterior-posterior dimension when patients transition from a RFS to NRFS per step. We also found no change in the vImp, contrary to our original hypothesis. No statistically significant changes were found in the mImp or lImp. The impulse values for the initial and 10 week assessment are shown in Table 2.

## CONCLUSIONS

We have observed approximately a 10% increase in the magnitudes of the anterior and posterior impulses, in the short-term, after transitioning habitual RFS runners to a NRFS pattern. This is accompanied by a strong increase in PSFS and SANE scores, showing an increase in subjective functional running ability. No significant changes in impulse were observed in the medial, vertical, or lateral directions. Additional work is necessary to identify the long-term effects of increased impulse when transitioning to a NRFS following injury.

# COORDINATION AND COORDINATIVE VARIABILITY OF THE LOWER LIMBS IN COMPETITIVE MALE DISTANCE RUNNERS

<sup>1</sup> University of Oxford, UK

<sup>2</sup> Oxford Gait Laboratory, UK

email: richard.c.franzese@gmail.com

## INTRODUCTION

This work quantifies coordination and coordinative variability in lower-limb motion, using continuous relative phase (CRP) [1] and CRP variability (vCRP), for a population of uninjured, competitive male distance runners. The effects of velocity and footwear are considered, with stride-specific foot-strike angle (FSA) as a covariate. Barefoot (BF) and shod (SD) conditions are studied because they mark mechanical boundary conditions for affecting running biomechanics.

Segmental coordination is different to joint kinematics; joint kinematics may change whilst coordination patterns for the segments involved do not. vCRP decreases with higher competitive standards [2] and may also decrease with injury [3]. Therefore quantifying CRP and vCRP for a trained population, under conditions which reflect training, may inform on future studies in untrained or recreational populations.

We hypothesize that CRP and vCRP vary with velocity and footwear use, and that FSA is a significant covariate during impact phase.

## METHODS

Segmental sagittal plane coupling, rather than joint angle coupling, was studied for pelvis-thigh, thigh-tibia (ThiTib), tibia-rearfoot, and rearfoot-forefoot. Hindfoot segment frontal-tibia segment transverse plane coupling (EVTIR) was also measured.

Nineteen habitually SD male distance runners (1500 m personal record: mean (st. dev.) = 3.59.8 (10.0); age: median = 21, min = 19, max = 31) were recruited from a College cross country club. Participants ran BF, then SD, on a treadmill (Ultim8 Fitness Ltd, UK) for at least 3 minutes per trial at

12.9 km h<sup>-1</sup>, 14.3 km h<sup>-1</sup>, and 16.0 km h<sup>-1</sup> in a randomized order for BF and SD conditions. Twelve MX cameras (Vicon, Oxford, UK) captured lower-limb kinematics data at 200 Hz. Pelvis and thigh segments were defined according to the Plug in Gait model, whilst tibia, rearfoot, and forefoot segments were defined using the Oxford Foot Model. Based on available data, between 15 and 31 consecutive strides per trial were analyzed.

The discrete Hilbert transform, implemented in MATLAB, was applied to the entire time series ( $O(10^3)$  points) of consecutive gait cycles as part of CRP calculation. Heel and toe marker trajectories were used to determine foot-strike [4] and toe-off [5] events. Swing and stance phase CRP time series were time normalized to 51 points, with impact phase defined as 0-16% of stance phase. Omitting the first and last gait cycles was sufficient to eliminate edge effects, and any remaining waveforms were omitted if they exhibited limit cycle oscillations upon visual inspection. Trials which contained 5 or more gait cycles were used for statistical analysis.

CRP was calculated per stride for the three periods as the circular mean. Given all time normalized gait cycles per trial, vCRP was calculated as the point-wise circular standard deviation across all valid gait cycles, thus generating a single waveform per trial. From this, the circular mean was calculated for each time period. The median FSA for which vCRP data was valid was used as the summary FSA.

Statistical analysis was performed using MATLAB and R. Hierarchical linear mixed-effects models (LMM) with saturated fixed effects were used. The inclusion of velocity, footwear, or an intercept as subject-level random effects was determined using likelihood ratio tests with  $p < 0.05$ . LMM are more

flexible than ANOVA analyses because they allow correlations between random effects to be modeled, may account for missing data, and quantify between-subject variability (BSV). A Bonferroni correction, owing to three comparisons per coupling relationship, was applied in tests for statistical significance such that  $p < 0.017$  was significant.

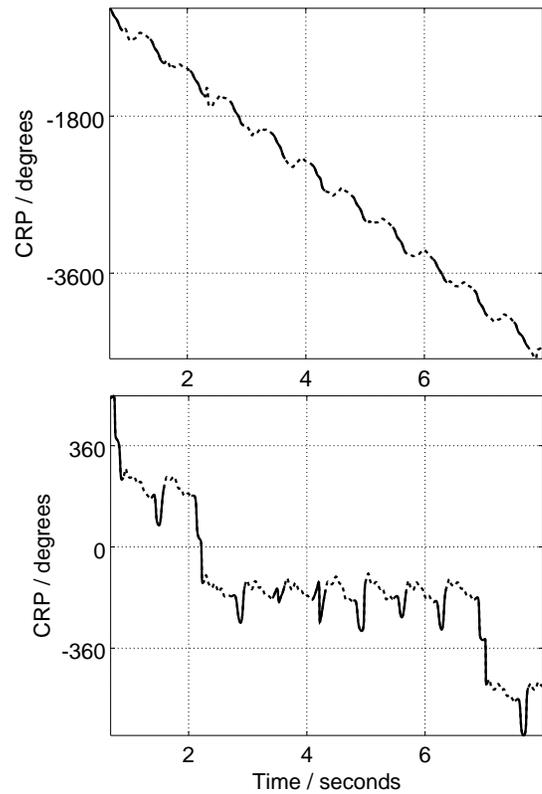

## RESULTS AND DISCUSSION

Footwear was a random effect for all six applicable statistical tests. This may reflect subject-specific responses to footwear as compared to BF running. Footwear was a significant fixed effect for ThiTib CRP during impact phase, such that CRP was more in-phase for SD running. However, when accounting for BSV in the effect of footwear, 13% of subjects were more out-of-phase for slow SD versus slow BF running. Generally, the magnitude of BSV was comparable to the size of the associated significant fixed effect. Therefore, whilst statistically significant, changes may be of limited biomechanical significance. However, CRP was more robust to changes in velocity and differences in FSA for SD running, possibly from habituation to the SD condition. Also, FSA was a significant covariate for all CRP couplings during impact.

vCRP magnitudes were smaller than for previous studies. This may reflect skill development, or arise from different phase space construction methods. vCRP for ThiTib reduced as velocity increased, but velocity, condition, and FSA were not significant for other vCRP coupling relationships.

Transient phase locking between segments for EVTIR CRP appears to emerge at higher velocities for BF running (Figure 1). This coincides with higher vCRP around mid-stance. This may arise from changes in rearfoot segment motion. However, EVTIR data from several trials were omitted because limit cycle oscillations were present in the CRP signal. The Hilbert transform is susceptible to oscillations due to feedback because it is an infinite impulse response filter. Therefore it is unclear whether this observation reflects a mechanism utilized by the foot to address an increased

functional demand of pronation, or arises from a signal processing artifact.

**Figure 1:** EVTIR CRP for a single subject running BF at 12.9 km h<sup>-1</sup> (top) and 14.3 km h<sup>-1</sup> (bottom), with stance phases as solid lines.

## CONCLUSIONS

Future studies of CRP should account for differences in velocity, footwear and FSA. Where studies use a variety of footwear, LMM for hypothesis testing is recommended, such that footwear may be modeled as a random effect. Further study of EVTIR with a larger population is encouraged, to ascertain whether a coordinative adaption occurs with changes in velocity.

### INTRODUCTION

The high frequency of knee injuries in runners has inspired scientists to study a number of running biomechanical variables. Discrete variables relative to joint motion and loading have been identified as possible risk factors for running knee injuries [1,2]. More sensitive metrics have been developed to assess the underlying organization of movement. Coordination variability, one such metric, has the ability to assess how an individual alters their movement organization throughout an entire movement each time they repeat a cyclical task. This provides insight to the adaptability and perhaps health of the individual's movement.

To date, the majority of biomechanical studies have assessed injury-related variables during either a one-time non-fatigued or exhaustive laboratory test. However, runners often complete submaximal runs during their regular training. Thus, the clinical implications of injury-related variables may be better understood if studied following a typical training run.

The purpose of this work was to compare lower limb segmental couples throughout a 40min submaximal run in runners of all levels. We expected that as the run progressed, runners would have a less flexible system resulting in a freezing of degrees of freedom as indicated by a decrease in coordination variability.

### METHODS

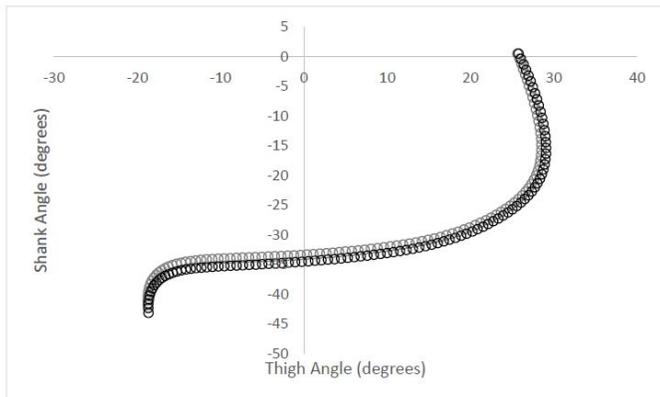

Fourty-four runners (24 men; 30±8 yrs; 68.1±11.4 kg; 1.74±0.1 m; 34.3±13.9 miles/week; 9.9±5.2 years of running experience) participated in the

study. Written consent approved by the IRB was obtained for all participants before testing begun.

Before testing, neoprene wraps were secured on both thighs and shanks and around the waist. Runners then ran at an easy effort on the treadmill for 5 minutes to allow the wraps to set into place. A 9-camera motion capture system (240Hz, Qualisys AB, Sweden) was used to collect kinematic data during running. Anatomical markers and tracking marker clusters were placed on both lower extremities to define segment coordinate systems. Following a standing calibration trial, only anatomical markers were removed and runners completed a 40-minute treadmill run. The run speed was set to 75% of the runners' best 10 km race time in the past 5 years to ensure a moderate run effort based on running ability (6.7±1.2 miles/hour). Four 6-second motion capture trials were collected after 10, 20, 30 and 40 minutes to obtain 3D lower limb kinematics during the run.

Visual3D biomechanical software (C-Motion, Germantown, MD, USA) was used to process and analyze all data. Kinematic data were interpolated using a least-squares fit of a 3rd order polynomial with a three data point fitting and a maximum gap of 10 frames. Data were then filtered using a fourth-order Butterworth low-pass filter at 8 Hz. The start and end of stance phase were identified using the minimal vertical pelvis velocity with a 15ms offset [3] and peak knee extension [4], respectively. Using a modified vector coding technique [5] coordination variability was assessed for early, mid and late stance of segment coordination at the knee. This was assessed for thigh-shank sagittal plane coupled motion and the thigh sagittal and shank transverse plane coupled rotation. The average variability for

each phase of stance of five steps was taken at each of the four collection times. These participant averages were used for analysis.

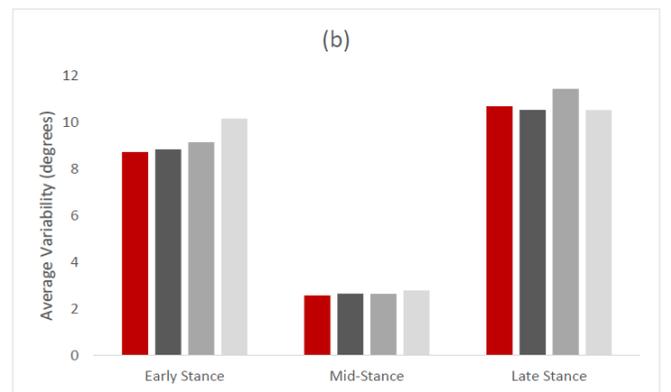

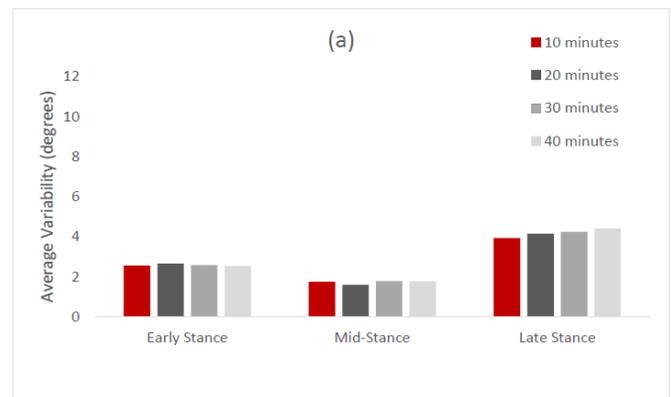

**Fig 1.** Sample Angle-Angle plot utilized for vector coding analysis.

Repeated measures ANOVAs with Time as the within-subject factor were used to evaluate all couples (23.0 SPSS, Chicago, IL, USA). Significance was set at an alpha level of 0.05.

## RESULTS AND DISCUSSION

There were no differences in coordination variability over time in any of the measured couples (Figure 2).

Although fatigue has previously been connected to changes in movement, these occurred during an exhaustive run [6]. We observed no effect of run time on coordination variability during this submaximal 40min run. There are a few factors that likely relate to this discrepancy between the current study and previous research. The runners in this study were well trained (i.e., ~35 miles/week) and a 40 minute run at a sub-maximal pace was in line with their normal training regimen. Furthermore, while this run was prolonged, it was not an exhaustive run. In these individuals performing a typical training run, they were able to maintain flexibility and adaptability in their movement. Perhaps if this were a novel task to the runners we would may have observed a decrease in variability over the course of the run.

**Fig 2.** Average Thigh Shank Coordination Variability during the Stance Phase of Running. (a) Sagittal plane motion of both segments. (b) Sagittal plane motion of the thigh coupled with transverse plane motion of the shank.

## CONCLUSIONS

These findings suggest that in well trained male and female runners, the completion of a submaximal prolonged run does not affect the adaptability of their system as evidenced by the unchanged coordination variability throughout the run. Future studies are needed as the current findings may be different in novice runners with less running experience or when completing a longer fatiguing run.

## INTRODUCTION

Improving the knowledge related to gait biomechanics across a range of running speeds may help to understand the contributing factors related to both running performance and running injuries. In fact, excessive running pace has been considered to be a risk factor for running injuries [1] but its influence on gait biomechanical variables remains poorly understood. For instance, rearfoot pronation and foot strike patterns have been associated to running injuries [2, 3] despite the fact that few studies have attempted to examine their behavior under different running speeds.

Regarding the spatiotemporal parameters, to our knowledge, no studies have examined the effect of increased running pace on stride width despite the fact that a narrow stride width has been associated with increased loading of the tibia during running. Therefore, the aim of this study was to investigate the effect of different running speed on foot strike index (FSI), spatio-temporal parameters and rearfoot pronation in competitive runners. We hypothesized that an increase in stride length, cadence and rearfoot pronation would be observed with increased running speed. In addition, we hypothesized that a shift towards forefoot strike as well as a narrower stride width would be present at higher speeds.

## METHODS

The data used in the present study were obtained from a public repository available at Figshare (DOI: [10.6084/m9.figshare.4543435](https://doi.org/10.6084/m9.figshare.4543435)). Briefly, twenty-eight competitive runners (27 males and 1 female) were analyzed. The information about demographics, anthropometrics and running habits can be accessed in the public repository. Three-

dimensional kinematics and kinetics data were obtained by a 12-camera motion capture system (Motion Analysis) and an instrumented treadmill (FIT, Bertec), while the subjects ran at 2.5 m/s, 3.5 m/s, and 4.5 m/s. The sampling frequency was 150 Hz for the kinematics and 300 Hz for the kinetics data. The FSI was calculated according to [4]. The data processing and data analysis were performed in Visual 3D software (C-motion). Either one-way ANOVAs or Kruskal-Wallis tests were performed to examine the effect of running speed considering the homogeneity of variances assumption. Post hoc pairwise comparisons were performed with Bonferroni adjustments whenever a main effect was observed. The level of significance was 0.05.

## RESULTS AND DISCUSSION

A main effect of running speed on stride length ( $X^2=71.33$ ;  $p<0.001$ ) and cadence ( $F=26.72$ ;  $p<0.001$ ) were observed. The post hoc analysis revealed that both stride length and cadence were significantly higher as the gait speed increased (Figure 1). It is possible to observe in Figure 1 that stride length increased at a greater extent compared to cadence, suggesting that runners may choose to rely more on larger strides than on more steps to cope with higher running speeds, particularly, within this range of gait speed (2.5 to 4.5 m/s). The peak eversion angle was also affected by gait speed ( $F=6.28$ ;  $p=0.003$ ), however, only when the extreme speed values were compared (2.5 m/s vs. 4.5 m/s) as displayed in Figure 1. Similar results have been reported in recreational runners during treadmill running at comfortable speeds [5]. Despite the fact that both rearfoot pronation and increased pace have been linked with running injuries, this relationship remains poorly understood and needs to be addressed in future studies.

Contrary to our hypothesis, no difference was observed for stride width ( $F=2.60$ ;  $p=0.08$ ) and FSI ( $F=0.217$ ;  $p=0.81$ ) which indicates that gait speed did not influence these variables. The lack of studies investigating similar question prevented any comparison. In regards to the effect of running speed on FSI, previous studies have produced contrasting results with some evidence suggesting the existence of an anterior shift of the center of pressure (as a result of increased speed); and others revealing lack of changes in foot strike patterns. The lack of agreement across studies may be explained by the differences related to the range of selected gait speeds, the method to calculate strike index and the controlled laboratory conditions (treadmill vs. overground). Future studies need to further address these issues.

## CONCLUSIONS

The results demonstrated that increased running pace was related to an increase in stride length,

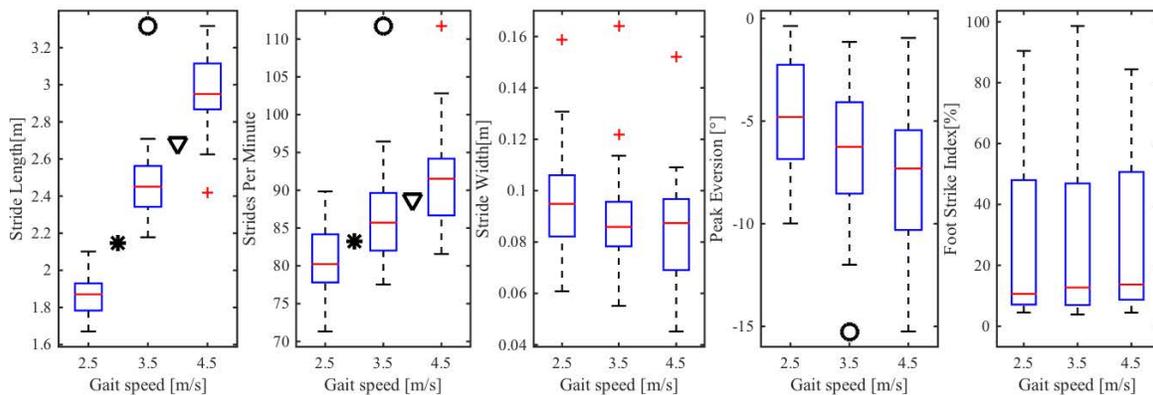

cadence and rearfoot pronation. In contrast, stride width and FSI were not affected by running speed.

## INTRODUCTION

Running is one of the most popular recreational activities worldwide, yet runners exhibit some of the greatest rates of overuse injuries. The gait parameters footstrike and stride length have received considerable attention in the scientific literature due to implications for running related overuse injuries.

Increased stride length has been associated with greater ground reaction forces, joint moments, impact accelerations, and energy absorption, factors that have been associated with an increased risk of running-related overuse injuries. Research has indicated that reducing stride length may decrease the risk of tibial stress fracture [1]. In terms of footstrike, running with a rear footstrike (RFS) pattern requires the tibialis anterior to decelerate plantar flexion as the foot contacts the ground. Correspondingly, running with a RFS has been associated with increased pressures in the anterior compartment of the lower leg. Alternatively, the triceps surae muscles are active to slow dorsiflexion when runners adopt a fore/mid footstrike (F/MFS) pattern. Hence, F/MFS running has been associated with higher Achilles tendon strain and plantar flexor moments [2].

While mechanical alterations and corresponding clinical implications are evident with alterations in both stride length and footstrike, these variables have been treated as independent factors in the literature. However, studies have reported data indicating flatter foot placement as stride length is decreased [3], which indicates that the variables of footstrike and stride length may be coupled. Therefore, the purpose of this study was to examine the relationship between footstrike and stride length in running, and to determine if these variables could be independently manipulated.

## METHODS

11 healthy active subjects (5 female, 6 male); mass:  $65.9 \pm 9.8$  kg; age:  $24 \pm 1.65$  years participated in this study. Participants completed two testing sessions that were separated by at least 24 h. Session 1 was used to determine the participant's preferred stride length and velocity. In Session 2, participants ran with their stride length manipulated to  $\pm 5\%$  and  $\pm 10\%$  of their preferred stride length. Participants completed these manipulated stride length trials with their self-selected footstrike (SSFS), as well as attempting to both RFS and F/MFS. 10 trials were completed for each stride length/footstrike condition.

To control running velocity to that of the preferred condition, subjects matched their speed to a marker on a motor driven pulley system located parallel to the runway. Stride length was controlled by having participants match foot falls to strips of tape placed along the runway.

3-dimensional motion analysis (Vicon, Oxford Metrics Ltd., UK) was captured as subjects ran across a 20m runway. Footstrike was determined from footstrike angle (FSA) based on the following:  $FSA > 0^\circ$  was defined as RFS, and  $FSA \leq 0^\circ$  was defined as F/MFS [4]. Participants also completed a brief questionnaire indicating the level of difficulty with adopting the RFS and F/MFS foot strike conditions.

A Pearson product moment correlation was conducted to examine the relationship between FSA and stride length. Repeated measures ANOVA tests were performed to examine the differences in FSA between the preferred condition and manipulated footstrike (SSFS, RFS, F/MFS) / stride length (-10%, -5%, +5%, +10%) conditions. Statistical significance was defined as  $p < 0.05$ .

## RESULTS AND DISCUSSION

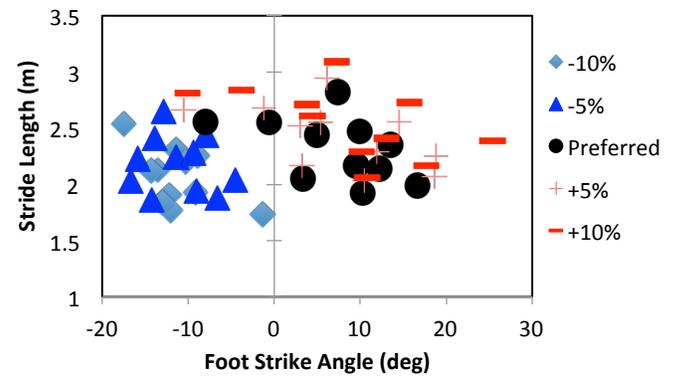

All but two participants were natural RFS runners as indicated by positive FSAs in the preferred condition. In the longer (+5% and +10%) stride length conditions nearly all participants continued to RFS. The two natural F/MFS strike runners were the only runners who did not adopt a RFS pattern with the longer stride length conditions. Thus, there was no significant difference in FSA between the +5%, +10% and preferred conditions ( $p > 0.05$ ). In the shorter stride length conditions all participants adopted a F/MFS position (Fig 1). FSAs for the -5% and -10% conditions differed significantly from the preferred condition (both  $p << 0.001$ ).

The correlation for the relationship between foot strike and stride length was low ( $r = 0.16$ ) and non-significant ( $p = 0.41$ ). This is likely due to the fact FSA did not continue to increase as stride length increased. At longer stride lengths runners adopted a RFS position and remained in a similar RFS position as stride length continued to increase.

Participants were able to adopt the imposed foot strike positions (F/MFS & RFS) at both longer and shorter stride lengths (Table 1). FSA was significantly different for the F/MFS condition at the longer stride lengths ( $p = 0.01$ ) and for the RFS condition at the shorter stride lengths ( $p = 0.02$ ). However, there was considerably more variability in FSA for the imposed foot strike conditions (Table 1). Additionally, participants reported greater difficulty with the reduced stride length RFS conditions.

**Table 1:** Footstrike angle for the stride length ( $\pm 5\%$  and  $10\%$ ) and footstrike conditions (SSFS, RFS, F/MFS). FSA  $> 0^\circ$  is RFS, and FSA  $< 0^\circ$  is F/MFS. \* Indicates a significant difference in FSA from the preferred condition, ^ indicates a significant difference in FSA from the other footstrike conditions (SSFS, RFS, F/MFS) at a given stride length.

	Footstrike	Stride Length Condition				
		-10%	-5%	Preferred	+5%	+10%
Footstrike Angle (deg)	SSFS	$-11.3 \pm 4.1^*$	$-11.1 \pm 3.9^*$	$7.2 \pm 7.0$	$6.8 \pm 9.3$	$8.6 \pm 9.0$
	RFS	$3.1 \pm 7.7^{\wedge}$	$3.2 \pm 8.3^{\wedge}$		$6.1 \pm 6.6$	$6.9 \pm 7.1$
	F/MFS	$-10.9 \pm 6.8$	$-8.5 \pm 7.2$		$-3.8 \pm 7.3^{\wedge}$	$-4.5 \pm 6.3^{\wedge}$

**Figure 1:** Foot strike angle (FSA) as a function of stride length for the preferred and SSFS altered stride length conditions. FSAs for the -5% and -10% differed significantly from the preferred condition ( $p < 0.05$ ).

## CONCLUSIONS

The results presented here indicate that footstrike and stride length are coupled, i.e. changing stride length leads to a corresponding change in footstrike. It is possible for individuals to uncouple these parameters, however it is done with difficulty and results in greater gait variability. When suggesting alterations in stride length or foot strike, clinicians should be aware of the associated changes in the coupled variable.

## INTRODUCTION

Kinematic and kinetic data describing the dynamics of lower-limb joints are critical for understanding the neuromechanics and energetics of human locomotion, and for guiding the design of assistive devices (e.g. lower-limb exoskeletons). From a basic science perspective, studies have provided insight into the sources of metabolic energy consumption by relating joint kinetics to whole-body oxygen consumption [1]. From an applied science perspective, kinematic and kinetic data are important for the geometric and material properties of lower-limb orthoses [2] and of motors sizing for powered exoskeletons and prostheses [3], as well as for guiding control software in both powered exoskeletons [4] and prostheses [5].

Combining experimental approaches like motion capture and force measurements with rigid body models (i.e. inverse dynamics) provides a means for obtaining lower-limb joint kinematics and kinetics data. Many studies have addressed walking or running at typical speeds on level ground [1,6]. Yet data acquisition is expensive and time-consuming, and therefore available joint-level data is limited to only a small subset of speeds. The same holds for data from locomotion uphill and downhill. Additionally, relationships describing how lower-limb joint kinematics and kinetics depend on the phase of gait have not been documented using parametric-equations, which if developed could help fill in data gaps in the literature without requiring exhaustive data acquisition.

Using an experimental data set, our aim was thus to develop a comprehensive parametric model of lower-extremity joint kinematics and kinetics during human running up and down slopes.

## METHODS

In two separate experiments, at two different labs (BGU and NCSU), sixteen healthy adults (6 females; 10 males; age =  $24.56 \pm 3.16$  years; height =  $1.73 \pm 0.09$  m; mass =  $68.01 \pm 13.98$  kg) ran on an instrumented split belt treadmill (FIT, Bertec, Columbus, OH, USA) at 2.25 m/s at nine grades (-10%, -7.5% -5%, -2.5%, 0%, +2.5% +5%, +7.5%, +10%). In each of the experimental conditions, force and motion data of at least 7 gait cycles (average = 20) were collected (MX40+, VICON, Oxford, UK or Oqus, Qualisys Medical AB®, Gothenburg, Sweden). Then the kinematics and kinetics of the leg joints were calculated using Visual3D software (C-motion Inc., Germantown, MD, USA). All kinematics and kinetics were normalized in time as percentages of one gait cycle. In addition, torque and power were normalized by the subject's height and weight.

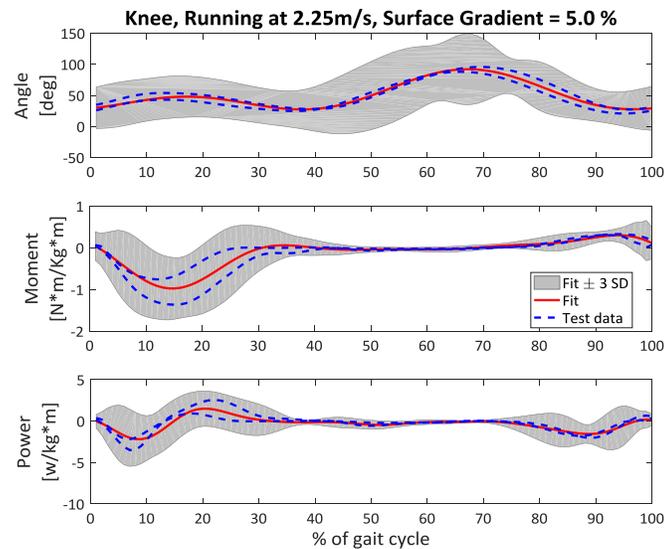

Then based on a method by Mizrachi et al. [7] we developed the prediction equations for running in different slopes using data from randomly selected 14 subjects (7 from each group). Each of the above equations was developed in two phases: First, an equation was fitted for each of the five training slopes (-10%, -5%, 0%, 5%, 10%) separately (45 equations = 3 joint\*5 slope\*[angle, torque, power]), where for each joint and given slope the equation's input was the percentage of the gait cycle. Since gait exhibits periodic behavior, we used a Fourier series in the form of sine and cosine with  $\omega = 2\pi / 100$  to model these equations. Then, in the second phase, we modeled the change in value of each of the Fourier series coefficients as a function of the slope, using a polynomial. For both phases we developed an algorithm that found the best fit (Adjusted  $R^2$ ), using the lowest order of series/polynomial. To test the prediction equations, we examined the two subjects who were not used in developing the equations. Also, we tested several slopes that were not included in the training set (-

7.5%, -2.5%, 2.5%, 7.5%). If the results of the test data fell within 3 standard deviations (SD) from the fit, we considered it as a successful fit. The 3SDs were calculated using the training data.

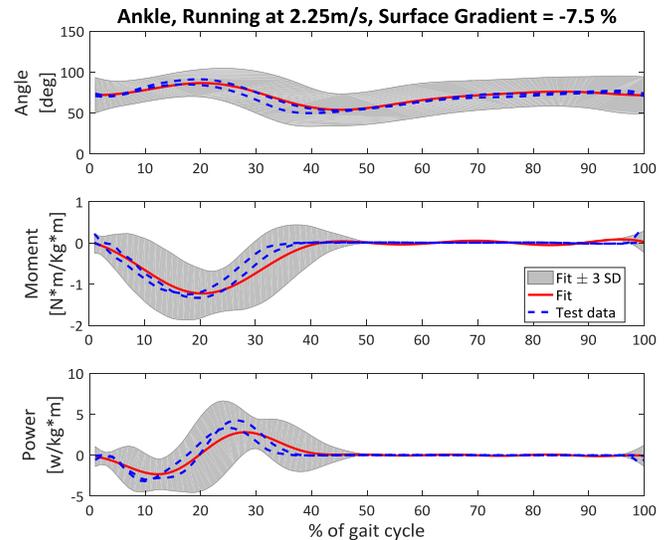

## RESULTS AND DISCUSSION

The prediction equations had an Adjusted  $R^2$  for the leg joint kinematics and kinetics ranging from 0.943 to 0.997. We also show that newly presented data (either for new subjects or new slopes), which were not used for the equations fitting, in most cases fell within 3 standard deviations from the prediction. Figure 1 is an example for the knee, at 5% slope of new subjects' data, and Figure 2 is an example for prediction on untrained subjects and slopes.

In addition, from our analysis we did not see differences between the male's and female's data. Furthermore, since the equations were developed based on data that were collected in two different sites, with different motion capture systems and with similar but not identical marker placements, we believe prediction equations are a good representation of the general healthy adult population.

**Figure 1:** Test of the predictions using new subjects at a 5% slope. The red curve represents the prediction equation, and the grey area  $\pm 3$  SD of the training set. The dashed lines represent the test subjects.

**Figure 2:** Test of the predictions using new slopes of -7.5% slope. The red curve represents the fit, and the grey area  $\pm 3$  SD. The dashed lines represent test data.

## CONCLUSIONS

The prediction equations enable predicting the leg joint angle, torque, and power during running as functions of the slope and percentage in the gait cycle. This set of equations could be used to gain a better understanding of locomotion, and may be helpful in the development of assistive devices such as prostheses and wearable robots.

# EFFECT OF TRANSITIONING RUNNING STYLE FROM A REARFOOT TO A NON-REARFOOT STRIKE PATTERN ON IMPULSE PER UNIT DISTANCE

Alec J. Smith, Erin M. Florkiewicz, Donald L. Goss, Gregory M. Freisinger

United States Military Academy, West Point, NY, USA

Email: [gregory.freisinger@usma.edu](mailto:gregory.freisinger@usma.edu)

## INTRODUCTION

Running is a primary form of physical conditioning and point of evaluation for military personnel. Lower extremity injuries are common in military training due to the frequency and dynamic nature of the associated loads [1]. Several approaches have been taken to mitigate running injuries among athletes and military personnel alike. One approach is the modification of a runner's foot strike pattern (FSP).

Transitioning runners from a rearfoot strike (RFS) to a non-rearfoot strike (NRFS) pattern has been shown to influence several factors related to running injuries, to include a reduction in average vertical loading rate (AVLR) [2]. This idea is well established, but there are likely other factors influencing running related injuries including cadence and the influence of total impulse.

The purpose of this study was to analyze the effect of a NRFS running program on overall impulses per unit distance. We hypothesized that impulse per unit distance will remain constant in the vertical, anterior, posterior, medial, and lateral directions following a running transition programs.

## METHODS

Nine runners recovering from lower extremity injuries at the United States Military Academy were recruited to participate in this study after providing IRB approved consent. All participants were cadets with previous running experience (5 males:4 females; mean age:  $20.3 \pm 2.2$  yrs; mean height:  $170.7 \pm 13.8$  cm; mean weight  $71.7 \pm 14.9$  kg).

Participants met each of the following six inclusion criteria: 1) previously a RFS runner; 2) recovering from a lower extremity injury; 3) able to walk pain free for 2 miles; 4) dorsiflexion range of motion of at

least 80% symmetry; 5) capable of performing 20 unassisted single leg heel raises; 6) able to perform a single leg hop for distance with at least 80% symmetry. These participants were clinically diagnosed and recovering from one of the following lower extremity injuries: patellofemoral pain syndrome (3), lower leg stress injury (2), lower leg fracture (1), plantar fasciitis (1), and anterior cruciate ligament reconstruction (2).

To encourage a transition to a RFS pattern subjects underwent an initial 30 minute training session. Training focused on soft landings, an increase in cadence, forward trunk lean and their strict adherence to a gradual walk-to-run progression. They then met with an assigned medical provider once a week for the first 4 weeks, then again at weeks 6, 8, and 10 upon which the training focuses were reinforced and PSFS (Patient Specific Functional Scale) data were collected. Initial and 10 week assessments were conducted before and after the 10-week training program. Assessments consisted of subjects running at a self-selected pace for five minutes. Speed was kept constant for both the initial and follow up assessment. Two-dimensional video was collected at 240 Hz [Casio, EX-ZR200; Tokyo, Japan] in the sagittal plane to confirm FSP. Ground reaction force data were collected on an instrumented treadmill [Bertec; Columbus, OH] at 1000 Hz, low-pass Butterworth filtered at 35 Hz, and normalized to bodyweight.

Impulse was calculated in the vertical, anterior, posterior, medial and lateral directions for five stance phases on each foot. The ensemble average of five stance phases for the left and right were used in further analyses. Average impulses were multiplied by the respective runner's cadence (in right foot steps per minute) and divided by their treadmill speed (in meters per second). Unit conversions yielded impulses per unit distance which was multiplied by

1000 meters to find impulse measured in bodyweight\*seconds per kilometer.

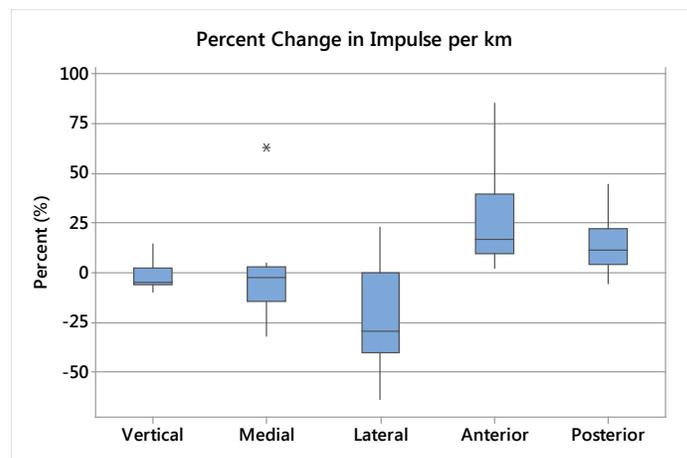

A paired t-test was used to test for statistical difference between the initial and follow-up assessments for the impulse variables and subjective measures. A significance level alpha = 0.05 was used.

## RESULTS/DISCUSSION

The transition from RFS to NRFS was verified by the high speed video for all subjects. Initial, follow up and change data are shown in Table 1 for the variables of interest. PSFS and running cadence significantly increased as expected following the running transition protocol.

Contrary to our hypotheses, significant differences were found in anterior, posterior and lateral impulses per km ( $p < 0.01$ ,  $p < 0.05$ ,  $p < 0.05$  respectively). However no differences were found in the vertical or medial directions. Boxplots for the percent changes in impulse per km are displayed in Figure 1.

Average individual anterior and posterior impulse per km increased by 26.3% and 14.3%, respectively, while vertical impulse did not increase. Our NRFS transition program emphasized increased running cadence, therefore resulting in a larger number of foot strikes per unit distance. While NRFS has shown a significant reduction in vertical loading rate compared to RFS, our results indicate an increase in total braking and propulsive impulse per unit distance. This increase in total impulse may influence running injury risk over the long-term.

**Figure 1:** Box plot of average percent change in impulse per kilometer.

## CONCLUSION

Anterior, posterior and lateral impulses per unit distance increased following a running transition program. Transitioning from a RFS to a NRFS improved subjective functional scores, however it is unknown how increased total impulse per unit distance may impact running injury risk. Additional research is necessary to further identify the long-term effects of kinetic changes induced from modifying running foot strike pattern.

# A BIOMECHANICAL INVESTIGATION OF COMPENSATION STRATEGIES USED BY RUNNERS IN RESPONSE TO REDUCED CORE STABILITY

Margaret E Raabe and Ajit MW Chaudhari  
The Ohio State University, Columbus, OH, USA

email: margaret.e.raabe@gmail.com, web: <http://u.osu.edu/osusportsbiomechanics/>

## INTRODUCTION

Insufficient core stability is believed to lead to less efficient movements and ultimately musculoskeletal injury, despite minimal scientific evidence supporting this theory. Additionally, compensation strategies that may be utilized by runners lacking sufficient core stability have yet to be investigated.

Altering movement patterns may be one strategy to compensate for poor core stability (kinematic compensation strategy, KIN). Another possibility would be to alter only muscular activation strategies (neuromuscular compensation strategy, NM). The compensation strategy chosen by a runner lacking sufficient core stability may be driven by a number of factors including energy cost, as the minimization of energy expenditure is believed to play a large part in locomotion [1]. Understanding the advantages and disadvantages of these strategies could ultimately provide insight into the influence of core stability on injury risk.

The purpose of this study, therefore, was to identify the biomechanical consequences associated with possible compensation strategies for reduced core stability during running using subject-specific musculoskeletal simulations.

## METHODS

Eight novice runners jogged overground in a motion capture laboratory before and after performing a fatiguing core stability knockdown protocol (CSKP) [2]. All runners in this subset of a previously-reported in vivo study [3] had a significant difference in at least one hip or knee kinematic variable post-CSKP. Four runners experienced experimentally reduced core stability and increased core muscle fatigue following the CSKP (CS group) and the remaining four experienced only core muscle fatigue and no change in core stability

following the CSKP (NCS group). Subject-specific kinematically-driven jogging simulations (Fig. 1) were developed in OpenSim [4] for each participant in four different conditions (pre-CSKP kinematics, no core fatigue; pre-CSKP kinematics, core fatigue; post-CSKP kinematics, no core fatigue; post-CSKP kinematics, core fatigue) in order to isolate and fully characterize the effect of utilizing either the KIN or NM strategy on lower extremity (LE) variables previously associated with running injuries.

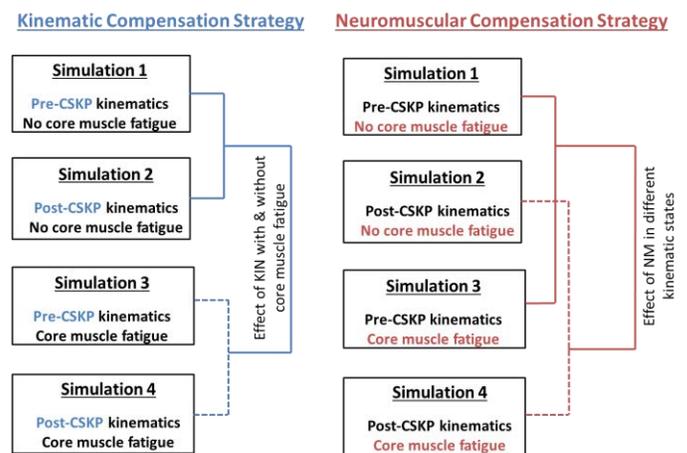

Figure 1. Schematic describing the four subject-specific simulations developed for each participant.

Linear mixed-models were used to test for a significant effect of a KIN or NM strategy in response to core muscle fatigue on the primary variables. The kinematic state (pre-CSKP, post-CSKP), the core fatigue state (none, fatigue), and their interaction were treated as fixed effects and participant was treated as a random effect ( $\alpha=0.05$ ). Results trending toward significance ( $0.05 \leq p \leq 0.1$ ) were also reported. These analyses were conducted separately for the CS and NCS groups to provide insight into which biomechanical changes may be driven by reduced core stability vs. core muscle fatigue. Loading variables presented are internal.

## RESULTS AND DISCUSSION

### Kinematic Compensation Strategy

Runners with experimentally reduced core stability following the CSKP adopted a KIN associated with reduced energy consumption estimated as total cubed muscle stress ( $3249.3 \pm 1317.5 \text{ MPa}^3$  vs  $3009.9 \pm 1259.1 \text{ MPa}^3$ ,  $p=0.059$ ), cumulative lumbar spinal compression ( $p \leq 0.06$ ), and peak core muscle force production (non-dominant psoas (NDom PS),  $p=0.06$ ; NDom internal oblique (IO),  $p=0.027$ ). However, these changes were accompanied by an increased peak patellofemoral joint reaction force ( $6.2 \pm 1.0 \text{ BW}$  vs  $6.6 \pm 0.7 \text{ BW}$ ,  $p=0.029$ ), peak knee abduction moment ( $4.3 \pm 0.9 \text{ \%BW} \cdot \text{h}$  vs  $5.1 \pm 0.8 \text{ \%BW} \cdot \text{h}$ ,  $p=0.01$ ), knee abduction impulse ( $0.6 \pm 0.2 \text{ \%BW} \cdot \text{h} \cdot \text{s}$  vs  $0.7 \pm 0.3 \text{ \%BW} \cdot \text{h} \cdot \text{s}$ ,  $p=0.02$ ), and peak knee extension moment ( $16.4 \pm 1.5 \text{ \%BW} \cdot \text{h}$  vs  $17.2 \pm 2.4 \text{ \%BW} \cdot \text{h}$ ,  $p=0.09$ ) during the stance phase of running (Figure 2). These LE loading changes have previously been associated with increased running injury risk.

	CS group N=4	NCS group N=4
peak patellofemoral joint reaction force	↑ $p=0.029$	$p=0.85$
peak knee abduction moment and impulse	↑ $p=0.01$ ↑ $p=0.02$	↓ $p=0.003$ ↓ $p=0.001$
peak knee extension moment	↑ $p=0.09$	$p=0.58$
estimated energy consumption	↓ $p=0.059$	$p=0.51$
lumbar spine compression force impulse	↓ $p \leq 0.06$	$p \geq 0.1$
peak core muscle force production (IO, PS)	↓ $p \leq 0.06$	$p \geq 0.1$

Figure 2. Biomechanical variables affected by a kinematic (KIN) compensation strategy in response to an experimental core muscle fatiguing protocol. The arrows indicate changes in parameters with a change in kinematics.

### Neuromuscular Compensation Strategy

An NM strategy adopted in response to simulated core muscle fatigue was associated with decreased compressive lumbar spinal loading (CS group: peak compression,  $p \leq 0.04$ ; compression force impulse,  $p \leq 0.06$ ; NCS group: compression force impulse,  $p \leq 0.08$ ), decreased superficial peak core muscle force production (CS and NCS group: Dom and NDom rectus abdominis (RA) and IO and Dom external oblique (EO),  $p \leq 0.033$ ) and increased peak deep core muscle force production (CS group: NDom multifidus (MF),  $p=0.18$ ; NDom quadratus lumborum (QL),  $p=0.18$ ; NCS group: Dom QL,

$p=0.21$ ; NDom PS,  $p=0.18$ ) (Figure 3). NM was not associated with significant changes in estimated energy consumption or LE loading during the stance phase of running, suggesting NM may be preferable to a KIN strategy that potentially results in increased LE loading and injury risk.

	CS group N=4	NCS group N=4
peak lumbar compression force	↓ $p \leq 0.047$	$p \geq 0.1$
lumbar compression force impulse	↓ $p \leq 0.06$	↓ $p \leq 0.08$
estimated energy consumption	$p=0.21$	$p=0.36$
lower extremity loading	$p \geq 0.1$	$p \geq 0.1$
peak superficial core muscle force (RA, EO, IO)	↓ $p < 0.05$	↓ $p < 0.05$
peak deep core muscle force production	↑ Ndom MF $p=0.18$ ↑ Ndom QL $p=0.18$	↑ Dom QL $p=0.21$ ↑ Ndom PS $p=0.18$

Figure 3. Biomechanical variables affected by a neuromuscular (NM) compensation strategy adopted in response to simulated core muscle fatigue. Arrows indicate changes in parameters with changes in core muscle fatigue.

### CONCLUSIONS

Results from this study suggest that novice runners with insufficient core stability may adopt altered movement patterns associated with increased lower extremity loading and ultimately a higher risk of sustaining a running-related injury. Since the only apparent adjustment required to utilize an NM strategy was an increase in force production of the deep core musculature, proper training of these muscles may give runners the ability to utilize lower-risk compensation strategies in the presence of core muscle fatigue and/or poor core stability. Future work may consider developing a neuromuscular training program specifically for runners and determining if this program can reduce LE loading during running and thereby reduce running injury incidence.

### INTRODUCTION

Our limited understanding of the trunk's role in producing running locomotion is partly due to lack of knowledge of the intra-trunk motions and how these motions change with running speed. [1, 2] Most studies have concentrated on lower lumbar and pelvic mechanics or represented the trunk as a single rigid unit which potentially dilutes the effect of individual trunk segments. [3]

Also, we have very little understanding of movement pattern changes in the trunk, if any, observed among middle-age runners even though changes in certain gait parameters and lower limb mechanics in walking and running have been reported in elderly runners. [4] Multiple studies have reported relationships between various musculoskeletal injuries and age, with more complex or multiple running related injuries documented especially for middle age runners [4], but their relation to altered trunk mechanics is not clear.

Thus, the purpose of the study was to determine if intra-trunk displacements change with increase in running speed and how these differ in middle age runners compared to younger runners. It was hypothesized that intra-trunk motions will increase with age and at faster running speeds, particularly for segments with lower anatomical constraints like the lumbar spine [5].

### METHODS

Sixteen young adult (YA) runners under the age of 40 (age: 32.7±4.9 yrs, mass:71.6±15.8 kg, height:1.70±0.09 m, 21.1±6.1 miles/week) and 14 middle age (MA) runners over 40 (54.6±7.9 yrs, 69.3±13.1 kg, 1.72±0.10 m, 20.2±9.5 miles/week) participated in this study. Locations of 24 reflective markers placed on the trunk and the pelvis were captured by a 7-camera system (120 Hz; Vicon) and was used to collect kinematic data during treadmill (PreCor C954) running. Participants ran at their self-selected jogging (JOG) and maximal (MAX)

treadmill running speeds for 10 minutes at JOG speed and about 15 sec at MAX. Data was collected for 10 sec during the runs. At the completion of running trials for each speed, participants rated their perceived exertion (RPE) using the Borg scale (6-20). Relative angles between adjacent trunk segments (upper [UP]: C7 to T8; middle [MID]: T9 to T12; lower [LOW]: L1 to L5; and pelvis [PEL] were calculated; maximum angular displacements were averaged across 10 strides. Displacements in the 3 planes of motion were compared between groups using a mixed-design ANOVA with speed (JOG and MAX) as the within-subject factor and age (YA and MA) as the between-subject factor ( $p<0.05$ ). *Post-hoc* comparisons with Bonferroni corrections were used to compare means when main effects were observed.

### RESULTS AND DISCUSSION

Speed ( $p = <0.001$ ) and age ( $p = 0.009$ ) main effects were observed for running speed as MA ran slower than YA runners at JOG and MAX paces (**Table 1**). This finding is consistent with those previously reported in the literature [6].

A speed main effect was also observed for Borg RPE ( $p=<0.001$ ; **Table 1**). This effect is due to higher RPE at the JOG and MAX speeds in MA compared to YA. These RPE results suggest both groups were able to reach their maximal efforts on a treadmill making the kinematic comparisons more meaningful and consistent.

The only interaction effect observed from the joint kinematic variables was observed for angular displacements of LOW-PEL joint in the transverse plane ( $p=0.015$ ; **Table 1**). No other interaction effects were observed. Age main effects were observed for all comparisons except for UP-MID angular displacements in the sagittal and frontal planes (**Table 1**). Generally, displacements were greater for MA compared to YA groups for both

running speeds. Speed main effects were observed mainly in the frontal plane for all 3 relative angles and in transverse plane for Low-Pel (lumbo-pelvic) angle (**Table 1**). Displacements decreased in the proximal 2 angles (UP-MID and MID-LOW) in the frontal plane, while it increased in the LOW-PEL for both frontal and transverse plane. This suggests that lumbo-pelvic (LOW-PEL) segmental arrangement potentially contributes the most towards net trunk angular, as the individuals increase their pace regardless of the age.

Overall, both MA and YA groups display greater angular displacements at slower speeds (MA > YA) especially in the transverse plane. Possible explanations include increase in trunk momenta to help cancel some of the greater total body angular momenta[1,7]; appropriately position the pelvis to allow increased leg rotations and longer step lengths[8]; transfer or generate mechanical energy to/from extremities[9]; and/or minimize nonessential center of mass (COM) motion via compensatory shifting of intra-trunk mass [10].

As the running speed increases, trunk mechanics is shifted to minimizing the nonessential COM motion at superior trunk segments (UP-MID and MID-LOW) and limiting the angular momentum and torque production at the lumbar spine (LOW-PEL). This could potentially be a compensatory strategy to increase efficiency of mechanical energy transfers between trunk-pelvis-lower extremity segments.[11] Minimal differences were observed in the UP-MID

joint potentially due to existing anatomical constraints restricting contributions to total body/trunk angular momentum [4]. Also, the observed differences in most comparisons were of small magnitude and should be interpreted with caution, giving full consideration to inter-participant variabilities in running speed ranges, skills and habituation towards running on a treadmill.

## CONCLUSIONS

These findings suggest that runners adapt to changes in speed and advancing age by modifying their trunk kinematics to be able to successfully achieve the performance goals. Future studies warrant including older adult runners (>60 years) to understand if the trend for change in mechanics continues and how it effects running performance.

## INTRODUCTION

The high injury incidences associated with running are well reported. Research suggests that more complex or multiple running-related injuries are observed in middle age runners [1]. Changes in certain running gait parameters have been reported in *older* (i.e., 60+ years) compared to younger runners (i.e., 20s) [1,2] and may play a role in injury development. However, little is known regarding movement patterns observed among *middle-age* runners (i.e., 40-59years). Predictive regression equation suggests decreased stride length, running velocity and peak knee flexion angles with age, while peak hip and ankle sagittal angles in the stance phase were not considered significant predictors [3]. To date, few running biomechanics studies in aging runners have tested more than one running speed.

Increases in running speed can alter running biomechanics. Specifically, increases in peak knee and ankle sagittal plane angles and ranges of motion (ROM) have been reported with increase in running speed. [4] Comparing running biomechanics between young and middle age runners at different speeds will help improve our understanding of age-related running gait patterns.

The objective of this study was to compare lower limb joint kinematics between young and middle age runners during treadmill running at self-selected jogging and maximal speeds. It was hypothesized, that peak knee and ankle angles will increase with increase in speed but minimal change in mechanics was expected between age groups.

## METHODS

Twelve young adult (YA) runners under the age of 40 (10 women; 32.8±4.9 yrs, 69.8±16.3 kg, 1.68±0.08 m, 21.1±6.1 miles/week) and 12 middle

age (MA) runners over 40 (7 women; 54.6±8.3 yrs, 68.0±13.8 kg, 1.68±0.08 m, 20.2±9.5 miles/week) participated in this study. A 7-camera motion capture system (120Hz, Vicon) was used to collect kinematic data during treadmill (PreCor C954) running. Participants ran at their self-selected jogging (JOG) and maximal (MAX) treadmill running speeds for 10 minutes at JOG speed and about 15 sec at MAX. Data was collected for 10 sec during the runs. At the completion of running trials for each speed, participants rated their perceived exertion (RPE) using the Borg scale (6-20). Sagittal plane joint angular kinematics (peaks and ranges of motion (ROM)) of the hip, knee and ankle were calculated for the right side only. The average of each angular kinematic variable for 7 consecutive strides were included in statistical analyses.

A mixed-design ANOVA was used with speed (JOG and MAX) as the within-subject factor and age (YA and MA) as the between-subject factor ( $p<0.05$ ). Paired t-tests with least significant difference were used to compare means when speed main effects were observed. Independent t-tests were used to compare means when age main effects were observed.

## RESULTS AND DISCUSSION

A speed main effect was observed for running speed as MA (5.4±2.1 m/s) ran slower than YA runners (7.2±2.1 m/s;  $p=0.019$ ). This finding is consistent with those previously reported in the literature [4]. Cadence was not different between YA and MA (Table 1). This finding suggests that higher cadence in older runners [2,3] is not a kinematic strategy used by middle age runners. An interaction effect was observed for Borg RPE ( $p=0.022$ ; **Table 1**). The lower RPE at MAX speed in MA compared to YA may suggest that MA runners were unable to achieve a maximal effort perhaps because they were

afraid to reach their true maximal speed on the treadmill.

The only interaction effect observed from the joint kinematic variables was for peak dorsiflexion ( $p=0.021$ ). YA generally had greater peak dorsiflexion than MA and, peak dorsiflexion was only reduced for YA for MAX compared to JOG speed (**Figure 1**). This findings suggests that increased running speed does not affect peak dorsiflexion in MA runners. This may be related to limited sagittal plane ankle mobility in MA. Smaller peak dorsiflexion would suggest a shorter lever arm for the ground reaction force which would explain the lower peak internal plantarflexion moment observed in runners in their 50s compared to runners in their 20s [3]. Contrary to that reported in the literature [3,6,7], knee ROM was similar between YA and MA (**Table 1**). These findings suggest that although older runners run with less knee flexion than young runners, MA runners still retain similar knee flexion during stance as YA runners. Since less knee flexion is generally paralleled by higher knee joint stiffness [7], the unchanged knee flexion in MA runners may suggest similar joint stiffness compared to YA runners. A group main effect was observed for hip extension ROM from foot strike to toe-off (**Table 1**). MA runners ran on average with less hip extension ROM compared YA. Lesser hip extension despite comparatively high cadence explains the slower speeds observed in MA compared to YA.

Finally, speed effects were observed for dorsiflexion excursion and hip extension at toe-off (**Table 1**). Greater dorsiflexion excursion, hip extension ROM and hip extension at toe-off were observed at MAX vs JOG speeds. This may be a

compensatory mechanism to unchanged peak knee flexion between groups to maintain cadence while speed is increased.

## CONCLUSIONS

These findings suggest that lower limb joint kinematics are generally not different between young and middle age runners. Only peak dorsiflexion and hip extension ROM were smaller in middle compared to young runners. The age by speed interaction for peak dorsiflexion suggests that middle age runners respond differently to an increase in running speed compared to young runners. We hope to add to these preliminary findings by including running biomechanics data from older runners (i.e., over 60 years).

# ESTIMATION OF TRUNK MUSCLE ACTIVATION DURING OVERGROUND RUNNING

<sup>1</sup> Jeffrey McClellan, <sup>1</sup> Tim Derrick

<sup>1</sup> Iowa State University, Ames, IA, USA  
email: jeffmc@iastate.edu

## INTRODUCTION

The low back is a commonly studied area of the body due to injury risk during tasks involving bending and/or lifting. Modeling research has been performed which estimates the compressive load on the lumbar spine during bending and lifting tasks, as well as during walking [1].

During running, research has been performed which estimates the joint reaction force at the L5-S1 joint [2], however there is no current research which examines the muscular contribution to lumbar compressive forces during running.

Thus, the purpose of this study was to 1) develop a musculoskeletal model which can estimate, via optimization, the magnitude and timing of lumbar muscle contractions during running, and 2) compare the timing of the modeled muscle activation to EMG recordings of trunk musculature.

## METHODS

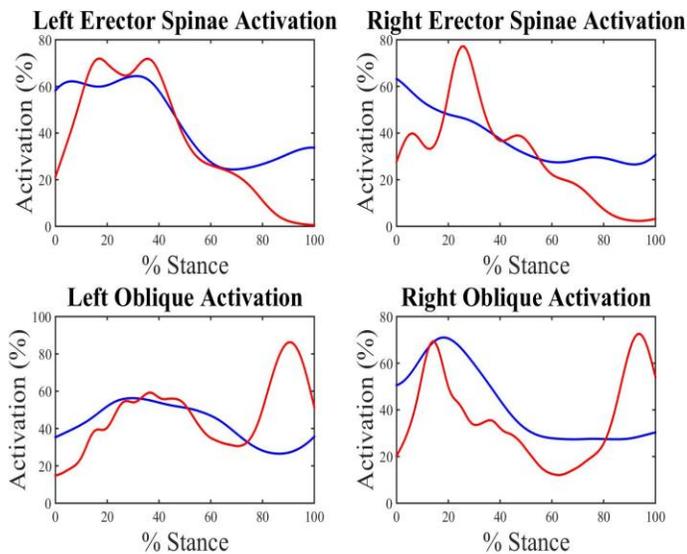

Five runners (27.8±8.9 y, 81.2±16.8 kg, 1.79±0.06 m, 25.4±10.3 km/w) were recruited to participate in this study. Informed consent was obtained from all participants, after which they were instrumented with electromyography (EMG) electrodes (2000 Hz, Delsys, Natick, MA) on the erector spinae, and obliques. 26 retro-reflective markers were then placed on the right shoe, leg, pelvis, trunk and left shoe. Participants completed 8 successful running trials over a force platform (2000 Hz, AMTI, Watertown, MA) at 4.25 m/s while wearing lab provided test shoes. Kinematic, Force, and EMG data were collected concurrently using a three dimensional motion analysis system (200 Hz, Vicon MX, Vicon, Centennial, CO).

All analyses were performed using custom matlab programs. Kinematic and kinetic data were low-

pass filtered at 20 Hz [3]. A rigid body model was used with inverse dynamics to estimate 3D joint moments, and reaction forces at the L5-S1 joint. Cylindrical ellipsoids were used to estimate trunk and pelvis volumes, while segment densities, centers of mass, and moments of inertia were calculated according to Pearsall [4]. A musculo-skeletal model was used to estimate muscle insertion, origin, fiber length, tendon slack length, and maximum contractile force, for the right and left erector spinae, internal obliques, and external obliques [5], while an approximation of the L5-S1 joint center was calculated as a point lying 5% along a line between the external location of L5-S1, and the midpoint between the right and left Anterior Superior Iliac Spine.

Muscle forces were calculated by first estimating dynamic muscle moment arms based upon 3D L5-S1 joint kinematics, and the pre-defined muscle origins and insertions. An optimization routine was then run using the muscle parameters, dynamic moment arms, and 3D L5-S1 joint moments in order to calculate the minimum muscle force needed to recreate the 3D joint moment.

Muscle forces calculated via optimization were compared to the recorded EMG signal, which was used as an estimation of muscle activation, with the internal and external oblique forces being combined. The EMG was processed by removing the DC offset, rectifying the signal, and applying a low-pass filter at 10 Hz. Since signal amplitude was not being considered, resultant EMG signals and muscle forces were expressed as a percent of the max recorded force/amplitude during the first 50 percent of stance. Group ensemble averages for muscle forces and the filtered EMG signal were created (Fig. 1), while average correlations between the conditions were calculated for each subject, and on the ensemble averages.

**Figure 1:** Group ensemble averages derived via EMG (blue) and optimization (red).

## RESULTS AND DISCUSSION

R-values for each individual subject/muscle group were quite variable, with correlations ranging from being moderate and negative, to strong and positive. Group ensemble averages tended to have stronger correlations between the conditions although R-values for the left obliques were negative (Table 1).

It should be noted that the muscle activation derived via optimization accounts for all flexor and extensor activation crossing L5-S1, while the muscle activation derived via EMG is location specific. This can lead to activation from additional muscles, which were not accounted for in our model, being attributed to either the erector spinae or the obliques. It is likely that this occurred among the obliques, as a flexor torque at the end of stance resulted in optimization generating large amounts of muscle activation that is not evident when viewing the EMG. It is possible that the rectus abdominis or the psoas muscles could have been active at this same point in time, producing the associated flexor torque.

The right erector spinae may have been similarly affected, as deeper multifidus activation could account for torque production not recorded by the EMG. Individual subject variability may also play a

role, as some individuals displayed EMG patterns that more closely resembled those derived via optimization.

High levels of EMG activation at ground contact and toe off not seen during optimization highlight the potential that some co-contraction is unaccounted for when performing optimization routines, which would lead to an underestimation of the muscular force produced.

**Table 1:** R-values comparing EMG activation and activation derived via optimization

Subject	Left ES	Right ES	Left Obl	Right Obl
1	0.43	0.33	-0.27	0.12
2	0.75	0.33	0.36	0.58
3	0.18	0.46	-0.41	-0.29
4	0.21	0.31	-0.18	0.16
5	0.77	0.24	0.19	0.52
Ensemble	0.85	0.64	-0.17	0.39

## CONCLUSIONS

The optimization method applied appears to do a reasonable job of approximating the timing of muscle activation during the first half of stance at the group level, but may not accurately depict the timing for individual subjects/trials. Additional muscle groups could be added to the optimization routine in order to more accurately depict muscle activation at the end of stance, although it is unknown if this addition would result in a marked difference in the extensor or flexor forces produced.

## INTRODUCTION

Stress fractures account for the greatest loss of training days among military recruits [1]. Among tibial stress fractures (TSF) risk factors, peak positive tibial axial acceleration (PTA) during running has been found to be higher in runners with a history of TSF [2,3]. PTA can be measured in the field using inexpensive accelerometers. For clinicians, assessing movement strategy can also offer insight into injury risks in runners. The Functional Movement Screen (FMS) is an assessment of several fundamental actions of the human locomotor system [4]. FMS has identified higher risk for injury in male runners who score lower on both the deep squat and active straight leg raise tests versus those who score higher [5].

In novice runners, PTA increases after a single prolonged run to fatigue as measured by gas exchange [6]. In highly trained runners, PTA does not increase over the course of 20min runs at lactate threshold pace (i.e., submaximal) [7]. Training and training-induced muscle damage may alter joint properties associated with shock attenuation [8]. Given that prolonged running alters motor control [6] and training can alter FMS scores [9], FMS test scores may be altered by a single bout of prolonged running and after cumulative training exposure.

Understanding the effects of prolonged running and cumulative training on PTA and FMS scores will provide important information on the appropriate timing of screening tests for injury risk. This may allow for more sensitive results when screening for injury risks to ultimately help reduce injury development. The **purpose** of this study is to assess the effects of prolonged running and cumulative running training on PTA and FMS deep squat and active straight leg raise in novice runners. We expected an increase in PTA and a decrease in FMS scores following both a prolonged run and a 3-week running training program in novice runners.

## METHODS

Sixteen novice runners were recruited for this study. However, only 9 were able to complete the entire study protocol (5 women; 26±7yrs; 73.0±16.3kg; 1.70±0.12m; 11.2±2.7 miles/week; 13.6±7.2 months of running experience). All participants read and agreed to IRB documents before participating.

Participants were instructed to reduce their training volume by at least 80% the week prior to the first testing session. During the first testing session, overall and lower limb fatigue was recorded using a visual analog scale (VAS; 0-10). Participants then performed two FMS exercises: deep squat (DS) and bilateral active straight leg raise (ASLR). The ASLR of each leg was scored out of a possible 6 points, while the DS was scored out of a possible 18 points. Following the FMS, a 3D accelerometer (480Hz, PCB Piezotronics, USA) was attached to the distal anteromedial aspect of the right tibia and aligned with its longitudinal (Z) axis [7] to collect PTA during running. Participants then completed a 30-min run at a preferred running pace (10.0±1.5 min/mile) on a treadmill (C962i, Precor, Woodinville, WA, USA). Tibial acceleration data were gathered after 4 min (Pre-Run), 15 min (Mid-Run), and 30 min (Post-Run) using motion capture software (QTM, Qualisys AB, Sweden). Immediately following the run, overall and lower limb fatigue and the FMS tests were performed once again.

For the next three weeks, participants followed a progressive training program. The program consisted of aggressive weekly mileage increases of 25% based on 3–6 runs per week. Participants were encouraged to run at their preferred training pace as long as the prescribed weekly running volume was met. Participants returned to the lab the week following the conclusion of the training program for the post-training testing session. Overall and lower

limb fatigue using the VAS and PTA were measured after a 5-min treadmill running.

Visual 3D software (C-Motion, Germantown, MD) was used to process and analyze PTA. Accelerometer data were filtered using a fourth-order Butterworth low-pass filter with a cutoff frequency of 60 Hz. The peak positive acceleration immediately following foot strike was extracted. The average of PTA from five consecutive foot strikes were included in the analysis. Repeated measures ANOVA with time as the within-subject factor were used to compare means ( $p < 0.05$ ).

## RESULTS AND DISCUSSION

Contrary to our hypotheses, PTA and FMS scores in novice runners were unchanged following the baseline run and the 3-week training program ( $p > 0.05$ ; **Table 1**). These results suggest that fatigue is required to cause a change in PTA over a 30-min acute run or prolonged running training. Cadence was also unaffected by the run and the training program and may explain the unchanged PTA. The findings suggest that submaximal running and an aggressive increase in running volume over a 3-week period did not alter PTA. Thus, some novice runners may not be at a higher risk of TSF because of rapid increases in mileage. However, risk of developing other injuries may be increased considering that some participants sustained an injury ( $n=2$ ) or became ill ( $n=3$ ) during the 3-week training period. The findings suggests that some novice runners are likely more resilient against injury risk factors when it comes to large increases

in running volume. Novice runners may be able to reduce their risk of injury development related to PTA by only performing easy, submaximal runs during training. A longer training period may be needed to induce a cumulative effect on training that alters PTA in an unfatigued state.

## CONCLUSIONS

These preliminary findings suggest that a submaximal run and a 3-week training program with large mileage increase did not alter PTA or movement quality in novice runners. Further study is needed to determine how quickly novice runners can progress to more exhausting runs, which may be able to help guide ‘couch to race’ training programs for beginners. We will add a group of experienced runners and a control population as we continue this line of research.

## INTRODUCTION

Running biomechanics are widely studied in adult subjects with unilateral transtibial amputation. While a few studies investigate the running mechanics of subjects with unilateral transfemoral amputation (TFA), even fewer investigate knee disarticulation (KD). KD differs from TFA in that the amputation is at the level of the knee joint, preserving most of the thigh muscles and the distal femur [1]. Previous literature found gait differences between KD and TFA: subjects with KD showed to have fewer running gait deviations over those with TFA due to the advantages of a longer lever arm such as better balance and more natural hip joint range-of-motion, notably in hip flexion [1]. Typical running deviations with TFA include minimal trunk flexion, decreased trunk rotation, and hip hiking [2]. Previous running research has lacked a comparison between KD and TFA, especially within the same patient. The purpose of this study was to describe the differences in overground running in a patient who transitioned from a unilateral KD to a unilateral TFA by comparing velocity, step width, trunk forward flexion and rotation, pelvic obliquity, and hip flexion/extension.

## METHODS

Overground running data at self-selected jogging speeds were collected at two different amputation levels from a 26-year old retired U.S. Marine Corps service member who sustained a right traumatic unilateral amputation. The first running study occurred 28 months after undergoing KD (height: 1.77m; weight: 82.2kg). The patient ran on an Ottobock® Modular Sports™ knee with an Össur® Flex-Run™ foot. The second study occurred 16 months after elective TFA following 44 months as KD (height: 1.75m; weight: 79kg). The patient ran

on an Ottobock® RS640 knee with an Össur® Flex-Run™ foot. Before both studies, the patient had been moderately active utilizing his running leg.

Equipment, set-up, and routine were the same across conditions: 50m straightaway on a track with 12 Raptor-E cameras (Motion Analysis Corp., Santa Rosa, CA, USA) used for marker tracking. Kinematic data were collected at 300Hz. A full-body, six degrees-of-freedom marker set was used with 32 markers. A successful session required a minimum of five strides for each leg. Target data were processed in Visual 3D (C-Motion Inc., Germantown, MD, USA) using a fourth-order, Butterworth filter with a cut-off frequency at 6Hz.

## RESULTS AND DISCUSSION

The patient ran at a slightly faster velocity with TFA than with KD (Table 1). The patient's step width increased by 0.137m with TFA (Table 1). The kinematic measures (Fig. 1A-D) did not surpass a clinically meaningful difference, however in trunk flexion (Fig. 1A) there is a large difference in peak flexion in mid-swing (3.8°), marked with a dot.

The velocity increase from KD to TFA conditions was small enough that it should not cause significant biomechanical changes. A possible explanation for TFA wider base of support could be due to poor balance and stability [1] or a discomfort caused by the proximal socket which extends further toward the pelvis with a TFA. Peak trunk flexion in mid-swing occurred at the same time as contralateral limb weight acceptance in the TFA condition. This will require further investigation.

Despite not finding any clinically meaningful differences, one limitation in this case study was the duration of time from surgery to the data collection and the amount of completed physical therapy

sessions. The patient had KD for 28 months prior to data collection and the most recent running data was collected 16 months after elective TFA. The addition of physical therapy sessions completed from his TFA surgery to his current running study collection may contribute to why differences were not seen between the two amputation levels. Additionally, the kinematics of the contralateral limb was excluded from analysis.

## CONCLUSIONS

This case study aimed to identify the temporal-spatial and kinematic differences in overground running from a patient who transitioned from a unilateral KD to a unilateral TFA. Literature has implied a preference for KD over TFA, however these findings suggest that differences might be minimal in terms of functional performance. It is interesting how similar the two conditions were,

given the different amputation levels. Future work will expand on these results and consider kinetics of this patient between KD and TFA.

## INTRODUCTION

While considering other factors, reducing the metabolic cost of running improves distance running performance [1]. Altered biomechanics, such as contact time, vertical and horizontal ground reaction force (GRF), stride frequency, and leg stiffness change the muscular demands and consequentially influence the metabolic cost of running [2].

Many individuals such as athletes with a leg injury, people with a leg amputation, and people with pathological gait, exhibit asymmetrical biomechanics during running. Yet, despite the prevalence of biomechanical asymmetries, it is unknown how asymmetries affect running performance. Thus, we sought to address whether asymmetric step frequency affects the metabolic cost of running. We hypothesized that greater biomechanical asymmetries between legs would increase the metabolic cost of running.

## METHODS

Ten healthy runners completed two testing sessions on two separate days. Subjects began each session by standing in place while we measured their metabolic rates and then completed seven running trials. First, subjects performed a 12-minute habituation trial at their preferred step frequency (PSF). PSF was then used for subsequent trials. For the remaining trials, subjects were instructed to run for 6 minutes while initiating ground contact with each beat of an audible metronome. Subjects ran two additional habituation trials, with symmetric PSF and 21% step frequency asymmetries, respectively. Subjects then ran 4 additional trials at different randomly selected asymmetric step frequencies, which were 0, 7, 14, and 21% of the absolute value of the symmetry index (SI) (Eq. 1) compared to their PSF (symmetric). For all trials, stride frequency (one stride = two steps) remained constant, and running speed was 2.8 m/s.

We measured GRFs at 1000 Hz for 30 seconds during minutes 3 and 5 of each running trial, filtered the GRFs, and used a 10 N vertical GRF threshold to calculate stride kinematics (step frequency, ground contact time), kinetics (stance average vertical GRF, peak vertical GRF, peak horizontal GRFs), and leg stiffness. We measured rates of oxygen consumption and carbon dioxide production using indirect calorimetry, and averaged these rates over the last two minutes of each trial. We used a standard equation [3] to calculate metabolic power for each trial, and then subtracted this metabolic power from standing to yield net metabolic power.

Biomechanical variable (BV) asymmetries were calculated using the absolute value of the SI and were expressed as a percentage (Eq. 1).

$$SI = \left| \frac{BV(\text{leg1}) - BV(\text{leg2})}{0.5 (BV(\text{leg1}) + BV(\text{leg2}))} \right| \times 100\% \quad \text{Eq. 1}$$

We only analyzed asymmetric running trials where runners achieved a step frequency asymmetry steady-state, which we defined as a change in step frequency asymmetry between minutes 3 and 5 that was within  $\pm$  two standard deviations of the average difference elicited during the PSF trial. We used independent linear mixed models to test the influence of each BV on the increase in the percentage of net metabolic power compared to the PSF trial. Significance was set at  $p < 0.05$ .

## RESULTS AND DISCUSSION

The main goal of this study was to examine the effects of step frequency asymmetries on the metabolic cost of running. We found that for every 10% increase in step frequency asymmetry, net metabolic power increased 3.5% ( $p < 0.001$ ) (Fig. 1). A previous study of walking also associated similar increases in metabolic cost to asymmetric biomechanics. Specifically, they found that step

# CHANGES IN SURFACE STIFFNESS ELICIT VERTICAL STIFFNESS CHANGES WITHOUT CHANGES IN METABOLIC DEMAND DURING BILATERAL HOPPING

## INTRODUCTION

Running is an increasingly popular physical activity that is associated with reduced disability and mortality [1]. However, as with any physical activity, there is injury risk. Lower extremity injuries occur in 19%-79% runners whose training or race distance exceeds 5 kilometers [2]. Lower extremity stiffness and loading rate are positively correlated and play a role in injury development. Greater loading rate is associated with bony injuries, while lesser loading rates may contribute to soft tissue injuries [3-5]. Additionally, lower extremity stiffness is modified automatically during each ground contact during running and hopping [6, 7]. Greater lower extremity stiffness has been shown to be associated with lesser metabolic demand during running [8]. However, it is unknown if changes in lower extremity stiffness affect metabolic demand. Therefore, the purpose of this study is to induce lower extremity stiffness changes and analyze any resultant metabolic demand changes during bilateral hopping.

## METHODS

12 runners (8 females, 4 males, 22.91 ± 5.99 y.o, 1.70 ± 0.12 m, 66.5 ± 10.83 kg, 25 ± 7.46 miles run/week ) volunteered for participation in the study. Subjects were required to be injury free for 6 months and run a minimum of 15 miles per week. Subjects were fit with a portable metabolic analyzer (K4b2, Cosmed) and whole body retroreflective markers (Vicon). Subjects completed bilateral hopping at 2 Hz on 3 different surfaces with unique stiffness characteristics. These included a “soft” (Airex foam pad), “medium” (Medium density foam), “hard” (Bertec force plate) condition. The order of the conditions was controlled via a balanced Latin square design to remove potential order effect. Subjects were required to hop for 4 minutes on each surface to achieve metabolic steady state and given a

5 minute seated rest to ensure metabolic demand returned to baseline between conditions. 3D lower extremity kinematics and kinetics were sampled throughout along with metabolic demand. Metabolic demand was averaged over the final 30 seconds of each four minute hopping trial. Vertical stiffness was calculated as the maximum vertical force divided by the change in center of mass depression during ground contact ( $F_{max}/\Delta y$ ) and averaged over 10 successive hops within the last 30 seconds of each 4 minute hopping trial [9]. Vertical stiffness was further normalized to subject’s body weight and standing center of mass position [ $(F_{max}/BW)/(\Delta y/y)$ ] [10]. Repeated measures ANOVAs were evaluated for the effect of surface stiffness on both metabolic demand and vertical stiffness during bilateral hopping. A priori alpha level set at 0.05.

## RESULTS

Metabolic demand was not statistically different across three different surface conditions ( $p = 0.265$ , Table 1)

Table 1: Metabolic demand and surface stiffness.  
Values expressed as mean ± SD.

Surface Condition	Metabolic Demand (O <sub>2</sub> ml/kg/min)
Hard	32.207 ± 4.25
Medium	32.778 ± 4.28
Soft	32.877 ± 3.74

Normalized vertical stiffness was statistically significantly different between surface conditions ( $p < 0.015$ ,  $F=6.804$ ). Bonferroni post-hoc test revealed that normalized stiffness differed significantly between soft and hard surface condition with greater vertical stiffness observed with the soft surface condition ( $p < 0.049$ , Table 2).

Table 2: Stiffness and surface condition. Values expressed as mean  $\pm$  SD. ‘\*’ = statistically significantly different ( $p < 0.05$ ).

Surface Condition	Vertical Stiffness (KN/m)	Normalized Stiffness
Hard	50.61 $\pm$ 26.89	.0402 $\pm$ .01*
Medium	50.74 $\pm$ 26.52	.0408 $\pm$ .01
Soft	59.00 $\pm$ 37.22	.0479 $\pm$ .02*

## DISCUSSION

Normalized vertical stiffness was significantly lower during the hard compared to the soft condition during bilateral hopping. This decrease in vertical stiffness was achieved without a significant metabolic compensation. This compensation in vertical stiffness is expected given the subjects were required to overcome the soft surface deformation to maintain the 2 Hz hopping frequency [11]. We did not see a significant difference in vertical stiffness between the medium and hard surface conditions. We also did not see any change with metabolic demand across all surface conditions.

## CONCLUSION

Inadequate and/or excessive lower extremity stiffness is linked with musculoskeletal injury and it is modified automatically to accommodate different surface conditions. Our subjects displayed greater stiffness to overcome the soft surface condition without significant metabolic compensation. This accommodation could have been completed by altering landing posture or increased reliance on non-

metabolic tissues (i.e. increased elastic energy return from tendons) while maintaining previous level of metabolic demand. Maintaining lower extremity stiffness while minimizing increases in metabolic demand is important given athletes display poorer lower extremity biomechanics that may expose them to a greater injury risk when fatigued [12]. This information can be applied practically by intervening with shoe modification (i.e. greater cushioning) to potentially increase or maintain lower extremity stiffness during running without a significant amount of metabolic compensation. Further analysis is needed to examine the non-metabolic methods and behaviors through which subjects are able to alter their stiffness values. This could lead to individual training programs to find the ideal lower extremity stiffness value while minimizing injury risk.

# JOINT TORQUE REQUIREMENTS AND CAPACITIES DURING RUNNING

<sup>1</sup> Timothy R. Derrick, <sup>2</sup> Elizabeth R. Boyer

<sup>1</sup> Iowa State University, Ames, IA, USA

<sup>2</sup> Gillette Children's Hospital, St. Paul, MN, USA

email: [tderrick@iastate.edu](mailto:tderrick@iastate.edu), web: <http://www.kin.hs.iastate.edu/>

## INTRODUCTION

Any situation that reduces the maximal dynamic muscle force capability – ageing, fatigue, lack of training, fiber damage etc. – might reduce maximum torque production below the requirements of the activity. This forces runner's muscles to approach their physiological capacity and may result in an altered running style. It is, therefore, useful to know which torques are closest to their dynamic capacity so that specific steps can be taken to insure an adequate reserve and enable the runner to maintain optimal running form. It is the purpose of this research to identify joint torques that approach their maximum dynamic limits during running and to determine when in the stance phase of the running cycle these relative weaknesses occur. We will also examine if the limitations are due to length or velocity constraints.

## METHODS

Seven young adults recreational runners (3 males, age: 21.3±2.1 yr; body mass: 68.9±6.7 kg; height: 1.84±0.07 m and 4 females, age: 25.3±5.2 yr; body mass: 56.6±11.3 kg; height: 1.64±0.08 m) participated in this study. All runners were healthy and currently free of injury. Reflective markers were placed on the right foot, leg, thigh and the pelvis in order to track the motion while runners ran at 3.5 m/s on a 30 m runway. They landed on a force platform (AMTI, 1000 Hz) with their right foot making contact with their preferred strike pattern while 8 cameras (Vicon, 200 Hz) recorded the location of the reflective markers.

Segment rotation matrices were calculated relative to a static trial using a least squares fit [1]. Anthropometrics were derived using geometric solids [2]. Three dimensional joint moments and

reaction forces were estimated using rigid body assumptions and standard inverse dynamics procedures. A 44-muscle, scaled musculoskeletal model [3] implemented in Matlab used the segment rotation matrices as input to derive length and velocity adjusted maximal dynamic muscle forces and moment arms for each frame of data. Multiplying these muscle forces by their moment arms allowed the estimation of maximal dynamic torque producing capacity at a joint. Actual dynamic muscle forces were estimated using static optimization by constraining the muscle forces to be less than the maximum dynamic muscle forces, and equal to the joint moments (3D hip joint moments, knee sagittal plane joint moment, and ankle sagittal plane joint moment). The solution that met these constraints and minimized the sum of the squared muscle stresses was selected as the actual dynamic muscle forces. Multiplying the actual muscle forces by their respective moment arms gave an estimate of the joint torque requirements of the task.

## RESULTS AND DISCUSSION

Regions in which the joint torque requirements were within .06BW of capacity for more than 5% of stance were identified by a shaded region (Figure 1). The sagittal plane hip moment is the only one in which the inverse dynamics estimate muscle torques did not approach the limitations of the joint muscles. However, the frontal and transverse plane hip moments did approach these limits.

It should be noted that the maximum positive and negative limitations identified in figure 1 were modelled and not measure directly. Direct measurement would allow a subject specific comparison but the major advantage of the current method is that the estimates of the limitations are

length and velocity dependent. This can be seen in the sagittal plane ankle moment when the plantar flexor (maximum negative moment) limitation approaches zero toward the end of the stance period. At this time the length and velocity of the plantar flexors drastically reduce their ability to produce torque.

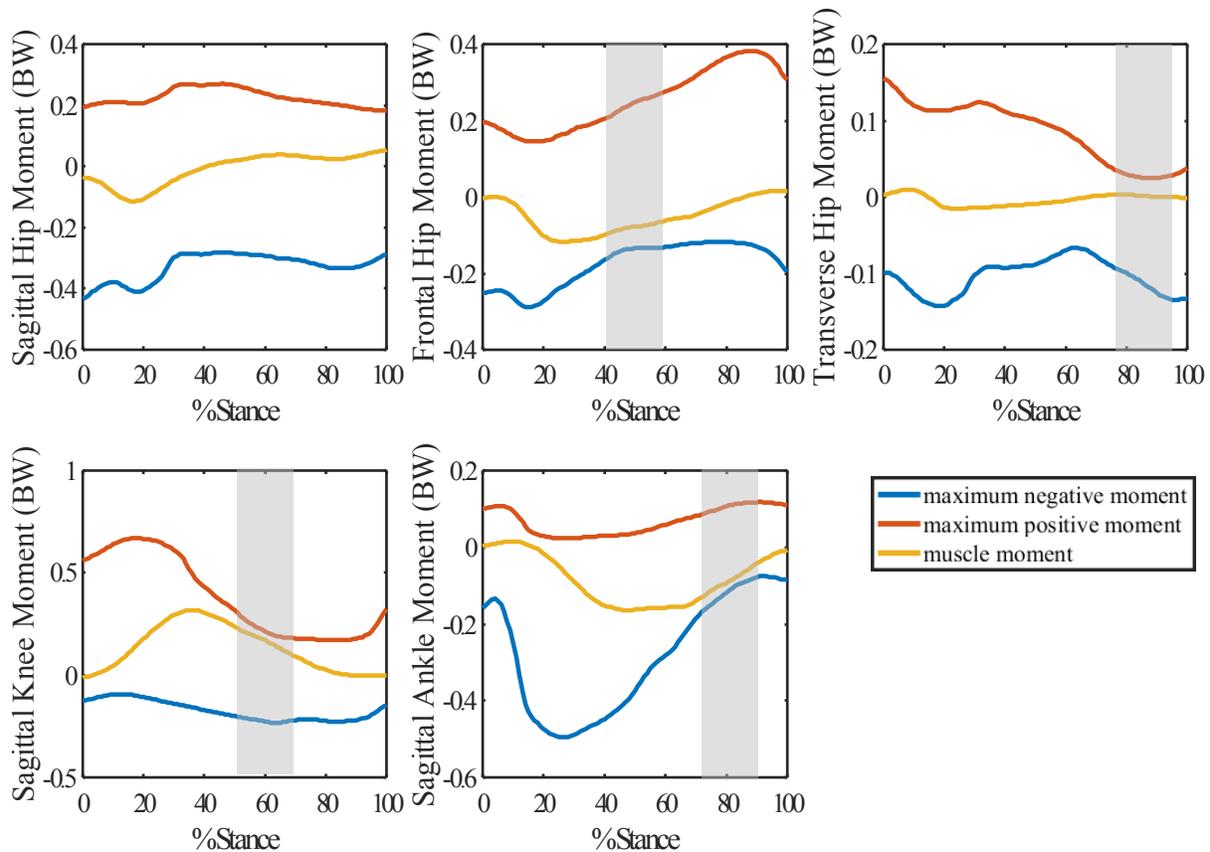

## CONCLUSIONS

This technique of comparing moments created by the joints during running to the maximum capabilities of the joint holds promise for identifying weak links in the lower extremity. As the torques approach their

limits at the joint, compensations take place that may put the runner in jeopardy of injury. This analysis is also useful at identifying which muscle groups should be strengthened or maintained to run effectively.

## INTRODUCTION

The consistency of a distance runner's biomechanical gait pattern may be relevant to injury and performance as variability measures may serve as important indicators. For example, Ferber [1] studied stride-to-stride variability in runners with patellofemoral pain syndrome and reported decreased stride-to-stride variability after three weeks of hip abductor strengthening.

For variability, it is important to determine which joints, phases, and critical instants are the most important to focus on for cohorts of interest. For both the stance and swing phases of running gait, the biomechanical patterns are very different. During early stance, the weight is accepted until the knee is maximally flexed, and the muscles are eccentrically loaded. During late stance, propulsion occurs (knee and hip extension), and the muscles are concentrically loaded. During early swing, the hip is flexed until the knee reaches its maximum height. Then, during late swing, the leg lowers with gravity. These drastically different biomechanics may cause significant differences in variability.

Therefore, the purpose of this study was to determine if there are significant differences in sagittal knee and hip joint variability between the early and late stance and swing phases for slow and fast running.

## METHODS

Participants were 24 highly trained runners (8 females, 16 males;  $36.1 \pm 10.8$  years; 30-80 miles per week). Six posterior-mounted Vicon Bonita cameras were used to assess treadmill running using a standard marker set-up [3]. Runners completed their preferred warmup and then ran 3-minutes at their "long run pace" (slow) and "half-marathon pace" (fast). Data were collected for 25 seconds during the final minute of each pace. Stance and swing data were normalized to 100 data points, and sagittal plane hip and knee joint angles were assessed.

The early swing phase was defined from toe-off to maximum hip flexion and late swing from maximum hip flexion to foot contact. Early stance phase was defined as foot contact to maximum knee flexion and late stance from maximum knee flexion to toe-off. Variability was assessed for each condition using two steps. First, the standard deviation was calculated on a point-by-point basis across the 10 strides. Second, the overall standard deviation for each individual phase was averaged.

A 4x2x2 ANOVA was used to test for significant main effects and interaction. The factors were the phase (early swing, late swing, early stance, late stance), joint (hip, knee), and speed (slow, fast). Secondary t-test comparisons were completed with Bonferoni corrections for multiple comparisons.

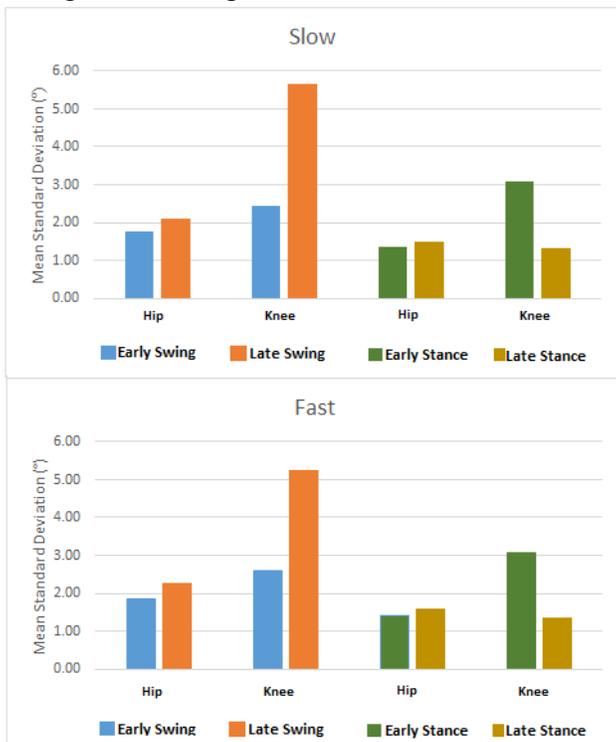

## RESULTS AND DISCUSSION

Overall, the runners in this study appeared to have consistent hip and knee kinematics for all phases as

evidenced by the overall low standard deviations (ranging from 1.33°-5.65°).

Interestingly, for running speed, there was no significant effect ( $p=0.40$ ) on joint variability (Figure 1) and for both the knee and hip, results appear to be very similar for both speeds (Figure 1). Running speed appears to have minimal impact on joint variability. Similar findings have been reported for running reliability. For example, Queen [4] analyzed 35 kinematic and kinetic variables at self-selected and standardized running speeds and found only two to have significant differences.

**Figure 1:** Hip and knee variability in early and late swing and stance phase.

For the knee, increased variability ( $p<0.001$ ) was observed during the early stance and late swing (Table 1) and knee variability more than doubled between early and late phases for both stance and swing with late swing and early stance exhibiting

**Table 1: Overall standard deviations (°).**

	Early Swing	Late Swing	Early Stance	Late Stance
Hip (slow)	1.76 ± 1.02	2.11 ± 1.23	1.35 ± 0.58	1.48 ± 0.86
Hip (fast)	1.86 ± 0.93	*2.26 ± 1.31	1.39 ± 0.47	1.58 ± 0.83
Knee (slow)	2.45 ± 1.24	*5.65 ± 4.18	3.08 ± 2.06	*1.33 ± 0.53
Knee (fast)	2.60 ± 1.12	*5.25 ± 3.79	3.06 ± 1.82	*1.36 ± 0.48

\* indicates significant difference between early and late phases

significant differences in knee variability across speed.

For the hip, there were no significant differences between the early and late stance phase. During swing, the hip exhibited increased variability ( $p<0.01$ ) during the late phase for both speeds; however, the differences were minimal (approximately 0.4°).

## CONCLUSIONS

Running speed had few effects on joint variability across four different phases of stance and swing and between a fast and slow running speed. Overall, the hip showed small changes in variability for the early and late phases and the knee had notable increases in variability for early stance and late swing. These findings are consistent with the literature on running reliability measures.

This study also revealed that variability can be phase dependent, which is similar to previous studies showing that continuous relative phase variability measures varied throughout the stance phase [2]. Future prospective research is necessary to determine the relevance of variability measures to injury.

# USING PHYSICAL EDUCATION AS A PEDAGOGICAL TOOL TO ENHANCE UNDERSTANDING OF BIOMECHANICS IN MIDDLE SCHOOL CHILDREN

<sup>1</sup> Kimberly A. Fournier, <sup>1</sup> Emily D. Clapham, and <sup>2</sup> Karie L. Orendorff

<sup>1</sup> University of Rhode Island, Kingston, RI, USA

<sup>2</sup> University of South Carolina, Columbia, SC, USA

Email: kimfournier@uri.edu

## INTRODUCTION

If we are to encourage students to pursue careers in integrative disciplines such as biomechanics, we must engage students as early as middle school and develop innovative projects that emphasize how STEM sciences (Science, Technology, Engineering, and Mathematics) can be applied and are relevant to their everyday lives.

There is an established relationship between academic achievement and physical activity in school-aged children [1, 2]. However, the scientific principles that underscore the specific physical activities employed in these studies often do not coincide with the specific measure of academic achievement or content being assessed. Instead, the focus is on physical fitness and its effect on test scores and cognitive processes such as executive function, concentration, and attention [2].

The Next Generation Science Standards (NGSS) are designed to engage students in multidisciplinary practices that enhance their understanding of core ideas in science [3]. Some of the core ideas emphasized at the middle school level for the physical sciences are related to *mechanics* (PS2.A: forces & motion; PS2.B: types of force interactions) and for the life sciences (*biology*) are related to structure and function of nerves (LS1.A: Structure and function and LS1.D: Information processing). The Society of Health and Physical Educators (SHAPE America) physical education standards are designed to deliver high quality physical education and develop knowledge and skills that will lead to a physically active lifestyle (Standard 1: Demonstrating competency in movement and Standard 2: Applying movement concepts to learning and the development of motor skills) [4].

As a unique contribution to the area of physical activity and academic achievement, we aimed to simultaneously engage middle school students in science standards (NGSS) and physical education standards (SHAPE America). We employed targeted physical activities that concurrently emphasized both SHAPE America physical education and NGSS standards in an effort to improve middle school level students' understanding of biomechanical principles. Herein, the activities administered during the inaugural National Biomechanics Day (NBD: April 7, 2016) at the University of Rhode Island (URI) are evaluated.

## METHODS

Fourteen 8<sup>th</sup> grade children (age 12-14 years; 9 female, 5 male) participated in the NBD activities. As a group, students first participated in physical activities designed to emphasize principles related to forces (Human Bowling, Balance Poses, Sumo) and life science principles related to neuromuscular control of movement (You're Getting on my Nerves). Students were then divided into 2 smaller groups in order to rotate through 2 additional sessions designed to quantify/analyze movement. In the first session, students learned to analyze movement using simple methodology such as 1) recording the progression of balance using agility balls and 2) using vertical jump measuring equipment. In the second session, students visited the Motion Analysis Laboratory for an interactive demonstration of sophisticated methodology used to analyze movement such as 1) motion capture, 2) forceplates, and 3) electromyograms (EMG).

Prior to participating in the activities, students completed an 8 question quiz (pre-quiz) designed to

assess prior knowledge related to vectors, forces, net force, biomechanics equipment and the neuromuscular control of muscle contractions. Students completed the same quiz again (post-quiz), once all activities had been completed.

A one-way MANOVA with 2 levels of time and an a priori alpha level of 0.05 was performed to assess change in quiz scores as a result of participating in the NBD activities. All statistical tests were performed using SPSS 16.0 for Windows (Chicago, Illinois). The protocol for the study was approved by an institutional review board and the parents or legal guardians authorized the informed consent for all children included in the study.

## RESULTS AND DISCUSSION

We hypothesized that physical education activities that explicitly emphasized elements of physical and life sciences would help provide 8<sup>th</sup> grade students with a more meaningful understanding of the content. By using physical education activities as a pedagogical tool; we hypothesized that students would enjoy learning and would make meaningful, real-world connections between biomechanics and everyday interests.

Most children had knowledge of forces and vectors (Q1-Q3b) prior to participating in the NBD activities. However, for questions related to neuromuscular control and application to real world activities (Q4-Q6), most students were unable to answer on the pre-quiz (Table 1). Quiz scores on those questions improved significantly after completing the activities. Overall, students improved their total score by 65.9%. When asked which NBD activity they preferred the most 85.7% (n=12) of students reported one of the physical education activities. The other two students reported enjoying “everything.”

Research indicates that individuals who are physically active perform better in school [1-2]. However, federal mandates aimed at improving student competencies in reading, mathematics, and science have resulted in less emphasis being placed on health and physical education in the curricula. Exposing students to multiple STEM disciplines via physical activity provides a unique opportunity for students to improve academic performance and make meaningful “real-world” connections in those same areas while simultaneously maintaining an emphasis on health and physical fitness.

## CONCLUSIONS

By using movement to understand the science of movement, children were able to improve their knowledge of interrelated STEM areas. Targeted physical activities emphasizing biomechanical principles appear to be viable pedagogical tool for enhancing the understanding of physical and life sciences in middle school curricula.

# ASSESSING MOTIVATION AND LEARNING STRATEGIES IN UNDERGRADUATE BIOMECHANICS STUDENTS

<sup>1</sup>Kimberly A. Fournier

<sup>1</sup>University of Rhode Island, Kingston, RI, USA  
email: kimfournier@uri.edu

## INTRODUCTION

Without the knowledge of the mechanics, it is difficult for kinesiology students to explain many of the phenomena they observe when studying human movement [1]. As most students fail to appreciate the relevance of biomechanical concepts underlying human movement, establishing meaningful and “real world” relevancy of biomechanics content is of critical importance, particularly when asking students to engage with challenging material (mathematics, physics, and applied anatomy). Therefore, in order to better serve kinesiology students in biomechanics by deepening their learning, instructors must first understand how students engage with the material.

Self-regulated learning theory (SR) defines learners as metacognitively, motivationally, and behaviorally engaged in their own learning [2]. Student learning is therefore influenced by a variety of factors including cognitive strategies, resource management, goals, values, and expectancies [3]. The Motivated Strategies for Learning Questionnaire (MSLQ) is a validated survey consisting of 81 Likert-type questions (15 subscales) that assess these cognitive, affective, and behavioral measures related to engagement [3].

In order to assess core biomechanics competencies, a Biomechanics Concept Inventory (BCI3) consisting of 25 multiple questions has been developed and validated [4]. Recently, the BCI3 has been used to investigate the influence of academic ability, interest, and study habits on learning [5]. While these factors accounted for a moderate amount of learning, a large amount of variance was still unaccounted for [5]. Therefore, factors related to learning biomechanics are likely complex and dependent on other cognitive processes [5].

The purpose of the current investigation was to build on previous work by quantifying learning strategies and barriers that influence student success when learning biomechanics. It was hypothesized that cognitive, affective, and behavioral measures collected with the MSLQ would help explain variance in learning core biomechanics concepts.

## METHODS

Sixty three college students (36 female; male; 27; 1 freshman; 28 sophomores; 26 juniors, 8 seniors) enrolled in two sections of an undergraduate biomechanics course (same instructor) completed the BCI3 during the first week of the Spring 2017 semester to assess baseline knowledge. The BCI3 will be administered again at the end of the semester. The course consists of four units (linear motion, angular motion, functional anatomy, and “hands on” analysis of movement) that are delivered using a variety of pedagogical strategies (lecture, applied calculations, active learning activities, and application of theory to practical analyses). The MSLQ will be administered prior to each of the four unit exams (same exam in both sections) to assess motivation and learning strategies with respect to the pedagogical approaches used to teach core competencies throughout the semester. Herein, preliminary data collected during the first unit of the Spring 2017 semester are evaluated.

Two, two-way mixed ANOVAs were used to evaluate scores from the three sections on exam 1 (A: algebra & trigonometry review; B: theory; C: applied calculations) and demographic factors (gender, classification year). Next, two one-way MANOVAs were used to evaluate MSLQ scores based on demographic factors (gender, classification year). Finally, two one-way

ANOVAs were used to evaluate BCI3 scores based on demographic factors (gender, classification year). A linear regression was performed to evaluate the relationship between BCI3 and exam 1 scores and multiple linear regressions were used to evaluate the MSLQ subscales and the three sections on exam 1. An a priori alpha level of 0.05 was set for all statistical tests and were performed using SPSS 16.0 (Chicago, Illinois). This protocol was approved by an institutional review board.

## RESULTS AND DISCUSSION

BCI3, MSLQ and exam 1 scores did not significantly differ based on classification year. BCI3 scores did not significantly differ based on gender (Table 1). An interaction was observed between the sections of exam 1 and gender ( $p = 0.015$ ); female students performed better on part B and part C, but not part A (Table 1). BCI3 scores were positively associated with exam 1 scores ( $p = 0.014$ ). MSLQ subscales were different based on gender ( $p = 0.023$ ); female students reported higher scores on L3 (Organization), L6 (Time & Environment), and L9 (Help Seeking) subscales (Table 1). MSLQ subscales were observed to be associated with scores on the sections of exam 1 ( $p = 0.005$ ), where L6 was positively associated with part B ( $\beta_1 = 0.44, p = 0.004$ ).

The hypothesis that the MSLQ would provide additional insight into learning biomechanics was supported. Students had a similar amount of baseline knowledge when compared to previously reported data [4]. No differences in initial BCI3 scores were observed based on demographics. Not surprisingly, students who scored higher on the BCI also scored higher on the first exam. The total score on exam 1 increased by 0.32% for every 1% increase on the BCI3. Similarly to previous research, gender appears to play a role in learning

biomechanics [5], where female students performed 6.4% better on theory and 16.1% better on applied calculation questions but not on basic algebra and trigonometry review questions.

MSLQ subscales assess skills that are critical to success in an undergraduate biomechanics course. While the motivational subscales (e.g. metacognition, critical thinking, self-efficacy) were not different based on demographics, gender differences were revealed for three learning strategies. Female students reported a greater ability to establish meaningful connections between the information being learned (clustering, outlining), a greater ability to regulate their time (effective use of time, setting realistic goals) and their study environment (organized, quiet, no distractions), and a greater ability to recognize when to seek help.

## CONCLUSIONS

A greater ability to organize information indicates that female students in the current study may be experiencing deeper learning. However, the ability to regulate one's time and environment is what appears to predict performance on the first exam.

# HIGH SCHOOL BIOMECHANICS COURSE DURING SUMMER STEM PROGRAM

<sup>1</sup> Antonia Zaferiou and <sup>2</sup> George Delagrammatikas

<sup>1</sup> Rush University Medical Center, IL, USA

<sup>2</sup> The Cooper Union, NY, USA

email: Antonia\_Zaferiou@rush.edu

## INTRODUCTION

The Cooper Union Summer STEM Program is a six-week engineering program offered to rising juniors and seniors in high school. The goals of the program are to expose high school students to STEM topics taught through hands-on project-based courses, increase STEM competency, build communication skills, expose high school students to a college environment, and introduce potential STEM careers.

During July and August 2016, a biomechanics, or “Body Physics” course was offered and summarized in this abstract.

## METHODS

21 high school students (12 male, 9 female) participated in the Body Physics course among the 212 students enrolled in the Summer STEM Program. Three undergraduate students participated as course teaching assistants. The course took place in a standard classroom, and the majority of the course focused on engineering design challenges that used every-day materials (e.g., cardboard, string, rubber bands, paper, etc.), following the approach of Iridescent Learning [1]. The final project leveraged the engineering school’s 3D printing, laser cutting, and machine-shop capabilities and resources in order to improve a prototype made first with every-day materials. The course also included activities in a computer lab using both open-source and technical software, and a free field trip to the Natural History Museum. Materials purchased for this course, including reusable equipment (e.g., inertial measurement unit sensors, motors, circuit board chips, etc.) cost approximately \$2,250.

In an informal and anonymous entry survey, students were asked why they were in this course, six of 15 of these open-ended responses included the words “combine”, “relationship”, “both”, or “together”, referring to how they hoped that a course on Body Physics would assist them in understanding the relationship between biology/anatomy and physics.

During the first class, students participated in Alan Alda’s science communication improvisational activities in order to meet their classmates and become more aware of their presentation and body language habits [2]. Following this introductory class, the three chapters of the course included: *Cardiovascular System, Motion Analysis, and Prostheses/Exoskeletons*. Each chapter included hands-on learning activities, a virtual visit from an expert in the field, iteratively building and testing prototypes, and peer-reviewed presentations.

## RESULTS AND DISCUSSION

*Presentations and Peer Review:* Throughout the course, students presented their work with their peers in order to improve their prototypes and presentation skills. Presentations included informal demonstrations for the whole class and to other classes touring through the classroom (as in a science fair), and formal presentations using Prezi, PowerPoint, Google Slides, Keynote, or video-based “PowToon”. Peer review was verbal or written, using the format “I like, but I wish...” (Fig 1).

		Presenter 1	Presenter 2 ...
Student 3	I like...	The design of your cardiovascular system.	How you made it more complex by adding more cups so the water would flow continuously.
	But I wish....	You showed more pictures.	There were less words in your presentation.
Student 4	I like...	how you had a strong presentation and added many pictures to support your claims	I like how you used Prezi to direct your presentation because it allowed for a very dynamic presentation that continuously engaged me
	But I wish....	you could limit the manual labor needed to use your prototype	you included more pictures on the major slide and limited the amount of text so I could visualize how your project functioned without imagining an incorrect version in my head
..			

**Figure 1:** Example peer-review of presentation via live google sheets in a computer lab, using the format “I like...but I wish...” for critical feedback.

**Figure 2:** Final prototype of an artificial arm mimicking deltoid and biceps functions using a set of programmed motors that rotate one direction to flex at the shoulder joint and the other direction to flex the elbow joint.

*Cardiovascular System:* Fluid-flow lab activities and a sheep heart dissection introduced students to the relationship between structure and function. The engineering design process was introduced to students via a skype interview of an engineer who makes fetal pacemakers, who stressed the importance of learning iteratively through multiple prototypes. Students concluded this chapter by building artificial cardiovascular system prototypes made out of every-day materials.

*Motion Analysis:* Introductory activities included an interactive review of Newton's Laws applied to skateboarding, inertial measurement unit (IMU) lab activity, Natural History Museum field trip, and center of mass/balance hands-on activities. Next, students used the computer lab to prepare and present about how biomechanics applies to their favorite hobbies. Finally, students used sports videos to calculate the body's acceleration and draw free body

diagrams at different movement events. Approximate center of mass movement was tracked and exported via PhysMo (open-source movement analysis program for Macs) and data were processed using Excel. One virtual visitor shared how the gaming industry uses motion capture and coding.

*Prostheses and Exoskeletons:* Students built, tested, and presented prototypes of prostheses or exoskeletons out of every-day materials. Virtual visitors included an implant design engineer and a robotic-surgery engineer.

*Final Project:* students self-selected groups based on which prototype project they wanted to further develop using more sophisticated building techniques and materials. Example projects included artificial arms (Fig 2), artificial legs, an exoskeleton arm (Fig 3), and an IMU sensor knee brace.

Educators can find these lessons on the ASB Teaching Repository website.

# A HANDS-OFF APPROACH TO STUDENT-CENTERED LEARNING OF BIOMECHANICS AND RESEARCH METHODS

Louis A. DiBerardino, III

Ohio Northern University, Ada, OH, USA  
email: l-diberardino@onu.edu

## INTRODUCTION

Active learning has become increasingly prevalent in the university classroom. Problem-based collaborative learning has been shown to be more effective than traditional lecture-based teaching, especially in the engineering disciplines [1]. Further, there are efforts to incorporate entrepreneurial-minded learning into engineering programs, including customer awareness and value creation. [2]. This focus allows for unique opportunities to assign projects that push students outside their typical engineering comfort zones while also applying what they have learned in new ways. In the spring semester of 2016 I developed a new elective course, ME4421 – Biomechanical Engineering, structured around problem-based entrepreneurial-minded learning approaches. This course is an elective for engineering students in their junior or senior year, with a single prerequisite of ENGR 2141 – Dynamics, taken sophomore year for Mechanical Engineering students. The course topics include application of engineering principles to clinical, occupational, and sports biomechanics, with focus on kinematics and kinetics of human movement, including experimental methods, analysis, and design. The course was taken by 16 students (14 males, 2 females), all of whom were mechanical engineering majors (6 juniors, 10 seniors). This presentation will outline a culminating project that I developed for the course, which gave students an opportunity to take ownership of their work while instilling the entrepreneurial mindset with collaborative problem-based learning.

## METHODS

In the final third of the semester, the “Accelerometers” project was assigned, giving students approximately four weeks for completion.

Students worked in pairs using a three-axis accelerometer to measure and analyze a task of their choosing related to human movement biomechanics. The assignment was purposely left open-ended, and little guidance was provided. The students had to learn how to effectively use the accelerometers to record data with no assistance from the instructor. They then were required to determine a *need* for its use in the realm of movement biomechanics, identifying how the accelerometer might be used to benefit the biomechanics community. Students were required to substantiate their claims with data and facts, and discuss how their use of the accelerometer *created value* for biomechanical engineers. Projects were presented as both written reports and oral presentations to the class. Students were evaluated based on the novelty of their application, experimental methods, discussion of value added, and the quality of their report and presentation.

The instructions given to the students were intentionally vague, and detailed discussion of current accelerometer use in biomechanics was omitted from the course. This allowed the students to experience the following entrepreneurial-minded learning outcomes from the project: apply creative thinking to ambiguous problems, identify opportunities to create value, and explore a contrarian view of accepted solutions, among other more standard engineering learning outcomes.

## RESULTS AND DISCUSSION

Students performed particularly well on this assignment. Of the eight teams, five received a grade of A, three received a B, and one a C. Students showed creativity in the topics they chose: kick force for normal vs. underinflated soccer ball, calculating stride frequency during running and walking, comparing foot accelerations for normal and

hypermobile ankles, soccer kick force for standing vs one-step lead-up, calculation of elbow moment while throwing a softball, tibial acceleration for forefoot vs. flatfoot landing during a basketball jump shot, head acceleration vs. ball inflation for a soccer header, and the effect of riding position on body acceleration when riding a bicycle over a speed bump. Five of the eight teams attempted more advanced calculations and analysis than simply comparing acceleration peaks. However, in most cases these more advanced calculations were incorrect to some degree. In terms of their discussion of the value their application has added to the field, one team provided an exceptional discussion, three teams were acceptable, three marginal, and one team did not discuss value at all.

Engaging students in entrepreneurial-minded learning forced them to utilize their own knowledge and curiosity to identify the usefulness of the tool and the value that their application provided. The students took more ownership over their work than I see on a typical class project, likely because they could choose a topic they were interested in exploring. I was very pleased with the quality of work that the students showed, especially considering how vague the task was. Many teams went beyond simply comparing amplitude peaks, which was an unexpected benefit to the project. While many of those more advanced calculations and analyses were incorrect to some degree, I did not harshly penalize the teams because their action of going beyond using the basic data was more important to the assignment outcomes than how correctly they were performed. The most important part of this project was how well students were able to identify the value they were adding to the field of biomechanics, whether it be a new technique/finding, or improvements over existing techniques that use more expensive hardware. As mentioned above, not all teams gave a satisfactory discussion of the value their project added to the field, but it was apparent that they had at least thought about it to some extent.

Students rated this course very favorably, and several specifically mentioned their satisfaction with the

project. The only negative comment I received regarding this assignment was that there should be clearer expectations. However, the project was designed in a manner to be purposely unclear. In my experience, there is usually much more negative feedback regarding projects, especially when the steps to complete the project are unclear. Students' positive comments reinforce that this project was well designed to foster higher-level learning outcomes while maintaining student interest.

While the project was a success, there are certain improvements that can be made. Now that I have experience with it, I plan to begin the project much earlier in the semester. This will allow students to create a detailed preliminary proposal so that I can discuss potential methodological issues with them, resulting in more sound experimentation and analysis. Many groups did not provide a literature review or comparison of the results to literature, so this should be made clear as a requirement. Finally, clearer expectations should be provided regarding how their application adds value to biomechanics.

## CONCLUSIONS

The accelerometer project was largely a success in achieving the stated learning objectives, and in positively engaging students in the experimental process of human movement biomechanics. Other instructors could use this project with various experimental equipment to achieve the same objectives. However, I would caution that the project success may be largely dependent on the grade level of the students.

# **PUTTING FUNCTION BACK INTO FUNCTIONAL ANATOMY: USING ACTIVE LEARNING TECHNIQUES TO EMPHASIZE HIGHER-ORDER THINKING TASKS**

Erin Feser & Tannah Broman

Arizona State University, Phoenix, AZ, USA  
email: erinfeser@asu.edu

## **INTRODUCTION**

A functional anatomy course is often incorporated into the curriculum of an exercise science or kinesiology undergraduate program. It is important for students to understand the anatomical structures related to human movement. Furthermore, it is vital for the students to be able to apply their knowledge in subsequent coursework and in the field. Knowing the value of the knowledge gained from this course it is important to ensure sound retention of course material and, furthermore, provide learning experiences that allow students to further their ability to apply the knowledge gained.

Faculty have many choices when it comes to deciding how to deliver course content. Active learning is a teaching technique that has repeatedly shown better learning and course performance measures when compared to traditional lecture [1]. Active learning suggests that students must do more than just listen [2]. Students should be engaged in higher-order thinking tasks such as analysis, synthesis, and evaluation. Therefore, instructional activities promoting active learning should involve students in doing things and thinking about what they are doing [3].

The Kinesiology degree program at Arizona State University has focused on incorporating active learning techniques into the required functional anatomy course to ensure students are challenged with higher-order thinking tasks. Many universities that offer a functional anatomy course may be interested in focusing on challenging the students through higher-order thinking tasks and would therefore benefit from learning more about our

experience with incorporating active learning into a functional anatomy course.

## **COURSE DESIGN**

This course, entitled KIN 334 Functional Anatomy and Kinesiology, is regularly delivered as an in-person lecture with a maximum enrollment of 40 students. There is no laboratory component. The course objectives state that after the course the students will be able to:

- Identify the joint type and ligaments of each of the major joints of the body
- Identify origin and insertion points for the muscles that produce primary human movements
- Classify the muscles that produce the primary movement for each of the major joints of the body
- Analyze basic movement in terms of muscle actions
- Analyze what muscles are involved in basic exercises and movements

Course content is divided into eight units. Each corresponding to a section of the body (e.g., shoulder joint). Following are a sample of the activities utilized within each unit of the course to target one or more of the objectives above.

**Palpation Activity** – Students are introduced to each muscle included in the unit through discovery rather than instructor led lecture. Students work with a partner to identify the origin and insertion of each muscle on the body and then work to palpate the muscle using the provided instructions. This activity leads to a more applied understanding of muscle locations since the focus is on using a real body over working off a skeleton or images from a textbook.

Contribution Analysis Activity – Students work in small groups to identify the joint actions two which each muscle might contribute. This requires students to incorporate prior knowledge such as location and line of pull of the muscle and the movement capabilities of the joint type. Instructor reviews the answers to the activity before the end of the class.

Effects of Origin and Insertion Activity – Students are asked to describe the specific aspects of a muscle's origin and/or insertion that allow for a given joint action (e.g. insertion on the radius as opposed to the ulna allows the biceps brachii but not the brachialis to contribute to supination). This activity requires students to employ higher-order analytical skills as opposed to less effective recall skills when learning muscle origins and insertions.

Movement Analysis Activity – Students work in small groups to identify the primary joint actions and muscles that contribute to everyday and exercise movements. Everyday movements are emphasized as these are more likely than sport movements to be encountered in clinical settings. This activity allows students to engage in a higher-order evaluation of movements and apply course content to relevant real-life settings.

## **BEST PRACTICES**

Success of these active learning techniques within the context of a functional anatomy course is dependent on proper implementation centered on effective evidence-based teaching strategies. Many of these activities benefit from the advantages of peer-learning as the students work in small groups. Compared to individual learning, peer-learning has shown positive effects on student academic success and performance on transfer tasks [4]. While the small group work is largely unstructured in this course, it is important to note the value it holds. Students problem solve as a team, encounter new material together, and feel more comfortable asking their peers questions than their professor. Additionally, students can engage as little or as much as they choose with whomever they choose. Thus, allowing for both introverts and extroverts to find a comfortable learning environment.

In addition, it is important to recognize that many of the activities are low stakes assignments graded primarily on in-class attendance and participation. Within a given unit, stakes are gradually increased with each activity, allowing students to build skills and knowledge and learn what is expected of them before being more formally assessed through end-of-unit quizzes and exams. The activity frequency is high which encourages student attendance, helps students stay on task during class, and facilitates regular practice of course material throughout the duration of the semester.

Lastly, traditional lecture is limited to only one short 10-20 minute introductory lecture at the beginning of each unit. The instructor plays a supportive and interactive role in the activities as opposed to being the “sage on a stage”. This allows for the majority of the class time to be devoted to student engagement in higher-order thinking tasks.

## **CONCLUSIONS**

Utilization of active learning techniques has initiated a large transformation to the student experience for this course. Instead of simply observing and passively listening to the instructor, the students can be more fully involved in the content. Naturally, this reinforces lecture material and permits higher-order learning objectives.

Active learning environments have been identified and empirically validated for increasing student performance and are often recommended over traditional lecturing as a teaching method [4]. Functional anatomy courses offer a great opportunity to incorporate active learning techniques throughout the course content to advance student performance and transfer capabilities.

# SIMULATOR TRAINING LEADS TO IMPROVED WIRE NAVIGATION IN FIREST YEAR ORTHOPAEDIC RESIDENTS

Steven Long, Geb Thomas, Madison Chrisman, Anna Rodriguez, Matthew Karam, and Donald D. Anderson

The University of Iowa, Iowa City, IA, USA

Email: [steven-long@uiowa.edu](mailto:steven-long@uiowa.edu), web: <http://www.uiowa.edu/uiobl>

## INTRODUCTION

The use of simulation training for the development of surgical skills is increasing, because of the opportunities such training affords for reducing training costs, standardizing training opportunities and assessments, and improving patient safety. Recent studies demonstrate that simulator training can improve performance in the operating room (OR), at least for laparoscopic surgery [1]. Orthopaedic surgery has been slower to fully adopt simulation training into its culture. This is perhaps due to the lack of literature conclusively showing that practice on an orthopaedic simulator can lead to improvements in the OR [2]. This project seeks to remedy this, at least for one essential orthopaedic skill: wire navigation.

Orthopedic surgeons often use intraoperative, 2D fluoroscopic images to navigate a wire along a predetermined trajectory through bone. One common application is in the treatment of intertrochanteric hip fractures. The study presented here aims to demonstrate that orthopaedic residents who train on a wire navigation simulator achieve greater levels of performance when compared to those who receive more conventional forms of instruction. In addition, this study also aims to demonstrate that the type of practice on the simulator can impact the amount of improvement shown.

## METHODS

Forty-two first-year orthopaedic surgery residents participated in this study. Participants included residents from the University of Iowa, University of Minnesota, the Mayo Clinic, and the University of Nebraska, all members in the Midwest Orthopaedic Surgical Skills (MOSS) Consortium. Residents were split into three different cohorts that each received varying levels of training.

The twenty-three residents in Cohort 1 received traditional training followed by a performance assessment. The traditional training included a didactic PowerPoint presentation on placing a guide wire in the treatment of an intertrochanteric hip fracture, then a video from the ABOS module on *Fluoroscopic Knowledge and Skills* demonstrating the proper technique for placing the guide wire. The performance assessment measured their ability to place the wire through the femoral neck and into the femoral head in a mock OR (Fig. 1).

**Figure 1** – A resident is shown placing a wire in the mock OR environment.

The thirteen residents in Cohort 2 received the same traditional training, then simulator training, then a performance assessment. Simulator training included 30 minutes to practice the task using the wire navigation simulator [3]. The simulator (Fig. 2) provided real-time feedback to the residents on their wire position relative to the ideal wire position while they practiced navigating the wire.

## RESULTS AND DISCUSSION

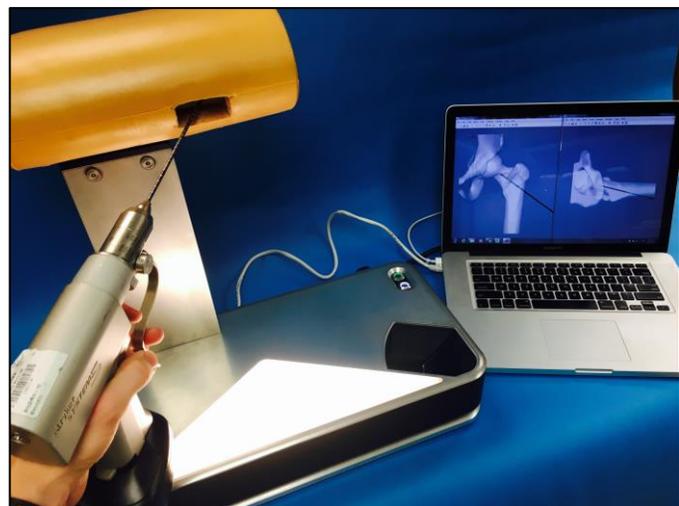

Both Cohorts 2 and 3 demonstrated significant improvement in their TAD compared to Cohort 1 (Table 1), indicating that training improved performance. Cohort 3 attained the best average TAD, roughly half that of Cohort 1, but at the cost of more fluoroscopic images and procedure time, suggesting that the training to proficiency changed Cohort 3's speed-accuracy tradeoff. These results indicate the effect that the different styles of training had on each group. In Cohort 2, simulator practice repeated the same procedure several times, possibly leading to a quick, decisive approach. Cohort 3 was taught to approach the task in a more analytical and algorithmic fashion. Possibly this cohort needed more time and more images in the assessment because they were being more analytical in their approach yielding higher mean TAD, arguably the most clinically relevant metric for surgical success. Perhaps with even more time to practice, Cohort 3 would be able to further streamline their technique to reduce their time and fluoroscopic images while still maintaining low TAD values.

**Figure 2** – The wire navigation simulator is shown here. Virtual fluoroscopy on the laptop screen reflects the actual wire position in a surrogate bone.

The six residents in Cohort 3 received the traditional training, then proficiency-based training, followed by a performance assessment. The proficiency-based training began with a computerized task identifying the correct wire entry point and end point on a series of fluoroscopic images, followed by guided simulator practice breaking down the task into sub-components, including identifying the proper starting point and wire trajectory in both AP and lateral images. Each element was rehearsed until a designated level of proficiency was attained. The third cohort was assessed in the same manner as the other two cohorts.

The performance assessment measured the wire's tip-apex distance (TAD), the number of fluoroscopy images taken, and the total time used during the procedure. The TAD describes the distance from the tip of the wire to the apex of the femoral head, and it has been clinically shown that smaller TAD values have less probability of failure following surgery [4].

# SOFTWARE-BASED TRAINING TO ENHANCE STUDENT LEARNING IN BIOMECHANICS

<sup>1</sup> Kota Z. Takahashi, <sup>1</sup> Angel Gonzalez, <sup>1</sup> Sidney Baudendistel, <sup>1</sup> Amelia Lanier, and <sup>1</sup> Nealy F. Grandgenett

<sup>1</sup> University of Nebraska at Omaha, Omaha, NE, USA  
email: ktakahashi@unomaha.edu

## INTRODUCTION

As the study of Biomechanics is inherently interdisciplinary, Biomechanics may be valuable for promoting STEM education in undergraduate students. For example, students with interests in health-related professions could gain a new perspective on how the human body produces movement by learning basic principles of physics and applied mechanics. Similarly, students with interests in technology, engineering, physics, or mathematics could gain an appreciation for the health-related professions by learning to apply Biomechanics principles. With the growing popularity of Biomechanics, evidenced by the establishment of the National Biomechanics Day, it is critical that teaching approaches continue to evolve such that Biomechanics can reach students and spark interests within various STEM-related backgrounds.

At the University of Nebraska at Omaha (UNO), we are currently implementing software-based training to supplement traditional lecture-based teaching. We have redesigned an existing course that traditionally enrolls students from background in Exercise Science, Physical Education, Athletic Training, and Biomechanics. The students of this class typically enter the semester without a strong quantitative background (i.e., no prior enrollment in Statics, Dynamics, Calculus-based Physics, etc). Thus, our goal for the software-based modules was to encourage rigorous problem-solving skills. While lecture-based teachings are fundamental to a student's learning, we felt that a complementary software-based training approach could facilitate real-world application of Biomechanics.

The purpose of this study was to examine the effects of software-based training of Biomechanics on undergraduate student performance. We hypothesized that following the completion of this

software-integrated course, students will: 1) show greater awareness of Biomechanics' role in STEM related fields, and 2) exhibit improved self-confidence of fundamental Biomechanics' concepts.

## METHODS

We have redesigned an existing course in undergraduate Biomechanics at UNO. The redesigned course was offered starting in Fall 2016. The class offers an hour lecture twice a week, as well as a two-hour weekly laboratory session. The laboratory sessions included introduction of Visual3D software (C-Motion Inc., Germantown, MD). The laboratory sessions were designed such that students were exposed to new topics each week, related to Biomechanics-based computation in Visual3D software.

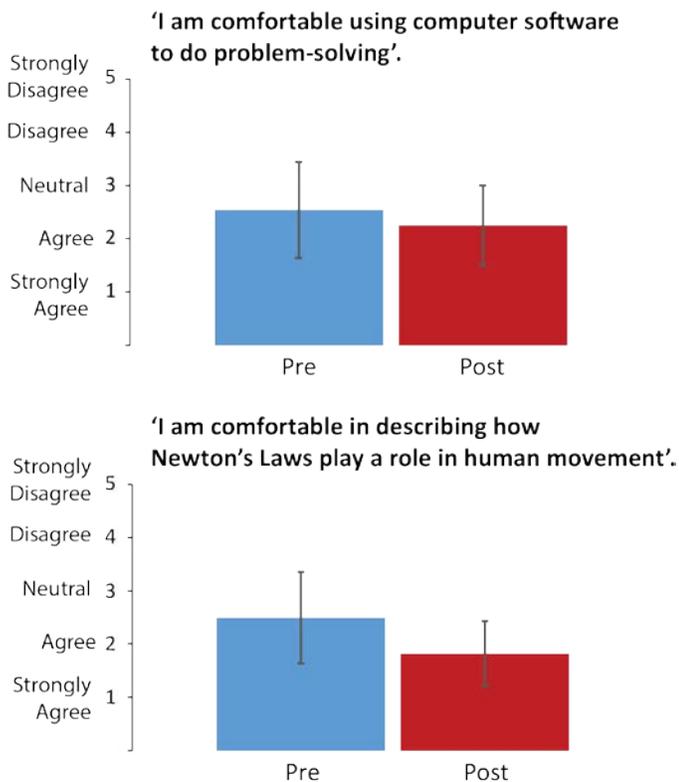

Once students were exposed to the basic features of the software, the semester progressed with assignments that were designed to challenge the students' critical thinking skills. For example, students were asked to compare and contrast human walking versus running. The students were also asked to analyze the effects of a simulated reduced gravity environment on human walking. The students concluded the semester with a Final Project involving a Clinical Gait Analysis Study. For the project, students were given actual walking data from patients with unique movement disorders. The students were then asked to synthesize the patient's movement limitations, using Visual3D software and Biomechanics-based concepts.

To evaluate student performance, we developed a questionnaire to assess the students' overall knowledge of Biomechanics and the students' awareness of Biomechanics' role in STEM related fields. The questionnaire included a narrative response, as well as questions based on a Likert scale. The students were asked to complete the

questionnaire at the beginning and at the end of the semester.

## RESULTS AND DISCUSSION

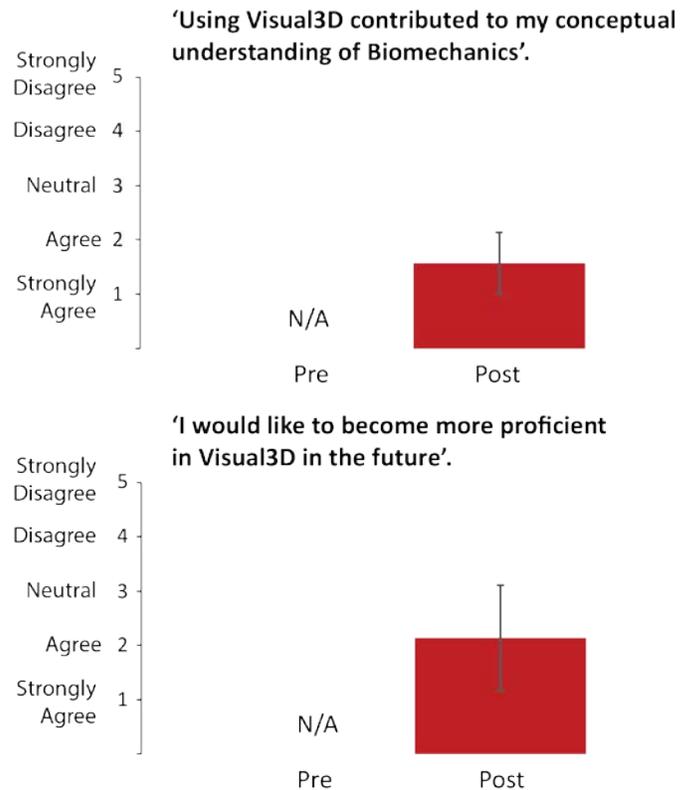

To date, 67 students consented to participate in this study. 24 students have completed the pre and post-semester questionnaire (from Fall 2016), and another 37 students have completed the pre-semester questionnaire (Spring 2017 ongoing). We are currently developing a scoring rubric to assess the narrative responses related to the students' awareness of Biomechanics' role in STEM related fields.

**Figure 1:** Following the completion of the software-integrated course, students became slightly more comfortable in computer-based problem solving and concepts fundamental to Biomechanics (N = 24). The questionnaires were completed at pre (blue) and post-semester (red).

Our preliminary results from 24 students show that our software-based training may improve student's confidence in performing problem-solving activities and understanding how Newton's Laws play a role in human movement (Figure 1). Furthermore, students have indicated that using Visual3D software has contributed to their understanding of Biomechanics,

and that students would like to be more proficient in the software in the future (Figure 2).

**Figure 2:** Following the completion of the software-integrated course (post-semester in red), students generally agreed that the use of Visual3D software contributed to their overall understanding of Biomechanics, and that students would like to become more proficient in the software in the future (N=24).

## CONCLUSIONS

Our preliminary results revealed that a software-integrated course in undergraduate Biomechanics can positively influence student performance.

# ASYMMETRICAL POSTURAL SWAY AS QUANTIFIED BY THE HURST EXPONENT USING AN ACCELEROMETER

<sup>1</sup> Dave P. Heller, <sup>1,2</sup> Kelsi Rempe, and <sup>1</sup>Brittany Oppland

<sup>1</sup> Rockhurst University, Kansas City, MO, USA

<sup>2</sup> Des Moines University, Des Moines, IA, USA

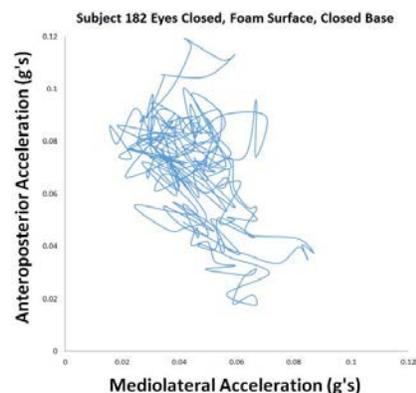

email: dave.heller@rockhurst.edu, web: <https://ruexerciseandsportscience.wordpress.com/>

## INTRODUCTION

The human body is an inherently unstable mechanical system requiring constant correction to maintain equilibrium in a gravitational field. The resulting kinematics of these corrections, known as postural sway, can characterize the dynamics governing the task of maintaining upright balance. Discrepancies in parameters quantifying postural sway can be clinical indicators of psychological, musculoskeletal, or neurological pathologies such as bi-polar disorder, multiple sclerosis, or concussion. Often these parameters include traditional measures of variability such as standard deviation (SD), range, normalized path length, etc. [2].

Postural sway measured using center of pressure (CoP) data from a force plate in the anteroposterior (AP) and mediolateral (ML) directions has been shown to exhibit non-linear properties. Non-linear parameters, such as the Hurst exponent (H), may therefore be more appropriate quantifiers of sway compared to traditional measures of variability. An increasingly popular way to measure postural sway is by tracking the AP and ML acceleration of the center of mass using an accelerometer (see Fig. 1). While a handful of studies (e.g., [1]) have applied non-linear analysis to CoP data, to our knowledge, this type of analysis has not been performed using acceleration data obtained from an accelerometer.

Therefore, the purpose of this analysis was to compare the Hurst exponents of postural sway acceleration data obtained from an accelerometer in the anteroposterior (AP) and mediolateral (ML) dimensions and compare them with traditional variability parameters.

**Figure 1:** Example plot of ML vs. AP acceleration.

## METHODS

13 participants (9 females, 4 males;  $20.2 \pm 1.1$  y,  $1.75 \pm 0.11$  m,  $74.5 \pm 14.1$  kg) from a group recruited for a previous study were used for the current analysis [2]. Participants stood wearing socks for 25 seconds (s) in 18 randomized stances combining eyes open or closed, bipedal stances that were closed, open, or tandem, unipedal stances on the dominant or non-dominant foot, on tile or foam surfaces. A smartphone containing an accelerometer application (iPhone app: acceleration sensor logger v 1.2; Regrex, Inc., Osaka, Japan) was secured with a Neoprene running belt at approximately the level of the subject's center of mass. Acceleration in g's in the X-, Y-, and Z-dimensions were measured at a sampling frequency of 10 Hz with an accuracy of 0.006 g, and a precision of  $\pm 0.005$  g [2].

The middle 20 s of data was analyzed to eliminate starting and ending effects. X-, Y-, and Z-acceleration values in g's were trigonometrically normalized with the gravitational vector and aligned with the participants' longitudinal, ML, and AP axes, respectively, using the method described by Moe-

Nilssen and Helbostad [3]. Hurst exponents in both the AP ( $H_{AP}$ ) and ML ( $H_{ML}$ ) directions were found using Rescaled Range Analysis described by Qian and Rasheed [4].  $H$  was quantified by finding the slope of the regression line of the log-log plot of the rescaled range (Range/SD) vs.  $n$ , where  $n = 200$ -,  $100$ -,  $50$ -,  $25$ -, and  $10$ -data point intervals [4].

Paired t-tests were used to find differences between  $H_{AP}$  and  $H_{ML}$  as well as between  $SD_{AP}$  and  $SD_{ML}$ .

## RESULTS AND DISCUSSION

$H_{AP}$  were found to be statistically significantly larger than  $H_{ML}$  during the same condition (mean  $\pm$  SD:  $0.989 \pm 0.028$  vs.  $0.871 \pm 0.031$ ;  $t = 21.3191$ ,  $p < 0.001$ , mean difference =  $0.115$ , 95% confidence interval:  $0.104$  to  $0.127$ ).  $SD_{AP}$ , however, were not statistically significantly different than  $SD_{ML}$  during the same condition (mean  $\pm$  SD:  $0.019 \pm 0.004g$  vs.  $0.017 \pm 0.004g$ ;  $t = 1.149$ ,  $p = 0.273$ , mean difference =  $0.001$ , 95% confidence interval:  $-0.003$  to  $0.001$ ).

The Hurst exponent quantifies how “persistent” the data is.  $H = 0.5$  represents a random pattern in the data.  $H < 0.5$  represents anti-persistence: a high value is followed by a low value.  $1 > H > 0.5$  represents persistence: a low value followed by another low value [3]. In the present study, for acceleration values measured over 20 s of quiet stance, both  $H_{AP}$  and  $H_{ML}$  exhibited persistent trends: e.g. low acceleration values tended to be followed by another low acceleration value. This is expected in the present analysis since the subject was able to maintain stability for the entire 20 s. However, one might expect to see anti-persistent trends on smaller time scales to counter transient perturbations.

In this study, over all conditions, mean  $H_{AP}$  was found to be significantly greater than mean  $H_{ML}$  ( $0.989 \pm 0.028$  vs.  $0.871 \pm 0.031$ ) meaning this persistent trend was smaller in the ML direction. The mechanism for this difference is unknown. It could be an indicator of a different strategy of postural control in the ML direction. The variability of postural sway in the ML direction was not significantly different than in the AP direction which could indicate that the Hurst exponent is a more

discriminating parameter of differing control strategies in the AP and ML directions.

Previous studies using CoP data to quantify postural sway give a wide range of  $H_{AP}$  and  $H_{ML}$  values ( $0.01$ - $0.93$ ). To our knowledge, only one of these studies has compared the two dimensions statistically finding no difference in  $H_{AP}$  and  $H_{ML}$  in healthy young participants [1]. Additionally, this is the first study to compare  $H_{AP}$  and  $H_{ML}$  of postural sway data using acceleration from an accelerometer.

## CONCLUSIONS

Mean  $H_{AP}$  of acceleration taken during eighteen different quiet stance conditions in a college-aged population was found to be significantly larger than mean  $H_{ML}$  values, while a mean measure of variability (SD) was not significantly different in the AP and ML directions. This could indicate that non-linear parameters such as the Hurst exponent are more discriminating descriptors of postural sway. This difference could also be an indicator of differing control strategies in the AP and ML directions while maintaining upright stability.

Future analysis will focus on possible differences in non-linear measures of postural sway due to gender, concussion status, visual condition, surface condition, and stance.

# VALIDATION OF INERTIAL MEASUREMENT UNITS

Leah Taylor, Emily Miller, Kenton R. Kaufman

Mayo Clinic, Rochester, MN, USA  
email: kaufman.kenton@mayo.edu

## INTRODUCTION

While optical motion capture systems provide a reliable analysis of human motion, they limit collection to a laboratory based setting. Technological advancements have led to the development of wearable devices such as Inertial Measurement Units (IMUs) as alternative tools to study human kinematics. Advantages of these devices include portability, allowing them to be used outside of a laboratory setting.

The objective of this study was to establish accuracy and precision metrics for a commercially available IMU. The sensor output was validated against the gold standard measures of custom made mechanical testing apparatuses rather than an optical system. This validation provides performance assessment of the IMU capabilities independent of external system error.

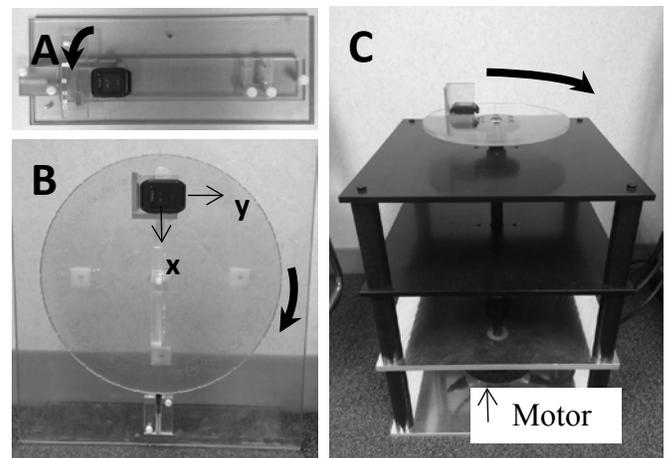

## METHODS

Commercially available IMUs were used (Opal version 2, APDM Inc., Portland, Oregon). These sensors contain tri-axial accelerometers, gyroscopes, and magnetometers. Validation testing was done to establish the accuracy and precision of the IMUs in static and dynamic conditions. The custom made testing apparatuses were used as the gold standard comparison for the sensor output.

A testing apparatus (Fig. 1A) was used to establish the sensors' performance during small angular displacements. The testing apparatus consisted of a movable arm utilizing a spring-loaded post to lock the arm into notches on a fixed base with an accuracy of 0.02 degrees for each notch. The sensor was rotated to each notch (0, 1, 3, 6, 10, and 15 degrees) and data was collected for 10 seconds at each position. This protocol was repeated five times for the three different sensor orientations. The three sensor orientations represented rotation about each of the sensors' axes. Fifteen trials were repeated for each of eight sensors.

A separate testing apparatus was used for large angular displacements (Fig. 1B). The device consisted of a rotating wheel with a spring-loaded post mechanism with notches at every 10 degree increment with an accuracy of 0.02 degrees. The sensor was rotated from 0 to 180 degrees in 10 degree increments with data collected for 10 seconds at each increment.

The dynamic testing device (Fig. 1C) was used to establish the sensors' angular velocity performance. The system was able to provide a known rotational speed within 0.003 degrees/second (dps). For testing, the angular velocity inputs for rotation about the X-and Y-axes were: 6, 150, 300, 600, 900, 1,200, 1,500, 1,800, and 2,000 dps. The inputs for rotation about the Z-axis were: 6, 150, 300, 600, 900, 1,200, and 1,500 dps. The same eight sensors used for static testing were included in the dynamic testing. Each of the eight sensors underwent five trials in each of the three positions. A trial consisted of the sensor being rotated at each of the above velocities for 10 seconds.

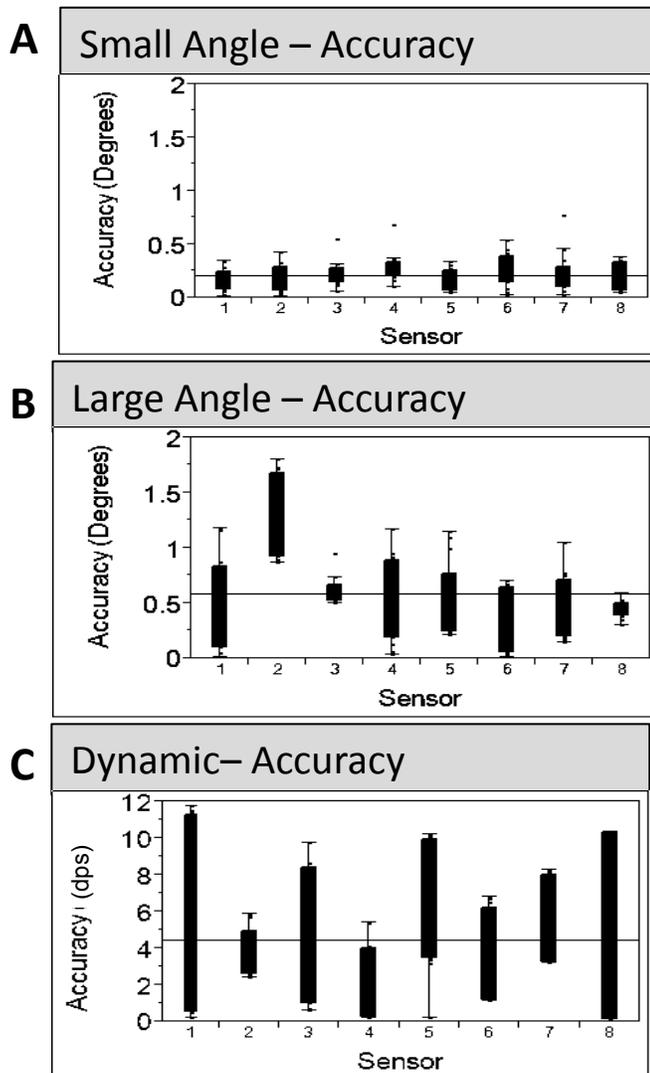

**Figure 1:** Testing apparatus for (A) small angular displacements (B) large angular displacements and (C) dynamic testing at fixed angular speeds. The sensor is in the position representing rotation about the Z-axis.

To evaluate static and dynamic sensor performance, accuracy and precision were assessed for the axis of rotation. Accuracy is reported as the absolute value of the difference between the test apparatus and the sensor output value. Precision was calculated using the standard deviation of each measurement point (angle or degrees per second) between trials. The difference (accuracy) and standard deviation (precision) were averaged across trials for each sensor and averaged for all sensors.

## RESULTS AND DISCUSSION

For both the large and small angular displacement testing; the average sensor output accuracy (Fig. 2A&B) was within  $0.6 \pm 0.1$  degrees of the true value.

**Figure 2:** Box plots indicating the accuracy for (A) small angular displacements, (B) Large angular displacements, and (C) dynamic velocities.

The sensors had equal precision on the static apparatuses with average precision of  $0.1 \pm 0.1$  degrees. An increase in angular velocity results in an increase in the difference between the testing device input and IMU output. The average percent error for a dynamic trial of a sensor was less than 1.5 dps. The dynamic testing average accuracy for all eight sensors was  $4.4 \pm 0.2$  dps (Fig. 2C) and precision was  $0.2 \pm 0.3$  dps.

This study demonstrated that a commercially available IMU has excellent utility and reliability. Under controlled static testing conditions, the IMUs showed exceptional accuracy and precision, average accuracy and precision was within  $\pm 1.0^\circ$ . This is superior to the manufacturer's reported static orientation accuracy estimates of 1.15 degrees (roll/pitch) and 1.50 degrees (heading) ([www.apdm.com](http://www.apdm.com)). These results have slightly lower accuracy and higher precision than the study by Lebel et al. comparing APDM Opal to Optotrak motion capture orientation at static positions (accuracy  $0.01^\circ \pm 2.9^\circ$ ) [1].

## CONCLUSIONS

The IMUs provide an accurate (within 0.6 degrees) and precise (within 0.1 degrees) measurement of static sensor orientation. The IMUs also provide an accurate (within 4.4 degrees per second) and precise (within 0.2 degrees per second) representation of angular velocity. The sensors are more accurate at lower velocities, but percent error remains relatively constant across angular velocities. When determining whether IMUs are the appropriate tool, it is important to consider the application specific demands and necessary reliability.

# Comparing Inertial Measurement Unit and Optical Infrared Passive Marker-Based Motion Capture Systems for Injury Prevention

Rafael Valbuena, Rebekah Koehn, and Craig M. Goehler

Department of Mechanical Engineering, Valparaiso University, Valparaiso, IN, USA  
email: [craig.goehler@valpo.edu](mailto:craig.goehler@valpo.edu)

## INTRODUCTION

Currently, several measurement systems for recording human motion kinematics exist, with the two most popular being camera-based motion capture (MoCap) and inertial measurement units (IMUs). The user may decide to select one system over the other depending on preferred accuracy and resolution of the data. MoCap is generally regarded as a more accurate measurement system [1], but there are often gaps in the data, which require the investigator to spend time in post-processing. While IMUs are anecdotally believed to provide less accurate information, the data requires little or no additional processing by the investigator and thus it is viewed as a more user-friendly measurement system.

Studies have been run in order to validate the use of IMUs in place of MoCap in specific applications [2]. However, the desired accuracy of the data differs from study to study and the exact nature of the differences between MoCap and IMU data is not explicitly stated. This study will take the first steps to determine if it is appropriate to use IMUs to collect joint kinematic data while completing a previously developed injury prevention protocol [3].

## METHODS

For this preliminary study, 1 male subject, age 21, participated in an IRB approved study that compared two quantitative techniques for human movement data collection. The subject was affixed with 28 passive reflective

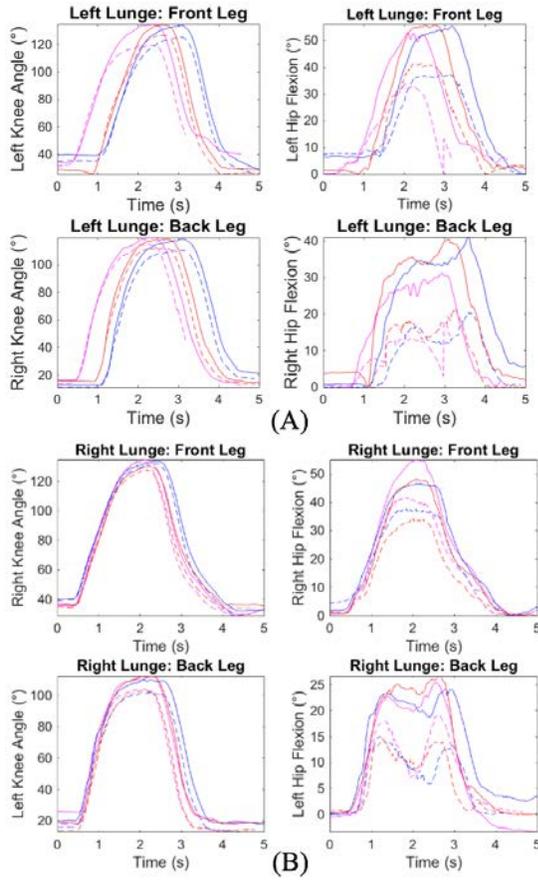

markers on both the upper and lower extremities based on the anatomical locations specified in a previous study [3], and 17 IMUs at locations specified by XSens. The subject completed a series of predetermined tests that utilized a variety of lower extremity movements. The subject performed each test three times.

MoCap data was collected using 11 VICON Bonita cameras. This data was processed, filtered, exported, and converted to ensure compatibility with OpenSim. A subject-specific full-body model was used to calculate the inverse kinematics for each trial. IMU data was collected using the XSens Awinda station and MVN Studio. Kinematics data was calculated using the internal model and exported directly from MVN Studio.

## RESULTS AND DISCUSSION

For this abstract, the results from the left and right in-line lunges were analyzed and compared between the two measurement systems. These results were plotted against normalized time in order to compare across the various trials. Figure 1 shows the corresponding knee and hip flexion angles for both tests. Both the MoCap and IMU systems produced curves with very similar shapes. The knee flexion results are consistent across all trials for each measurement system, with the exception of the peaks where the IMUs exceed the maximum angle of the MoCap data in three of the four knee flexion plots. Although the hip flexion plots also show very similar

trends, the difference in maximum angles was more pronounced than in knee flexion.

**Figure 1:** Comparison of knee and hip flexion versus time for MoCap (VICON), represented with solid lines, and IMU (XSens), represented with dashed lines, during (A) left and (B) right in-line lunge tests.

A statistical analysis of the data was performed to quantitatively confirm what the plots qualitatively demonstrate. As seen in Table 1, the IMU system showed a higher estimate of the maximum flexion angle than the MoCap system for all trials.

**Table 1:** The average (SD) maximum knee and hip flexion angles across all trials of the in-line lunge tests. The results from both the MoCap and IMU system are shown.

	Right Lunge				Left Lunge			
	Front Leg		Back Leg		Front Leg		Back Leg	
	Knee Flexion	Hip Flexion						
<b>MoCap (Vicon)</b>	130.87 (3.00)	37.92 (3.81)	103.01 (0.92)	16.30 (2.56)	123.86 (3.80)	37.44 (3.79)	112.41 (2.18)	19.89 (1.69)
<b>IMU (Xsens)</b>	132.98 (2.47)	49.89 (4.47)	111.51 (1.15)	26.90 (2.80)	134.10 (0.19)	54.70 (1.50)	118.83 (0.54)	37.58 (5.42)
<b>% Difference</b>	1.61	31.57	8.25	65.03	8.27	46.10	5.71	88.94

Interestingly, the relative difference in peak knee flexion between the two systems ranged between about 1% and 8%, while the relative difference in hip flexion measurements ranged between about 30% and 90%. This suggests that the hip flexion data is difficult to directly compare between the two systems, potentially due to differences in the kinematic models used in both cases.

These results indicate that the use of IMUs for recording information about human kinematics might be plausible for some of our applications with an appropriate calibration that accounts for the offset, but it depends highly on the desired measurement variable and allowable margin of error.

Future work will utilize a goniometer as a common standard in order to quantify the difference in accuracy between the two systems. We will also analyze additional joints across multiple motions to see if the observed trends are consistent. Furthermore, we will study the same movements with the subject moving at slower speeds in order to discard any possible discrepancy due to the speed and momentum issues that may be present with the IMUs.

# Assessing the Effect of Soldier Clothing and Individual Equipment (CIE) on Road March Biomechanics with IMUs

Clifford L. Hancock and Leif Hasselquist

U.S. Army Natick Soldier Research, Development and Engineering Center, Natick, MA, USA

Email: Clifford.L.Hancock4.civ@mail.mil

## INTRODUCTION

The U.S. Army continually seeks to improve soldier CIE. Next-generation CIE is often examined via human factors evaluations or indoor laboratory testing. However, conducting experimentation in operationally relevant conditions is also beneficial since the equipment is evaluated where and how soldiers will realistically use the equipment. When assessing the effects of equipment on biomechanics in operationally relevant conditions, inertial measurement units (IMUs) are particularly useful tools since they can be worn underneath equipment and, unlike optical motion capture, are not confined to small capture volumes. Therefore, the purpose of this study was to assess the effect of various equipment configurations on the biomechanics of soldiers performing two identical road marches during an operationally relevant scenario with IMUs.

## METHODS

Twenty-six U.S. Army enlisted male soldiers' ( $23.9 \pm 3.81$  years;  $1.743 \pm 0.08$  m;  $77.5 \pm 12.04$  kg) IMU (APDM, USA) data was analyzed from the march portions of an operationally relevant scenario. The scenario consisted of 6 sections: 1) a baseline marksmanship test, 2) a 3-mile march, 3) the Load Effects Assessment Program-Army (LEAP-A) obstacles, 4) a room clearing exercise, 5) a second 3-mile march, and 6) a second marksmanship test. The LEAP-A, in particular, was a strenuous activity that was intended to fatigue test participants in between road marches.

Each test participant individually completed the entire scenario three times but on separate days. Each day, test participants were outfitted with IMUs on their feet (secured to the boot laces), pelvis (secured near the sacrum), and sternum. Afterwards, the participants donned one of three randomly assigned equipment conditions. Specifically for the scenario's march sections, equipment condition 1 consisted of a

uniform, helmet, boots, and a mock weapon (7.3 kg). Equipment condition 2 consisted of the components of condition 1 plus body armor and a backpack (47 kg). Equipment condition 3 consisted of the components of condition 1 plus heavier body armor and a backpack (52 kg). March speed was monitored by GPS watches (Garmin, USA) and was maintained at 3 mph. Each hour long IMU march signal was divided into three 20 minute intervals (A=0-20, B=20-40, and C=40-60 minutes). Each interval was processed with a custom gait analysis algorithm developed by the University of Michigan [1].

As in previous research, dependent variables were calculated during each time interval of each march and included: 1) mean anterior-posterior (AP) lean angle of the torso, 2) standard deviation AP lean angle, 3) mean medial-lateral (ML) lean angle, 3) standard deviation ML lean angle, 4) principal components analysis (PCA) of the pelvis, 5) PCA of the feet, and 6) mean stride length [2].

For analysis, subject-based means were calculated for each dependent measure during each time interval. A repeated measures two-way ANOVA examined the main effects of and possible interactions between marches (pre and post) and equipment conditions (1, 2, and 3). When significant interactions were observed, tests of simple effects were utilized to compare all possible pairs of march conditions to each equipment condition.

## RESULTS AND DISCUSSION

For mean AP lean angle during time interval A, the ANOVA revealed a significant main effect of equipment condition ( $p < 0.000$ ). During time interval A, mean AP lean angle for equipment conditions 2 and 3 was  $9.05^\circ$  ( $p < 0.000$ ) and  $11.39^\circ$  ( $p < 0.000$ ) greater than for equipment condition 1, respectively (Figure 1). Time intervals B and C showed similar results, except mean AP lean angle for equipment condition 3 was also  $3.00^\circ$  ( $p = 0.032$ ) and  $2.75^\circ$

( $p=0.035$ ) greater than for equipment condition 2 during time intervals B and C, respectively.

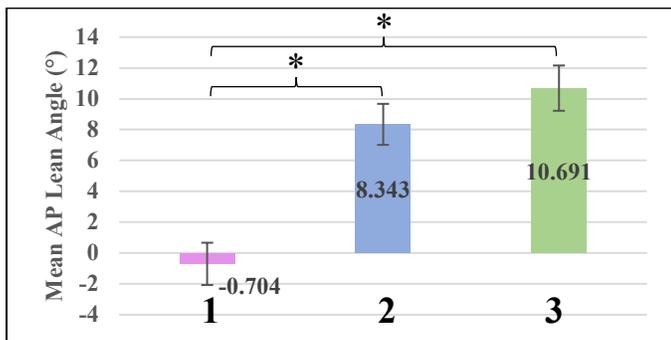

Figure 1 – Marginal means of Mean AP Lean Angle (time interval A) for the equipment conditions (1, 2, and 3) collapsed over march conditions. Positive values indicate forward lean. \* denotes  $p<0.05$ .

While there were no significant differences for mean ML lean angle ( $p>0.05$ ), there were significant interactions for standard deviation AP and ML lean angles during each time interval. The increase in weight from equipment conditions 1 to 3 caused increased mean forward lean angle and more variation about that mean. Additionally, for equipment conditions 2 and 3, standard deviation AP and ML lean angles were greater during the post-march than the pre-march during each time interval. The fatigue developed during the LEAP-A portion of the scenario, particularly while wearing equipment conditions 2 and 3, likely caused the increased variation about the mean during the post-march in both the AP and ML directions.

The ANOVA also revealed a significant interaction for  $PCA_{feet}$  during time intervals A ( $p=0.002$ ) and B ( $p<0.000$ ). During time interval A of the post-march, equipment condition 1 had 0.703% greater  $PCA_{feet}$  than equipment condition 2 ( $p=0.041$ ). While wearing equipment conditions 2 and 3 during time interval A,  $PCA_{feet}$  was greater in the pre-march than the post-march by 0.528% ( $p=0.007$ ) and 0.712% ( $p<0.000$ ), respectively. Time interval B showed similar results. The  $PCA_{feet}$  analyses revealed that when participants wore greater load, or fatigued between marches, the movement of the feet became less planar indicating a slightly altered, compensatory, movement strategy.

The  $PCA_{pelvis}$  analysis revealed a significant main effect of equipment condition for each time interval ( $p<0.001$ ), and pairwise comparisons showed that

equipment conditions 2 and 3 displayed less sagittal plane movement of the sacrum IMU as compared to equipment condition 1. The additional load caused participants to alter their pelvis motion during gait, resulting in greater out of sagittal plane movement. However, despite statistical differences, the small percentage differences evident for both  $PCA_{feet}$  and  $PCA_{pelvis}$  were likely not operationally meaningful.

A previous study concluded that increased equipment load caused decreased transverse pelvic rotation which was likely a result of higher stride frequency and shorter stride length [3]. However, the present study did not reveal any significant differences in stride length ( $p>0.05$ ) despite increased load. Additionally, the  $PCA_{pelvis}$  analysis revealed that additional motion occurred out of the sagittal plane as equipment load increased which may have shifted to the transverse plane. Further analysis is required to determine if pelvic motion has shifted to the frontal, transverse, or a combination of both planes. In the present study, the fact that participants also carried weapons likely influenced pelvic and torso motion since carrying weapons has been shown to alter trunk range of motion and transverse rotation [4].

## CONCLUSION

The present study demonstrated that IMUs are a promising tool when evaluating the effect of soldier equipment on biomechanics during operationally relevant scenarios. While a relatively small number of dependent variables were presented, additional metrics could be derived from the raw IMU signals to develop a more complete understanding of the effect of a particular piece of equipment. As further algorithms are developed to translate raw IMU signals into meaningful and valuable measures, the analysis of equipment effects on soldier biomechanics will become more comprehensive, allowing the U.S. Army to better design and select the optimal equipment for the future soldier.

## INTRODUCTION

Running is associated with high rates of injury: up to 92.4% of runners sustain a musculoskeletal injury each year [1]. Thus, developing metrics to predict and prevent running injury is integral to preserving the musculoskeletal health of the ~55 million Americans who run regularly [2].

Theory posits that combinations of high magnitudes and numbers of vertical ground reaction forces (vGRFs) contribute to injury; however, in spite of much research, the relationship between vGRF and injury remains unclear [e.g., 3]. This lack of clarity may be due, in part, to the fact that measuring vGRFs typically requires costly equipment and expertise and is largely restricted to laboratory and clinical settings. These constraints limit the amount of data that can be collected and the ecological validity of that data, requiring inferences about overall loading profiles to be made based on limited and potentially biased samples. Extrapolation of these laboratory-based results may not realistically represent the number or magnitude of loads experienced by runners.

To overcome these constraints, our lab previously developed a model that estimates peak vGRFs from hip acceleration data, participant mass, and the type of locomotion (walk or run) [4]. The mean absolute difference between model-predicted and force plate-observed vGRFs was 8.3%, supporting this technique's potential to quantify the peak magnitude of vGRFs during running.

Building on this model, the current study quantifies the magnitude and number of loads experienced by competitive runners and compares those measures with reported pain/fatigue and injury. Runners with high magnitudes and numbers of loads were predicted to report higher pain/fatigue and injury.

## METHODS

Nine male NCAA Division I middle and long distance track runners were followed for 60 days ( $18.7 \pm 1.0$  years old,  $64.2 \pm 7.3$  kg,  $178.4 \pm 4.6$  cm; mean  $\pm$  SD). Coaches provided prescribed daily running distances/times for each participant. Participants completed daily questionnaires describing overall post-training pain/fatigue on a scale from 1 (none) to 9 (extreme) and reported the location and severity of any injuries.

During training runs each participant wore a tri-axial linear accelerometer (ADXL345, Analog Devices, Norwood, MA;  $\pm 8$  g, 48.4 – 52.4 Hz,) on their right hip. Custom MATLAB scripts (R2016a, The MathWorks, Natick, MA) were used to filter the gravity component from the acceleration signal. Steady-state portions ( $>10$  strides) were isolated, and the number and magnitude of right-side acceleration peaks were calculated. Magnitudes were then converted to peak vGRF estimates [4].

19.3% of accelerometer and 29.2% of pain/injury data were missing due to item non-response (e.g., participant removed accelerometer during run). Missing data were multiply imputed using prescribed training, anthropometrics, and all analysis variables and assuming that values were missing at random. Fifty imputed data sets were generated with SPSS (v24.0, IBM Corp., Armonk, NY) and pooled for analysis using Rubin's rules [5].

Injured and uninjured participant mean pain/fatigue, mean estimated peak vGRF, mean strides per run, mean cumulative loading per run (strides\*vGRF), and rate of load accumulation (cumulative load across two-weeks) were entered into independent samples t-tests. Significance was set at  $p < 0.05$  and corrected with a False Discovery Rate to mitigate chance of Type I error.

## RESULTS AND DISCUSSION

Across the 60-day study, three participants (33%) lost training time due to injury (self-reported foot, adductor, and hamstring injuries with 7, 10, and 33 days lost). Injured and uninjured participants did not report significantly different pain/fatigue ( $p = 0.346$ ) suggesting that our pain/fatigue questionnaire, and/or runners themselves, were insensitive to impending injury; thus, underscoring the need for additional objective metrics.

In contrast, while the mean number of strides per run did not differ between injured and uninjured participants ( $p = 0.828$ ; Fig 1a), injured participants had significantly greater peak vGRFs ( $p < 0.001$ ; Fig 1b) and cumulative loading per run ( $p = 0.006$ ; Fig 2a). Injured runners also demonstrated a trend toward faster rates of load accumulation ( $p = 0.079$ ; Fig 2b) and outlying peak vGRF vs. mean strides per run values, suggesting greater injury risk at high load magnitude-number combinations (Fig 3).

## CONCLUSIONS

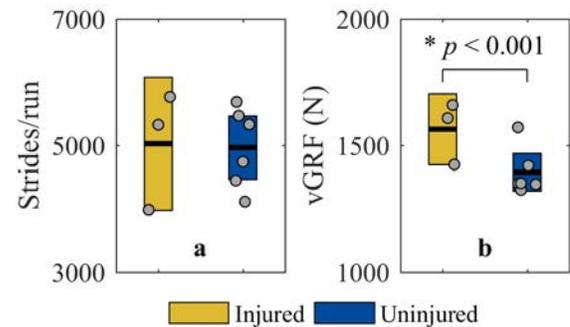

Although limited by a small sample size, the present results suggest that the accelerometer-based model used here is capable of capturing inter-participant differences in loading profiles that may be predictive of running injury.

# THE USE OF A SINGLE INERTIAL SENSOR TO ESTIMATE 3-DIMENSIONAL GROUND REACTION FORCE DURING ACCELERATIVE RUNNING TASKS

## INTRODUCTION

The magnitude and orientation of the ground reaction force vector ( $F$ ) are often used as an index to assess performance in linear acceleration and change of direction tasks [1, 2]. In-ground force plates (FP) are considered the gold standard for measuring  $F$ , however, their use in the field is limited by their cost and the constraints they place on movement.

To overcome these limitations, previous studies have investigated the use of a single wearable accelerometer for estimating kinetic parameters during accelerative tasks [3, 4]. The sensor is typically placed close to the body's center of mass (COM) thus enabling estimation of  $F$  via Newton's 2<sup>nd</sup> Law with knowledge of the subject's mass. These studies suggest that misalignment of the accelerometer measurement axes relative to the FP may underlie some of the observed error. Inertial measurement units (IMUs) are equipped with on-board sensors that allow them to determine the orientation of the IMU relative to an inertial reference frame (and thus also the FP frame assuming the FP vertical axis is aligned with the gravity vector) and compensate for the aforementioned frame misalignment.

Previous studies have not attempted to compensate for this potential error source using IMUs. Thus, the purpose of this study was to assess the validity of 3-D  $F$  estimates from a single IMU during accelerative running tasks by comparison to a force plate.

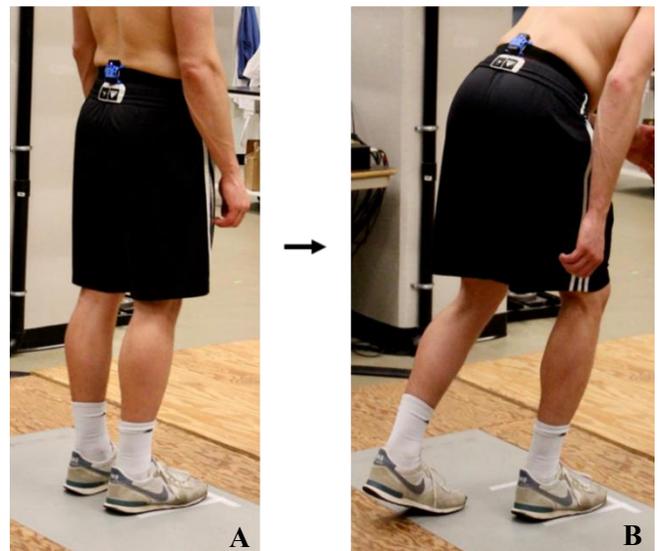

## METHODS

Fifteen subjects (12 male, 3 female, age:  $23.20 \pm 2.11$  yrs) volunteered to participate in this study. The movement tasks assessed were:

1. A linear standing sprint start (SS), and
2. A 45° change of direction task (COD)

Subjects performed six trials of the SS task (three to assess  $F$  during the initial push from stance and three to assess  $F$  during the first foot contact after the initial push). Subjects also performed six trials of the COD task (three to the left and three to the right) to assess  $F$  during the first foot contact after the initial push (i.e. the plant foot).

The IMU was attached to the sacral region of the subjects using an elastic strap and double-sided tape (Fig 1). Subjects were positioned with their hips pointed straight forward in order to align the forward axes of the IMU and FP. This allowed the determination of the FP heading (angular deviation of horizontal plane axes) relative to the local

**Figure 1:** Subject on force plate with IMU attached to sacral region. **A.** Static orientation trial - hips aligned with forward axis of the force plate. **B.** Subject assumed standing sprint start stance.

magnetic field vector. Subjects then assumed their stance for three seconds before performing the task. Average accelerometer and magnetometer output during stance was used to determine IMU attitude and heading relative to the FP. The attitude and heading allowed the construction of the composite quaternion representing the orientation of the IMU relative to FP. The angular rate signal measured by the gyroscope was then used to time-integrate the quaternion orientation at each instant during the movement. The acceleration vector measured by the IMU was then resolved in the FP frame and scaled by the subject's mass to provide an estimate of  $\mathbf{F}$ .

Step average  $\mathbf{F}$  ( $\bar{\mathbf{F}}$ ) was determined for the IMU and FP by averaging the  $\mathbf{F}$  estimates measured during foot contact (when FP measured  $F_z > 10$  N). IMU estimates of  $\bar{\mathbf{F}}$  and instantaneous  $\mathbf{F}$  were compared to the same measured by FP. The ratio of the forward component of  $\mathbf{F}$  ( $F_x$ ) relative to  $F_{res}$  expressed as a percentage ( $RF$ ) was also compared between IMU and FP to consider the potential application of the IMU method to assess linear acceleration performance [1]. Error in the IMU estimates of  $\mathbf{F}$  was quantified using root mean square error (RMSE), relative error (absolute percent difference), and Pearson's product moment correlation coefficient ( $r$ ).

## RESULTS AND DISCUSSION

The IMU method gave valid estimates of  $\bar{F}_x$ ,  $\bar{F}_z$ ,  $\bar{F}_{res}$ ,

and  $RF$  during SS and  $\bar{F}_z$  and  $\bar{F}_{res}$  during COD suggested by significant correlations, low relative error, and low RMSE (Table 1). Despite large absolute errors in the IMU estimate of the other components, correlations with FP estimates were significant for all components of  $\bar{\mathbf{F}}$  except  $\bar{F}_y$  during SS suggesting the IMU estimate may be able to detect similar changes in measured values compared to FP over time. The IMU did not provide accurate estimates of instantaneous  $\mathbf{F}$  for any components for the SS task (RMSE: 376.64 N to 476.57 N) nor for the COD task (RMSE: 436.44 N to 632.54 N). The average angular error of the IMU estimate of  $\bar{\mathbf{F}}$  during both SS and COD was less than  $10^\circ$  suggesting the IMU can provide valid estimates of the orientation of  $\bar{\mathbf{F}}$ .

The ability to accurately estimate directional step-averaged  $\mathbf{F}$  during athletic tasks is useful when evaluating performance [1, 2]. The results of this study broaden the scope of IMU applications to perform field-based human movement analyses.

# Use of Inertial Measurement Units (IMUs) in the Analysis of Bounding Rush Performance in Soldiers

Meghan P. O'Donovan, Jonathan T. Kaplan, Clifford L. Hancock and <sup>1</sup>Leif Hasselquist

<sup>1</sup>Natick Soldier Research, Development, and Engineering Center, Natick, MA, USA

e-mail: meghan.p.odonovan.civ@mail.mil, web: <https://www.nsrdec.army.mil/>

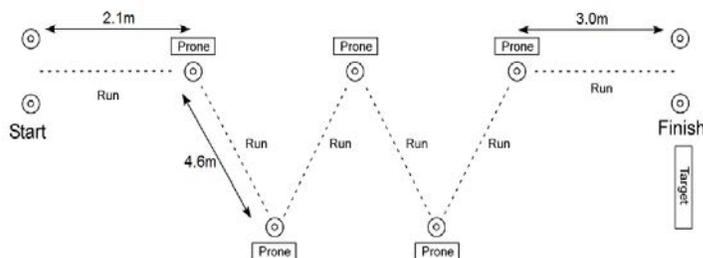

## INTRODUCTION

Realistic operations for military personnel can be difficult to recreate in laboratory settings. To draw meaningful conclusions about Soldier performance, laboratory assessments try to match the tasks and environments Soldiers operate in as closely as possible. The military is investigating the use of wearable technologies, such as Inertial Measurement Units (IMUs), to gather information about Soldier performance directly from the operational tasks Soldiers conduct in the field. The purpose of this study was to: 1. Analyze the performance of Soldiers conducting a bounding rush task in the field and 2. Determine if IMU derived measures relate to overall performance of a bounding rush task.

## METHODS

Forty male Soldiers (ht:  $1.74 \pm 0.07$  m, wt:  $78.5 \pm 11.5$  kg, age:  $23.9 \pm 3.81$  yrs) participated in this study. Each participant conducted the bounding rush task as part of a military obstacle course completed in the field. Participants completed the bounding rush task in the following load configurations: Level I consisted of uniform, boots, helmet, and simulated weapon (M4 carbine) for a total weight of 7.3 kg; Level II consisted of Level I components with the addition of a body armor vest for a total weight of 31 kg; and Level III consisted of Level II components with additional ballistic-protection added to the armor vest for a total weight of 36 kg. An IMU (APDM, USA) sampling at 128 Hz was affixed to the sacrum of each participant prior to the start of the course. The bounding rush task was the 7<sup>th</sup> obstacle of the course and began with the participant standing upright, rushing 2.1 m forward, dropping to a prone position, completing four diagonal 4.6 m rush-to-prone repetitions, and lastly, rushing 3.0 m toward the finish (Figure 1). In each prone position, the participant was required to acquire a sight picture of a target placed near the finish before proceeding. Participants were instructed to complete the bounding rushes as quickly as possible to maximize

effort and task performance. Only the four 4.6 m rushes that included prone-to-prone transitions were analyzed.

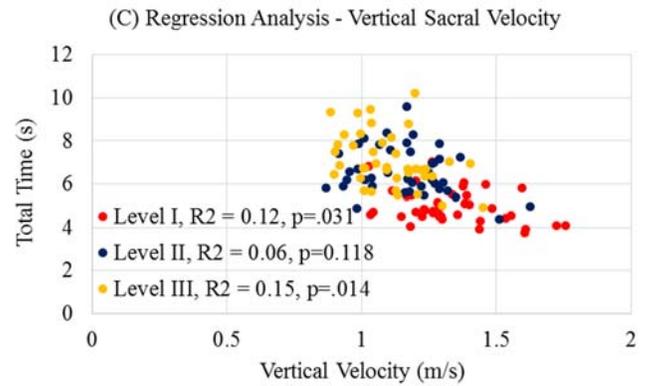

**Figure 1:** Schematic of the bounding rush task.

Dependent measures were averaged across the four rush repetitions. Timing data, including total time (time to complete the bounding rush) and time to standing (time to reach the maximum vertical displacement of the sacrum), was collected via the sacral mounted IMU. In addition, maximum sacral velocity (both horizontal and vertical) was recorded and averaged for each rushing bout. IMU derived measures were analyzed via dedicated algorithms (University of Michigan, MI, USA) [1]. A one-way repeated measures ANOVA was run for the three configurations (I, II, and III) to determine if there was a significant effect of load configuration on the dependent measures. A subsequent regression analysis was conducted to determine the strength of the linear relationship between total time (rush performance) and the other IMU derived measures.

## RESULTS AND DISCUSSION

ANOVA results showed a significant effect of load configuration on total time ( $p < 0.001$ ). Post-hoc pairwise comparisons revealed that increased load significantly increased total time to complete the bounding rush task (I:  $4.95s \pm 0.78$ , II:  $6.59s \pm 1.11$ , III:  $7.12s \pm 1.26$ ), thus decreasing task performance ( $p < 0.05$  for all comparisons tested). This agrees with previous work examining the effects of load on sprint performance [2] and indicates a clear difference in performance between the three load configurations.

ANOVA results also indicated a significant effect of load configuration on other IMU derived measures. Specifically, time to standing in the Level I configuration was significantly faster than both the Level II ( $p<0.001$ ) and the Level III ( $p<0.001$ ) configurations. However, there was no significant difference between Levels II and III ( $p=0.21$ ). Maximum horizontal sacral velocity in the Level I configuration was significantly greater than in both the Level II ( $p<0.001$ ) and the Level III ( $p<0.001$ ) configurations. However, there was no significant difference in max horizontal sacral velocity between the Level II and III configurations ( $p=0.486$ ). Maximum vertical sacral velocity in the Level I configuration was significantly greater than in both the Level II ( $p<0.001$ ) and III configurations ( $p<0.001$ ). Max vertical sacral velocity was also significantly higher in the Level II configuration than in the Level III configuration ( $p<0.023$ ).

**Figure 2:** Regression plots for IMU derived metrics including (A) time to standing, (B) max horizontal sacral velocity, and (C) max vertical sacral velocity.

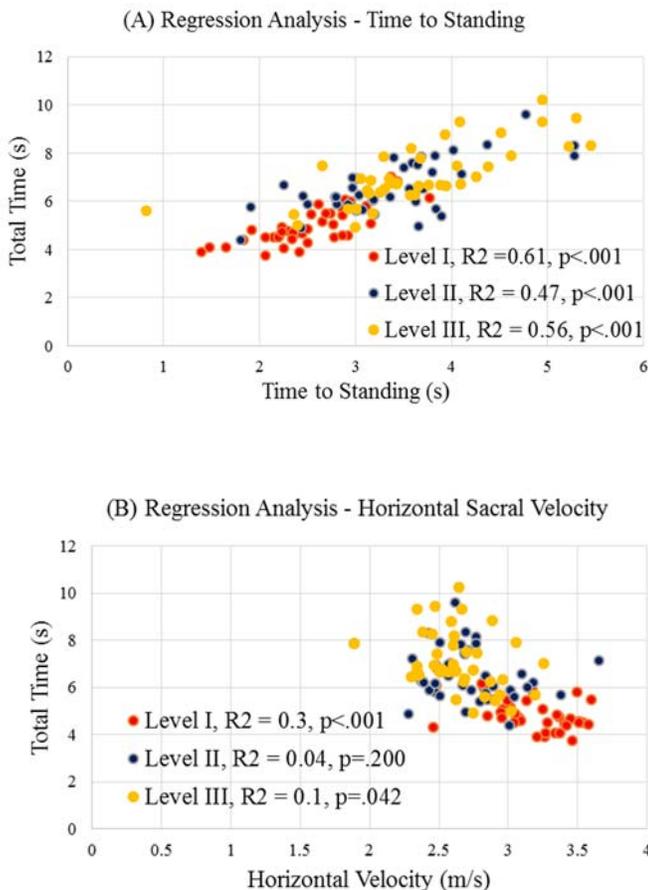

Load configurations I and III displayed significant negative correlations between max horizontal and vertical sacral velocity and total time ( $p<0.05$ ) but with low coefficients of determination. There was no significant correlation between horizontal nor vertical sacral velocity and total time for the Level II configuration. All three load configurations displayed significant, positive correlations between time to standing and total time ( $p<0.001$ ) with higher coefficients of variation (Figure 2A). The regression results indicate that performance on the bounding rush task was best predicted by the transition time from prone to standing while the ANOVA results indicate that max vertical sacral velocity was the most sensitive to changes in load configuration.

## CONCLUSIONS

This study indicated that increased load resulted in greater time to complete a bounding rush task, thus reducing maneuverability in the field. This study has also shown, through several significant correlations between the IMU metrics and task performance, that IMU-derived measures have the potential to be an effective tool to analyze task performance strategies for operationally relevant maneuvers in the field. It is important to note that additional IMU derived measures (e.g., sacral accelerations, sprinting time, footfall distance, etc.) not included in this analysis could also be used to quantify task performance and require further investigation.

## INTRODUCTION

The ability to analyze human movement in different environments (water and land) is an essential tool of biomechanical analysis for sport and rehabilitation applications. Most of the previous research regarding kinematic effects of aquatic exercises has used video analysis [1]. However, the reliance on video analysis for kinematic parameters in aquatic environment has been questioned as the surrounding water induces differences in the refractive index in comparison to air, which can increase the risk of image geometric distortion and/or parallax error [2]. Additionally, underwater optical motion capture systems are expensive, complicated, and limited to laboratory settings [4]. The use of inertial motion sensors has become popular among researchers when tracking human movement in aquatic environments. The sensors potentially provide a wider field of acquisition, faster set-up, and a practical calibration, with a reliable accuracy reported in analyzing the joint kinematic in sagittal plane [3]. However, wireless inertial motion sensors cannot be used for underwater applications that require high sample rates (>128Hz) or real-time data monitoring.

This paper covers the validation of a GoPro sports camera motion capture system as an inexpensive and reliable way to capture underwater movement.

## METHODS

A single GoPro Hero 4 Black (image rate 240 Hz; image resolution 1280x720 pixels) camera enclosed in a modified waterproof housing, was used. The GoPro Wi-Fi signal was boosted with a passively coupled range extender (TP-Link AC750), permitting a cable to be extended out of the water to a small aerial. This set-up enabled wireless control and monitoring of the camera from a nearby laptop computer using the GoPro camera control software (version 2.0.5 for windows).

A waterproof chessboard was used to perform 2D plate calibration in dry and aquatic conditions [5]. A physical cylindrical segment model was developed to stimulate the human leg movement pivoting in sagittal plane (i.e. Hip extension and flexion). The model was set in a 3 × 1.5 × 2 m pool.

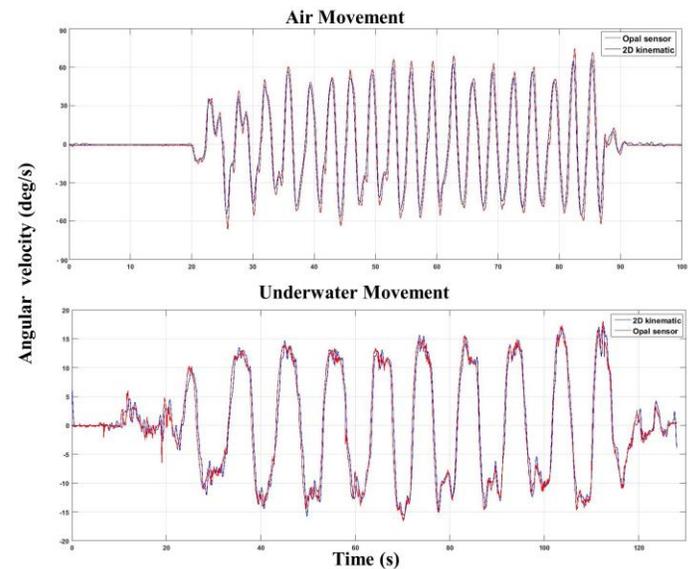

Kinematic data measured from analysis of the GoPro video was compared to data from three tri-axial inertial motion units (accelerometers + gyroscopes + magnetometers; Emerald, APDM, Portland, OR, USA). The units were fixed along the leg segment model and the model was attached to a turning force with a fixture arm to both sides of the pool. The direction of movement of the model and its range of motion simulated hip flexion-extension of a stiffened leg. The angular velocities of power-head (Biodex isokinetic dynamometer) used to drive the model were set to 30°/s and 10°/s for air and underwater conditions respectively. Reflective markers were attached exactly on the centre of the inertial motion units on each segment of the leg model in order to be able to track the movement in the sagittal plane. An analogue clock with a smooth sweep second hand (100 twitches per second, 31 cm diameter, Time Company) was also used as part of the camera validation. The angular velocity of the clock's second-hand was measured from the GoPro video during five cycles of 60 seconds in water and dry-land conditions. A reflective marker was attached to the tail of the second hand to track the movement. One samples T-tests were used to compare measured velocities in air and water to the expected angular velocity of the clock and the leg segment model. Pearson's cross-correlation analysis was used to compare measurements between the inertial sensors and the markers placed on the segmental leg model. Statistical significant was set at  $p < 0.05$ .

## RESULTS AND DISCUSSION

The results are presented in Table 1. The nonlinear direct linear transformation (DLT) showed a mean re-projection error of 0.21 and 0.28 for air and underwater conditions respectively. This is within an acceptable range for the pixel accuracy in both conditions. The expected mean angular velocity of the wall clock's second-hand ( $6^\circ/s$ ) was not significantly different to the values measured in air ( $p < 0.626$ ) and underwater ( $p < 0.157$ ). Similarly, the angular velocity measured along the leg model was not significantly different for marker ( $p < 0.852$ ) and sensor ( $p < 0.578$ ) when compared to the expected velocity of  $30^\circ/s$ ; likewise, marker ( $p < 0.927$ ) and sensor ( $p < 0.673$ ) measurements were similar to expected  $10^\circ/s$  underwater velocity.
