

**ASB2017** AMERICAN SOCIETY  
OF BIOMECHANICS  
UNIVERSITY OF COLORADO **BOULDER**

**ABSTRACTS**

# Table of Contents

Keynote Lectures.....	1
K1_1--X-ray Reconstruction of Moving Morphology (XROMM) Yields New Insights into Musculoskeletal--(Brainerd).....	1
K2_1--Developing useful smart clothing-Where does biomechanics fit--(Steele).....	2
Plenary Award Lectures.....	3
BA_1--and one thing just led to another--(Grabiner).....	3
FA_1--Translational Journeys - From Head Impact Sensors to Wrist Implants to Toy Controllers--(Crisco).....	4
FA_2--Collaborators-A Key to Fun and Exciting Research--(Neptune).....	5
FA_3--Simulated ACL and Menisci Deficiency Predicts Altered Knee Mechanics During Walking--(Smith).....	6
FA_4--Resolving the Debate-Ankle Push-Off During Human Walking Contributes to Accelerating Both--(Zelik).....	8
Wednesday, August 9, 10:30-noon.....	10
S1A--Touch of Grey-The Aging Runner--(Paquette).....	10
P1B_1--Locomotor Adaption to Lateral Center of Mass Movement Amplification Requires Active Stabilization--(Gordon)....	12
P1B_2--Is There a Learning Effect for Balance Assessment Tests--(Orendurff).....	14
P1B_3--Relating Obesity, Cognition and Biomechanics of Fall Recovery in Older Adults- Preliminary Results--(Coon).....	16
P1B_4--Biomechanical Measures of Clinician-Defined Balance Impairments in Persons Post-Arthroscopy for Femo--(Brown).	18
P1B_5--Below-Knee Amputees Make Specific Anticipatory Locomotor Adjustments To Resist Lateral Perturbation--(Major).	20
P1B_6--Altered Sensory Organization during Quiet Stance Following Neurotoxic Chemotherapy--(Monfort).....	22
P1C_1--EMG Assessment of a Shoulder Support Exoskeleton during On-Site Job Tasks--(Gillette).....	24
P1C_2--Spatial Dependency of Shoulder Muscle Demand During Dynamic Unimanual Pushing and Pulling--(McFarland)..	26
P1C_3--Submaximal Normalizing Methods to Evaluate Load Sharing Changes in Repetitive Upper Extremity Work--(McDonald).	28
P1C_4--Shoulder Musculature Activation During Human Brachiation--(MacLean).....	30
P1C_5--MRI vs CT-Based Shape Registration Accuracy for Quantifying Shoulder Motion Using Biplane Fluoroscop--(Akbari-Shandiz).	32
P1C_6--Post-Mastectomy Breast Reconstruction Surgeries Compromise Passive Shoulder Stiffness--(Leonardis).....	34
T1D_1--Human-Exosuit Interfaces Absorb and Return Energy, Reshaping Exosuit to Human Power Flow--(Yandell).....	36
T1D_2--Hopping with a Full-leg Exoskeleton Lowers Metabolic Cost and Muscle Activity--(Allen).....	38
T1D_3--Tuned or Not Ultrasound Measurements of Soleus Fascicle Dynamics During Human Walking with Elastic --(Dick).	40
T1D_4--Effect of Speed on the Mechanics and Energetics of Walking with an Elastic Ankle Exoskeleton--(Nuckols).....	42
T1D_5--Effects of Ankle Exoskeleton Power and Actuation Timing on Movement Variability and Metabolic Cost o--(Antonellis).	44
T1D_6--A Unilateral Ankle Assisting Soft Robotic Exosuit Can Improve Post-Stroke Gait During Overground Wal--(Sloot)..	46
T1E_1--A Mechanical Role for Incompressible Fluid in Stretched Muscle--(Sleboda).....	48
T1E_2--Intramuscular Pressure Variability Differs from Force Variability during Ramped Isometric Contractio--(Davies).....	50
T1E_3--Intraoperative Measurement of Human Muscle Properties--(Evertz).....	52
T1E_4--Reduced Muscle Stem Cell Number Compromises Serial Sarcomere Addition--(Dayanidhi).....	54
T1E_5--Positive Force Feedback Allows For Faster and Safer Recovery in Perturbed Hopping - At A Cost--(Punith).....	56
T1E_6--Stretch-Shortening Cycle Performance in Dancers--(Rice).....	58
Wednesday, August 9, 1:30-3:00.....	60
S2A--ASB-GCMAS Joint Symposium-Technical Challenges in Clinical Motion Analysis-Finding Solutions--(Kaufman).....	60
R2B_1--Effects of Passive and Powered Ankle-foot Prostheses on Level-ground Walking EMG--(Jeffers).....	62

R2B_2--Effects of Different Power of Powered Prosthesis on Gait Asymmetry and Metabolic Cost--(Choi).....	64
R2B_3--Displacements and Strains of the Gel Liner for Below Knee Prosthetic Users--(Lenz).....	66
R2B_4--Temporal Spatial Improvements for Amputees During Rehabilitation--(Kingsbury).....	68
R2B_5--Intact Knee Joint Kinetics During the First Six Months of Prosthetic Use--(Krupenevich).....	70
R2B_6--Longitudinal Changes in Mediolateral Trunk and Pelvic Motion among Persons with Lower Limb Amputatio--(Hendershot).	72
R2B_7--How Do Prosthetic Stiffness, Height, and Running Speed Affect the Biomechanics of Athletes with Bila--(Beck)....	74
R2B_8--Power and Work Generated Throughout the Running-Specific Prosthesis Keel during Running after Amputa--(Baum).	76
R2B_9--Dynamic Balance During Running Using Running-Specific Prostheses--(Sepp).....	78
S2C--ASB-SICB Joint Symposium-Insights from Animal Biomechanics--(Rubenson).....	80
T2D_1--Effects of an Occupational Wearable Assistive Device on Low Back Loads--(Mokhlespour Esfahani).....	83
T2D_2--Workstation Configuration and Packaging Type Influence Grocery Store Cashier Arm Postures--(Lang).....	85
T2D_3--An Investigation of Cervical Spine Kinematics in Various Tablet Reading Postures--(Douglas).....	87
T2D_4--Finger Flexor Tendon and Subsynovial Connective Tissue Motion with External Mechanical Pressure and --(Farias Zuniga).	89
T2D_5--Applied Hand-Rung Forces After a Ladder Perturbation--(Pliner).....	91
T2D_6--Comparison of 50th Percentile Human Headforms to an Adult Male Population Using 3D Modeling and Prin--(Liu).	93
T2E_1--Differences Between In Vivo Tendon Moment Arms Measured Geometrically And From Tendon Excursion--(Baxter).	95
T2E_2--Are Ultrasound-Based Estimates of Achilles Tendon Kinematics Consistent with the Expected Behavior o--(Matijevich).	97
T2E_3--Do Triceps Surae Muscle Dynamics Govern Non-Uniform Achilles Tendon Deformations--(Clark).....	99
T2E_4--How Do Material Transverse Isotropy and Pre-Tension Influence Simulations of Nonuniform Displacement--(Knaus).	101
T2E_5--Assessing Non-Uniform Stiffening of the Achilles Tendon Using Surface Wave Elastography--(Salman).....	103
T2E_6--In Vivo Tendon Stress is Predicted by Non-Invasive Wave Speed Measurement--(Martin).....	105

Wednesday, August 9, 5:30-6:30.....

P3A_1--High-Acceleration Training During Growth Increases Optimal Fiber Lengths in an Avian Bipedal Model--(Salzano).	
P3A_2--In Vivo Determination of Optimal Muscle Fascicle Length and PCSA Using Multi-scale Measurements--(Terrell)....	109
P3A_3--Individuals With Lower Limb Trauma Prioritize Stability Over Maneuverability When Navigating A Virt--(Sheehan).	111
P3A_4--ACL Reconstruction Graft Geometry is Associated With Asymmetric In Vivo Cartilage Contact Patterns--(Vignos).	113
P3B_1--Incremental Lateral Wedging- Effects on Knee Moment in Medial Knee Osteoarthritis--(Mejia).....	115
P3B_2--Effect of the AtlasGäó Knee System on Stress in the Medial Tibial Cartilage--(Hillstrom).....	117
P3B_3--Articular Cartilage Contact during Gait in Obese Individuals with Knee Pain--(Li).....	119
P3B_4--Abnormal Muscle Forces During Gait are Related to Cartilage Health After Hip Arthroscopy in Femoroac--(Samaan).	121
P3C_1--Muscle Contractile Properties in Mice with LGMD2i Muscular Dystrophy--(Rehwaldt).....	123
P3C_2--Towards Subject-Specific Tendon Models- An Experimental and Modelling Framework--(Rankin).....	125
P3C_3--3D X-Ray Motion Analysis Indicates Treadmill Exercise Exacerbates Knee Osteoarthritis in MMT Rats--(Cooper).	127
P3C_4--Putting on the brakes- the effect of drag loading on the maneuverability of bottlenose dolphins--(Shorter).....	129
T3D_1--Rotator Cuff Tendon Forces During Weight-Relief Lift in Tetraplegia--(Peterson).....	131
T3D_2--Upper Extremity Kinematics of Wheelchair Lacrosse Athletes during Overhead Throw--(Riebe).....	133
T3D_3--Handrim Biomechanics of Pediatric Manual Wheelchair Mobility--(Schnorenberg).....	135
T3D_4--The Relationship Between Propulsion Pattern and the Development of Upper-Extremity Pain in Manual Wh--(Walford).	137

T3E_1--The Effect of Lumbar Belts on Psychological and Biomechanical Outcomes--(Shahvarpour).....	139
T3E_2--The Influence of Lumbar Spine Postures on Monitor Location When Using Sit to Stand Workstations--(Fewster)....	141
T3E_3--Time-Varying Contributions to Lumbar Lordosis during and Unstable Sitting Task in People Who Do and --(Viggiani).	143
T3E_4--Landing Mechanics During A Stop Jump In Individuals With Low Back Pain And Low Back Injuries--(Johnson).....	145
<b>Thursday, August 10, 10:30-noon.....</b>	<b>109</b>
R4A_1--Soft Tissue Increases Stability and Propulsion During Human Running--(Masters).....	147
R4A_2--Differential Leg Joint Function During Human Running--(Jindrich).....	149
R4A_3--The Energetics of the Human Foot Across a Range of Running Speeds--(Kelly).....	151
R4A_4--Hip Alignment, Position at Foot Strike and Peak Hip Adduction Angle in Female Runners--(Brindle).....	153
R4A_5--Influence of Stride Frequency on Knee Joint Stiffness and Anterior Tibial Shear Forces in Female Run--(Thakkar).	155
R4A_6--Multiscale Entropy of Center of Mass Acceleration as a Measure for Cumulative Running Fatigue--(Gruber).....	157
R4A_7--Changes in Mechanics Across a Marathon--(Ruder).....	159
R4A_8--Changes In Running Mechanics During The 2016 US Olympic Trials Marathon--(Hunter).....	161
R4A_9--Coasting to a Sub-2-Hour Marathon using an Optimal Drafting Approach--(Arellano).....	163
P4B_1--Gait Effects on Joint Mechanics and Clinical Outcomes in Hip Dysplasia Patients--(Thomas).....	165
P4B_2--Kinematic Variability and Local Dynamic Stability in Individuals with Hip Dysplasia--(Loverro).....	167
P4B_3--Hip Strength and Hip Moments during Gait in Women with and without Stress Urinary Incontinence--(Hartigan).....	169
P4B_4--Hip Lateral Rotator Muscle Force during Variations of the Single Leg Squat--(Khuu).....	171
P4B_5--Deep Hip Muscle Activation Is Altered During Squatting in Symptomatic Femoroacetabular Impingement--(Diamond).	173
P4B_6--Sagittal Plane Hip Impulse During Gait is Greater After Surgical Intervention for Femoroacetabular I--(Malloy).....	175
S4C_1--Enhancing the Biomechanics Classroom with Entrepreneurial Mindset Learning Activities--(Troy).....	177
S4C_2--Active Learning in Biomechanics Using Wearable Sensors--(McGinnis).....	179
S4C_3--Teaching Undergraduate Biomechanics to Students With Diverse Abilities--(Thompson).....	181
S4C_4--The Teaching Repository as a Tool for You--(Bigelow).....	183
S4C_5--Getting Started with the Science of Teaching and Learning (SoTL) in Biomechanics--(Fournier).....	184
T4D_1--Sagittal Plane Control of Trunk Posture after Spinal Cord Injury--(Audu).....	185
T4D_2--What's Your Potential The Influence of Kinematics on a Muscle's Ability to Contribute to the Sit-To--(Schloemer)..	187
T4D_3--Simple and Two-Element Hill-Type Muscle Models Cannot Replicate Realistic Muscle Stiffness--(Marjaninejad)....	189
T4D_4--Modeling Stiffening in the Neck in Specified Directions Through Muscle Coactivation--(Mortensen).....	191
T4D_5--A Mechanistic Damage Model for Ligaments--(Barrett).....	193
T4D_6--Differences in the Active State of a Simulated Ankle Muscle Using Two Foot Models--(Wager).....	195
T4E_1--Effects of Remote Pain on Muscle Fatigue During Repetitive Movements--(Cowley).....	197
T4E_2--Stiffness Perception at the Human Ankle and Knee--(Azocar).....	199
T4E_3--Mechanical and Visual Perturbation of Human Walking to Find General Principles of Locomotion Control--(rafiee).	201
T4E_4--Effect of Mirror Visual Feedback on Motor Adaptation and Learning--(Stone).....	203
T4E_5--Segmental Coordination During Turning In People With Parkinson's Disease--(Curtze).....	205
T4E_6--Specific Manual Tasks Transform EMG into a Probe for Neural Dysfunction in Parkinson's Disease--(Laine).....	207
<b>Thursday, August 10, 1:30-3:00.....</b>	<b>209</b>

S5A--Principles of Energetic Optimization in Healthy and Pathological Movement--(Finley).....	209
P5B_1--Ankle-Foot Orthosis Alignment Affects Center Of Pressure Velocity--(Ruble).....	212
P5B_2--Finite Helical Axis Variation Between Cavus, Neutrally Aligned, And Planus Feet Under Passive Loadin--(Thorhauer).	214
P5B_3--Foot Pressure Analysis to Assess Planovalgus Foot Deformity Correction Using the Calcaneal-Cuboid-Cu--(Karakostas).	216
P5B_4--Concurrent Validity of an Automatic Technique to Calculate Plantar Contact Area at Mid-Stance During--(Lidstone).	218
P5B_5--Running Strike Pattern, Midtarsal Locking, and the Windlass Mechanism--(Bruening).....	220
P5B_6--Net Ankle Pseudo-Stiffness Is Influenced By Walking Speed But Not Age For Older Adult Women--(Collins).....	222
S5C--Non-Academic Career Paths in Biomechanics--(Hass).....	224
T5D_1--Validation of a Model Based Tracking Technique to Measure In Vivo Patellofemoral Kinematics--(Pitcairn).....	226
T5D_2--Intrarater Reliability of a Novel Semi-Automated Approach to Determine Knee Articular Cartilage Morph--(Kwon)....	228
T5D_3--Feasibility of Biplane Fluoroscopy for Quantification of Shoulder Kinematics during Manual Wheelchai--(Mozingo).	230
T5D_4--Comparison of Real-Time MRI Pulse Sequences for Tracking Tissues of the Actively Moving Wrist--(Shaw).....	232
T5D_5--Extended Field-of-View Ultrasound of the Extensor Carpi Ulnaris--(Adkins).....	234
T5D_6--Intra-Op Biomechanical Guidance Improves Articular Fracture Reduction--(Kern).....	236
T5E_1--Explicit Modification of Step Length Asymmetry Transfers to Over-Ground Walking Post-Stroke--(Sanchez).....	238
T5E_2--Plantar Flexor Stimulation Improves Poststroke Gait Kinematics--(Makowski).....	240
T5E_3--A Uni-Lateral Soft Exosuit for the Paretic Ankle Can Reduce Gait Compensations in Patients Post-Stro--(Kudzia).	242
T5E_4--The Influence of Lateral Stabilization on Hemiparetic Walking--(Frame).....	244
T5E_5--Merged Plantarflexor Muscle Excitation Module Predicts Poor Balance in Post-Stroke Hemiparetic Subje--(Brough).	246
T5E_6--Task-Specific Perurbation Training Provides a Viable Rehabilitation Strategy to Reduce Falls in Stro--(Honeycutt).	248
<b>Thursday, August 10, 5:30-6:30.....</b>	<b>250</b>
P6A_1--Residual Limb Skin Strain Within a Socket Prosthesis in Transfemoral Amputees During Walking--(Gale).....	250
P6A_2--Shoulder Posture, Torque Magnitude, and Torque Direction Highlight the Heterogeneous Elasticity of t--(Leonardis).	252
P6A_3--Biaxial Testing of the Passive Properties of Native and Regenerated Muscle Tissue--(Wallace).....	254
P6A_4--Movement Restriction Increases Thoracolumbar Fascia Stiffness in a Porcine Model--(Glinka).....	256
P6B_1--Path-Specific von-Mises Stresses Inflicting the Pre- and Post-THR Femur During Walking--(Bendjaballah).....	258
P6B_2--Evidence of Low Back Injury In The Absence of Radiographic Detection--(Gale).....	260
P6B_3--Bone Microarchitecture and Running Biomechanics in First-Time Marathon Runners--(Sattler).....	262
P6B_4--Finite Element Analysis Prediction Of Glenohumeral Joint Growth Following Neonatal Brachial Plexus I--(Dixit)....	264
P6C_1--Multi-Scale Model in Co-Simulation to Estimate Patellofemoral Contact Stress in Total Knee Replaceme--(Razu)..	266
P6C_2--Biomechanical Gait Variable Estimation Using Wearables after Total Knee Arthroplasty--(Youn).....	268
P6C_3--Concurrent Osteoarthritis of Contralateral Knee Alters Joint Biomechanics of the Knee with a Mobile---(Wang).....	270
P6C_4--Knee Biomechanics of Dissatisfied Total Knee Replacement Patients during Stair Ascent--(Zhang).....	272
T6D_1--Muscle Activity during Postural Stability Tasks- Role of Military Footwear and Workload--(Chander).....	274
T6D_2--Lower Extremity Kinematics in Military Footwear During Slip Events--(Wilson).....	276
T6D_3--The Effects of a Carbon Fiber Shoe Insert on Speed and Power in Collegiate Athletes--(Gregory).....	278
T6D_4--Lower Extremity Stiffness When Running in Minimalist, Neutral, and Ultra-Cushioning Shoes--(Borgia).....	280
T6E_1--Plantar Pressure Changes with Use of a Custom Dynamic Ankle-Foot Orthosis--(Stewart).....	282

T6E_2--Segmental Turning Velocity and Coordination in Adults with mTBI--(Fino).....	284
T6E_3--Individuals With A Prior Traumatic Brain Injury Exhibit Decreased Neuromuscular Complexity During Ga--(Acuna).	286
T6E_4--Plantarflexor Remodeling Following Achilles Tendon Rupture Repair- A Case Study--(Baxter).....	288
<b>Friday, August 11, 1:30-3:00.....</b>	<b>290</b>
R7A_1--Longitudinal Data from Wearable Sensor System Suggests Movement Improves Standing Posture--(McGinnis)....	290
R7A_2--Quantifying the Shoulder Movement of Manual Wheelchair Users in the Real World Using Inertial Measur--(Cain).	292
R7A_3--Joint Moment Estimation Using Inertial Sensor Measurements with Gaussian Process Regression--(Simons).....	294
R7A_4--Accuracy of a Shoe-Worn Device to Measure Running Mechanics--(Hunter).....	296
R7A_5--Using Inertial Sensors for Assessing Performance During Stair Running--(Ojeda).....	298
R7A_6--An Adaptive Filtering Algorithm to Estimate Sprint Velocity Using a Single Inertial Sensor--(Gurchiek).....	300
R7A_7--Energy Expenditure During Exercise Using Novel Piezoelectric Foam Sensors--(Evans).....	302
R7A_8--A Smart Pressure Insole for Gait Retraining Outside of the Laboratory--(He).....	304
R7A_9--Self-report and Performance Measure Outcome Estimation Using Wearables after Total Knee Arthroplasty--(Youn).	306
P7B_1--A New Measure of Trip Risk Integrating Minimum Foot Clearance and Dynamic Stability Across the Swing--(Schulz).	308
P7B_2--Using Detrended Fluctuation Analysis To Assess System Stability During Running--(Agesta).....	310
P7B_3--Do Inverted Pendulum Models of Stability Make Consistent Predictions of Dynamic Balance for Assessin--(Pickle).	312
P7B_4--Does Dynamic Stability Govern Propulsive Force Generation in Human Walking--(Browne).....	314
P7B_5--Aging Effects on Leg Joint Variability during Walking in the Presence Of Optical Flow Perturbations--(Qiao).....	316
P7B_6--How Healthy Older Adults Negotiate Stepping Objects While Walking--(Salinas).....	318
S7C--Jim Hay Memorial Session MTU Mechanics of the Lower Extremity-Lessons Learned from Sport--(McNittGray).....	320
T7D_1--Material Properties of Ankle Plantarflexor and Dorsiflexor Muscles - Effect of Aging--(Lee).....	322
T7D_2--Differences in Hamstring Muscle Quality Between Highly Active and Sedentary Older Adults--(Casto).....	324
T7D_3--Cognitive and Neuropsychological Differences between Elderly Populations with Good and Poor Balance --(Pechtl).	326
T7D_4--The Relationships Between Physical Capacity And Biomechanical Plasticity In Old Adults--(Kuhman).....	328
T7D_5--Age and Falls History Effects on the Modular Control of Walking with Optical Flow Perturbations--(Allen).....	330
T7D_6--Power Training Increased Neuromuscular Activation of the Extensor Muscles During Gait in Old Adults--(Beijersbergen).	332
T7E_1--Does Metabolic Cost Explain Mass-Based Changes in Preferred Reaching Speed--(O'Brien).....	334
T7E_2--Mechanics & Energetics of Walking with a Flat Center of Mass Trajectory--(Johnson).....	336
T7E_3--The Metabolic Cost of Walking on Rough Terrain--(Gast).....	338
T7E_4--Why is the Energy-Speed Curve for Human Walking U-Shaped--(Miller).....	340
T7E_5--A Passive Hip Exoskeleton for Reducing Metabolic Cost of Walking- A Simulation Study--(Saadatzi).....	342
T7E_6--Energy Cost of Walking in a Passive-Elastic Ankle-Metatarsophalangeal Exoskeleton--(Green).....	344
<b>Friday, August 11, 3:30-5:00.....</b>	<b>346</b>
S8A--Osteoarthritis Examined from Full Human to Cellular Perspectives-ASB-OARSI Symposium--(DeVita).....	346
P8B_1--The Effect of Achilles Tendon Moment Arm Length on Stretch-Shortening Cycle Performance in the Verti--(Madden).	349
P8B_2--Biomechanical Differences in Female Athletes with Varying Levels of Leg Stiffness--(Waxman).....	351
P8B_3--Modified Hockey Skate Blade Profiles Affect Skating Biomechanics And Performance--(Vienneau).....	353
P8B_4--Inverse Dynamics of Swinging Baseball Bats of Various Moments of Inertia--(Crisco ).....	355

P8B_5--Energy Generation Strategies Related to Peak Elbow Varus Torque in High School Baseball Pitchers--(McNally)..	357
P8B_6--Arm Slot and its Relation to Shoulder and Elbow Safety and Efficiency in Youth Baseball Pitchers--(Plunkett).....	359
S8C--Unanswered Questions in Biomechanics-Bases of Muscle Force Production--(Herzog).....	361
T8D_1--Power Imbalance Nearly Eliminated in Whole-Body Analysis--(Ebrahimi).....	365
T8D_2--Lower Extremity Joint Kinetics in Young Adults Walking with Varied Step Lengths--(Krupenevich).....	367
T8D_3--The Functional Utilization Of Propulsive Capacity During Human Walking--(Conway).....	369
T8D_4--Joint Power Generation During Gait Across Mood Phases in Bipolar Disorder--(Kang).....	371
T8D_5--Multi-Objective Control of Lateral Stepping While Walking--(Dingwell).....	373
T8D_6--Regulation of Whole-Body Angular Momentum and Muscle Activation During Walking Adaptability Tasks Po--(Vistamehr).	375
T8E_1--Assessing Movement Asymmetry using the Normalized Symmetry Index in ACL Patients--(Queen).....	377
T8E_2--Failure Modalities Induced by a Novel Mechanical Impact Simulator Designed to Induce ACL Failure--(Bates).....	379
T8E_3--Sex Differences in Knee Forces & Moments that Occur with ACL Rupture on Cadaveric Impact Simulations--(Schilaty).	381
T8E_4--The Combination of Tissue Collagen Quantity and Quality Estimated From MR T2 Relaxometry Predicts T--(Beveridge).	383
T8E_5--Effect of Return-to-Sport Training on Gait Mechanics and Knee Loading after ACLR--(Capin).....	385
T8E_6--Knee Force Vector and Tibia Plateau Orientation during The Stance Phase of Gait- A Comparison of ACL--(Zarei).	387
<b>Wednesday Posters: Ergonomics.....</b>	<b>389</b>
001A--Characterization of Force and Impulse for Touchscreen Gestures--(Asakawa).....	389
002B--Gender Differences in Upper Limb Joints Contributions During a Lifting Task--(Martinez).....	391
003A--Hammer Symmetry of Inertia Influences Complexity of Swing Motion--(Ferdous).....	393
004B--Are Psychophysically Determined Safe Lifting Loads Associated with an Underlying Limiting Joint Stre--(Banks).....	395
005A--Force Redistribution for Seated Individuals via Repositioning--(Scott).....	397
006B--Effects of Head-Worn Display Use on Obstacle Crossing Performance in a Simulated Occupational Task--(Kim).....	399
007A--Contact Force Distribution on the Fingers During Spherical Gripping--(Sinsel).....	401
008B--In Vivo Quantification of Muscle Fatigue in Upper Extremity during Pulling and Gripping using Regio--(Zheng).....	403
009A--Changes in Knee Kinetics are Required for Deceleration with Body Borne Load--(Cameron).....	405
010B--The Influence of Hand Location and Exertion Type On Lumbar Twist During Simulated Industrial Tasks--(McKinnon).	407
011A--Tracing on a Touch Screen- Influence of Age, Implement, Hand, and Friction--(Heintz).....	409
012B--Mass Properties Comparison of Dismounted and Ground Mounted Head-Supported Mass Configurations to Ex--(Wurzbach).	411
013A--Effect of Load Carriage Systems on Shooting Performance During a Tactical Engagement--(Higginson).....	413
014B--Muscle Activation & Strength Assessment in Native_Non-Native Sign Language Users--(Roman).....	415
015A--Are Hybrid Sit-Stand Postures a Good Compromise Between Sitting and Standing--(Noguchi).....	417
016B--Postural Evaluation of Dental Care Professionals Using Motion Analysis and Electromyography--(Abnos).....	419
017A--Biomechanical Differences in Lifting Between a Manual Vs. Power Cot--(Capehart).....	421
<b>Wednesday Posters: Exoskeletal Devices.....</b>	<b>391</b>
018B--Biomechanically-Assistive Garment Offloads Low Back During Leaning and Lifting--(Lamers).....	423
019A--Using Elastic Ankle Exoskeletons to Counteract Age-Related Structure-Function Deficits--(Nuckols).....	425
020B--Dynamic Simulation of Elastic Ankle Exoskeleton Effects on Plantarflexor Muscle-Tendon Neuromechanic--(Poppo).	427
021A--An Instrumented Ankle Foot Orthosis for Quantifying the Influence of Plantarflexion Resistance on Jo--(Bolos).....	429

022B--Effect of Powered Exosuit Training on Impulse during Gait--(Bowers).....	431
023A--Assessing Slip and Trip Risks When Wearing an Upper-Extremity Exoskeleton--(Alemi).....	433
024B--Effects of a Leg Kinetic Energy Harvester on Soldiers' Gait--(Batty).....	435
025A--Performance of a Powered Ankle Exoskeleton Using Neuromuscular Model-Based Control Over a Range of W--(McCall).....	437
026B--Ankle Foot Orthosis Stiffness and Margins of Stability During Walking--(Rosenberg).....	439
027A--Comparison of a New Ankle Orthosis to a Standard Brace on Ankle Dynamics During Walking--(Chung).....	441
028B--Emulation- A Quantitative Approach to the AFO Fitting Process--(Totah).....	443
029A--Effects of Personalized Passive-Dynamic Ankle-Foot Orthoses Bending Stiffness on Gait of Individuals--(Koller).....	445
030B--User Biomechanics during Exoskeleton-Assisted Gait- Theoretical Approach and Case Study--(Smith).....	447
031A--Mechanics and Energetics of Walking with a Powered Ankle Exoskeleton Using Neuromuscular Model-Based--(Philius).....	449
032B--Predictive Simulation Framework for Combined Device and Human Mechanics--(Saadatzi).....	451
033A--Design and Control of a Modular Lower-Limb Exoskeleton Emulator for Accelerated Design and Evaluatio--(Heer).....	453
<b>Wednesday Posters: Jumping and Landing.....</b>	<b>425</b>
034B--Mid-Flight Trunk Motion Increased Unilateral Loading During Landing- a Center of Mass Analysis--(Hinshaw).....	455
035A--Performance Constraints do not Alter Landing in Reactive Jumps--(Stephenson).....	457
036B--Kinematic Analysis of Parkour Landings from a Drop Height of 2.7 Meters--(Dai).....	459
037A--Landing Mechanics in Controlled Screening Tasks and Simulated Games in Volleyball--(Beardt).....	461
038B--Implications of Added Body Mass on Lower Limb Joint Kinetics During Vertical Jumping--(James).....	463
039A--Classifying Landing Performance Using Frequency Domain Analyses--(Sha).....	465
040B--Altered Lower Extremity Kinematics and GRFs in Distracted vs. Focused Landing--(Rider).....	467
041A--Differential Effectiveness of Visual Feedback on Drop Landing Performance--(Rutherford).....	469
042B--Gender Differences in Hip Joint Forces during Unilateral Drop Landings--(Irmischer).....	471
043A--Dynamic Postural Stability and Landing Mechanics during a Single-Leg Landing in Individuals with a P--(Winters).....	473
044B--Dynamic Valgus During Drop Landing Results in Decreased Lateral Plantar Pressure--(Ferrigno).....	475
045A--Fatigue-related Changes in Joint Mechanics, Stiffness, and Energy Absorption during Landings--(Fu).....	477
<b>Wednesday Posters: Spine.....</b>	<b>479</b>
046B--Perturbation of Systems Contributing to Control of Posture in Persons with LBP--(Rowley).....	479
047A--In Vivo Human Facet Joint Gapping During Cervical Spine Manipulation--(Anderst).....	481
048B--Impact of External Loading Assumptions on Sagittal L5S1 Moments During Lifting--(Banks).....	483
049A--Estimation of Mechanical Demands of a Lowering and Lifting Task on the Lower Back in Patients with A--(Shojaei).....	485
050B--Effect of Cervical Decompression Surgery on Biomechanics on Neuromuscular Control during Gait in Adu--(Haddas).....	487
051A--Effect of Trunk Position and Angle of Pull on Spinal Loading During a Row Exercise--(Stutzenberger).....	489
052B--The Effect of Twist on the Mechanical Properties of the Intervertebral Disc--(Harvey-Burgess).....	491
053A--Lumbopelvic Postural Control System Organization is Altered in Individuals with Low Back Pain--(Butowicz).....	493
054B--Validating the Use of Ultrasound to Measure Lumbar Vertebral Twist--(Mayberry).....	495
055A--Low Velocity Collision Characteristics Associated with Claimed Low Back Pain--(Fewster).....	497
056B--The Influence Of Walking Breaks While Standing On Gluteus Medius Activity And Low Back Pain--(Daniels).....	499
057A--Validation of Biplane Fluoroscopy for Cervical Spine Kinematics--(Kage).....	501

058B--Flexion Relaxation Response Between People With and Without Standing-Induced Low Back Pain and a Cli--(Baker).	503
059A--A Comparison of Muscle Activity during Spine Extension in People with and Without Standing-Induced B--(Viggiani).	505
060B--Intervertebral Disc Pressure Variation in Cadaveric Thoracic Spines Under Applied Dynamic Moments--(Anderson).	507
061A--Low Back Loading During Sit-to-Stand in People with a Unilateral Transtibial Amputation--(Actis).....	509
062B--The Influence of Walking Breaks on Lumbar Spine Kinematics During Prolonged Standing--(Payne).....	511
063A--The Relationship Between Family History, Biopsychosocial Factors and Seated Posture on LBP Developme--(Barrett).	513
064B--Active End-Range Spine Flexion Changes in Response to Prolonged Sitting--(Snow).....	515
065A--Changes in Trunk Mechanical Properties Following Prolonged Sitting- A Pilot Study--(Park).....	517
067A--Comparison of Lumbar Spine Acceleration Profiles of Every Day Activities and Examination of Their Fr--(Guzman).	519
068B--Differences in Principal Components in Sit-to-Stand in Participants With and Without Lower Back Pain--(Nunez Jr.).	521
069A--The Effects of Breast Size and Body Image on Posture, Muscle Activation and Back Pain During 2 Hours--(Wanninayake).	523
070B--Directional Contact Forces Investigation in the Upper Cervical Spine Under Antero-Posterior Forces A--(Mesfar).....	525
<b>Wednesday Posters: Sport and Exercise.....</b>	<b>527</b>
071A--Effects of Lumbopelvic-Hip Complex Instability on Throwing Mechanics Amongst Female Handball Athlete--(Gilmer).	527
072B--Effect of Hand Position on Scapular Kinematics in a Traditional Push-up--(Arens).....	529
073A--Neural Network Prediction of Joint Torques in Olympic Weightlifting--(Kipp).....	531
074B--Muscle Synergies in Female Athletes with Generalized Joint Hypermobility--(Geiser).....	533
075A--Ice Hockey Skating Mechanics- Transition From Start To Maximum Speed For Elite Athletes--(Budarick).....	535
076B--Ball Contact Initiates Forearm Deceleration in a Volleyball Spike--(Thompson ).....	537
077A--Quantifying Contact Loading During a Volleyball Spike--(Schmitz).....	539
078B--Evaluation of Bicycle Pedaling Ability Using Vertical and Horizontal Components of Pedaling Force Ve--(Kitawaki)..	541
079A--Lower Leg Morphology and Plantarflexion Strength in Dancers--(Rice).....	543
080B--Morphological and Functional Characteristics of 110m Hurdlers- Volume and Isometric Strength of The--(Okutani).	545
081A--Building a Better Gluteal Bridge--(Lehecka).....	547
082B--The Effect of Knee Support on the Lower Body Joint Loads and Motions of Baseball Catchers--(Dooley).....	549
083A--Modifying Stance Alters the Peak Knee Adduction Moment During a Golf Swing--(Hooker).....	551
084B--Leg Muscle Function of Front Row Rugby Union Scrummaging--(Yaghoubi).....	553
086B--Both Anticipation and Dual-Task Alter Lower Limb Biomechanics during a Loaded Single-Leg Cut--(Seymore).....	555
087A--Ball Release Velocity And Pre-Release Range Of Motion For Five Types Of Softball Pitches--(Meyer).....	557
088B--The Influence of Modern Climbing Holds on Finger Forces and Force Dispersion Patterns--(Herman-Dunphy).....	559
089A--Assessing Performance Correlations among Tasks in a Challenging Obstacle Course--(Vitali).....	561
090B--The FIFA11+ and Distribution of Energy Absorbed Across Lower Extremity Joints in Female Soccer Playe--(Marmon).	563
091A--Knee Adduction Moment and Muscle Activation During a Sidecut on a Raised Surface--(Schroeder).....	565
092B--Comparison of Barbell Kinematics in the Hang Clean and Hang Clean High Pull- Implications for Specif--(Light).....	567
093A--Effect of Leg-Drive on Upper Extremity Muscle Activity during a Bench Press--(Chia).....	569
094B--Coordination of the Ankle and toe Joints in Dancers--(Jarvis).....	571
095A--Kinematic Analysis of Trunk Coordination Throughout the Rowing Stroke Sequence--(Minnock).....	573
096B--Effects of Ballistic-intent Training on the Static Force Capacity of the Neck--(Pelland).....	575

097A--Biomechanical Differences Between a Split-Step and Sidestep Cut in Female Tennis Players--(Hamada).....	577
098B--Energy Flow in Youth Baseball Players in Relation to Pitching Performance and Efficiency--(Howenstein).....	579
099A--Effect of Start Technique on Pro-Agility Test Performance in Division I Football Players--(Ficklin).....	581
100B--Kinematic Predictors of Energy Flow in Youth Baseball Pitchers--(Howenstein).....	583
101A--Kinetics Of Steeplechase Hurdling Performance--(Tracy).....	585
102B--Empirical Based Modeling Approach for the Quantification of Dynamic Knee Stability--(Morgan).....	587
103A--Using a Treadmill to Accurately Measure Power Output in Bicycling--(Straw).....	589
104B--Diagnostic Validity of Static and Dynamic Postural Assessments within 24-48 Hours Post-Concussion--(Szekely)....	591
105A--Pelvis Rotational Velocity and Energy During Baseball Batting--(Dowling).....	593
106B--Does the Fibonacci Sequence Predict Segmental Velocities of the Overhand Throw--(Weimar).....	595
107A--Ulnar Collateral Ligament Properties in baseball Pitchers Throughout A Single Collegiate Season--(Curran).....	597
108B--Directional Compression and Muscle Activity in a Retired World Cup Alpine Skier--(Zavala).....	599
109A--Using the Motus Baseball Pitching Sleeve to Compare Pitching and Long Toss Throwing Arm Biomechanics--(O'Loughlin).	601
110B--Comparison of Kinematic and Kinetic Profiles of Lower Limbs during Baseball Pitching in Adolescent P--(Mathews).	603
111A--Evaluation of Static and Sport-Like Postural Tasks 24-48 Hours Post-Concussion--(Szekely).....	605
112B--Biomechanical Differences Between Sexes and Limb Dominance during a Cutting Maneuver--(Craft).....	607
<b>Wednesday Posters: Aging.....</b>	<b>609</b>
113A--Segment Relationships Adapt to Walking Speed Differently in Healthy Young and Elderly Adults--(Craig).....	609
114B--Kinematic Comparison Of Three Postural Limits Of Stability Tests In Community Dwelling Older Adults--(Allison)....	611
115A--Effect of an Older Adult Golf Training Program on Postural Control--(Du Bois).....	613
116B--Effects of Electrical and Mechanical Stimulation on Foot Sensitivity in Healthy Elderly Subjects--(Zippenfennig).....	615
117A--Differences in Coordination Between Young and Old Runners--(Harrison).....	617
118B--Movement Variability During Split-Belt Treadmill Walking In Healthy Older Adults--(Terza).....	619
119A--On How Age, Disease and Biomechanical Capacities Interact to Affect --(Mirshams Shahshahani).....	621
120B--Effects of Golf Training on Gait Parameters in Older Military Veterans--(Marcione).....	623
121A--More Push from your Push-off- Joint-Level Modifications to Modulate Propulsive Forces in Old Age--(Browne).....	625
122B--Let's Face It, I Am Getting Older- A Longitudinal Study of Balance Recovery from Forward Lean Releas--(Carbonneau).	627
123A--The Effect of Attention and Stance on the Rambling and Trembling Components of Postural Sway in Olde--(Hernandez).	629
124B--The Effects of Dual-task Walking and Talking in Different Conditions and Environments on Elderly Gai--(Leeder).....	631
125A--Force Fluctuations During Hybrid Force_Motion Tasks In Young and Older Adults--(Joshi).....	633
126B--High-Density EMG Recordings of Calf Muscle Activity in Older Adults During Walking--(Mani).....	635
127A--Characterizing Hip Motion and Influence of Age During Common Activities--(Fuller).....	637
<b>Wednesday Posters: Clinical Biomechanics.....</b>	<b>639</b>
128B--Individuals with Knee Osteoarthritis show Asymmetry in Pedaling Mechanics--(Buddhadev).....	639
129A--Strength of Arthroscopic Knot Tied with Compromised Suture- Effect of Defect Location--(Grindel).....	641
130B--The Effect of Isolated Weber B Fibular Fracture Displacement on Tibio-Talar Contact Pressures--(Malekzadeh).....	643
131A--Development of a Disposable Point-of-Service Digital Manometry Device to Assess Anorectal Function--(Attari).....	645
132B--Lower Body Kinematics and Joint Reaction Forces with Distal Femoral Endoprotheses Following Limb Sa--(Fritz).	647

133A--Evaluation of Transforaminal Lumbar Interbody Fusion Cage Placement- Minimally Invasive Versus Open--(Cui)...	649
134B--A Biomechanical Comparison of Syndesmotomic Repair Techniques during External Rotation Stress--(Goetz).....	651
135A--An Intra-Operative Biomechanical Guidance System For Reducing Articular Fractures--(Kern).....	653
<b>Wednesday Posters: Gait.....</b>	<b>655</b>
136B--The Anthropometric Model Influences Whole-Body Center of Mass Calculations in Gait--(Catena).....	655
137A--Lower Extremity Kinematics of Cross-Slope Roof Walking--(Brelhoff).....	657
138B--Joint Mechanical Power Compensations While Walking with Ankle Restriction--(Christensen).....	659
139A--Contributions to Increased Walking Speed During Fixed and User-Driven Treadmill Walking--(Ray).....	661
140B--The Examination of Movement Coordination between Barefoot and Minimal Foot Support Boots in Walking--(Wu)...	663
141A--Spatiotemporal Variability of Children's Gait During Walk-to-Run Transitions--(Kung).....	665
142B--Trunk Neuromuscular Control Strategies Among Persons With Lower Limb Amputation While Walking and Pe--(Butowicz).	667
143A--The Impact of Anthropometric Changes and Physical Activity on Dynamic Balance during Pregnancy--(Werner).....	669
144B--Kinematic Gait Characteristics of a Heterogeneous Population--(Thurman).....	671
145A--Mass Affects Kinetic Symmetry In Children's Knees During Gait--(Shultz).....	673
146B--Detection of Gait Pattern Differences Using Fast Fourier Transform Analysis--(Vessicchio).....	675
147A--Do We Minimize Energy When Choosing Between Gait Patterns--(Antos).....	677
148B--Biomechanics of Simulated Weight Gain Compared to an Obese Population during Stair Descent--(Ransom).....	679
149A--The Biomechanical Implications of Simulated Weight Gain on the Lower Extremity during Gait--(Ransom).....	681
150B--Effects of Walking with Increased Step Width on Knee Adduction Moment--(Edd ).....	683
151A--Using Perturbation Experiments to Infer How Humans Control Walking--(Joshi).....	685
152B--Knee Flexion Modifications During Pediatric Gait Using Visual Feedback--(Oliveira).....	687
153A--Lower Extremity Joint Contributions to Frontal Plane Trunk Dynamics in Persons with Lower Extremity --(Yoder)....	689
154B--Asymmetrical Limb Loading Affects Spatial and Temporal Gait Parameter Differently in Comparison to S--(Bowman).	691
155A--The Effects of Gait Speed on Foot Rockers--(Agnew).....	693
156B--To Walk or to Run Metabolic Cost is not the Answer--(Summerside).....	695
157A--Frontal Plane Pelvis-Trunk Coordination During Asymmetric Load Carriage While Walking on an Uneven S--(Wang).	697
158B--Differences in Lower Body Kinetics when Walking and Walking While Holding Weapon Aim--(Neugebauer).....	699
159A--Structural Parameters of the Foot and the Biomechanics of Walking With and Without Wedged Footwear I--(Lewinson).	701
160B--Lower Extremity Joint Stiffness and Work Performed Across Different Walking and Running Speeds--(Jin).....	703
161A--Step Width During Treadmill Walking is Long-Range Persistent--(Oludare).....	705
162B--Application of Harmonic Transfer Functions Method of Analysis to Understand Responses to Mechanical --(Ehtemam).	707
163A--Statistical Evaluation of Walking Velocity and Knee Adduction Moment- Allometric Scaling--(Andrews).....	709
164B--Gait Initiation Mechanisms in Unilateral Transtibial Amputees.--(Roberts).....	711
165A--Do Kinetic Differences Exist During Curb Ascent In Persons With Ertl And Non-Ertl Transtibial Amputa--(Ferris).....	713
166B--Gait Stability in People with Unilateral Transtibial Amputation Across Walking Speeds--(Wedge).....	715
167A--Fourier Analysis of Vertical Ground Reaction Forces in Habitually Unshod Persons--(Trentadue).....	717
168B--Comparisons of the Variability of Accelerations between Left and Right Foot in Human Walking--(Chavanaves).....	719
169A--Preliminary Evidence that Foot Mechanical Energy During Walking is Dissipated as Heat--(Patterson).....	721

170B--Characterizing Ambulatory Tendencies for Lower Limb Amputees--(Kim).....	723
171A--Whole-body and Segmental Angular Momentum During Turning--(Nolasco).....	725
<b>Wednesday Posters: Knee Mechanics.....</b>	<b>727</b>
172B--Effects of Wide Step Width on Stair Ascent Knee Kinetics in Obese Participants--(Yocum).....	727
173A--Central Activation Deficits of the Quadriceps Muscle in Patellar Tendinopathy--(Sprague).....	729
174B--Effect of Fatigue and Real-Time Visual Feedback During Drop Landings on Patellofemoral Joint Stress --(Olbrantz).	731
175A--Differences in Knee Joint Load Distribution with Varying Cartilage Properties--(Kaplan).....	733
176B--Strength Deficits and Knee Biomechanics Symmetry in Young Adult Osteosarcoma Survivors--(Garcia).....	735
177A--Comparison of Knee Kinematics and Kinetics During Stair Descent in Single-Radius and Multi-Radius To--(Sumner).	737
178B--Knee Mechanics and Muscle Activation Timing in Athletes with Complex Knee Injuries--(Hatcher).....	739
179A--Spatial-Temporal Measurements Indicate Knee Loading Asymmetry after Total Knee Arthroplasty--(Ouattas).....	741
180B--Functional Implications of Menstrual Cycle on Knee Laxity, RFD, and EMD--(Hawkins).....	743
181A--FEA of Lateral Meniscus Posterior Root Avulsions on Tibiofemoral Contact Mechanics--(Fojtik).....	745
182B--Surface Stiffness and Knee Joint Load Effects while Running--(Price).....	747
183A--Patellar Forces And Torsions Resulting From Decreased Activation Of The Vastus Medialis Muscle--(Siegel).....	749
184B--Effects of Age, Gender, and BMI on Maximum Knee Flexion in Single and Dual Leg Bodyweight Squats--(Herlihy)..	751
<b>Wednesday Posters: Pathological Gait.....</b>	<b>753</b>
185A--Functional Ballistic Movements in Children with a History of Ponseti Correction for Talipes Equinova--(Berg-Poppe).	753
186B--Postural Control and Activation of Muscles Controlling the Knee in Children with Idiopathic Toe Walk--(Berg-Poppe).	755
187A--Ponseti v. Posteromedial Release- Asymmetry of Foot Pressures in Children with Unilateral Clubfoot--(Wallace)....	757
188B--The Effect of Prolonged Activity and Lower Limb Trauma on Variable Terrain Walking Stability--(Sheehan).....	759
189A--Locomotor Adjustments in Children with and without Down Syndrome while Negotiating Stairs--(Liang).....	761
190B--Coordination Patterns of Muscle Synergies During Gait in Cerebral Palsy--(Steele).....	763
191A--Validity of Using Head Motion to Detect Dual-Task Gait Imbalance in Adolescents with Concussion--(Pitt).....	765
192B--Effects of Surface Irregularity on Hemiplegic Gait after a Novel Robotic 3-D Ankle Training--(Kim).....	767
193A--Combined Pelvic Assistance Force with Visual Feedback to Improve Gait Patterns in Individuals with P--(Hsu).....	769
194B--Real-Time, Autonomous Tracking of Whole-Body Bradykinesia in Parkinson's Disease--(Roy).....	771
195A--Evaluating the Primary Gait Screen as a Measure of Gait Velocity in Persons with Movement Disorders--(Schmitt)..	773
196B--Osteoarthritis Influences Functional Mobility Performance in Patients with Parkinson's Disease--(Roper).....	775
197A--Quantifying Limp Using Temporal Gait Variables--(Hughes-Oliver).....	777
198B--Stabilizing Forces and Energy Cost of Cerebral Palsy Gait with Pediatric Posterior Walker--(Tumperi).....	779
199A--Metabolic and Mechanical Demands of Symmetrical and Asymmetrical Walking on a Split-belt Treadmill--(Stenum).	781
200B--Effect of Frequency on Whole Body Movement Control in Children with and without Down Syndrome During--(Beerse).	783
201A--Biomechanical analysis of Timed Up-and-Go (TUG) test in children with and without Down syndrome--(Beerse).....	785
202B--Parameterizing Joint-level Variability During Walking for Stroke Victims--(Martin).....	787
203A--Torsional Malalignment Syndrome and Maximum Internal Varus Knee Moment During Gait in Individuals wi--(Case).	789
204B--Does Walk-DMC Predict Surgical Outcomes Extension of Synergy Analysis in Cerebral Palsy to a Second--(Shuman).	791
205A--Analysis and Modeling of Gait Biomechanics in Response to Volumetric Muscle Loss Injury--(Dienes).....	793

206B--Application of Temporal Waveforms for Evaluation of Gait Training in Children with Cerebral Palsy--(Hegarty).....	795
207A--The Influence of Locomotor Training on Mediolateral Dynamic Balance in Individuals with Post-Stroke --(Vistamehr).	797
208B--Kinematic Analysis of Sit-to-Walk in Bipolar Disorder--(Kang).....	799
209A--Lower Limb Coordination Difference in a Dynamic Balance Task Following Stroke--(Boehm).....	801
<b>Wednesday Posters: Prosthetics.....</b>	<b>803</b>
210B--Quantifying the Effects of Toe and Ankle Joint Stiffness, and Their Interplay, on Walking Biomechanics--(Honert).....	803
211A--Kinematic Differences in Partial Hand Amputees Using an Externally Powered Hand Prosthesis--(Wanamaker).....	805
212B--Biomechanical Outcomes of Prosthetic Foot Stiffness during Weighted Walking--(Golyski).....	807
213A--Characterization of Prosthetic Feet for Weighted Walking--(Koehler-McNicholas).....	809
214B--Effects of Robotic Prosthesis Controllers and Positive Work on Metabolic Cost--(Handford).....	811
215A--Finite Element Analysis of Socket to Limb Interface Simulating Gel Liner Slip versus No Slip--(Lenz).....	813
216B--A Dart Thrower's Motion Wrist Should Improve Prosthetics--(Davidson).....	815
217A--Preliminary Validation of Transfemoral Prosthetic Gait Simulator--(Henson).....	817
218B--Adaptation to Gradual and Sudden Increases in Prosthetic Ankle Power--(Selgrade).....	819
219A--Is Grasp Performance of a Novel Myoelectric Hand Prosthesis Impacted by Training--(Bhaskaran).....	821
220B--People with Amputation Walking with a Powered Knee Prosthesis Exhibit Varying Asymmetric Behavior--(Brandt).....	823
221A--Increases in ROM and Circumference of the Forearm after 6 Months of Using a 3D Printed Transitional --(Dudley).....	825
222B--Top Sprinting Speed is Influenced By Prosthetic Model, but not Stiffness or Height, for Athletes with--(Taboga).....	827
223A--Kinematic and Kinetic Analysis of a Biarticular Clutched Spring Prosthesis for TT Amputees--(Willson).....	829
224B--The Point Digit- Mechanical Design and Testing of a Ratcheting Prosthetic Finger--(Segil).....	831
225A--Development of Low Cost 3D Printed Transitional Prostheses--(Pierce).....	833
226B--Using Biomimetic Models and Intramuscular EMG for Control of Myoelectric Prostheses--(Mansouri ).....	835
227A--Prosthetic Feet with Biarticular Elements Replicate Gastrocnemius Function in Simulation--(Anderson).....	837
228B--Variable Stiffness Prosthetic Foot--(Glanzer).....	839
229A--Transfemoral Prosthesis Control for Slope Walking with Principal Component Analysis--(Hong).....	841
230B--3D Printed Prostheses- Not Just Plastic Toys--(Than).....	843
231A--Quasi-Passive Two Degree of Freedom Prosthetic Ankle--(Greene).....	845
<b>Wednesday Posters: Rehabilitation.....</b>	<b>847</b>
232B--Automatically Detecting Destabilizing Wheelchair Conditions and Applying Electrical Stimulation to M--(Armstrong).	847
233A--Dynamic Balance is Different Between Fallers and Non-Fallers with Multiple Sclerosis--(Peebles).....	849
234B--Force Distributions on the Fingers when Squeezing a Spherical Rehabilitation Ball--(Wu).....	851
235A--The Effects of a 10-Week Balance, Flexibility, and Resistance Training Intervention on Postural Stability--(Tolbert).....	853
236B--12-Week Exercise Intervention on Joint Kinetics During Curb Negotiation in Cancer Survivors--(Fraijo).....	855
237A--Kinematic and Stability Changes in Women Using a Sacroiliac Belt- A Case-Control Study--(Cigoja).....	857
238B--EMG of Facial Muscles for Subvocal Speech Recognition--(Meltzner).....	859
239A--The Examination of Hip Joint Kinematics with iWalk in Walking Gait--(Champagne).....	861
240B--A Stress Progression Sequence of Exercises During Achilles Tendon Rehabilitation--(Gheidi).....	863
241A--Speed Impacts Maneuver Stability in Individuals With Spinal Cord Injury--(Viramontes).....	865

242B--Effects of Movement Pattern Biofeedback Training After Total Knee Arthroplasty--(Cheuy).....	867
243A--The Effect of Functional Electrical Stimulation Assisted Rowing and Intravenous Zoledronic Acid on T--(Fang).....	869
244B--Sensory Stimulation Can Improve Motor Functions in Individuals with Multiple Sclerosis--(Almuklass).....	871
245A--EMG Responses to Lateral Pelvis Force Perturbation in Humans with Spinal Cord Injury During Walking--(Wu).....	873
246B--Sensor-based Activity Detection and Classification of Manual Wheelchair Users--(Fortune).....	875
247A--Impact of Geared Wheels on Energy Expenditure during Manual Wheelchair Mobility--(Jahanian).....	877
248B--Eccentric Control after Spinal Cord Injury- Translating From an Animal Model--(Worthen-Chaudhari).....	879
249A--Modifications in Wheelchair Propulsion Technique Over Time--(Russell).....	881
250B--A Neuromuscular Control Comparison between Walking Sticks and Walker during Gait in Adult Scoliosis --(Haddas).	883
251A--Biomechanical Evaluation of a Pneumatic Sleeve Orthosis for Lofstrand Crutch-Assisted Gait--(Xiao).....	885
252B--Supervised Walking Exercise Therapy Improves Gait Biomechanics in Patients with Peripheral Artery Di--(Schieber).	887
253A--Design of a Compact and Portable Hand Rehabilitation Device for Stroke-Survivors--(Anil Kumar).....	889
<b>Wednesday Posters: Upper Extremity.....</b>	<b>891</b>
254B--Effects of Push-Up Plus Variants on Upper Extremity Muscle Demands--(Cudlip).....	891
255A--Analysis of Resorative Predictors of Glenohumeral Capsule Plication--(Kraszeswski).....	893
256B--Minimum Detectable Change Values for Upper Limb Kinematics in Healthy Adults--(Engdahl).....	895
257A--Development of a Propulsion-Specific Regression Model to Predict Scapulothoracic Motion--(Cloud).....	897
258B--A Method for Estimating the Load Distribution in the Anterior Bundle of the Ulnar Collateral Ligamen--(Miller).....	899
259A--4DCT For Assessment of Wrist Ligament Injuries--(Zhao).....	901
260B--Synergistic Shoulder Muscle Activation During Arm Elevation in Different Body Positions--(Stapleton).....	903
261A--Movement Toward Predictive Hand Forces--(Drost).....	905
262B--The Effect of Simulated Rotator Cuff Tear Severity on Glenohumeral Joint Force--(Arce).....	907
263A--Biomechanics of Thumb Carpometacarpal Osteoarthritis Progression--(Crisco).....	909
264B--Optimal Placement of Ultrasonic Sensors for Improved Measurement of Scapular Kinematics--(Vicini).....	911
265A--Characterizations of the Electromyography and Vibromyography Signals During Muscular Fatigue in the --(Xu).....	913
266B--The Influence of Resting Pectoralis Minor Muscle Length on Scapular Kinematics--(Pollen).....	915
267A--Assessing Glenohumeral Joint Conformity with a Statistical Shape Model--(Sintini).....	917
268B--A Finite Element Modeling Approach to Studying Instability in Reverse Shoulder Arthroplasty--(Permeswaran).....	919
269A--Wrist Biomechanical Properties via Six Degree-of-Freedom Robotic Testing--(Badida).....	921
270B--Quantifying The Passive Extension Torque Of The Second Metacarpophalangeal Joint--(Mukherjee).....	923
271A--Determining Return of Scapulohumeral Rhythm in Patients After Reverse Shoulder Arthroplasty--(Permeswaran)...	925
272B--Iterative Learning Control of an Elbow Joint Motion Simulator--(Schimoler).....	927
273A--Thumb Carpometacarpal Joint Motion In Asymptomatic Participants--(Cussen).....	929
274B--A Subject-Specific Shoulder Capsule Mesh Model Trained with In-Vitro Data--(Kraszewski).....	931
<b>Thursday Posters: Anterior Cruciate Ligament.....</b>	<b>933</b>
275A--The Influence of Hamstring Stiffness on ACL Loading Characteristics--(Waxman).....	933
276B--Effects of Functional Knee Brace on Symmetry During Landings in ACL-R Patients--(McConnell).....	935
277A--Limb Asymmetries in Post-ACL Reconstruction Patients--(Veltri).....	937

278B--Sex Differences of MCL and ACL Strains with Cadaveric Impact Simulations--(Schilaty).....	939
279A--Short-term Effects of Femoral Nerve Block on Sagittal Plane Gait Mechanics in Individuals Following --(Nagelli).....	941
280B--Inter-joint Compensations During Early Gait in Individuals Following ACL Reconstruction--(Lin).....	943
281A--Simplified Jump Landing Task Does Not Demonstrate Increased ACL Load--(Wilkie).....	945
282B--Male Athletes Who Walk Asymmetrically Report Similar Function to Those Who Walk Symmetrically 1 Year--(Johnson).	947
283A--Effect of Foot Rotation on ACL Injury Risk Variables During Drop Landing--(Peel).....	949
284B--Coordination Variability in the One Leg Hop Test 20 years after ACL Injury--(Srinivasan).....	951
285A--Energy Absorption Strategies and Muscle Strength in Adolescent Males and Females During a Lateral-Ve--(Goto)..	953
286B--Lower Extremity Segment Coordination Following Anterior Cruciate Ligament Reconstruction--(Besand).....	955
287A--Individuals Following Anterior Cruciate Ligament Reconstruction Adjust Center of Pressure Location t--(Chan).....	957
288B--Sex and Leg Differences in ACL Stress During Unilateral Landings--(Weinhandl).....	959
289A--Hamstrings Activity Contributes To Knee Mechanics During Gait Following ACL Reconstruction--(Pamukoff).....	961
290B--Quadriceps Strength And Gait Asymmetry In Individuals With ACL Reconstruction--(Moffit).....	963
291A--Bicomponent Ultrashort Echo Time T2 Comparison of Native vs Reconstructed ACL--(Denning).....	965
292B--Effect of Torque Magnitude and Timing of In Vitro Anterior Cruciate Strain and Joint Kinematics--(Hale).....	967
<b>Thursday Posters: Footwear.....</b>	<b>969</b>
293A--Reliability of a Device to Measure Torsional Stiffness of Running Footwear--(Zifchock).....	969
294B--Influence Of Military Type Footwear And Workload On Co-Contraction Index In Unilateral Static Balanc--(Hill).....	971
295A--Effect of Military Footwear Type on Ankle Stability Following a Simulated Military Workload--(Simpson).....	973
296B--Footwear Differences in Lower Limb Joint Power Generation During Maximal Vertical Jumping--(Smith).....	975
297A--Influence of Minimalist, Neutral, and Ultra-Cushioning Shoes on Joint Coordination During Running--(Borgia).....	977
298B--The Effects Of A Novel Energy Storage And Return Military Boot On Walking Performance--(Ruble).....	979
299A--Influence of Occupational Footwear on Muscle Activity during a Simulated Workload--(Luginsland).....	981
300B--Does Footwear Affect the Rate of Fatigue During Repeated Sprints--(Frank).....	983
301A--Foot Strike Index, Running Cadence, and Loading Rate While Running in a Traditionally Cushioned Zero--(Urrutia).	985
302B--Effect of Differing Running Shoe Midsole Thickness on Gait Kinetics and Kinematics--(Vollmar).....	987
303A--Landing Mechanisms of Grand Jet+- with Soft Shoes and Pointe Shoes in Ballet Dancers--(Lin).....	989
<b>Thursday Posters: Modeling and Simulation.....</b>	<b>991</b>
304B--Ligament Strain Response between Contralateral Pairs of Lower Extremities during In Vivo Landing Sim--(McPherson).	991
305A--The Influence of Femur and Tibia Rotations on Patellar Tendon Stress and Strain- A Sensitivity Analy--(Park).....	993
306B--Anthropometric Scaling of Musculoskeletal Models--(Roos).....	995
307A--Automation of Volumetric Mesh Generation, Mesh Assembly and Model Input from Surface Representations--(Landis).	997
308B--A Three-Dimensional Mesh Wrapping Model of the Gluteus Maximus--(Vigotsky).....	999
309A--Validating Subject-Specific Muscle Architecture Data for Musculoskeletal Models Using Diffusion Tens--(Charles)...	1001
310B--Reducing Passive Muscle Force- a Process for Patient Specific Muscle Model Parameter Calibration in --(Pariser)..	1003
311A--Knee Contact Force Predictions Altered By Objective Functions During Optimization--(Kuska).....	1005
312B--Upper Extremity Model Sensitivity to Ligament Attachment Points--(LeVasseur).....	1007
313A--Simulating the Effects of Squatting on Pelvic Kinematics to Better Understand Implications During Ch--(Hemmerich).	1009

314B--A Database for Musculoskeletal Segment Length and Circumferences for Individualized Anthropometric R--(Owings).	1011
315A--Comparing Subject Specific and Scaled Generic Musculoskeletal Models for Studying Knee Biomechanics--(Charles).	1013
316B--Musculoskeletal Models Scaled with CT Images versus Skin Markers in a Population with Hip Deformity --(Song)....	1015
317A--Assessment of Spasticity By Novel Stretch Reflex Activation Model--(Kang).....	1017
319A--Joint Contact is Sensitive to Geometry Coarseness and Stiffness in OpenSim--(Krach).....	1019

## **X-RAY RECONSTRUCTION OF MOVING MORPHOLOGY (XROMM) YIELDS NEW INSIGHTS INTO MUSCULOSKELETAL FORM AND FUNCTION**

Elizabeth Brainerd, Ph.D.

Professor of Biology and Medical Science

Department of Ecology and Evolutionary Biology

Brown University

Providence, RI USA

Over the past decade at Brown we have developed X-ray Reconstruction of Moving Morphology (XROMM), which combines dual-fluoroscopy with bone models from CT scans to produce highly accurate animations of 3D bones moving in 3D space. In combination with XROMM, radio-opaque markers can be placed in muscles to measure muscle strain (fluoromicrometry). Researchers have used XROMM to study *in vivo* skeletal motion in numerous behaviors and species including: terrestrial locomotion of turtles, alligators, birds, rats, horses, humans and dogs; arboreal locomotion of sloths; jumping in frogs and humans; feeding in ray-finned fishes, geckos, ducks, sharks, stingrays, opossums and pigs; flight in birds and bats; lung ventilation in lizards and alligators; and track formation in dinosaurs. In turtles we found that the pelvis rotates substantially within the shell, thereby increasing stride length during terrestrial walking. In suction-feeding fish we found the use of axial musculature to power rapid expansion of the head for suction feeding. Axial muscles have traditionally been viewed as swimming muscles in fish, but now the structure and physiology of axial muscles should be reevaluated in light of their dual feeding and swimming roles. XROMM combined with fluoromicrometry shows great promise for future insights, due to the combination of 3D skeletal kinematics captured simultaneously with muscle strain from many individual muscles or regions of large muscles.

## **DEVELOPING USEFUL SMART CLOTHING: WHERE DOES BIOMECHANICS FIT?**

Julie Steele, Ph.D. FASMF  
Professor and Director of the Biomechanics Research Laboratory  
School of Medicine  
Faculty of Science, Medicine & Health  
University of Wollongong  
Wollongong NSW 2522 Australia

Wearable sensors make up one of the fastest growing technology markets worldwide, with smart clothing forming a major component of this market. Smart clothing includes items that can sense and monitor human motion and/or specific biophysical signals, as well as items that can respond to these signals. These items have enormous potential to enhance human performance and health. For example, smart clothing can be designed to improve the performance of elite athletes through to simply helping people live healthier and safer lives. However, to be effective it is imperative that wearable devices are designed and developed based on valid and reliable scientific evidence or they risk merely serving as gimmicks. Furthermore, to be comfortable to wear the devices must be designed to suit characteristics of the individuals for which they are designed, taking into account the structure and function of the human body and the forces involved in an activity. For this reason, biomechanics plays a vital role in developing meaningful wearable technologies. This presentation will describe development of the “Bionic Bra”, a unique item of smart clothing, including an overview of the technology underlying the device and how biomechanics has played an integral role in developing this novel concept.

**...and one thing just led to another**

Mark D. Grabiner, PhD  
Professor, Department of Kinesiology and Nutrition  
Professor, Department of Bioengineering  
Director, Clinical Biomechanics and Rehabilitation Laboratory  
Associate Vice Chancellor for Research and Research Integrity Officer  
University of Illinois at Chicago  
Chicago, IL USA

A random encounter in an elevator initiated the pursuit of what initially seemed to be a reasonably simple question: Is it possible to reduce the incidence of falls by older adults? We started with some simple premises that narrowed our focus while at the time defining our experimental approach: avoiding a trip-related fall is a motor skill; the motor skill can be adequately described by some set of key biomechanical variables; intervention that improves the key variables will increase skill level and decrease trip-related falls. Answering this simple question took longer than we expected, but along the way additional questions inspired by seemingly random events created new (and sometimes surprising) opportunities and paths of inquiry.

## **TRANSLATIONAL JOURNEYS – FROM HEAD IMPACT SENSORS TO WRIST IMPLANTS TO TOY CONTROLLERS**

J.J. Trey Crisco, Ph.D.

Henry Frederick Lippitt Professor of Orthopaedic Research

The Warren Alpert Medical School of Brown University and Rhode Island Hospital

Professor of Engineering (Research), School of Engineering, Brown University

Providence, RI USA

We are biomechanists because we are driven by the thrill of applying hard sciences to biological systems. The process of these applications can be referred to as basic science, science that advances a specific field, and this is a lifetime pursuit. Relatively recently, translational science, science that can build upon basic findings and lead to successful products has become the favored science for many academic institutions. For academic biomechanists, embarking on a journey in translational science can be rewarding, humbling, and even a distraction from basic science pursuits. Moreover, financial success, coveted by our academic institutions, may not be the most realistic or rewarding measure of successful translational science. I hope to provide some insights from my perspective into these issues. The talk will focus on my translational works that range from head impact sensing technology, to total wrist implant arthroplasty, to products for therapy and mobility of children with impairments. I will discuss my successes and failures in these translational endeavors with the hope of smoothing some of the bumps and straightening the path for those considering a similar journey.

## **COLLABORATORS: A KEY TO FUN AND EXCITING RESEARCH**

Richard R. Neptune, Ph.D.  
John T. MacGuire Professor  
University of Texas at Austin  
Austin, TX USA

The study of the biomechanics and neuromotor control of human movement is exceedingly complex and involves a wide range of disciplines including engineering mechanics, muscle physiology, neuroscience, control theory, rehabilitation science, modeling and simulation, experimentation, upper extremity, lower extremity, prosthetics, orthotics and so on. It is hard for one to be an expert in each of these fields, and thus collaborations are an effective way to broaden the areas in which one can do research. This talk will highlight my career path and how I've been very fortunate to collaborate with some of the world's leading scientists to do fun and exciting research that would not have been possible without them.

# SIMULATED ACL AND MENISCI DEFICIENCY PREDICTS ALTERED KNEE MECHANICS DURING WALKING

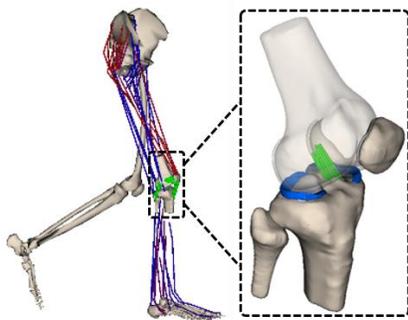

<sup>1</sup>Colin R Smith, <sup>1</sup>Scott CE Brandon, <sup>1</sup>Darryl G Thelen

## INTRODUCTION

Rupture of the anterior cruciate ligament (ACL) leads to an increased risk of early onset osteoarthritis (OA), especially in cases of a concomitant meniscal injury [1]. It has been hypothesized that altered knee mechanics resulting from such injuries contribute to the initiation of OA [2]. However, it is challenging to assess how soft tissue injuries will affect knee mechanics during functional movement. *In vivo* cartilage loading results from the interaction of movement dynamics, neuromuscular coordination, passive ligamentous structures, and cartilage properties and morphology, all of which are known to change following soft tissue injury [3]. We have developed an integrated multibody knee model and movement simulation framework to investigate the influence of these factors on cartilage loading. In this study, we performed virtual resections of the ACL and menisci to study their influence on cartilage loading and functional knee mechanics during walking.

## METHODS

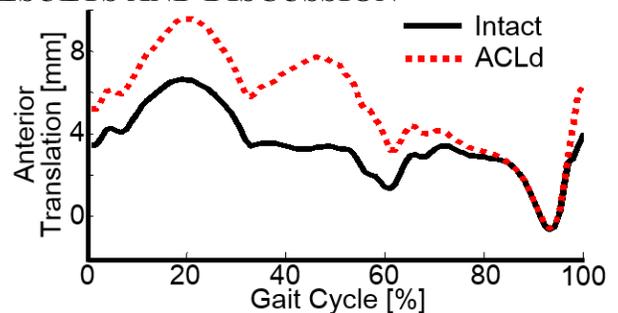

**Figure 1:** Multibody knee model with 6 DOF joints, ligaments, and cartilage and meniscal contact.

A multibody knee model with independent femur, tibia, patella, and medial and lateral menisci bodies was constructed from magnetic resonance images and integrated into a generic musculoskeletal model [2] (Fig. 1). The bodies were connected by six degree of freedom (DOF) joints and constrained by ligaments and articular contact. Fourteen ligaments

and the meniscal horns were represented as bundles of nonlinear springs. An elastic foundation model was used to compute contact pressure for cartilage-cartilage and meniscal-cartilage interactions.

Full body kinematics and ground reaction forces were measured in a motion analysis lab during overground walking (1.2 m/s). A novel simulation routine, Concurrent Optimization of Muscle Activations and Kinematics (COMAK), was used to predict muscle forces, ligament loads, and cartilage and meniscal contact pressures during walking [2]. COMAK simultaneously optimizes muscle activations and secondary knee kinematics (5 tibiofemoral DOF, 6 patellofemoral DOF, and 12 menisci DOF) to satisfy both whole-body and joint-level movement dynamics, while minimizing a weighted squared muscle activation objective function. The simulation was repeated for four cases: intact, ACL deficient (ACLd), menisci deficient and combined ACLd and menisci deficient.

## RESULTS AND DISCUSSION

**Figure 2:** Predicted anterior tibial translation in the healthy and ACL deficient knee during walking.

Compared to the intact simulation, the ACLd knee demonstrated increased anterior translation (Fig. 2) and internal rotation throughout stance (max: 4.4 mm, 3°). In early and mid-swing, these kinematics converged towards the intact pattern, but diverged again in terminal swing. A similar trend was predicted for the menisci deficient knee. The

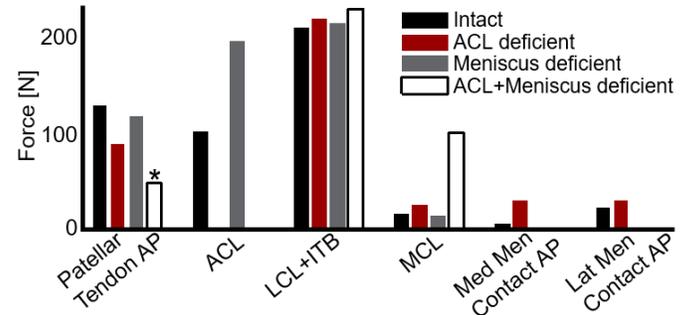

combined ACLd and menisci deficient knee induced substantially larger anterior translation throughout stance, with instances of posterior tibial subluxation in swing.

Both ACL deficiency and menisci deficiency substantially altered cartilage loading on the tibial plateau throughout the gait cycle (Fig 3). At the instant of peak ACL force in the intact simulation, the primary change in the ACLd knee was a posterior shift in the medial (2.4 mm) and lateral (2 mm) center of pressure (COP). In the menisci deficient case, there was an increase in peak pressure (+1.3 MPa) and a posterior shift in the medial COP (1.5 mm). The combined ACLd and menisci deficient knee experienced a dramatic increase in peak contact pressure (+6.2 MPa) and posterior shifts in the medial (9.7 mm) and lateral COP (3.3 mm).

The medial meniscus provided the primary restraint to anterior tibial translation in the ACLd case, along with secondary contributions from the lateral meniscus, MCL, LCL and IT band (Fig. 4). In the menisci deficient knee, the peak loading in the ACL increased by 1.9x to provide anterior restraint. In the combined ACL and meniscus deficient knee, the loading in the MCL increased by 6.6x at the instant of peak ACL loading in the intact knee. In the ACLd and menisci deficient cases, the anterior shift of the tibia oriented the patellar tendon more vertically in the sagittal plane, and thus reduced the anterior restraint required of the passive knee structures. In the combined ACLd and menisci deficient case, the magnitude of the anterior tibial translation resulted in a brief portion of stance where the patellar tendon applied a posterior force to the tibia.

Our simulation predictions corroborate experimental studies of the ACL deficient knee. Using dual fluoroscopy and MRI, Li et al. found a posterior shift

of tibial contact on the medial plateau in ACL deficient knees during lunging [3]. Similar to our simulation predictions, Andriacchi et al found alterations in anterior translation and internal rotation during the terminal portion of swing, which persisted throughout stance [4].

**Figure 4:** Loading in the passive knee structures at the instant of peak ACL force during gait in the intact knee. AP: Anterior force component. (\*) Denotes the patellar tendon applied a posterior force to the tibia.

## CONCLUSIONS

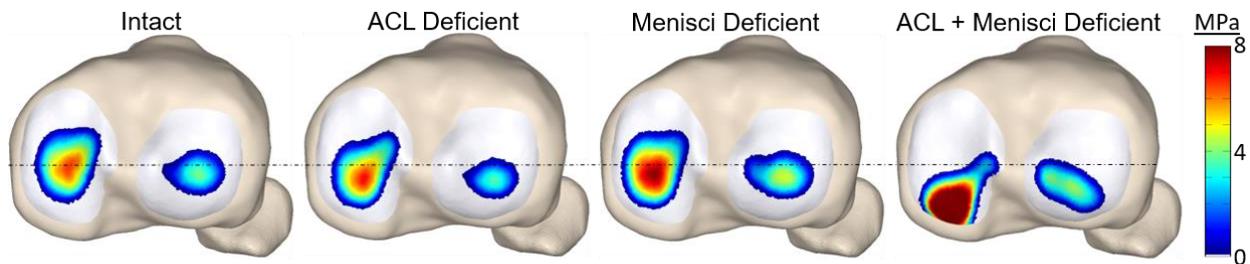

Our simulation predictions suggest that injury to the ACL and/or meniscus leads to altered cartilage contact locations and pressure magnitudes during walking. In the future, we intend to use this simulation framework to investigate muscle coordination and movement strategies that can restore normative cartilage loading patterns in knees with ACL deficiency and/or meniscal damage.

# RESOLVING THE DEBATE: ANKLE PUSH-OFF DURING HUMAN WALKING CONTRIBUTES TO ACCELERATING BOTH THE SWING LEG AND THE CENTER-OF-MASS

<sup>1</sup>Karl E. Zelik and <sup>2</sup>Peter G. Adamczyk

<sup>1</sup>Vanderbilt University, Nashville, TN, USA

<sup>2</sup>University of Wisconsin – Madison, WI, USA

email1: [karl.zelik@vanderbilt.edu](mailto:karl.zelik@vanderbilt.edu), email2: [peter.adamczyk@wisc.edu](mailto:peter.adamczyk@wisc.edu)

web1: [my.vanderbilt.edu/batlab](http://my.vanderbilt.edu/batlab), web2: <http://uwbadgerlab.engr.wisc.edu>

## INTRODUCTION

Muscle–tendon units about the ankle joint generate a burst of positive power during the step-to-step transition in human walking, termed ankle push-off. However, the functional role of this push-off has been debated for decades, without scientific consensus. One school of thought has emphasized that this push-off power primarily contributes to accelerating the swing leg, while another school of thought has emphasized the effect on accelerating the body’s center-of-mass (COM). There is reasonable empirical evidence to support each perspective, yet these descriptions appear *prima facie* to be in contradiction. The purpose of this work was to unify these seemingly polarized perspectives, and to show that these two possibilities are not mutually exclusive. We demonstrate that both descriptions are valid, and that the principal means by which ankle push-off affects COM mechanics is by a localized action that increases the speed and kinetic energy of the push-off limb. This abstract summarizes findings from our recent JEB Commentary [1].

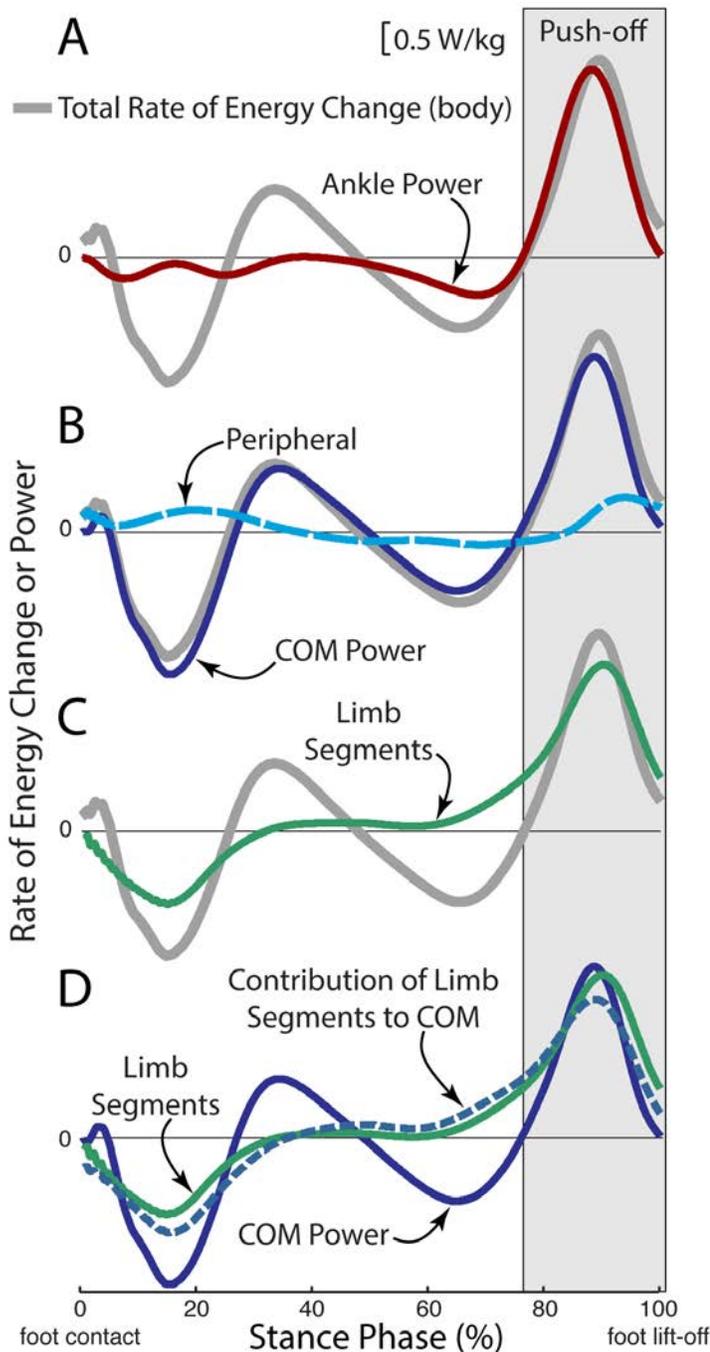

## METHODS

We reanalyzed level-ground walking data from [2], and computed several energy change and work estimates. First, we partitioned Total (whole-body) mechanical energy change into (a) energy changes due to the motion of the body’s COM (using individual limbs method), plus (b) energy changes due to motion relative to the body’s COM, which we termed Peripheral energy change. Second, we used an alternative way to partition Total mechanical energy change, into contributions from individual body segments and segment groups. For

simplicity, we identified three segment groups: (a) push-off limb (trailing limb thigh, shank, and foot), (b) leading limb and (c) head-arms-trunk. Third, we computed how much of the push-off limb segmental energy change also appears as COM energy change during the push-off phase of gait.

## RESULTS AND DISCUSSION

We found that under normal walking conditions (1.4 m/s), the vast majority (>85%) of push-off limb energy change contributes directly to COM energy change during push-off (Fig. 1). This observation is consistent across gait speed: >80% at 0.9 m/s, and >90% at 2 m/s. Work provided by ankle push-off manifests principally as increased speed of the push-off limb. The push-off limb increases in segmental kinetic energy with little energy transferred to the torso through the hip. But because the limb is included in body COM computations, this localized segmental acceleration also accelerates the COM, and most of the segmental energy change also appears as COM energy change. Thus, ankle push-off primarily contributes to accelerating both the swing leg and the COM during human walking. It is, in fact, the same energy change in both the push-off limb and the COM, with only a small part of limb energy being purely Peripheral (non-COM). Thus, interpretation of ankle mechanics should abandon an either-or contrast of leg swing vs. COM acceleration. Instead, ankle function should be interpreted in light of both mutually consistent effects. This unified perspective informs our fundamental understanding of the role of ankle push-off, and has implications for the design of clinical interventions (e.g. prostheses, orthoses) that restore function to individuals with disabilities.

**Figure 1:** Estimates of the rate of energy change ( $\dot{E}$ ) and power (work rate) for an individual limb during human walking. (A) Ankle power (red line) overlaid on Total  $\dot{E}$  (gray line, due to motion of and about the COM). (B) The majority of Total  $\dot{E}$  during Push-off (gray box) is attributable to COM  $\dot{E}$  (blue line), and smaller contributions are from Peripheral  $\dot{E}$  (due to segmental motion relative to the COM, dashed cyan line). (C) The majority of Total  $\dot{E}$  during Push-off is also attributable to segmental  $\dot{E}$  from the push-off limb (green line). (D) The contribution of limb segmental  $\dot{E}$  (green) to overall COM  $\dot{E}$  (solid blue) is shown here in dashed blue. During Push-off, the majority of the limb  $\dot{E}$  goes into this contribution (dashed blue), which in turn accounts for the majority of COM  $\dot{E}$ . Data depicted are inter-subject means at 1.4 m/s ( $N=9$ , [1,2]).

## CONCLUSIONS

The debate whether push-off from ankles powers leg swing or COM rankles.

But a unified view indicates both are true: two effects inextricably tangled.

### INTRODUCTION

Running has been a popular mode of aerobic exercise in the U.S. for over four decades, and road race participation continues to increase every year. Running is a lifelong activity that can be enjoyed by most, and many runners continue to participate in organized races into their 80s. Unfortunately, more running-related injuries have been reported in older compared to younger runners. Factors that may be related to the greater number of injuries as runners age include changes in tendon composition (i.e., reduced stiffness), reduced muscle strength and joint flexibility and, although controversial, changes in running biomechanics. For this reason, there has recently been a large interest in research focused on age-related changes in running biomechanics, but more work is needed to further understand the mechanisms responsible for age-related declines in performance and higher numbers of injuries in older runners. To this end, many factors need to be studied to bridge the gap between age-related changes in running biomechanics and injury development. This symposium highlights current and new research on the ‘aging’ runner and introduces new research ideas for future work.

#### The symposium will follow this schedule:

Introduction – **Paul DeVita** – 5 mins

Symmetry And Stiffness In The Aging Runner –  
**D.S. Blaise Williams III** – 15 min

Coordination Variability In Older Runners – **Julia  
Freedman Silvernail** – 15 min

Is Running Exposure Protective Against Age-  
Related Biomechanical Changes? – **Max R.  
Paquette** – 15 min

Effects Of Exercise Intervention On Age-Related  
Changes In Running Biomechanics – **Reginaldo  
K. Fukuchi** – 15 min

Discussion – 20 min

### SYMMETRY AND STIFFNESS IN THE AGING RUNNER – Blaise D. S. Williams III

As individuals age, musculoskeletal characteristics such as bone density, joint range of motion, muscle strength and neuromuscular control decrease. These changes likely influence the overall lower extremity mechanics during running. While clear benefits of running exist, the combination of this high stress activity on the aging musculoskeletal system likely results in a different risk of lower extremity injury. In fact, there is an increasing percentage of older runners competing in distance running and a subsequent shift in the overall categories of injuries toward those more common in older runners. If specific differences in lower extremity stiffness and symmetry during running exist in older runners, interventions (i.e., specific training, equipment) targeting these differences in the aging runner should be developed. The availability of these interventions and an understanding of the distinct differences in the aging runner will help to guide decision making and could reduce the risk of running-related injuries and the subsequent deconditioning and disability that may occur with aging. The overall objective of this presentation is to compare the effect of age on dynamic lower extremity stiffnesses (i.e., individual joint and total leg), which contribute to shock attenuation during running and to compare the effect of age on lower extremity symmetry during running, which may be an indicator of declining neuromuscular function.

## **COORDINATION VARIABILITY IN OLDER RUNNERS – Julia Freedman Silvernail**

Running continues to expand in its popularity as a means of physical activity participation. While remaining physically active promotes healthy aging, runners continue to be injured at high rates. This includes an increased risk of some injuries for older runners. Initial biomechanical differences between older and younger runners have been identified when investigating movement characteristics. Yet when recruited to match running volume, these groups tend to look more similar, especially when assessing discrete movement variables. Measures of coordination provide a metric of the underlying organization of movement by quantifying the contributions of individual segments to overall joint motion. Furthermore, how one varies movement coordination upon repetition of a movement provides insight to the flexibility of the system. An injured state leads to a more constrained system where less movement options are available, indicated by a decrease in coordination variability. This presentation will discuss discrete biomechanical comparisons of older and younger runners with similar weekly running volume. Additionally, comparisons of movement coordination and coordination variability between age groups will be presented. This will provide a more robust biomechanical comparison of older and younger runners by utilizing continuous, sensitive measures.

## **CAN RUNNING EXPOSURE PRESERVE AGE-RELATED BIOMECHANICAL CHANGES? – Max R. Paquette**

Aging is associated with loss in functional performance as well as changes in tendon properties and muscle architecture, in particular plantarflexor muscles and Achilles tendon or plantarflexor complex. Mechanical and morphological properties of gastrocnemius can influence their capacity to generate angular power at the ankle joint. Consequently, compared to younger runners, older runners have reduced ability to generate ankle angular power and work during running. This age-related reduction in ankle power generation is paralleled by lower vertical push-off and propulsive ground reaction force in older compared to younger runners. Ultimately, maintenance of ankle joint and plantarflexor power appear to be essential for performing daily activities in addition to more

intense exercise, such as running. It is well accepted that humans are able to adapt and modify their motor task organization using sensory feedback information, especially for repetitive motor task. Repetitive practice enhances motor task organization which maybe a mediator for adaptations to the musculoskeletal system. Endurance running training can have a positive impact on endurance performance, muscle strength, musculotendinous properties, and lower limb joint kinetics in older runners. This author hypothesizes that running training exposure, specifically training intensity, may have preserving effects on lower limb biomechanics of older runners at submaximal running speeds. Further, the author suggests important considerations related to training factors when designing running biomechanics studies in the aging runner.

## **EFFECTS OF EXERCISE INTERVENTION ON AGE-RELATED CHANGES IN RUNNING BIOMECHANICS – Reginaldo K. Fukuchi**

Age-related changes in running biomechanics have been consistently observed in the literature. These changes have been attributed, among other factors, to the loss of strength and flexibility with aging. In fact, few studies, that considered both running biomechanics and the levels of strength and flexibility, have confirmed this association between atypical running biomechanics with general weakness and lack of flexibility. Despite the fact that strengthening and stretching exercises have been recommended to mitigate the effects of aging and to prevent running injuries; and the fact that older age has been considered a risk factor for running injuries, the effects of strengthening or stretching exercises on running biomechanical patterns are poorly understood in older runners. The author will present the findings of a randomized controlled trial study on the effects of exercise intervention on running biomechanics of older runners. Based on these findings, the author will suggest areas to be addressed for future studies. In addition, the author will present a public repository that includes not only running biomechanics data but also data related to running habits, strength, flexibility and foot strike patterns. We suggest that this continually expanding data set would be useful for addressing important biomechanical research questions related to the aging runner.

# Locomotor Adaption to Lateral Center of Mass Movement Amplification Requires Active Stabilization

## INTRODUCTION

Control of frontal-plane stability is critical for community ambulation, but relearning how to control center of mass (COM) dynamics following neurologic injury has proven exceptionally difficult. To effectively enhance locomotor stability we need to develop interventions that target frontal plane COM control. Recent motor learning research suggests that *movement amplification* that increases the intensity and variability of task-specific practice may be an effective strategy for improving control of upper-limb movements [1]. Movement amplification strategies greatly contrast with many existing locomotor training paradigms that employ external *stabilization* techniques to reduce lateral control requirements. Our purpose was to investigate how non-impaired populations respond to a movement amplification paradigm designed specifically to challenge control of frontal-plane COM gait stability. We also compared locomotor adaptations during movement amplification to the effects of frontal-plane COM stabilization.

Specifically, we investigated locomotor adaptation when lateral stability was challenged using a negative viscosity force field that amplified lateral COM velocity, and when lateral stability was assisted using a positive viscosity force field that resisted lateral COM velocity. We hypothesized that participants would *decrease* lateral COM velocity in response to both force fields. We further hypothesized that in the stabilization field, subjects would rely on the external force field allowing a reduction in active control of frontal-plane COM stability. This adaptation would be reflected by a decrease in movement variability and metabolic cost of transport. In contrast, we theorized that in the destabilization field, subjects would increase their

active control of frontal-plane COM stability, as reflected by an increase in movement variability and metabolic cost of transport.

## METHODS

11 young healthy individuals gave informed consent and participated in the study (10 female,  $24 \pm 2.2$  years and  $71 \pm 7.5$  kg). Subjects walked on a wide treadmill that allowed variability in lateral position during three force field conditions that included both laterally stabilizing and destabilizing environments. For all conditions, subjects completed two 5-minute trials of treadmill walking at their preferred speed. Highly controlled lateral forces were applied to a pelvis harness via a set of cables driven by linear motors. The condition order was randomized:

- 1) **Stabilization** – A stabilizing viscous force field applied forces proportional in magnitude and opposite in direction to the subject's lateral COM velocity, reducing the requirements to actively maintain straight-ahead walking.
- 2) **Null** – No forces were applied.
- 3) **Destabilization** – A destabilizing viscous force field applied forces proportional in magnitude and in the same direction as the subject's lateral COM velocity, amplifying the subject's lateral motion. This field increased the requirements to actively maintain straight-ahead walking.

The first trial of each condition allowed the subject to adapt to the novel walking environment. Kinematic and metabolic data were recorded during the last 2 minutes of the second trial of each condition to assess subjects' performance during steady state walking.

## RESULTS AND DISCUSSION

As hypothesized, average peak lateral COM speed per stride during the Stabilization and Destabilization conditions tended to decrease vs. the Null condition (Figure 1). This decrease in COM speed was only significant ( $p < 0.05$ ) for the Stabilization condition. Metabolic cost of transport increased significantly during Destabilization vs. the Null condition ( $p < 0.05$ ) (Figure 1). The lack of change in peak lateral COM velocity when walking in the Destabilizing field (which amplifies movements) suggests that subjects made locomotor adaptations to actively control and reduce their frontal-plane COM dynamics. This control required effort, as evidenced by the significant increase in metabolic cost of transport.

In addition, the variability of peak lateral COM speed between strides increased significantly from Stabilization to Null to Destabilization conditions ( $p < 0.05$ ) (Figure 1). The increase in movement variability when walking in the Destabilization condition may increase movement errors and allow individuals a greater opportunity to practice corrective behaviors required to control lateral COM dynamics.

## CONCLUSIONS

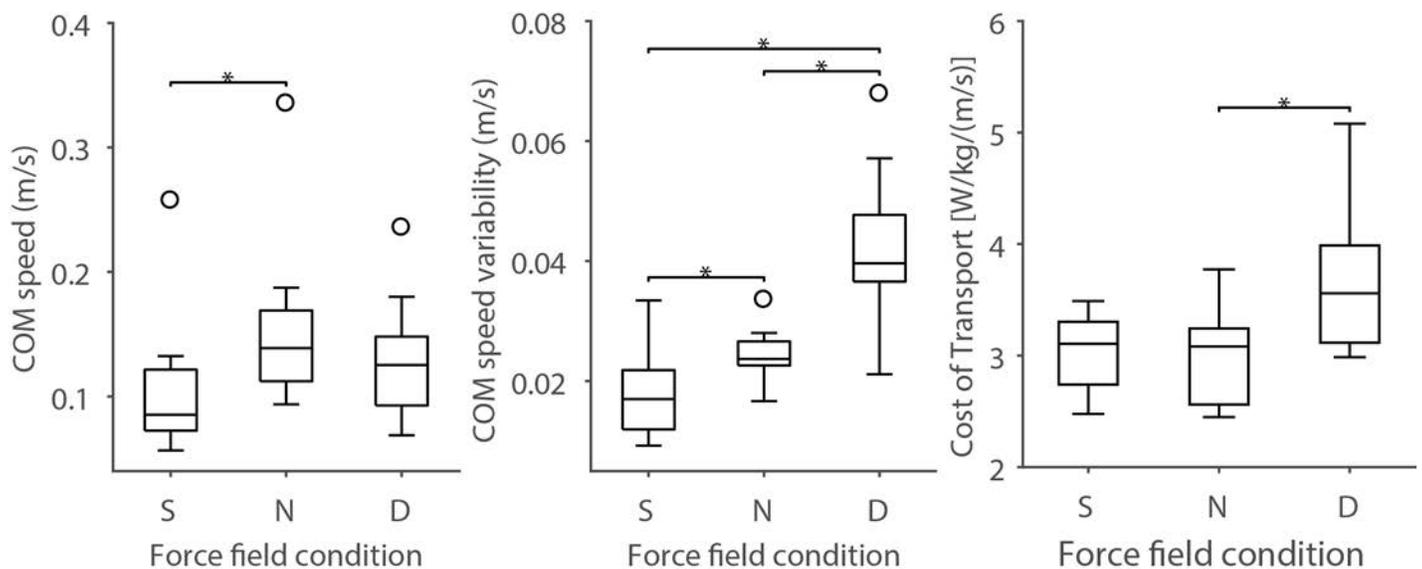

Results from the current study suggest that a movement amplification paradigm can be applied to challenge frontal-plane stability during human locomotion and yields significantly different responses than a stabilization paradigm. Individuals adapted to the destabilizing viscous force field by decreasing lateral COM velocity (similar to the stabilizing field), but increased both metabolic cost of transport and movement variability (in contrast to the stabilizing field). Applying this movement amplification paradigm to gait rehabilitation may be uniquely valuable for training active control of frontal-plane stability.

## INTRODUCTION

Balance is complex construct with many domains. Assessing balance improvements following an intervention requires repeated testing but some question remains as to the learning effect as participants habituate to the balance test [1]. If there is a substantial learning effect from repeatedly undergoing the balance assessment, changes attributable to the intervention would be more difficult to ascertain. Depending on the balance test used, the learning effect may be more substantial.

Observational evidence suggests that individuals become more comfortable with balance tests, performing better on repeated tests.

It was hypothesized that improvements in the performance of the Balance Error Scoring System (BESS) would not be statistically significant with four repeated tests over 10 days, whereas improvements with the Y Balance test would should a statistically significant learning effect over four repeated tests over 10 days.

## METHODS

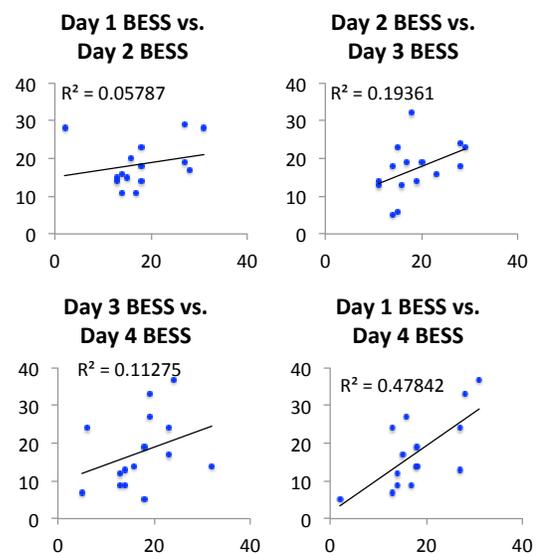

Sixteen healthy, recreationally active adults gave informed consent to participant in this IRB-approved protocol (9 females, 7 males 29 +/-5 years; low to high intensity exerciser 2-6 x week). Over a 10-day period, each participant completed the BESS and the Y Balance protocol four times following a standardized warm up (Figure 1). The total error score on the BESS test for both firm and foam surfaces was calculated for each day. The total distance achieved in the anterior, posteriolateral and posteromedial directions on the Y Balance test was calculated for each day. Each individual's scores were plotted across days to determine if a statistically significant slope was observed across the days.

**Figure 1.** Balance Error Scoring System (BESS) and Y-Balance tests.

## RESULTS AND DISCUSSION

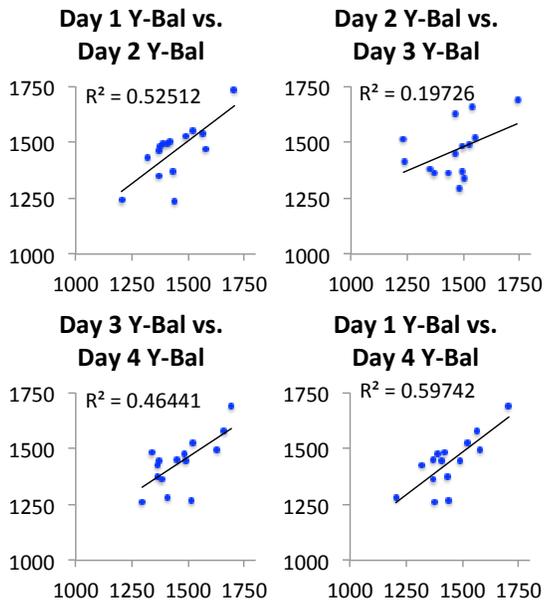

The relationship between scores on the BESS test across specific days is shown below in Figure 2.

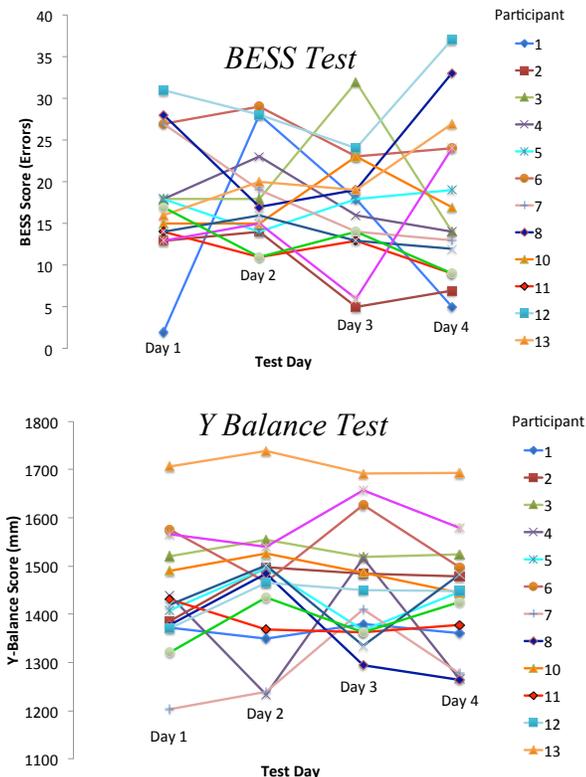

**Figure 2.** BESS scores on Day 1 vs. 2; Day 2 vs. 3; Day 3 vs 4; and Day 1 vs. 4.

The relationship of the scores on the Y Balance test across specific days is shown below in Figure 3.

Contrary to the hypothesis, the slope of the scores on both the BESS and the Y Balance tests did not show a significant slope across the four days ( $P = 0.3-0.9$ ). The score across the four days for each participant are shown in Figure 4.

**Figure 3.** Y Balance scores on Day 1 vs. 2; Day 2 vs. 3, Day 3 vs.4; and Day 1 vs. 4.

**Figure 4.** Individual scores for each participant across 4 tests performed over a 10-day period.

Only a few participants exhibited an observable trend across the four days, some improving slightly and some worsening slightly. Most participants had high amounts of variance, for example participant 1 on the BESS; despite this the individual had very low variance and almost no trend to their scores on the Y Balance test. These data suggest that there is very little learning effect for either test, even after repeating the tests 4 times in a relatively short period of time. Since many interventions designed to improve balance may last weeks or months it appears unlikely that assessing balance improvements with either the BESS or the Y Balance test would present a confounding learning effect. The BESS is clearly more focused on reducing small errors while in a variety of challenging postures in quiet stance. The Y Balance test is more focused on reaching the limits of stability in three directions, and may be more susceptible to improvements in knee and ankle strength than the BESS. However, neither test specifically mimics the rate of dynamic balance perturbation recovery that likely occurs for individuals to experience a substantial reduction in falls and injuries. Therefore there remains some question as to the most specific and sensitive test battery to determine improvements from injury prevention programs administered to a range of patient populations. Injury prevention programs such as PEP [2] or FIFA 11+ [3] may reduce injuries by improving balance. Either the BESS or the Y Balance tests may be sensitive to these improvements.

## CONCLUSIONS

There does not appear to be any learning affect for the BESS or Y Balance test in active adults over a 10 day test-retest format.

# RELATING OBESITY, COGNITION AND BIOMECHANICS OF FALL-RECOVERY IN OLDER ADULTS: PRELIMINARY RESULTS

<sup>1</sup> Matthew Coon, <sup>1</sup> Vasanth Subramanian, <sup>1</sup> Jacqueline Ortiz, <sup>1</sup> Noah J. Rosenblatt

<sup>1</sup> Center for Lower Extremity Ambulatory Research, Rosalind Franklin University of Medicine and Science, North Chicago, IL, USA

Email: noah.rosenblatt@rosalindfranklin.edu

## INTRODUCTION

Obesity is a growing epidemic affecting at least 30% of older Americans<sup>1</sup>. Epidemiological studies have shown that obesity increases the risk of falling in older adults<sup>2</sup>, although the mechanisms to explain this are not well established. From a mechanical point of view, following a large change in momentum of the center of mass - as may occur following obstruction of the swing limb during gait (i.e. a trip) - increased inertia due to greater body mass may negatively affect whole-body kinematics and increase the likelihood of a fall. The example of a trip during gait is salient as trips are the leading cause of falls by community-dwelling older adults<sup>3</sup> and the risk of falling in response to a lab-induced trip appears to increase with obesity<sup>4</sup>. However, the effect of body mass on biomechanics of the fall-recovery response following a trip by older adults has not been reported. Given that aspects of the fall-recovery response may involve cortical pathways<sup>5</sup> and that obesity alters brain structure and impairs cognitive function<sup>6</sup>, the latter may partly explain obesity-related falls. However, to our knowledge a relationship between cognitive function in older adults and biomechanics of fall-recovery has not been demonstrated.

The purpose of this on-going study is to provide a modifiable mechanism for obesity-related falls by community-dwelling older adults. Here we use preliminary data collected to date to test the following: H1) obesity negatively impacts biomechanics of fall-recovery following a lab-induced trip; H2) there is a relationship between cognitive function and biomechanics of fall-recovery; H3) the effect of obesity on biomechanics may be partly explained by obesity-related cognitive declines.

## METHODS

To date, 20 participants have been recruited. Inclusion criteria are: 65+ years of age, no neuromuscular conditions that interfere with gait, no joint replacements, ability to walk one mile at any pace without pain or assistive device and body mass in-

dex (BMI) of 18.5-25 kg/m<sup>2</sup> (normal weight) or  $\geq 30$  kg/m<sup>2</sup> (obese). Patients with diabetes had to have their condition controlled and score at least 8/10 on a monofilament test for neuropathy. We analyzed biomechanical data from 13 participants (N=5 normal weight, 74.8 $\pm$ 8.5 yrs, 21.7 $\pm$ 2.0 kg/m<sup>2</sup>, 3 male; N=8 obese, 72.9 $\pm$ 5.0 yrs, 32.9 $\pm$ 1.7 kg/m<sup>2</sup>, 6 males) and measures of cognitive function from 19 participants, including all of those completing the biomechanical data collection (N=8 normal weight, 74.9 $\pm$ 8.7 yrs, 22.4 $\pm$ 2.2 kg/m<sup>2</sup>, 5 male; N=11 obese, 72.2 $\pm$ 5.4 yrs, 33.7 $\pm$ 2.1 kg/m<sup>2</sup>, 8 males). Missing data reflects technical issues, withdrawals or participants not yet completing the study. In addition to using BMI to quantify obesity, participants also received a whole body DEXA scan to quantify percent body fat in the trunk, in the legs and in the whole body. Hip, thigh and waist circumferences were also taken.

Biomechanics of fall-recovery were evaluated using a previously established method<sup>4,7</sup> in which the swing limb was unexpectedly obstructed by a hidden obstacle while the participant wore a safety harness. Motion analysis cameras were used to record the motions of passive reflective markers placed on the body according to the Plug-in-gait model for the normal-weight group and an obesity-specific model<sup>8</sup> for the obese group. From the marker data we calculated: flexion/extension of the trunk and the related angular velocity at the instance that the recovery step made contact with the ground ( $\theta_{\text{trunk}}$ ,  $\omega_{\text{trunk}}$ , respectively), the distance (in the direction of travel) between the trunk center of mass and the toe marker at the same instance ( $\text{COM}_{\text{dist}}$ ), and the total time from the onset of the trip to this instance (recovery time). Similar measures have been shown to affect the likelihood of a successful recovery following a lab-induced trip<sup>7</sup>.

To quantify cognitive function we used four assessments from the NIH toolbox - a validated, tablet-based application to assess cognitive as well as emotional, sensory, and motor function<sup>9</sup>. Assessments included: 1) The Flanker Inhibitory Con-

trol and Attention Test (FIT), to assess executive function; 2) The Picture Sequence Memory Test (PST), to assess episodic memory; 3) the List Sorting Working Memory Test (LST); and 4) The Patten Comparison Processing Speed Test (PCT). Each was scored from 0-100 (mean = 50; standard deviation = 10) after correcting for age based on values from a national database.

To test H1 we used unpaired t-tests to compare kinematics between groups and correlated each kinematic with each anthropometric (BMI, circumferences and fat percentages). To test H2 we repeated the analysis with cognitive scores. To test H3 we planned to analyze only those kinematics that were significantly associated with anthropometrics *and* cognitive scores. We planned to run partial correlations between these kinematics and anthropometrics after covarying for cognitive scores.

## RESULTS AND DISCUSSION

One participant in each group fell (unambiguously relied on the harness to avoid hitting the ground) following the lab-induced trip; both were after-step fallers and included in all analysis.

H1 was not supported. No kinematic differences existed between groups. There were also no significant correlations between any anthropometrics and kinematics and only that between  $\theta_{\text{trunk}}$  and waist circumference “trended” toward significance – e.g.,  $p \leq 0.1$  ( $r=0.64$ ;  $p=0.07$ ). H2 was supported. Specifically,  $\theta_{\text{trunk}}$  was significantly correlated with age-corrected LST score ( $r=.61$ ;  $p=0.04$ ). In addition,  $\text{COM}_{\text{dist}}$  was significantly correlated with age-corrected FIT score ( $r=0.61$ ;  $p=0.03$ ) and with age-corrected PST score ( $r=0.67$ ;  $p=0.01$ ). There was a “trend” toward significance between recovery time and age-corrected PST ( $r=0.48$ ;  $p=0.0097$ ). Given these results, partial correlations were not conducted to test H3. However, to better understand the relationship between obesity and the chosen cognitive assessments in this cohort, correlations were conducted among variables but no significant associations were found.

Given the number of measures to quantify obesity and fall-recovery it is surprising that we observed no significant correlations between the two. However, the sample size may still be too small, particularly given that the variance in anthropometrics is limited by the low number of participants

with Class II and higher obesity ( $\text{BMI} > 35$ ). In addition, a clinically meaningful (albeit non-significant) effect of obesity on fall-risk following a lab-induced fall was previously shown in women only, who may fall at higher rates than men<sup>10</sup>. In contrast, 68% of our participants were male.

The absence of significant associations between obesity and cognitive function is also surprising. However, cognitive function encompasses many domains and the battery of assessments used herein may not directly address previously reported functional changes due obesity<sup>6</sup>. Since beginning this study, the NIH-toolbox has added several cognitive assessments to their battery as well as summative scores of three functional domains based on these assessments. Given our results, it seems reasonable to include these measures and scores moving forward. It is also possible that the strength of the relationship between obesity and cognition was weakened in this cohort given they were fairly active (as per activity data not reported here); physical activity may promote cognitive functioning<sup>6</sup>.

To our knowledge this is the first study to show an association between biomechanics of fall-recovery and cognitive function which seem logical. For example, of the kinematics considered  $\text{COM}_{\text{dist}}$  is the only one that captures coordination of the foot and trunk and it is reasonable that such coordination would rely on attentional resources (FIT score). However, given the time-critical nature the fall-recovery response, we would have also expected PCT to be an important correlate. Regardless, if correlations persist with additional participants, then cognitive training and/or physical activities that improve cognition could help increase efficacy of existing fall-prevention<sup>11</sup> interventions targeting fall-recovery mechanics.

## INTRODUCTION

Persons with femoroacetabular impingement syndrome (FAIS) present with aberrant movement patterns during functional tasks even after surgical intervention.[1] While gait, squatting, and stair climbing are popular tasks for biomechanical evaluation to better assess movement patterns in this population, clinical tests of movement quality have received minimal attention.

The forward step down (FSD) is a clinical tool to evaluate functional quality of movement. Steady balance is one of five clinical criteria evaluated in the FSD task [2] and is commonly impaired in individuals with non-arthritic hip pain.[3] Balance training is one component of post-operative rehabilitation [4] and may significantly contribute to improving quality of movement in this population. Understanding the biomechanical parameters and clinical identification of poor quality of movement in these individuals will better inform targeted intervention strategies.

The purpose of this study was to investigate quality of movement during a FSD in persons after hip arthroscopy for FAIS by identifying biomechanical measures of balance that are associated with clinician-defined balance impairments. We theorized quality of movement is impaired bilaterally, and thus we hypothesized that regardless of limb, persons with clinician-defined unsteady balance during a FSD would demonstrate significantly higher center of pressure displacement area, path length, medial-lateral movement, and peak velocity and

significantly higher lateral trunk, pelvis, hip, and knee excursion compared to persons with steady balance.

## METHODS

Twenty-two participants (15 women) who underwent hip arthroscopy for FAIS consented to participate in this study.

### *Clinician-defined Balance*

For each limb, participants completed five repetitions of a FSD off an 8-inch box. Using 2-dimensional (2D) video of the participant during the FSD, a physical therapist (PT) with a board-certified sports specialty and five years of experience graded quality of movement on predefined criteria.[3] Steady balance was one criterion with participants receiving a dichotomous grade of either steady (0) or unsteady (1) balance.

### *Center of Pressure*

Center of Pressure (CoP) data were collected during the FSD using Bertec force plates. CoP displacement area was measured by calculating the area of an ellipse encompassing 85% of the plotted CoP path during the FSD.[5] CoP path length and medial-lateral movement were calculated by tracking the x and y coordinate positions of the CoP throughout the FSD. CoP peak velocity was defined as the highest change in CoP position over one frame of collected data (0.004sec). All CoP measures were normalized to participant height.

### *Kinematics*

A standard three-dimensional (3D) motion analysis system was used to capture kinematics of the trunk, pelvis, and lower extremity during the FSD. Variables of interest included frontal plane excursion of the trunk, pelvis, hip, and knee.

### Statistical Analysis

Shapiro-Wilk tests confirmed normality for all variables except CoP peak velocity. A multivariate analysis of variance (MANOVA) was performed to assess for interaction of limb (involved or uninvolved) by balance rating (steady or unsteady)( $P < 0.05$ ). If significant interactions were observed, post-hoc t-tests were performed. Main effects were reported if no interactions were found. Related-samples Wilcoxon Signed Rank tests were performed to assess for differences between limbs and balance ratings for CoP peak velocity ( $P < 0.05$ ).

## RESULTS AND DISCUSSION

Thirteen participants (59.1%) were classified as steady on both limbs, three (13.6%) were classified as unsteady on both limbs, two (9.1%) were unsteady on the involved but steady on the uninvolved, one (4.5%) was unsteady on the uninvolved but steady on the involved, three (13.6%) only had the involved limb analyzed due to collection issues (two had unsteady balance and one had steady balance).

**Table 1. Demographics**

Means  $\pm$  standard deviations; Inv. = involved, Un.= uninvolved  
Table excludes participants who only had 1 limb analyzed (n=3)

	Both Steady (n=13)	Both Unsteady (n=3)	Inv. Unsteady (n=2)	Un. Unsteady (n=1)
Age (y)	35 $\pm$ 9	39 $\pm$ 11	42 $\pm$ 4	48
BMI (kg/m <sup>2</sup> )	24.8 $\pm$ 1.7	24.3 $\pm$ 1.37	22.8 $\pm$ 0.6	24.9
Years from Surgery	2.2 $\pm$ 1.1	2.7 $\pm$ 1.0	1.9 $\pm$ 0.1	1.3

There was no significant interaction of limb and balance rating (steady vs unsteady)( $P > 0.10$ ). There was a significant effect of balance rating for trunk, pelvis, and hip excursion and CoP path length medial-lateral movement, and displacement area ( $P < 0.05$ ). Participants with unsteady balance had significantly more trunk, pelvis, and hip excursion, significantly longer CoP path length, significantly

more CoP medial-lateral movement, and significantly higher CoP displacement area (Table 2). There was no significant difference between limbs or balance ratings for CoP peak velocity ( $P > 0.05$ ).

**Table 2. Biomechanical Measures of Balance**

Means  $\pm$  standard deviations; Exc. = excursion; M-L = medial-lateral; CoP values are normalized by height (m)

	Steady	Unsteady	P =
Limbs (N)	30	11	NA
Trunk Exc. (°)	13.4 $\pm$ 5.6	19.5 $\pm$ 7.3	<b>0.02</b>
Pelvis Exc. (°)	10.9 $\pm$ 2.5	15.9 $\pm$ 2.9	<b>0.001</b>
Hip Exc. (°)	18.5 $\pm$ 4.9	25.3 $\pm$ 4.6	<b>0.001</b>
Knee Exc. (°)	12.1 $\pm$ 5.6	12.1 $\pm$ 5.1	0.87
CoP Length (m/m)	0.009 $\pm$ 0.001	0.01 $\pm$ 0.002	<b>0.001</b>
CoP M-L (m/m)	0.004 $\pm$ 0.001	0.005 $\pm$ 0.001	<b>0.001</b>
CoP Area (cm <sup>2</sup> /m)	0.143 $\pm$ 0.047	0.182 $\pm$ 0.067	<b>0.05</b>
CoP Peak velocity [m/(sec*m)]	0.005 $\pm$ 0.002	0.005 $\pm$ 0.002	0.65

These results demonstrate that larger frontal plane trunk, pelvis, and hip excursion and higher CoP variability characterize unsteady balance in individuals who have undergone hip arthroscopy for FAIS.

## CONCLUSIONS

Because abnormal movement patterns persist after surgical intervention for FAIS [1], further investigation is needed to compare quality of movement in this population to movement patterns of healthy controls. Our future work comparing these two populations to better understand contributing factors to steady balance will focus on CoP measurements and kinematic assessment of the trunk, pelvis and lower extremity due to their relationship to clinician-identified balance impairments.

# BELOW-KNEE AMPUTEES MAKE SPECIFIC ANTICIPATORY LOCOMOTOR ADJUSTMENTS TO RESIST LATERAL PERTURBATION

<sup>1,2</sup> Matthew J Major, <sup>1</sup> Xinlin Chen, <sup>1</sup> Chelsi K. Serba, <sup>1</sup> Nicholas Reimold, <sup>1</sup> Franklyn Ndubuisi-Obi, and <sup>1,2</sup> Keith E. Gordon

## INTRODUCTION

Approximately half of community dwelling persons with lower-limb amputation fall every year [1]. Frontal-plane asymmetries observed during quiet standing [2] suggest that persons with below-knee amputation (BKA) may have limited ability to respond to lateral perturbations during gait. Currently, the mechanisms underlying successful recovery following lateral perturbation are poorly understood. Characterizing the control mechanisms used to maintain locomotor stability may inform interventions to minimize fall risk. This pilot study quantified anticipatory gait adjustments of persons with unilateral BKA when *a priori* information of an impending lateral perturbation is varied. Due to the loss of an active ankle joint and critical forms of proprioception [2, 3], we theorized that persons with BKA will depend on passive stability mechanisms deemphasizing requirements to accurately sense and respond to perturbations. Specifically, we hypothesized that persons with BKA will increase the Margin of Stability (MoS) on their impaired (prosthetic) side during steps prior to a lateral perturbation directed toward their impaired side.

## METHODS

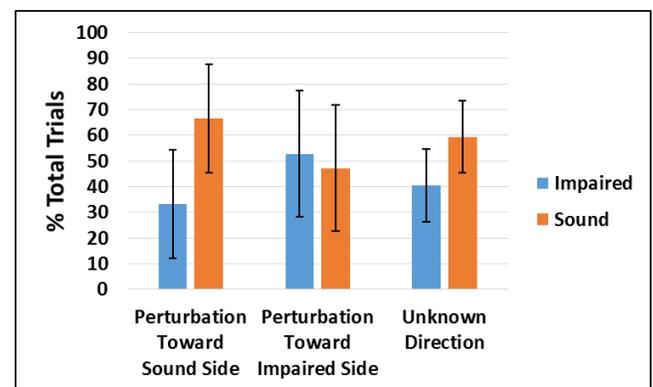

Six subjects with unilateral BKA ( $48 \pm 8$  yrs,  $70 \pm 11$  kg,  $1.7 \pm 0.1$  m) experienced lateral perturbations during a series of treadmill walking trials. *A priori* knowledge of the perturbation direction was randomly varied, but timing of the perturbation was provided through both visual and audio cues. We examined three conditions: 1) Known perturbation direction (toward the impaired or sound limb), 2) Unknown perturbation direction, 3) Baseline - no perturbation. Subjects walked at their self-selected speed for all 30 perturbation trials (6 trials x 3 conditions x 2

perturbation direction). Lateral perturbations of 12% bodyweight were generated by motorized cables attached to a waist harness.

Positions of markers on the fifth metatarsals and pelvis were recorded at 100 Hz (Qualisys, Göteborg, Sweden), and used to define the lateral base-of-support (BoS) and body center-of-mass (CoM), respectively. Matlab (Natick, MA) software estimated MoS of each side as the minimum lateral distance between the extrapolated CoM (XCoM; a velocity-adjusted CoM position [4]) and the BoS during stance. The MoS was averaged for each side across 12 total steps, occurring during the 4 steps prior ( $n-1$  through  $n-4$ ) to perturbation step ( $n$ ).

## RESULTS AND DISCUSSION

Frequency of the side (impaired or sound) of the last heel strike prior to the perturbation step, and MoS for the perturbation conditions during the four steps prior to perturbation compared to baseline are reported in Figures 1 and 2, respectively.

**Figure 1:** Freq. ( $\pm 1$ SD) of heel strike limb at  $n$  step.

Subjects were  $\sim 50\%$  more likely to be on their sound limb when the perturbation was directed toward the sound limb. In contrast subjects were equally likely

to be on their sound or impaired limb when perturbations were directed toward their impaired limb or when the perturbation direction was unknown. These results may suggest a preference to have the sound limb in contact with ground at the time of the perturbation when they are aware that the perturbation will not be toward the impaired side.

The MoS of both limbs did not noticeably change when the perturbation direction was directed toward the sound side. However, when the perturbation direction was unknown or directed toward the impaired side, subjects displayed an increase in the MoS of the impaired limb during the last two steps prior to perturbation ( $n-1$  or  $n-2$ ) when compared to baseline. Across the unknown direction and impaired side perturbation conditions, the average increase in MoS compared to baseline was 12 mm. This increase in MoS may be reflective of using passive mechanisms to reduce the likelihood that the XCoM exceeds the BoS thus requiring a large response to restore balance. Interestingly, when subjects did not expect a perturbation or were aware that a perturbation would be toward their sound side, they walked with relatively symmetric MoS.

These results support the hypothesis that individuals with BKA increase the MoS on the impaired side when the perturbation direction is toward that side. Accordingly, it seems reasonable that when subjects were unaware of the direction of the impending perturbation, they increased impaired side MoS as a precautionary measure for maintaining locomotor balance. This precaution may also be reflected by the generally greater percentage of trials in which subjects were positioned in sound limb stance at the time of perturbation. Overall, given that minimal change to the MoS for either side was displayed

when the perturbation direction was toward the sound side, the results broadly suggest that below-knee prosthesis users may utilize passive mechanisms to enhance stability when they expect to be perturbed toward their impaired side. However, research is needed to better understand the consequences of this strategy when recovering from the type of perturbations imposed in this study.

## CONCLUSION

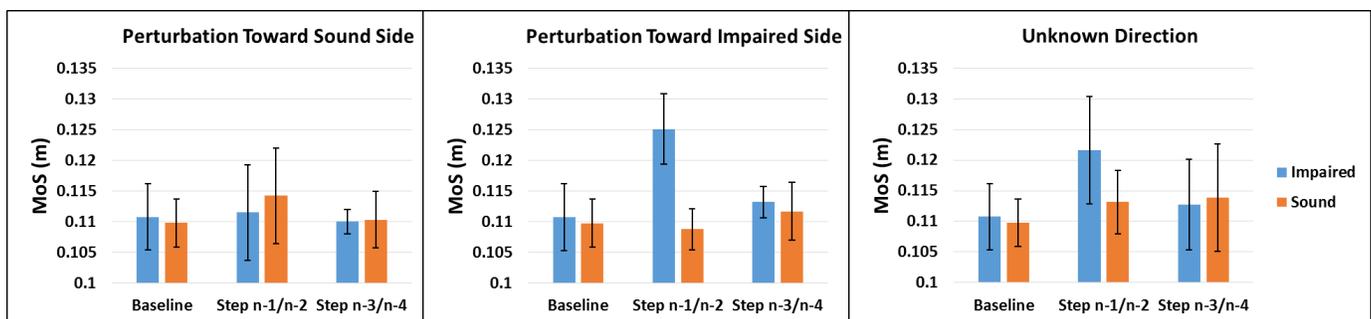

Persons with BKA seem to emphasize passive mechanisms for maintaining locomotor stability by increasing the MoS on their impaired side when expecting a perturbation toward that limb. Future work will focus on the consequences of such a strategy by exploring the response dynamics following the perturbation for each condition tested.

The Ohio State University, Columbus, OH, USA

**email:** monfort.30@osu.edu **web:** <http://u.osu.edu/osusportsbiomechanics/>

## INTRODUCTION

Advances in diagnosing and treating cancer have contributed to improved survival rates and an increasing number of cancer survivors [1]. Many cancer patients receive chemotherapy as a component of an effective anti-cancer treatment, but common chemotherapy agents such as taxanes and oxaliplatin can present patients with adverse effects due to their neurotoxicity [2]. The effects of this neurotoxicity can persist well beyond completion of chemotherapy and are associated with an increased risk of falling [3].

Our previous research has reported the natural history of balance impairments in cancer patients receiving chemotherapy [4]; however, the sensory system mechanisms that may drive this instability are largely unknown. Sensory organization tests have previously been used to systematically interfere with sensory systems to gain insight into postural control strategies and impairments [5]. The purpose of this study was to investigate contributions of sensory system factors to postural instability through a sensory organization approach. Our hypothesis was that cancer survivors who received neurotoxic chemotherapy would rely less on somatosensation during quiet stance.

## METHODS

Seventeen cancer survivors participated in the study after providing IRB-approved informed consent. These participants comprised a group who did not receive chemotherapy (CONTROL; n=6; f/m = 6/0;  $59.3 \pm 9.7$  yrs;  $78.0 \pm 14.1$  kg;  $1.62 \pm 0.05$  m) and a group who recently completed oxaliplatin- or taxane-based chemotherapy (CHEMO; n=11; f/m = 9/2;  $51.7 \pm 12.9$  yrs;  $83.4 \pm 18.8$  kg;  $1.68 \pm 0.05$  m).

Patients completed three 30 second trials of quiet

stance under the following four conditions: Eyes Open (EO)-Rigid surface, EO-Foam surface, Eyes Closed (EC)-Rigid surface, and EO-Rigid with head tilted back at a 45° angle (EO-Tilt). Center of pressure (CoP) data were recorded at 1000 Hz using a balance plate (Bertec Corp.) and low-pass 4<sup>th</sup>-order Butterworth filtered at 20 Hz. The average planar mean velocity (MVEL) over the three trials was used to assess balance for this study. Increased MVEL represents overcorrecting in CoP adjustments [4].

The sensory interference conditions were normalized to EO-Rigid. Increased MVEL during sensory interference conditions were interpreted as a greater reliance on a given sensory system for postural control during natural, unperturbed quiet stance (i.e., 'EC' for vision, 'Foam' for somatosensation, 'Tilt' for vestibular). Additionally, the quotient of EC-Rigid and EO-Foam was used to more directly represent relative reliance on vision versus somatosensation during quiet stance.

Patients also had their vision and somatosensation tested independently of the balance tasks. Visual acuity was assessed using a low-contrast logMAR chart. Passive, ipsilateral joint reposition sense at the ankle was measured to assess proprioception, an aspect of somatosensation. We used a mobile-app (CoreX Therapy) based approach where patients attempted to match an angle of 15° plantarflexion that was previously demonstrated to them. Five trials were collected. The mean absolute error of the three remaining trials after removing the most and least accurate trials was the outcome for this test.

Two-sample independent t-tests were used to test for differences between groups. Additionally, a bootstrapped Pearson correlation analysis between ankle joint reposition error and the ratio of EC to Foam conditions was used to investigate effects of

altered proprioception on postural control strategy in the CHEMO group. Significance was defined at  $\alpha=0.05$  without correcting for multiple comparisons due to the exploratory nature of this study.

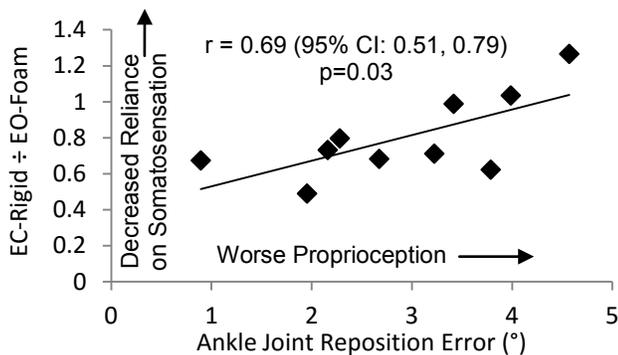

## RESULTS AND DISCUSSION

There were no significant differences between groups in age, mass, height, logMAR scores, or ankle joint reposition sense (all  $p>0.05$ ). The CHEMO group demonstrated less of an effect of the somatosensory interference condition (i.e., EO-Foam) compared to the CONTROL group ( $p=0.03$ ) (Table 1). An increased effect of EC relative to Foam in the CHEMO group was also observed ( $p=0.019$ ).

**Table 1.** Effects of sensory interference conditions on MVEL during quiet stance.

	CONTROL	CHEMO	p-value
EO-Rigid (mm/s)	10.3 ± 2.6	15.5 ± 8.3	0.26
EC-Rigid ÷ EO-Rigid	1.4 ± 0.2	1.6 ± 0.3	0.16
EO-Foam ÷ EO-Rigid	2.6 ± 0.5	2.0 ± 0.3	<b>0.03</b>
EO-Tilt ÷ EO-Rigid	1.2 ± 0.2	1.2 ± 0.2	0.90
EC-Rigid ÷ EO-Foam	0.5 ± 0.1	0.8 ± 0.3	<b>0.019</b>

In addition to the group differences, ankle joint reposition sense was significantly associated with the relative effects of the EC and Foam conditions on MVEL ( $r = 0.69$ ,  $p=0.03$ ) in the CHEMO group. This may suggest a shift towards relying more on vision relative to somatosensation in patients with worse ankle joint reposition sense (Figure 1).

**Figure 1.** Relationship between ankle joint reposition error and relative effect of EC vs. Foam conditions in the CHEMO group. Results of bootstrapped Pearson correlation are shown.

The results of this study support that (1) cancer survivors who complete chemotherapy treatment demonstrate altered balance compared to survivors

who did not receive chemotherapy, and (2) impaired ankle joint reposition sense appears to be associated with these effects. The decreased effect that standing on a foam surface had on the CHEMO group is consistent with these patients compensating for potential diminished somatosensation by increasing reliance on other sensory information (e.g., vision) and less on proprioception that may be impaired during chemotherapy. This interpretation is further supported by worse ankle joint position sense in the CHEMO group being associated with decreased reliance on somatosensation. These findings complement previous findings of exaggerated balance impairments during vision deprived conditions in breast cancer survivors who completed taxane-based chemotherapy [5].

The small sample size is among the limitations of this study. Study enrollment is currently ongoing and the outcomes from additional participants will improve the confidence of our findings and enable a more thorough analysis.

## CONCLUSIONS

Cancer survivors recently completing chemotherapy demonstrated an altered balance control strategy that is consistent with relying less on proprioception during standing balance. These findings support the hypothesized somatosensory-driven mechanism of postural instability in this population and provide guidance for developing interventions that mitigate these detrimental effects of chemotherapy.

# EMG ASSESSMENT OF A SHOULDER SUPPORT EXOSKELETON DURING ON-SITE JOB TASKS

Jason C. Gillette and Mitchell L. Stephenson

Iowa State University, Ames, IA, USA  
email: gillette@iastate.edu

## INTRODUCTION

In 2014, there were 88,980 cases of shoulder injuries that caused individuals to miss work (8.2 cases per 10,000 workers). These shoulder injuries resulted in 26 median days away from work, the longest recovery time of any body part [1]. Common causes of shoulder pain include bursitis, tendinitis, tendon tears, impingement, instability, and arthritis [2]. In order to avoid muscle fatigue and tendinitis, it has been suggested that sustained overhead postures and repeated loads above 40% shoulder strength should be avoided [3].

If worksite modification is limited or not feasible, then an assistive device may be of value to a worker to reduce shoulder loads. For example, a table-mounted arm support was shown to reduce anterior deltoid and upper trapezius muscle activity during pipetting [4]. The purpose of the current study was to assess a passive exoskeleton used by workers during on-site job tasks. This exoskeleton was designed to fit like a backpack frame with cuffs proximal to the elbow that support arm weight during overhead shoulder postures and transfer loads to the pelvis/hip.

## METHODS

Six experienced workers (2 female/4 male, age  $41 \pm 7$  yr; mass  $76 \pm 11$  kg; height  $1.71 \pm 0.08$  m) at two industrial manufacturing sites volunteered for this study. These individuals worked in the following areas: assembly (three workers), painting, parts hanging, and welding. Workers were assessed during a challenging cycle of their job that was repeated during a work shift. The following conditions were compared: 1) consecutive job cycles with and without the exoskeleton, 2) at the beginning and end of the work shift without wearing the exoskeleton that day, and 3) at the beginning and end of the work shift wearing the exoskeleton throughout that day.

Informed consent was obtained from all workers, along with background information, a pre-survey, and a post survey. Data were collected using a Delsys Trigno wireless electromyography (EMG) system at a sampling frequency of 1926 Hz using Delsys EMGworks software. EMG sensors were placed on eight muscles: right and left anterior deltoid, biceps brachii, upper trapezius, and erector spinae. Maximum voluntary isometric contractions (MVIC) were performed in the following postures: shoulder abduction empty can, seated elbow flexion, and prone spinal extension. EMG data were analyzed using custom written code in Matlab.

EMG signals were inspected to remove any non-physiological artifacts. The EMG data were bandpass filtered with a 4<sup>th</sup>-order zero-lag Butterworth filter from 20-450 Hz, and the data were rectified. Next, the EMG data were low-pass filtered at 10 Hz to create a linear envelope. A moving window was used to determine the maximum one second of sustained EMG amplitudes for both the MVICs and job tasks. The maximum one minute of distributed EMG amplitudes measure were determined by dividing the data into consecutive one second intervals and finding the maximum 60 s of muscle activity distributed throughout the job task.

Maximum one second sustained and one minute distributed EMG amplitudes were divided by the maximum one second MVICs to determine a percent of maximum contraction (%MVIC). Next, right and left side muscles were averaged together. The EMG amplitudes presented here are an overall average (consecutive, beginning of shift, end of shift) and the end of shift where fatigue is of most concern. Comparisons were made between job tasks performed without the exoskeleton and with the exoskeleton. Paired t-tests were used for comparisons, with  $p < 0.05$  considered statistically significant (Table 1).

## RESULTS AND DISCUSSION

*Overall.* Maximum one second sustained EMG amplitudes were significantly reduced with the exoskeleton for the biceps brachii ( $p = 0.01$ , 18% reduction) and approached significance for the anterior deltoid ( $p = 0.06$ , 18% reduction). Maximum one minute distributed EMG amplitudes were significantly reduced with the exoskeleton for the biceps brachii ( $p = 0.02$ , 27% reduction) and anterior deltoid ( $p = 0.04$ , 23% reduction), while approaching significance for the erector spinae ( $p = 0.07$ , 19% reduction).

*End of Shift.* Maximum one second sustained EMG amplitudes were significantly reduced with the exoskeleton for the anterior deltoid ( $p = 0.05$ , 31% reduction) and approached significance for the biceps brachii ( $p = 0.08$ , 25% reduction). Maximum one minute distributed EMG amplitudes were significantly reduced with the exoskeleton for the biceps brachii ( $p = 0.03$ , 39% reduction), while approaching significance for the anterior deltoid ( $p = 0.07$ , 28% reduction). Though non-significant, maximum one minute distributed EMG amplitudes with the exoskeleton showed a 28% reduction for the upper trapezius and a 30% reduction for the erector spinae.

Across EMG amplitude measures, the exoskeleton provided the most benefit for the anterior deltoid and biceps brachii. For these two muscles, EMG amplitudes were all significantly reduced or approaching significance with the exoskeleton, along with percent reductions that ranged from 18-39%. The anterior deltoid's primary functions are shoulder flexion and abduction, which were directly assisted by the exoskeleton. While the biceps brachii plays a

secondary role in shoulder movements, the exoskeleton benefits are likely due to increased upper arm stability to indirectly benefit elbow flexion.

One concern with the exoskeleton's design to transfer loads from the shoulder to the pelvis/hip was that muscles of the lower back would have increased muscle activity. However, the EMG amplitudes for the erector spinae with the exoskeleton were reduced 7-30% across measures and even approached a significant reduction for overall maximum one minute distributed EMG amplitude. One potential explanation is that reduced fatigue in the anterior deltoid and biceps brachii helped prevent the worker from using anterior trunk lean as a compensation. Another potential explanation is that the exoskeleton frame promoted a more upright posture.

In summary, the exoskeleton appeared to provide benefits across the muscles tested, although additional participants would allow for further generalization. If we use a 40% strength guideline for repetitive loads, then the anterior deltoid one minute distributed EMG amplitude at the end of shift approaches this value without the exoskeleton (36 %MVIC), while the exoskeleton provides a larger margin of safety (26 %MVIC). Shoulder-supporting exoskeleton usage is most likely to benefit job tasks that involve repetitive overhead movements that challenge the anterior deltoid muscles.

# SPATIAL DEPENDENCY OF SHOULDER MUSCLE DEMAND DURING DYNAMIC UNIMANUAL PUSHING AND PULLING

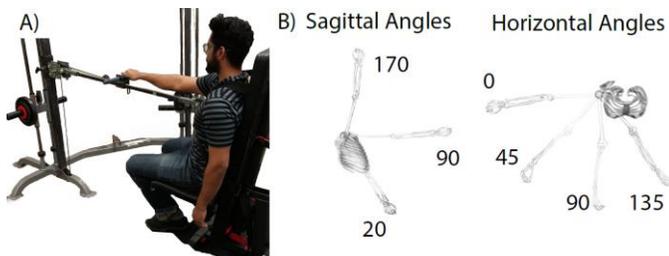

Daniel C. McFarland, Michael N. Poppo, Emily M. McCain, and Katherine R. Saul  
North Carolina State University, Raleigh, NC, USA  
email: dcmcfarl@ncsu.edu

## INTRODUCTION

Work-related musculoskeletal disorders (MSD) place a large burden on the economy and workers' health; MSD are the leading cause of work disability and lost productivity [1]. Shoulder MSD worker compensation claims result in the second highest total cost of MSD claims by body region [2], and push-pull tasks, in particular, are significantly related to shoulder complaints [3]. To effectively design workplaces to minimize work-related shoulder MSD, knowledge of the demands placed on shoulder muscles during these tasks is needed; however, little is known regarding shoulder loading during dynamic push-pull tasks [4]. Prior studies on pushing and pulling focused on dynamic full-body tasks (such as cart pushing) and isometric seated tasks [5,6]. Loading under these conditions cannot be directly applied to seated dynamic tasks since EMG and force exertion under dynamic conditions frequently differ from those recorded isometrically [7,8] and foot placement influences pushing force [9]. Therefore, our goal was to quantify how muscle demand, a measure of the overall load placed on the muscular system, varies with task target and task direction.

## METHODS

A series of seated unimanual push and pull tasks were performed by 13 healthy young adults 19 to 32 years old (Fig. 1A).

**Figure 1:** A) Subjects pushed/pulled 15% of their isometric max B) Sagittal and horizontal angles

Tasks were performed at a combination of 3 sagittal angles (20°, 90°, 170°) and 4 horizontal angles (0°, 45°, 90°, and 135°) for a total of 12 task targets (Fig. 1B). Electromyographic (EMG) recordings of the anterior, middle, and posterior deltoid, biceps brachii, lateral head of triceps brachii, latissimus dorsi, pectoralis major, and serratus anterior were collected at 2000 Hz. Raw EMG data was post-processed by removing the DC offset, bandpass filtering with cutoff frequencies of 20 and 300 Hz, full-wave rectifying, RMS filtering with a 200 msec window, and normalizing to peak value recorded during the testing protocol.

Muscle demand for each task was calculated as an average of each participant's weighted total of normalized EMG output [10]. Physiological cross-sectional areas (PCSA) from the literature were used to determine weightings for each muscle [11,12,13].

$$\sum_{i=1}^8 Norm\_EMG_i \left[ \frac{PCSA_i}{\sum_{i=1}^8 PCSA_i} \right]$$

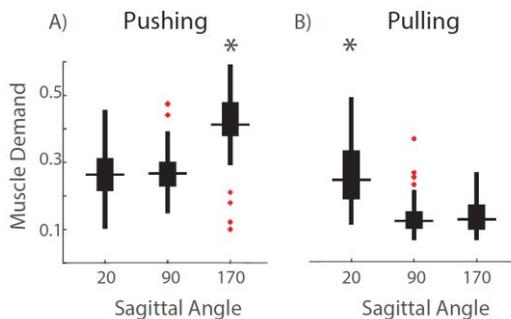

Differences in muscle demand were analyzed across sagittal and horizontal task targets using a two-way ANOVA ( $\alpha < 0.05$ ) and Tukey's HSD post-hoc test. Influence of task direction (push or pull) on muscle demand was analyzed with a one-way ANOVA ( $\alpha < 0.05$ ).

## RESULTS AND DISCUSSION

Sagittal target location influenced muscle demand for both pushing ( $p < 0.0001$ ) and pulling ( $p < 0.0001$ ). For pushing, sagittal angle of 170° resulted in a significant increase ( $p < 0.0001$ ) in muscle demand from both angles 20° and 90° (Fig. 2A). For pulling, sagittal angle of 20° resulted in a significant increase ( $p < 0.0001$ ) in muscle demand from both angles 90° and 170° (Fig. 2B). There was no difference in muscle demand among horizontal targets for either task direction.

Dynamic pushing resulted in higher muscle demand than pulling ( $p < 0.0001$ ). Mean muscle demand for pushing was  $0.3144 \pm 0.1072$  whereas mean muscle demand for pulling was  $0.1780 \pm 0.0937$ . Pushing was nearly twice as demanding as pulling, which may make it more likely to cause fatigue and lead to MSD.

Studies of isometric push-pull exertions have reported an increase in total muscle activity – i.e., the summation of EMG levels of the recorded muscles – for more elevated targets for both pushing and pulling [6, 10]. However, in this dynamic study the lowest sagittal target is associated with the largest muscle demand for pulling. One potential reason for this difference is that during a dynamic pull from a low target, subjects must elevate the handle against gravity whereas during a pull from a high target subjects lower the handle. Working against gravity during the pull from the lowest target likely makes this task more demanding. In contrast, subjects in the isometric study maintained the limb posture for the duration of the contraction, and it is well documented that maintaining elevated postures is a risk for fatigue and MSD [6].

**Figure 2:** Muscle demand during A) pushing and B) pulling to sagittal targets.

Isometric pushing and pulling have been reported to have increased total muscular activity for lateral targets [6], whereas horizontal targets in the dynamic tasks did not influence muscle demand. For the dynamic tasks in this study, pushing/pulling was defined as away from/towards the torso; however, in the prior isometric study, pushing/pulling were always in the anterior and posterior directions. This difference in task definition likely alters limb posture more dramatically among the isometric tasks, and thereby varies muscle demand more markedly across horizontal targets.

Workspaces can be designed based on results from this study to reduce worker fatigue and prevent MSD; however, study limitations should be taken in consideration when interpreting these results. Limitations include potential subject fatigue during testing or asymptomatic injuries. To reduce the effects of fatigue, rest allowances were provided between tasks, and task order was randomized.

## CONCLUSIONS

The primary findings have possible implications for arm function through the workspace:

1. Dynamic pushing and pulling tasks have different muscle demand and workspace location dependence compared to isometric tasks. Thus, care should be used when generalizing from isometric to dynamic tasks for workplace design.
2. Elevating the limb during dynamic pushing and pulling results in increased muscle demand. Thus, workspace design should avoid pushing and pulling tasks that result in motion against gravity. Horizontal target location of the task, however, appears to have reduced influence on muscle demand, and is thus a less important constraint. Priority should be given to locating push tasks at low demand locations since pushing is more demanding than pulling.

# SUBMAXIMAL NORMALIZING METHODS TO EVALUATE LOAD SHARING CHANGES IN REPETITIVE UPPER EXTREMITY WORK

Alison C. McDonald, Daanish M. Mulla, Peter J. Keir

Department of Kinesiology, McMaster University, Hamilton ON, Canada, L8S 4K1

Email: mcdonaac@mcmaster.ca

## INTRODUCTION

The anatomy of the shoulder allows multiple load distribution strategies between muscles thus load-sharing adaptations to fatigue are expected. The relationship between EMG and muscle force changes with muscle fatigue, making the interpretation of load sharing relationships between muscles challenging when workers are exposed to repetitive demands (McDonald et al, 2015; Tse et al, 2015). Two common methods for normalization include using a maximum voluntary exertion (MVE) or a submaximal reference exertion (RVE); the latter may be better suited to estimate sub-maximal loads (Jonsson, 1982). The purpose of this investigation was to evaluate the efficacy of normalizing EMG data to repeated, static, submaximal exertions to mitigate the fatigue artifact in EMG amplitude, to better reflect load sharing.

## METHODS

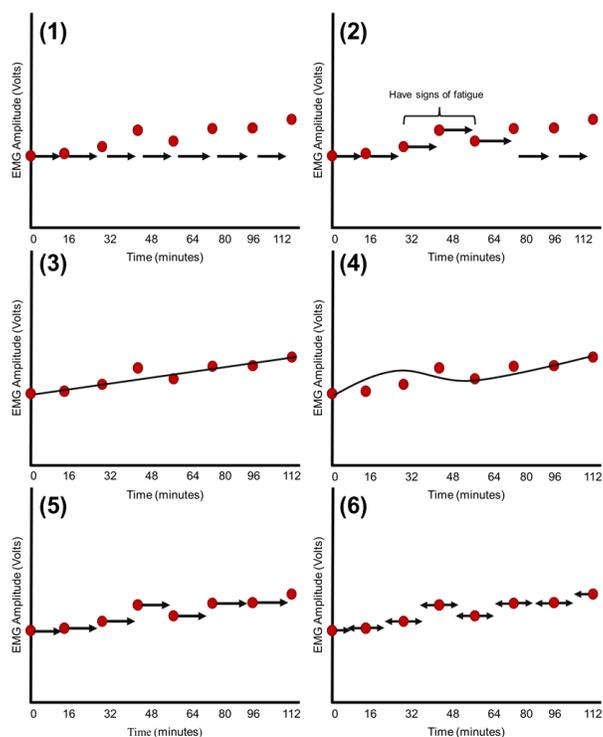

Twenty right hand dominant men completed repetitive simulated work tasks, in 60-second work cycles, until exhaustion. Surface EMG (Trigno, Delsys Inc., Natick, MA, USA) was recorded from 11 muscles for a complete work cycle every 3 minutes. Every 12 minutes, participants completed a series of 4 submaximal (30% MVC) and 1 maximal reference exertions. The series of four reference exertions were selected to activate all of the included muscles (Boettcher et al, 2008). Submaximal forces were recorded with a force transducer (Mark-10, Copiague NY) and a manual goniometer confirmed each posture. EMG data were recorded for 3 seconds after achieving the target force. This cycle continued until one of the termination criteria was met: 1) participant declared they could no longer continue, 2) participant was no longer able to complete the work tasks, 3) participant was no longer able to

maintain the 30% MVC force level for any of the 4 reference exertions.

Fatigue was defined as an 8% or greater decrease in median power frequency between reference exertions. Linear envelope EMG was used for the amplitude analysis (2<sup>nd</sup> order, dual-pass BW filter,  $f_c = 4$  Hz). Reference contraction EMG data were used in 6 normalizing methods including a *Standard Normalizing Method (SNM)* (normalized to initial reference exertion) and 5 novel methods (Figure 1).

EMG from one of the work tasks (drill task) was used to evaluate the methods. The novel methods included: (i) *Fatigue Only (FON)*: When myoelectric fatigue was present, the following 12 work cycles were normalized to that reference exertion. All muscles/work cycles not exhibiting signs of fatigue were normalized to the initial reference exertion. (ii) *Linear (LMN)* and (iii) *Cubic (CMN) Models*: A least squares regression model was used to create linear and cubic functions to predict the submaximal EMG amplitude for every third minute. The predicted value was then used to normalize the corresponding work task EMG. (iv) *Points Forward (PFN)*: Each reference exertion was used to normalize the 12 work cycles completed after it. (v) *Points Forward/Backward (PFBN)*: Each reference exertion was used to normalize the 6 work cycles completed before it and the 6 work cycles completed after it.

Random slope, random intercept mixed effects models were used to identify differences between participants and between the normalization methods. All novel methods were compared to the *Standard Normalizing Method*. Pearson product moment correlations assessed how well the predicted points from the linear and cubic normalization models fit the reference exertion data.

**Figure 1:** Schematic representation of the 6 normalizing methods (1) SN, (2) FON, (3) LMN, (4) CMN, (5) PFN, (6) PRFN. Circles represent mean EMG data during from reference exertions and the black arrows/lines depict which time points are normalized to each reference exertion.

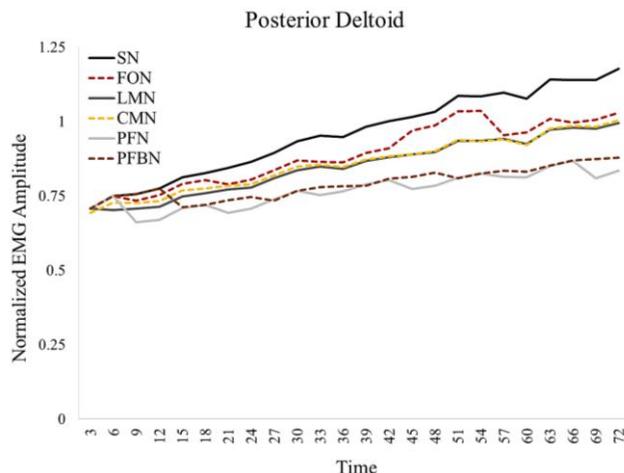

## RESULTS AND DISCUSSION

Participants performed the work cycles for 57-240 minutes, completing between 5-20 sets of reference exertions. The muscles that displayed signs of myoelectric fatigue and the time points where fatigue appeared differed between participants. Shoulder flexion strength decreased from  $108.8 \pm 24.0$  N to  $77.6 \pm 28.6$  N.

The significant differences between the novel methods and the SN method were dependent on the muscle and the number of time points in the analysis. Statistically significant changes were consistent between the FO method and LMN and CMN methods ( $p < 0.05$ ). The amplitude of posterior deltoid muscle was significantly lower when normalized to these 3 methods than when normalized to the standard method (Figure 2). There were more muscles with significant

differences from the SN method with the PFN and PFBN methods.

Correlation analysis showed that the predicted cubic model points correlated better to the actual data points than the linear predicted values.

**Figure 2:** Adjusted predictions of the 6 normalization methods with 95% confidence interval for the posterior deltoid muscle.

## CONCLUSIONS

The purpose of this analysis was to develop a method to reduce fatigue artifacts in EMG data, thus results of the PFN, PFBN and FON methods are of interest. These methods are dependent on the local reference data and subject to any variability/fluctuations in these data. The cubic and linear model methods produced results that are consistent with the fatigue only normalizing method, however may be less susceptible to small local fluctuations. Based on the correlation findings, we believe that the Cubic Model Normalizing method has promise as a novel method to mitigate the effects of muscle fatigue on EMG amplitude and improve our understanding of load sharing changes with repetitive work.

# SHOULDER MUSCULATURE ACTIVATION DURING HUMAN BRACHIATION

<sup>1</sup> Kathleen F.E. MacLean, and <sup>1</sup> Clark R. Dickerson

<sup>1</sup> University of Waterloo, Waterloo, ON, Canada  
email: k4maclea@uwaterloo.ca, web: uwaterloo.ca/diesel

## INTRODUCTION

The human shoulder is highly mobile and is adapted for many different non-locomotor behaviors. Though likely evolving from a weight-bearing locomotor past, the modern human shoulder has reduced power and force capabilities, and is less adapted for overhead postures than its nearest primate relatives [1]. Thus, the modern human shoulder is susceptible to damage in high-load and overhead postures despite an evolutionary history possibly derived from arboreal locomotion [2].

The modern human capacity for and adaptation to climbing behaviors, including brachiation, is unknown. Studying possible ancestral upper extremity behaviors like climbing are of anthropological and biomechanical interest. The purpose of this study was to examine the activation patterns of the shoulder musculature in experienced and inexperienced climbers while performing an overhead brachiation task.

## METHODS

Thirty young adults were recruited, 15 climbers (12M/3F; age 25[3.6] stature 1.71[0.08] m; body weight 66.9[9.0] kg) and 15 non-climbers (12M/3F; 24[2.9]; 1.75[0.07] m; 74.7[12.1] kg). All climbers had > two years of climbing experience and partook in climbing activities at least every two weeks.

Each participant completed a brachiation task across a series of eight horizontally aligned rungs spaced 40cm apart, raised approximately 2.2m off the floor (Figure 1). Six separate brachiation trials were completed. For each trial, right-side EMG (Noraxon, 2 USA Inc., Arizona, USA) was collected for two complete right arm swings, from initial right-arm contact with a rung to subsequent right-arm contact with the next rung, for a total 12

collected brachiation trials. Surface electromyographic (EMG) electrodes were placed over 12 upper extremity muscles: anterior and posterior deltoid, pectoralis major sternal and clavicular head, supraspinatus, infraspinatus, upper and middle trapezius, latissimus dorsi, serratus anterior, biceps brachii and triceps.

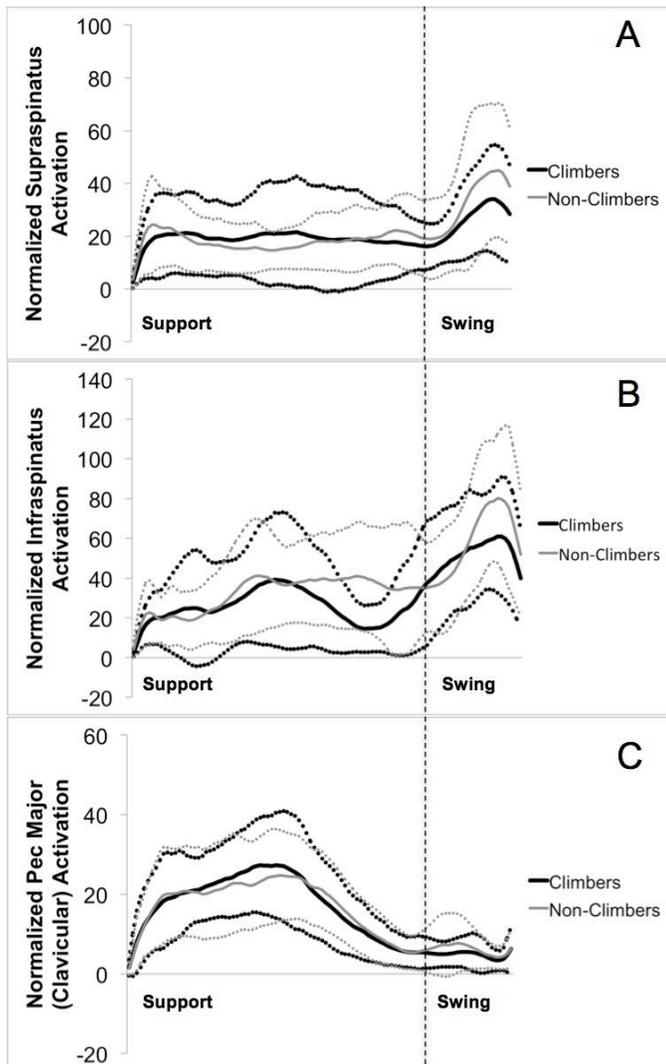

**Figure 1:** Experimental climbing setup

EMG was full-wave rectified, high pass filtered at 30Hz, and linear enveloped at 4Hz. EMG was amplitude normalized to muscle specific maximum voluntary exertions (MVE), and time normalized from right arm rung contact (initiating a double arm support phase) to subsequent right arm rung contact (following a right –arm swing phase). Brachiation trials were averaged within participants to obtain a mean representative trial, from which peak and average EMG was extrapolated. Between group comparisons were completed using a one-way ANOVA for each muscle at  $p < 0.05$ .

## RESULTS AND DISCUSSION

No significant differences were found between the climbing and the non-climbing participant group in peak or average EMG for any of 12 muscles measured. Both participant groups had similar

waveform shapes and activation amplitudes in all muscles (Figure 2). No muscle had an average EMG of less than 15% MVE. Four muscles had an average EMG of greater than 30% of MVE: infraspinatus, biceps brachii, serratus anterior and pectoralis major sternal. Peak EMG for all muscles ranged from 30% MVE to over 100% MVE for serratus anterior and pectoralis major sternal.

**Figure 2:** Muscle waveforms for right-arm support phase and swing phase of the climb task. Dotted lines represent one standard deviation

The muscle specific waveforms demonstrated the activation pattern of each muscle, giving insight into the role of each of the 12 muscles during the phases of brachiation. Three are shown in Figure 2. Supraspinatus was active throughout, with increased activity in swing to maintain humeral elevation

(Figure 2A). Infraspinatus controlled rotation of the right humerus during the swing phases of both arms, where increases in activation occurred (Figure 2B). Both infraspinatus and supraspinatus also performed the role of stabilizing the position of the humeral head in the glenoid during brachiation [3]. The role of the pectoralis major (clavicular) was isolated to mostly the support phase to stabilize the glenohumeral joint under the high load of full body mass (Figure 2C). It had limited contribution to swing as the unloaded, upward accelerations of the arm likely required the use of other shoulder muscles such as the deltoids.

There was large variability in both participant groups in all muscles, suggesting highly different activation levels and strategies between participants. Most of the shoulder musculature is multifunctional, allowing differences in activation to be compensated for with numerous other synergistic muscles. As no unique muscular activation pattern arose to distinguish participant groups, experience does not appear to be a contributing factor in multifunctional muscular recruitment at the shoulder for a climbing task. Unlike other primates, the non-locomotor, multifunctional evolution of the human upper extremity developed muscular redundancies that may deter the adoption of predictable and efficient biomechanical patterns in brachiation [4].

## CONCLUSIONS

Time normalized muscle waveforms discretized the roles of individual shoulder muscles throughout the support and swing phases of a brachiation task of biomechanical and anthropological significance. Highly variable muscular recruitment strategies were employed in both participant groups, suggesting divergent methods for brachiation independent of climbing experience.

## INTRODUCTION

Biplane three-dimensional to two-dimensional (3D-2D) registration approaches have been used recently for measuring 3D *in vivo* glenohumeral joint kinematics [1]. In this approach, computed tomography (CT) has become the gold standard for reconstruction of 3D bone models, with high geometric accuracy. One possible alternative, which would not expose subjects to radiation, is magnetic resonance imaging (MRI). However, MRI provides lower bone contrast compared to the CT.

In this study we compared the relative glenohumeral kinematic accuracy of CT-based registration and MRI-based registration with radiostereometric analysis (RSA; gold standard) during dynamic biplanar fluoroscopy to determine if MRI-based registration provides sufficient accuracy for measurements of clinically relevant angular bone and joint parameters.

## METHODS

**Image acquisition.** Two male fresh-frozen cadaveric torsos (age: 72, and 62 yrs.), were imaged with 1.6 mm diameter tantalum beads implanted into the humerus and scapula of the shoulders (three shoulders were analyzed due to technical difficulties with MR imaging of the 4<sup>th</sup> shoulder). The cadaveric torsos were fixed to a custom apparatus that allowed unconstrained motion of the shoulder complex.

A custom biplane fluoroscope was used for all 2D dynamic imaging (consisting of two 65 kW pulsed x-ray generators and two 16 inch image intensifiers, optically coupled to synchronized high-speed video cameras). A custom calibration cube was imaged using the fluoroscopic setup to define the orientation of the x-ray sources and detectors.

Biplane radiographic images of the shoulder were acquired at 60 frames/s (85 kV, 200 mA, 3 ms), while

passively moving the humerus through two simulated motions using a pulley system: frontal-plane elevation and internal/external (IE) rotation.

Prior to the bead implantation, MRI shoulder scans were acquired on a 3T scanner using a VIBE sequence, (Siemens Prisma\_fit; Forchheim, Germany; voxel size: 0.89×0.89×0.9 mm), developed for scanning bones to produce 3D models with high geometric accuracy.

Following tantalum bead implantation in each bone of interest, CT imaging was acquired on a clinical CT scanner (Siemens Somatom Sensation 64; Forchheim, Germany; kVp: 140; voxel size: 0.48×0.48×0.6 mm) to obtain the CT-based 3D bone models and 3D positions of the beads relative to the bone coordinate systems.

**Image analysis.** 3D models of the humerus and scapula were manually segmented from reconstructed CT and MRI images (Mimics; Materialise, Plymouth, Michigan). Coordinate systems were computed for CT-based bone models using ISB anatomical reference frames [2]. To find 3D positions of the beads relative to the MRI-based bone models, the MRI-based surface models were aligned to the CT-based surface models using CloudCompare v2.6.3, retrieved from <http://www.cloudcompare.org/>. First, the 3D models were brought into gross alignment using at least four equivalent landmark pairs. Then, the fine alignment function was applied, which is based on the iterative closest point algorithm (ICP) [3].

To quantify bone rotations and translations, the 3D-2D intensity-based image registration was performed using open-source software (Autoscooper, Brown University, RI, USA) [4]. Using this software, a pair of digitally reconstructed radiographs (DRRs), constructed from the 3D bone models, was manually

matched to each set of two 2D calibrated and undistorted fluoroscopy images (Fig.1). This technique benefits from the bone density information within the bone models rather than using purely external edges. In order to prevent the influence of the implanted beads on image registration, traces of the beads were removed from the CT images manually.

The 3D positions of the beads were tracked from the biplane fluoroscopy images using freely available software (XMA Lab; Brown University) [5]. An independent phantom study, in our lab, has shown this RSA approach to be accurate to within  $\pm 0.2$  mm and  $\pm 0.2^\circ$ .

**Comparison analysis.** We evaluated the accuracy of the 3D-2D registration by computing the root-mean-squared (RMS) error between the 3D-2D registration results and the RSA analysis, for each of six poses of the humerus and scapula across the three shoulders.

## RESULTS AND DISCUSSION

With the CT models, overall RMS errors were 0.6 mm (Max ABS error: 2.3 mm) for all translations, and  $1.1^\circ$  (Max ABS err:  $3.0^\circ$ ) for all rotations for the humerus; and were 0.8 mm (Max ABS error: 2.4 mm) for all translations, and  $0.7^\circ$  (Max ABS err:  $2.0^\circ$ ) for all rotations, for the scapula.

With the MRI models, overall RMS errors for all humerus were 1.6 mm (Max ABS error: 3.9 mm) for all translations, and  $1.8^\circ$  (Max ABS error:  $5.1^\circ$ ) for all rotations; and for scapula, 1.3 mm (Max ABS err: 3.5 mm) for all translations, and  $1.2^\circ$  (Max ABS error:  $3.1^\circ$ ) for all rotations. Detailed results are shown in Table 1.

## CONCLUSIONS

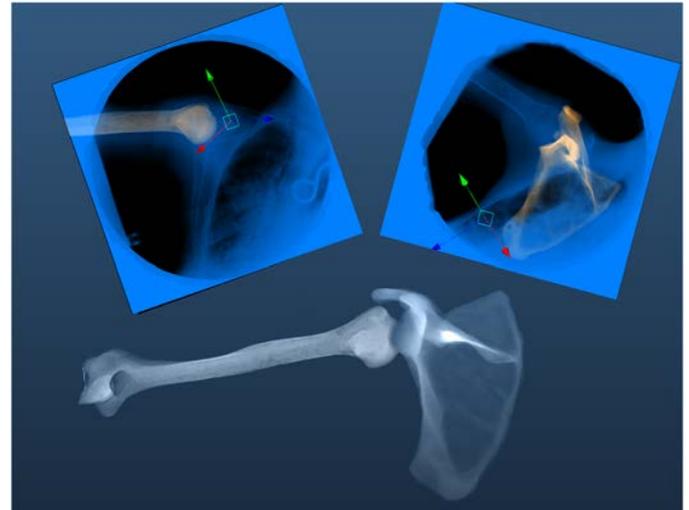

Our results show that, measurement performance with CT-derived bone models was descriptively

superior to measurements performed with MRI-derived models, as we expected. However, our MRI-based registration accuracy indicates that the overall RMS errors were less than 1.6 mm and  $1.8^\circ$  for the humerus and less than 1.3 mm and  $1.2^\circ$  for the scapula, which is an acceptable accuracy for many clinical research questions.

Measuring 3D *in vivo* glenohumeral joint kinematics accurately is important, as it allows for quantification of small changes in clinically relevant parameters.

## INTRODUCTION

Following a mastectomy, ~70% of breast cancer patients elect to undergo breast reconstruction surgery to replace tissue volume and restore the appearance and feel of natural breast tissue [1]. Implant-based reconstruction has increased in popularity in recent years [2]. The “implant only” technique removes the inferior and medial attachments of the pectoralis major. A tissue expander is placed under the muscle, which is slowly inflated overall several months to stretch the muscle in order to accommodate an implant. In women who undergo radiation therapy, expansion of the pectoralis major is associated with increased reconstruction rates. For these patients, an alternative “lat flap” procedure is performed by removing the medial and inferior attachments of the latissimus dorsi and bringing it from the back into the chest. The implant is then placed between the latissimus dorsi and pectoralis major. Both techniques are associated with functional deficits of the upper extremity, including poorer patient-reported outcomes and reduced strength and range of motion [3]. However, it is unknown how these techniques affect shoulder joint stiffness, a measure that provides insight into a patient’s ability to control her arm during activities of daily living [4]. The present project aims to characterize changes in multidimensional shoulder stiffness following reconstructions utilizing the pectoralis major or latissimus dorsi.

## METHODS

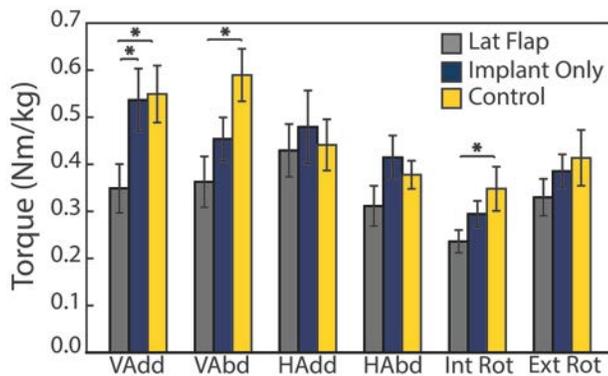

Six “implant-only” and seven “lat flap” female patients at least 18 months post-reconstructive surgery were recruited for this study (Table 1). Four lumpectomy patients whose tumors were surgically removed with the remaining breast intact served as controls. Participants were placed in a removable cast with their elbow flexed 90°, and their shoulder elevated 90° (Figure 1). The cast was attached to the crank arm of a single axis rotary motor with a high-precision encoder and six-degree of freedom load

**Figure 1:** A single axis rotary motor perturbed the shoulder in either the vertical (A) or horizontal (B) directions. Visual feedback assisted subjects in matching desired torque.

cell. This motor was centered on the glenohumeral joint and controlled in real time using MATLAB xPC Target (2011a). Strength was measured prior to data collection by performing maximum voluntary contractions (MVC) in vertical add/abduction, horizontal add/abduction, and internal/external rotation.

Subjects were perturbed with small, stochastic perturbations (0.06 rad) for 60 second trials in one of two planes of motion (vertical or horizontal ad/abduction). Lumpectomy controls were only examined in the vertical direction. Resultant shoulder torques were measured as participants were asked to stay relaxed or to maintain a net torque level scaled to  $\pm 10\%$  of their MVC in each perturbation direction. Joint impedance, the dynamic relationship describing the torque response to an imposed change in joint angle, was estimated for each trial using a frequency response function [5]. These estimates were fitted with a 2<sup>nd</sup> order linear model to approximate the inertial, viscous, and stiffness properties of the joint. Two trials were performed in each of the six testing conditions and two perturbation directions, yielding 12 total trials. Between group stiffness comparisons were analyzed with a linear mixed model. T-tests were used to analyze between group strength and within group stiffness data. Bonferroni corrected multiple comparisons were utilized when appropriate. All significances are reported at  $\alpha = 0.05$ .

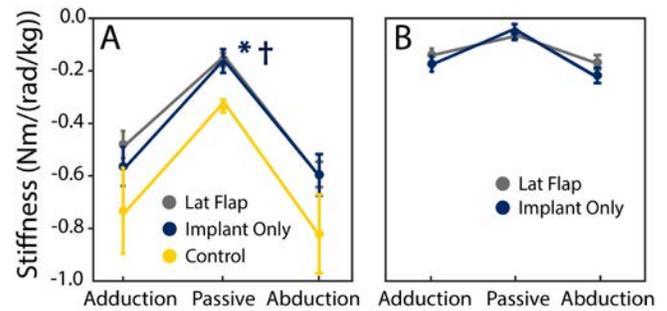

**Figure 2:** Mean maximal shoulder strength in six directions for breast reconstructive surgery patients compared to lumpectomy controls. Error bars represent SE. \* -  $p < 0.05$

## RESULTS AND DISCUSSION

Several significant differences in shoulder strength existed between the experimental groups (Figure 2). The lat flap group exhibited lower maximal vertical adduction torques than both the implant only ( $p = 0.04$ ) and lumpectomy control groups ( $p = 0.04$ ). The lat flap group also exhibited lower vertical abduction ( $p = 0.02$ ) and internal rotation torques ( $p = 0.05$ ) when compared to the control group.

Within the lat flap and implant only groups, passive stiffness was greater in the vertical direction than in the horizontal direction (implant only:  $p = 0.01$ , lat flap:  $p = 0.002$ ). No significant differences were observed within the groups for active stiffnesses, except between vertical adduction and abduction stiffness in the lat flap group ( $p = 0.05$ ).

There was a significant group main effect for passive vertical stiffness ( $p = 0.014$ ). Both lat flap ( $p = 0.041$ ) and implant only groups ( $p = 0.01$ ) exhibited lower passive vertical stiffness when compared to the control group (Figure 3). There were no significant group main effects for active vertical abduction or adduction stiffnesses. In the horizontal direction, there were no significant differences between the implant only and the lat flap group for the passive condition or active horizontal adduction. The lat flap group trended towards a significantly reduced active horizontal abduction stiffness ( $p = 0.064$ ).

**Figure 3:** Passive and active shoulder stiffness for breast reconstructive surgery patients compared to controls when the shoulder is perturbed in the vertical (A) or horizontal (B) direction. Error bars represent SE. \*, † -  $p < 0.05$ .

Implant-based breast reconstructions significantly affects the passive integrity of the shoulder joint, which may make the joint more prone to future injury. The “lat flap” patients presented additional morbidity relative to the “implant only” patients given their reductions in vertical add/abduction and internal rotation strength. No significant changes in active shoulder stiffness were found when normalized to each patient’s strength. This suggests that other shoulder muscles may compensate for lost function from the pectoralis major or latissimus dorsi. Future studies need to longitudinally examine pre- and post-operative passive and active shoulder stiffness to better appreciate how each reconstruction surgery impacts a given breast cancer patient.

## CONCLUSIONS

Implant-based breast reconstructions negatively reduced the passive integrity of the shoulder joint.

## INTRODUCTION

Soft exosuits and rigid exoskeletons, two types of wearable assistive devices, have demonstrated the potential to improve mobility outcomes for individuals with disabilities, and to augment healthy human performance [1]. However, transmitting power from an assistive device to the human body is challenging because biological tissues and interface materials deform and displace when forces are applied, absorbing power. Inefficient device-to-human power transmission undermines the performance benefits of wearable assistive devices. Experiments on a recent running exoskeleton found that about 50% of the mechanical power provided by the device was lost in transmission to the body [2]. Although the practical difficulties of physically coupling wearable devices to the human body are well-known, only a few studies have published objective data characterizing interface dynamics [3], due partly to the lack of methods to quickly estimate these quantities. The objective of this work is two-fold: first to present a novel methodology for quickly estimating interface power during dynamic tasks using common motion capture and force measurements, and second to apply this method to quantify how a soft robotic exosuit interacts with and transfers power to the human body during locomotion.

## METHODS

We performed a motion analysis study on one healthy male subject (age: 27) wearing a soft robotic ankle exosuit (Fig. 1), similar to [4], while collecting synchronous motion capture, motor encoder, load cell, and ground reaction force data. The subject walked on an instrumented treadmill at 1.5 m/s for 5 minutes while the exosuit generated

plantarflexion assistance about the ankle using a walking controller to apply peak cable force of up to 500 N. We then performed a new biomechanical analysis to quantify exosuit-to-human power transmission using force and motion data, which enabled us to parse augmentation power (powering ankle plantarflexion) vs. interface power (due to deformation and motion of interface materials and underlying soft tissues).

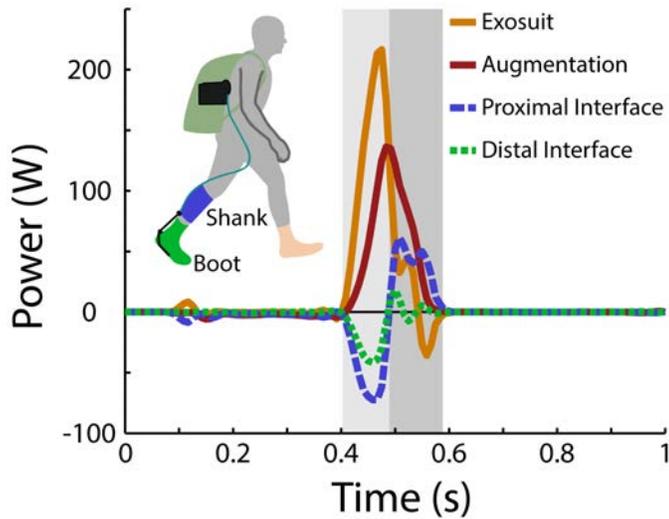

## RESULTS AND DISCUSSION

We found that interface dynamics complicate the transmission of power from wearable assistive devices to the human body, resulting in three key consequences (Fig. 1): (i) During exosuit loading (as applied forces increased), about 55% of exosuit end-effector power was absorbed into the interfaces. (ii) However, during subsequent exosuit unloading (as applied forces decreased) most of the absorbed interface power was returned viscoelastically. Consequently, the majority (about 75%) of exosuit end-effector work over each stride contributed to augmenting ankle plantarflexion. (iii) Ankle augmentation power (and work) was delayed relative to exosuit end-effector power, due to these interface energy absorption and return dynamics.

## CONCLUSIONS

Physical human-device interfaces can absorb and return substantial energy, complicating power transmission. In order to optimize the performance of wearable assistive devices and fully realize their human augmentation benefits, it is important to account for these human-device interface dynamics. Here we present a new method to quantify power transmission and isolate power contributions from human-device interfaces using common force and

motion measurements, which provides insight into how to improve the design and control of wearable assistive devices.

**Figure 1:** Human-exosuit interfaces absorb and return energy, reshaping exosuit to human power flow. Exosuit end-effector power (i.e., device output, orange line) contributes to motion/deformation of the proximal (shank, dashed blue line) and distal (boot, dashed green line) interfaces, and augments ankle plantarflexion (red line). Power is absorbed into interfaces during exosuit loading (as applied forces increase, light gray box), then returned during exosuit unloading (as applied forces decrease, dark gray box), contributing to ankle augmentation. Results are shown for a representative stride.

# HOPPING WITH A FULL-LEG EXOSKELETON LOWERS METABOLIC COST AND MUSCLE ACTIVITY

<sup>1</sup> Stephen P. Allen, and <sup>1,2</sup> Alena M. Grabowski

<sup>1</sup> University of Colorado Boulder, CO, USA; <sup>2</sup> VA Eastern Colorado Healthcare System, Denver, CO, USA

## INTRODUCTION

During hopping, leg muscles consume metabolic energy to support bodyweight and modulate leg stiffness [1]. Previous studies have shown that changes in leg stiffness are primarily achieved by adjusting ankle stiffness via the plantar flexor muscles during hopping [2]. Use of an in-parallel, springy, ankle-only exoskeleton reduces metabolic demand 18% and plantar flexor muscle activity 24% when compared to hopping without assistance but equivalent mass of the exoskeleton [3]. Moreover, the use of an exoskeleton acting in parallel to the entire leg with a non-linear stiffness profile, substantially reduces metabolic demand by 24% when compared to normal hopping [4].

The underlying reason for the metabolic reduction when hopping with the full-leg exoskeleton is not fully understood. Therefore, we determined how hopping with springs in parallel to each leg affects the metabolic cost and leg muscle activity during two-legged hopping. We also determined how hopping with weight equivalent to that of the exoskeleton affected metabolic cost and muscle activity. We hypothesized that while using the exoskeleton, subjects would decrease their metabolic demands and leg muscle activity compared to normal hopping and hopping without assistance but with added weight equal to that of the exoskeleton.

## METHODS

9 healthy recreational runners [4M, 5F; Avg(SD): 23(6) yrs; 64.3(6.8) kg] gave written informed consent. Subjects hopped in place on both feet at 2.2, 2.4, 2.6, 2.8, 3.0, and 3.2 Hz to the beat of a metronome during 4 experimental sessions. Each session was performed at the same time of day, and separated by at least 2 days to account for potential fatigue effects. During sessions 1-3, subjects hopped without an exoskeleton (NORM), with the exoskeleton (EXO), and without the exoskeleton but

with weight (WT) equal to that of the exoskeleton (57.9 N). All trials were 5 min, with at least 3 min rest between trials. We measured rates of oxygen consumption and carbon dioxide production (Cosmed K4b<sup>2</sup>, IT) throughout each trial, averaged rates for the last 2 min [4], and calculated net metabolic power (NMP) using a standard equation [5].

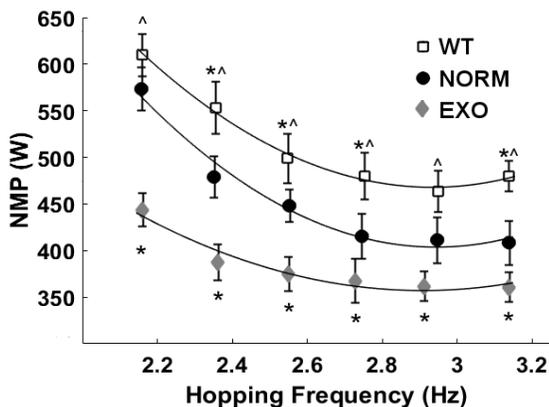

During session 4, subjects hopped for 1 min at all frequencies and conditions while we simultaneously collected vertical ground reaction forces (GRFs) (AMTI, Watertown, MA), and surface electromyography (EMG) from the soleus (SO), medial gastrocnemius (MG), lateral gastrocnemius (LG), and rectus femoris (RF) muscles of the right leg (Delsys, Boston, MA) at 1080 Hz.

We used a custom Matlab (Mathworks, Natick, MA) program to determine ground contact events using a 10N vertical GRF threshold and calculate muscle activity. Raw EMG data were bandpass filtered (10-499Hz), rectified, and root-mean-squared with a 50 ms moving window. We analyzed 15 consecutive hops from each trial. For each muscle, we normalized each trial to the maximum of the subject hopping at 2.2 Hz NORM. We calculated whole hop cycle integrals (iEMG) of the normalized EMG for each subject using trapezoidal integration. Onset/offset threshold was established using the average plus 3 standard deviations of clear periods of inactivity as determined by visual inspection [6]. We used a one-way ANOVA to test for significant differences between conditions at each hopping frequency, and performed post-hoc t-tests when applicable. Significance was set to  $p = 0.05$ .

## RESULTS AND DISCUSSION

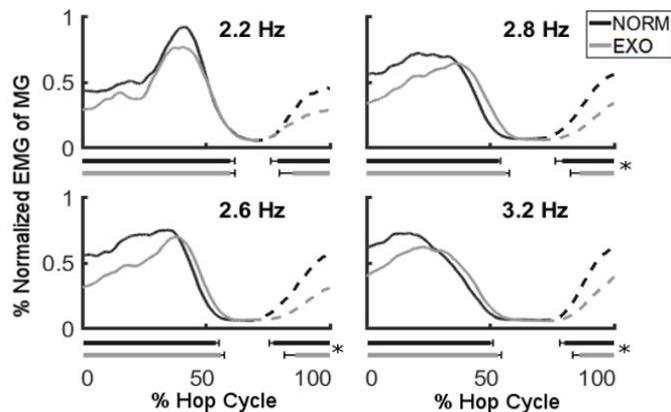

During EXO trials, average NMP decreased by 16% across all frequencies compared to NORM hopping. Whereas during WT trials average NMP increased

by 15% compared to NORM at 2.4 to 2.8, and 3.2 Hz (Fig 1).

**Figure 1.** Average ( $\pm$  SEM) net metabolic power (NMP) at average hopping frequencies. \*indicates significantly different from NORM ( $p < 0.05$ ). ^indicates significantly different from EXO ( $p < 0.001$ ).

During EXO trials, average MG iEMG decreased by 18% compared to NORM across all frequencies (Fig 2), and average LG iEMG decreased by 20% compared to NORM across 2.6 to 3.2 Hz. In general, MG and LG iEMG during the WT condition were not significantly different than NORM. However, there was one significant difference at 3.2 Hz, where LG iEMG was 11% lower than NORM. There were no significant changes in SO and RF iEMG between conditions.

**Figure 2.** Normalized MG EMG group ensemble. Horizontal bars represent average ( $\pm$  SEM) onset/offset timing. \*indicates significantly different onset timing from NORM ( $p < 0.05$ ).

During the EXO conditions, average MG onset timing occurred 9% later in the hop cycle compared to NORM across 2.6 to 3.2 Hz (Fig. 2) and average LG onset timing occurred 7% later in the hop cycle

compared to NORM across 2.8 to 3.2 Hz. Average MG and LG onset timing did not differ in the WT condition compared to NORM, except for 3.2 Hz when LG onset timing occurred 3% later in the gait cycle.

In accordance with previous results [4], we found that use of a full-leg, springy exoskeleton reduces NMP at multiple hopping frequencies compared to NORM, whereas the WT condition increased NMP compared to NORM. However, contrary to our hypothesis, only MG and LG had reduced iEMG during EXO hopping, which could explain the decrease of NMP in the EXO compared to NORM conditions. Previous work found reductions in SO iEMG with an ankle-only exoskeleton [3]; however, the full-leg exoskeleton had no significant effect on SO iEMG. Ensemble plots of the SO EMG depict a visible trend of a reduction within the stance phase of the EXO condition as compared to NORM, but this was not significant.

MG and LG are activated during the aerial phase prior to ground contact during all conditions. However, the EXO condition has a visibly reduced LG and MG EMG during the aerial phase that are not present in NORM or WT. In fact, there were no iEMG or timing differences between WT and NORM. It is likely that subjects may have altered body position, adopted different hopping strategies, or recruited other muscles not analyzed in this study for the WT condition. Further analysis is needed to understand the mechanism responsible for the increase in NMP while hopping with added weight.

## CONCLUSION

Using a full-leg, springy exoskeleton during hopping requires much less metabolic energy than normal hopping, which is likely due to reduced MG and LG muscle activity. In contrast, weighted hopping without an exoskeleton increases metabolic cost, but elicits no change in MG, LG or SO muscle activity.

## INTRODUCTION

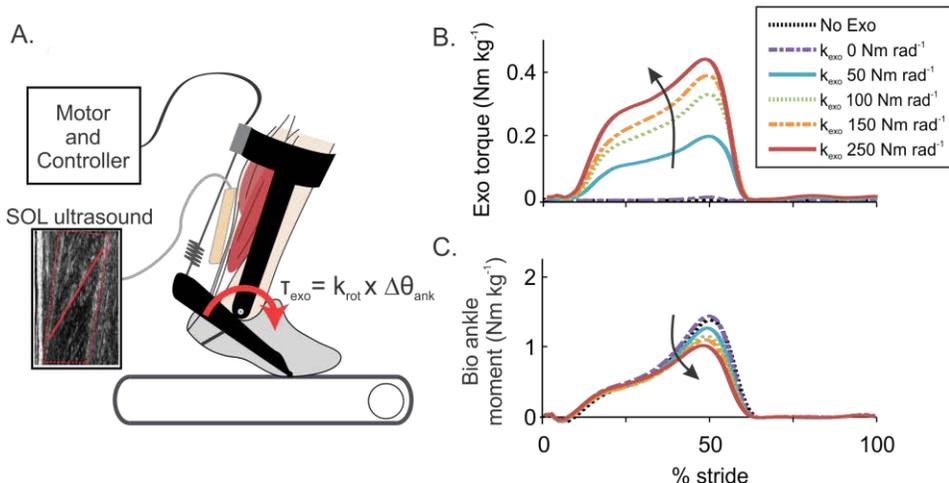

Biologically inspired robotic devices assisting the ankle joint have the potential to augment healthy locomotion [1] and restore impaired neuromuscular deficits as a result of age or disease [2]. Most efficacy studies focus at most on whole body and joint level dynamics, but to date we have a limited understanding of how these devices alter the underlying muscle-tendon behaviour in walking.

Previous work done in our lab has shown that at intermediate stiffnesses, passive ankle exoskeletons reduce the energetic cost of walking by up to 7% [1]. However, at stiffnesses below or above this optimal value metabolic demands are greater than unassisted walking. We theorize that these aforementioned changes in metabolic cost due to stiffness are directly linked to the underlying muscle-tendon dynamics [3]. In this study, we aimed to determine how elastic ankle exoskeletons affect joint mechanics and plantarflexor fascicle dynamics in relation to metabolic cost during human walking. We hypothesized that the stiffest ankle exoskeletons ‘de-tune’ muscle force-length behaviour and offset the benefits of decreased muscle force, leading to suboptimal improvements in metabolic cost. Specifically, we hypothesized that a reduction in the

plantarflexor force requirements would result in a compensatory increase in soleus fascicle lengths due to the decreased stretch of the series elastic element (Achilles tendon).

## METHODS

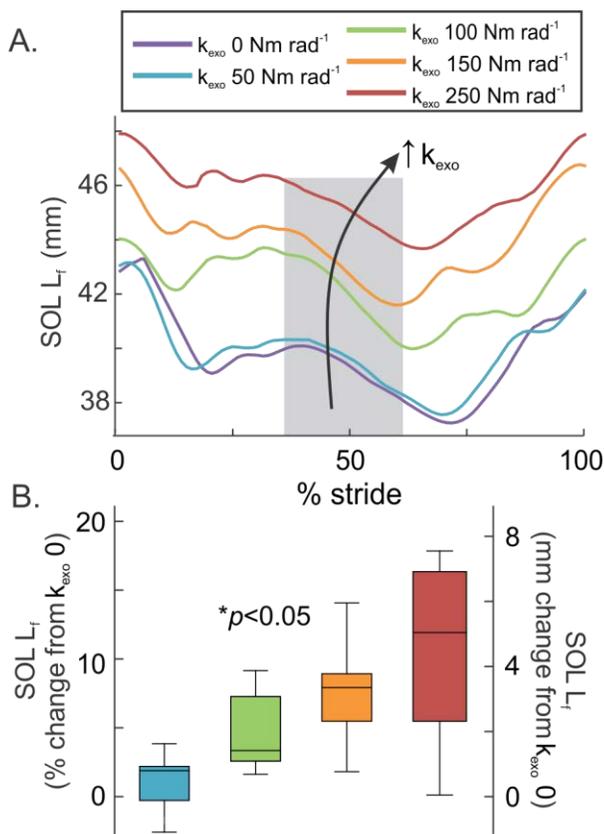

Eleven subjects (7M, 4F; mean: 27.5y; 74.2kg) completed the IRB approved protocol. We used an exoskeleton emulator to apply a range of ankle exoskeleton rotational stiffnesses ( $k_{\text{exo}}$ ) to the user (0, 50, 100, 150, 250  $\text{Nm rad}^{-1}$ ). The emulator provided torque from benchtop motors to bilateral ankle exoskeletons through a Bowden cable transmission while subjects walked on an instrumented treadmill at  $1.25 \text{ m s}^{-1}$  (Fig. 1A). A torque-angle relationship was imposed to emulate rotational stiffness at the ankle. Following an initial training day, we collected a comprehensive set of kinetic (Bertec), kinematic (Vicon), B-mode ultrasound (Telemed), EMG (Biometrics), and metabolic data (OxyCon Mobile). We performed inverse dynamics analysis (Visual3D) to determine joint moments. Soleus ultrasound images were analyzed [4] to determine time-varying fascicle lengths during walking at the five exoskeleton stiffnesses. We performed an ANOVA to test the effect of  $k_{\text{exo}}$  on soleus fascicle length during walking.

**Figure 1:** (A) Experimental setup. During exoskeleton assisted walking at five stiffnesses, we imaged soleus (SOL) fascicles using B-mode ultrasound. (B) Exoskeleton torque increased with spring stiffness ( $k_{\text{exo}}$ ). (C) Biological contributions to the ankle moment, averaged across the 11 subjects and normalized to body mass, decreased with increased exoskeleton stiffness.

## RESULTS AND DISCUSSION

Exoskeleton torque increased with exoskeleton stiffness ( $k_{exo}$ ) and resulted in a concomitant decrease in the biological ankle moment (Fig. 1 B/C). Compared to the no assistance condition ( $0 \text{ Nm rad}^{-1}$ ), the stiffest exoskeleton condition ( $250 \text{ Nm rad}^{-1}$ ) reduced the peak biological plantarflexion moment by 29%. Increases in  $k_{exo}$  were also accompanied by a reduction in ankle range of motion and therefore total muscle-tendon unit (MTU) length changes. Range of motion decreased from  $-17.7$  to  $15 \text{ deg.}$  at  $0 \text{ Nm rad}^{-1}$  to  $-7.3$  to  $14.3 \text{ deg}$  at  $250 \text{ Nm rad}^{-1}$  which translates to, on average, a 7 mm reduction in MTU length change at the highest stiffness.

**Figure 2:** Effect of varying  $k_{exo}$  on soleus (SOL) fascicle behaviour during exoskeleton assisted walking. (A) Time-varying fascicle lengths ( $L_f$ ) for 1 subject, averaged over 5 strides and normalized to the stride period, show increases in fascicle operating lengths with increases in exoskeleton stiffness ( $k_{exo}$ ). Shaded region depicts timing of peak MTU length during the gait cycle. (B) SOL fascicle length at peak MTU length in the  $k_{exo} = 0$  condition) are shown as box and whisker plots (median, interquartile range, range) for the 11 subjects.

Despite this reduced MTU length change, and in support of our hypothesis, we found an increase in SOL fascicle length with increasing  $k_{exo}$  (Fig 2A). SOL fascicle length (determined at peak MTU length) increased from 47.5 mm during the no assistance condition ( $0 \text{ Nm rad}^{-1}$ ) to 52 mm at the highest stiffness condition ( $250 \text{ Nm rad}^{-1}$ ) when averaged across 11 subjects (Fig. 2B). This translates to an average SOL fascicle length increase of 11% when the highest exoskeleton stiffness was applied (Fig. 2B).

We found greatest reduction in metabolic cost ( $-4.2\%$  compared to no assistance) at the  $50 \text{ Nm rad}^{-1}$  condition, which coincides with the condition where SOL fascicle lengths were most similar to unassisted walking (Fig 2A). This suggests that, in young healthy adults, small amounts of added stiffness provide some metabolic benefit, but high levels of stiffness likely interfere with the normally efficient and highly tuned plantarflexor muscle-tendon interaction.

## CONCLUSIONS

Our results are consistent with [1] but we now highlight the mechanistic links between disrupted muscle-tendon dynamics and whole body energetic costs during robotically-assisted locomotion. In conclusion, we have shown that exoskeletons which are too stiff shift fascicles towards unfavorable contractile conditions. This effectively ‘de-tunes’ the plantarflexors normal muscle-tendon mechanical behaviour and is a likely contributor to negating metabolic improvements.

# EFFECT OF SPEED ON THE MECHANICS AND ENERGETICS OF WALKING WITH AN ELASTIC ANKLE EXOSKELETON

Richard W. Nuckols, Gregory S. Sawicki

Joint Dept. of Biomedical Engineering, NCSU and UNC-Chapel Hill, Raleigh, NC, USA  
email: rwnuckol@ncsu.edu

## INTRODUCTION

Our previous research indicates that bilateral elastic ankle exoskeletons with intermediate stiffness springs placed in parallel with the human calf-Achilles' tendon complex reduce the metabolic demand during level walking at 1.25 m/s by 7% [1]. However, whether this same parallel stiffness is optimal at other walking speeds has yet to be determined. Previous work suggests that the quasi-stiffness of the ankle in able-bodied subjects increases with increasing walking speed [2], thus we theorized that optimal stiffness of assistive devices should scale with walking speed.

We hypothesized that 1.) an optimal ankle exoskeleton stiffness exists for each speed, where metabolic demand is reduced relative to no assistance and 2.) as walking speed increases the optimal stiffness should also increase.

## METHODS

We recruited eleven healthy, young adults (7M, 4F; mean:27.5y, 74.2kg) to complete the IRB approved protocol over a four-day testing period. Participants walked at three walking speeds (1.25, 1.5, 1.75 m/s) while we applied five ankle exoskeleton rotational stiffness conditions ( $k_{exo}$ =0, 50, 100, 150, 250 Nm/rad). We delivered mechanical assistance using a custom exoskeleton emulator consisting of bilateral ankle exoskeletons driven by a benchtop motor and transmission, using a control system that imposed a torque-angle relationship to emulate an elastic device providing rotational stiffness.

The order of the four testing days, the purpose, and measurements collected were:

1. Training – 95 minutes (Metabolic Demand)
2. Gait Mechanics (Inverse Dynamics, EMG, B-Mode Ultrasound of Soleus)
3. Steady State Metabolic Demand
4. Stiffness Sweep (Instantaneous Metabolic Demand)

We recorded kinematics using reflective markers (Vicon), muscle activity in the medial and lateral gastrocnemii, soleus, and tibialis anterior using surface EMG (Biometrics), soleus fascicle lengths using B-mode ultrasound (Telemed), and whole body metabolic power with indirect calorimetry (OxyCon Mobile).

We performed a mixed-model ANOVA with a first ( $k_{exo}$ ) and second order term ( $k_{exo}^2$ ) to determine the effect of exoskeleton stiffness on metabolic demand. We then ran a post-hoc pairwise t-tests at each speed to compare the condition that yielded the largest reduction in metabolic cost against the no assistance condition ( $p < 0.05$ ).

## RESULTS AND DISCUSSION

For all walking speeds, exoskeleton torque increased and biological ankle moment decreased with increasing exoskeleton stiffness (Fig 1A). Compared to the no assistance condition (0 Nm/rad), for the stiffest condition (250 Nm/rad) we observed a reduction in average (peak) biological moment of -11% (-29%) at 1.25 m/s, -9% (-22%) at 1.5m/s, and -8% (-22%) at 1.75 m/s. Interestingly, in early stance (0-40%) exoskeleton assistance enhanced total ankle moment while biological moment decreased only slightly. Conversely, in late stance (40-60%) the exoskeleton primarily offset the biological contribution and total ankle moment remained nearly constant or decreased slightly. These changes in ankle joint mechanics were accompanied by systematic decreases in soleus muscle activation across all exoskeleton conditions at all speeds (Fig 1B). At the stiffest condition, we observed on average across speeds a reduction of 17% in integrated soleus EMG during stance phase of walking.

Across speeds, we observed a decrease in relative exoskeleton contribution as walking speed increased. From the slowest to the fastest walking speed, peak

exoskeleton torque decreased by 20% at the highest stiffness despite a 12% increase in peak total ankle torque. This reduction in exoskeleton assistive torque is explained by a decrease in peak ankle dorsiflexion with increased walking speed, suggesting that efficacy of passive devices may be limited by natural ankle joint kinematics especially at fast walking speeds.

Exoskeletons reduced metabolic cost of walking only at the slowest (-4.2% at 1.25 m/s) and fastest (-4.7% at 1.75 m/s) walking speed, and the optimal stiffness did not increase with speed (50 Nm in each case) (Fig 1C). Surprisingly, for walking at 1.5 m/s, exoskeletons increased metabolic cost across all stiffness conditions.

## CONCLUSIONS

Currently we are analyzing ultrasound images of the soleus muscle captured for each stiffness and speed. These data may provide insight into how exoskeletons can disrupt ‘tuned’ ankle dynamics and counteract decreases in biological force and activations offsetting potential metabolic benefits. We are particularly interested in the changes in muscle mechanics at the intermediate speed where we were unable to achieve a reduction in metabolic demand.

The most compliant spring proved effective at both the slowest and fastest, but not the intermediate

walking speed. However, the exoskeleton did not respond to added demands of faster walking in a manner similar to that of biological plantarflexors. Counter to our hypothesis, the optimal elastic ankle exoskeleton spring stiffness did not increase with walking speed.

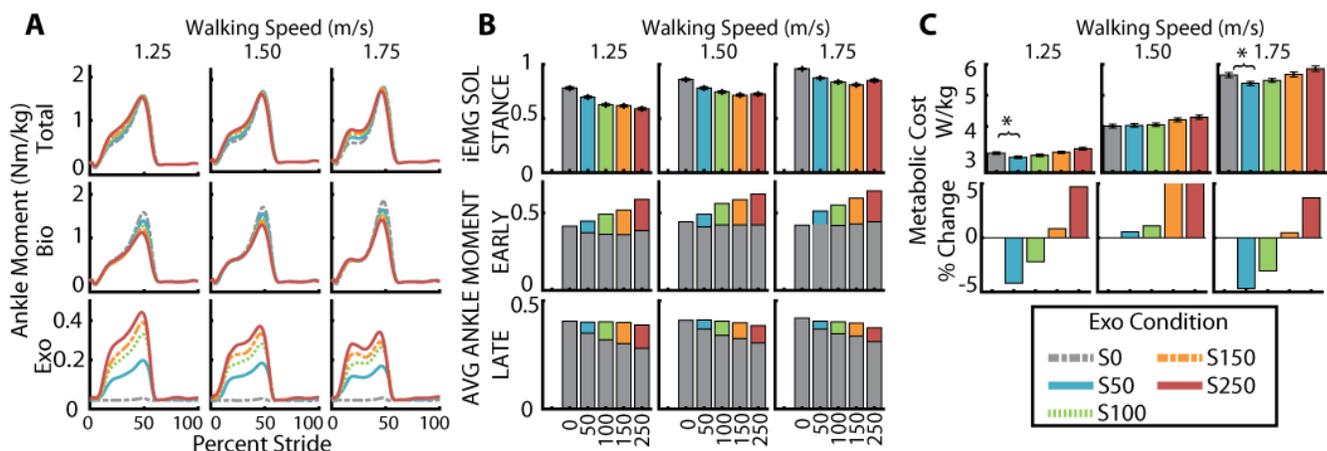

The metabolic reductions we report here (~5%) still do not approach reductions seen in the most successful active devices (~23%) [3]. Despite this, passive devices remain advantageous given their minimal weight and simplified design in comparison to active systems. In fact, our results suggest that a single compliant exoskeleton spring can achieve metabolic reductions across a range of walking speeds. Furthermore, elastic systems, like the one tested here, may simplify prescription of devices intended to restore structural stiffness to joints in specific populations (*e.g.* older adults).

## INTRODUCTION

While humans use many strategies to reduce metabolic energy cost, walking still requires a considerable amount of metabolic energy. Lower extremity exoskeletons have become an established technology designed to reduce metabolic cost. However, it was suggested that they might increase the variability of the locomotor system making the system unstable [1], but optimal assistance settings for gait variability remain unclear. This could be a main concern for people with a mobility disorder.

The purpose of this study was to investigate the effect of ankle exoskeleton power and actuation timing on gait variability and examine if the optimal parameters for gait variability are the same as for metabolic energy cost of walking. We hypothesized that late push-off timing [2,3] and lower push-off work [1] would reduce gait variability.

## METHODS

Ten healthy female subjects participated in this study (age  $23 \pm 1.2$  y; weight  $61.0 \pm 4.5$  kg; height  $168.1 \pm 5.2$  cm). The bilateral exoskeleton consisted of an ankle-foot orthosis at each leg with a hinge at the ankle joint and pneumatic muscles [4].

The experiment consisted of a habituation session and a data collection session. A number of conditions were applied in each session: a Powered-Off condition ( $4.03 \text{ W}\cdot\text{kg}^{-1}$ ), in which subjects walked with the exoskeleton but without assistance from the pneumatic muscles; and 10 powered exoskeleton conditions. The powered conditions were based on a two-dimensional parameter sweep of three actuation timings (36%, 42% and 48%) for which three exoskeleton power levels were applied ( $0.21 \text{ W}\cdot\text{kg}^{-1}$ ,  $0.41 \text{ W}\cdot\text{kg}^{-1}$  and  $0.50 \text{ W}\cdot\text{kg}^{-1}$ ) and a fourth actuation

timing (54%) for which only one power level was applied were used. In the habituation session, subjects learned to walk with the exoskeleton and became accustomed to the experimental set-up. They walked in all powered conditions and the Powered-Off condition on the treadmill at  $1.25 \text{ m}\cdot\text{s}^{-1}$ . Experimental data were collected on a separate day. Each subject performed the same walking protocol as in the habituation session, and all conditions lasted for four minutes.

Subjects wore a face mask connected to a gas analysis system (Cosmed). Exoskeleton sensor data (foot switches, displacement sensors and load cells) was acquired continuously during the entire experiment. Full body 3D kinematics were recorded using 14 infrared cameras (200 Hz; Qualisys).

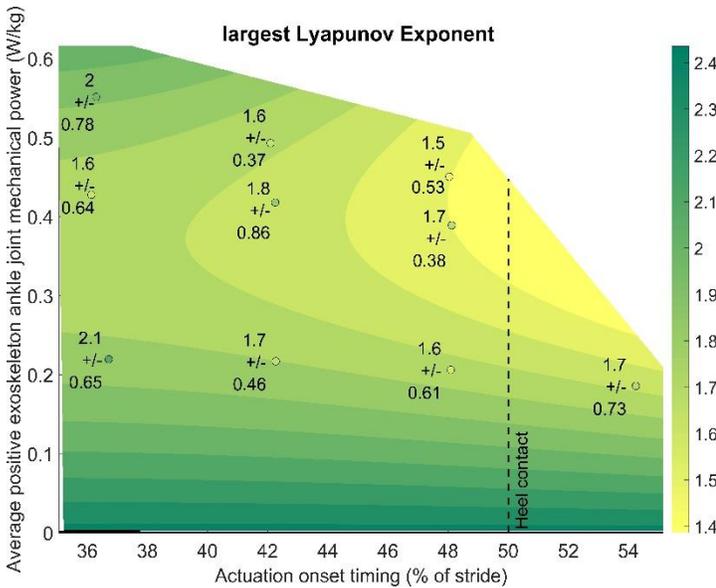

We quantified the metabolic energy cost of walking based on  $\text{O}_2$  consumption and  $\text{CO}_2$  production during the last two minutes of each condition using a standard equation [5]. Net metabolic cost was calculated by subtracting the metabolic cost of standing at rest from gross metabolic cost during walking and was normalized to body weight.

We quantified the pattern of stride-to-stride fluctuations of the ankle angle kinematics using the largest Lyapunov Exponent [6]. An increase in the largest Lyapunov Exponent indicates higher divergence in the stride pattern (i.e., increased amount of variability), whereas a decrease indicates lower divergence (i.e., reduced amount of variability).

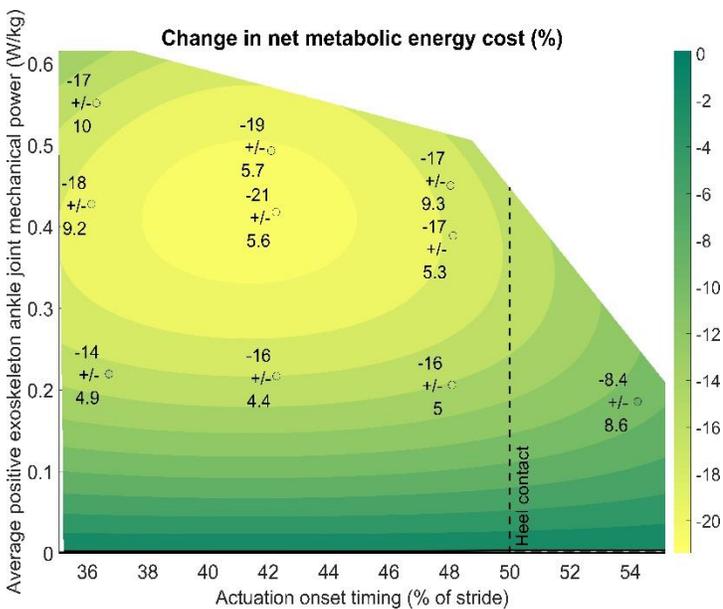

## RESULTS AND DISCUSSION

The Lyapunov Exponent of all powered conditions was lower than that in the Powered-Off condition ( $4.03 \pm 0.74 \text{ W}\cdot\text{kg}^{-1}$ ) (Fig 1). The lowest Lyapunov

Exponent was determined when assistance was achieved at  $48 \pm 1\%$  of the stride and average power of  $0.50 \pm 0.06 \text{ W}\cdot\text{kg}^{-1}$ . These results are different from what was found in a previous study [1] since we found that movement variability was lower during walking with the exoskeleton active.

**Figure 1:** largest Lyapunov Exponent for ankle exoskeleton motion across different conditions. largest Lyapunov Exponent is depicted versus actuation timing and average positive exoskeleton power.

**Figure 2:** Net metabolic energy cost. Net metabolic cost is depicted versus actuation timing and average

positive exoskeleton power. Metabolic cost for the powered exoskeleton conditions is expressed as the reduction versus the Powered-Off condition.

The lowest net metabolic cost was observed when assistance was achieved at  $42 \pm 0.8\%$  of the stride and average power of  $0.4 \pm 0.03 \text{ W}\cdot\text{kg}^{-1}$ , with a reduction of  $21 \pm 5.6\%$  compared to Powered-Off ( $4.03 \pm 0.74 \text{ W}\cdot\text{kg}^{-1}$ ) (Fig. 2). These optimal settings for metabolic cost are different from the optimal settings for reducing variability.

## CONCLUSIONS

We found settings that resulted to a more stable locomotor system and settings that resulted to a 21% reduction in metabolic cost compared to walking with the exoskeleton while inactive. We will apply mixed-model ANOVA to draw clear conclusions about the effects of ankle exoskeleton power and actuation timing on gait variability and metabolic energy cost. Our findings may be broadly applicable to enhance our understanding of the role/ability of lower limb exoskeletons to maintain balance and prevent falls, as well as gaining new insights for optimizing exoskeleton actuation settings to provide a more stable and metabolic efficient human locomotor system.

## INTRODUCTION

Stroke is the leading cause of long-term disability, often resulting in a slow and energetically inefficient gait due to a reduction in push-off power at the end of stance and the inability to lift the foot from the ground during swing (i.e. foot clearance). To improve the quality of life of stroke patients, a soft wearable robot (exosuit) has been developed, which has demonstrated the capacity to improve paretic propulsion, foot clearance and walking efficiency during treadmill walking [1,2].

The long term vision for the exosuit is that it can be used for overground gait training and to improve gait in a community setting. However, it is well known that stroke patients' ambulatory ability on the treadmill and overground are different [3,4]. During overground walking, there is an increase in gait variability due to a lack of an imposed speed, a less restricted walking area and more visual distractions. It is currently unknown if the same benefits observed on the treadmill would be seen during overground walking. Therefore, the objective of this study was to determine if the soft exosuit can improve push-off and foot clearance in patients post stroke during overground walking.

## METHODS

Nine patients with hemiparetic stroke (4 F, 49±13y, time since stroke 4±2y) walked overground at preferred walking speed. They wore a soft robotic ankle-assisting exosuit (Fig. 1) that was designed to transmit assistive forces from a specially designed lightweight body worn actuation system (3.2 kg) to the shank-mounted textile. The soft exosuit provided

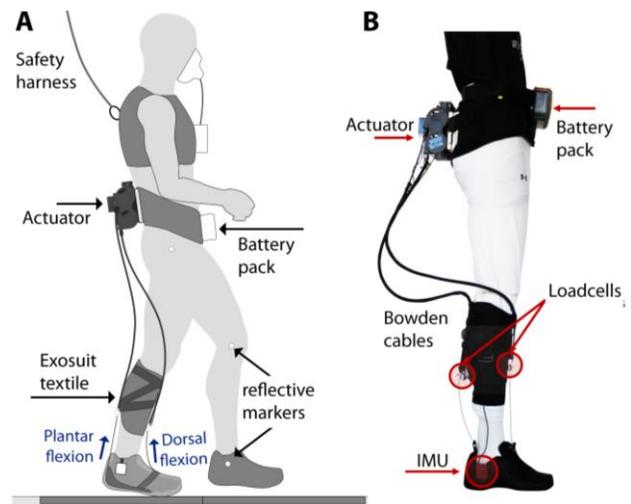

Fig. 1: Experimental setup (A) and exosuit components (B)

ankle plantarflexion assistance during push-off (peak applied force of 25% bodyweight) and ankle dorsiflexion assistance to achieve at least a neutral angle during swing phase [1,2].

Ground reaction forces (ground embedded force plates, AMTI, Watertown, MA) and kinematics (motion capture system, VICON, Oxford, UK) were measured. To understand the effect of exosuit assistance, subjects first walked with it unpowered, followed by a powered exosuit condition. Subjects walked until at least 5 strides were captured per condition with good landing on the force plate.

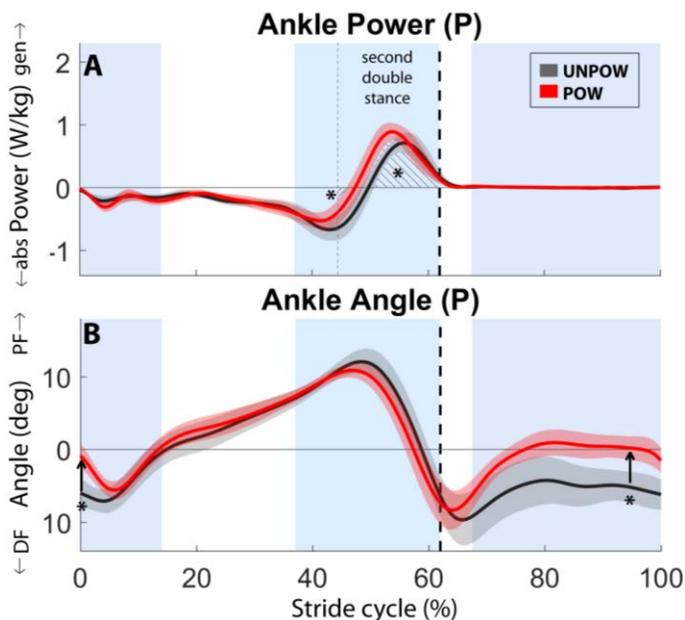

The propulsion impulse (i.e. the integral over the propulsion force), peak ankle torque during stance, average positive and negative ankle power during second double support, and maximal ankle dorsiflexion during swing and at initial contact were calculated for both the paretic and non-paretic leg. Conditions were compared on a group level using paired t-test (significance set at  $p < 0.05$ ).

## RESULTS AND DISCUSSION

On the paretic side, walking with the powered exosuit improved push-off (Fig. 2). We observed a 14.0% increase in propulsion impulse ( $p=0.03$ ), a 24.5% increase in average positive ankle power ( $p=0.04$ ) and a 41.3% decrease in average negative ankle power ( $p=0.006$ ). The powered exosuit also assisted foot clearance during swing and foot placement on the paretic side in terms of a  $5.2^\circ$  increase in maximal ankle dorsiflexion during swing ( $p=0.002$ ) and a  $4.9^\circ$  increase at initial contact ( $p=0.003$ ). No differences were found for the peak paretic ankle torque or any of the variables from the non-paretic leg (Fig. 3).

These results are similar to our prior work with a tethered soft exosuit that was shown to improve push-off and foot clearance during treadmill walking [1,2]. Taken together, these results suggest that soft wearable exosuit is able to assist post-stroke patients in different walking conditions. Moreover, it provides encouraging evidence that the exosuit technology is able to correctly identify gait events and timely assist paretic ankle deficits during the more variable overground walking.

Overall, the results support the suitability of the exosuit for common overground gait training. Given

**Fig. 2:** Ankle power (A) and angle (B) for the paretic (P) limb. Mean values, standard error, toe off (dashed vertical line) and timing of support (plantar flexion support: light blue shade; dorsiflexion: blue shade) are indicated.

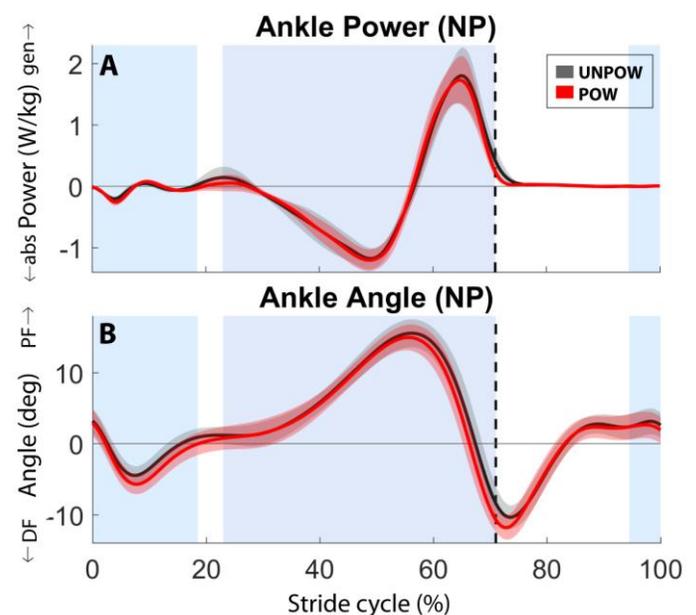

the known heterogeneity of stroke patients, the wearable exosuit provides exciting opportunities for subject specific gait training, with the potential of tuning the level of assistance to *a patient's* progress.

## CONCLUSIONS

This study demonstrates the capability of a body worn exosuit that targets the paretic ankle to assist push-off and foot clearance in post-stroke patients during overground walking. This builds on past work that demonstrated similar capabilities during treadmill walking. These results are an important step in evaluating and optimizing a wearable soft exosuit for overground gait training in stroke patients and in translating the technology to community-based use. Moreover, we expect that the exosuit can also similarly benefit patients with other gait deficits and neurological disorders.

# A Mechanical Role for Incompressible Fluid in Stretched Muscle

<sup>1</sup> David A. Sleboda and <sup>1</sup> Thomas J. Roberts

<sup>1</sup> Brown University, Providence, RI, USA  
email: david\_sleboda@brown.edu

## INTRODUCTION

Muscles maintain a constant volume of intracellular fluid. This fluid plays an important role in facilitating normal biochemical function, but its role in determining the biomechanical properties of muscle have been considered in only a few theoretical analyses.

We investigate the mechanical role of fluid within muscle using a combination of physical modelling and experiments on live, isolated skeletal muscle. We test the hypothesis that incompressible muscle fibers can limit reorientation of muscle's extracellular matrix, influencing the passive force produced during stretch.

## METHODS

Passive length-tension profiles for bullfrog semimembranosus muscles were measured before and after increasing intracellular fluid volume. Muscle fluid volume was altered by soaking in dilute, hypotonic physiological Ringer's solution for 1 hour. This allowed movement of fluid from bath to muscle via osmosis. Muscle volume increase was confirmed via separate measurements of muscle weight.

Isolated muscles were clamped at one end to a rigid post and at the other to a force and length-transducing servomotor (Aurora 310 B-LR). Passive tension was recorded at a series of static muscle lengths before and after volume increase. Active length-tension curves were collected prior to measurement of passive tension. All lengths were normalized to the length at maximal force production ( $L_0$ ) and all passive forces were normalized to the passive force produced at 115%  $L_0$  in the isotonic condition.

The mechanical response of muscle to increased internal volume was compared to that of a simple physical model composed of a fluid-filled bladder ensheathed in helical, cross-hatched fibers. The helical sheath represented muscle's collagenous extracellular matrix while the bladder represented a volume of incompressible muscle fibers. Tension produced by the model in response to stretch was measured before and after bladder volume was increased in simulation of the osmotic perturbation applied to muscle.

The effect of volume increase on passive muscle and the physical model were compared. Pre- and post-perturbation length-tension curves were log-transformed so that their shapes could be characterized by slope. The locations of log-transformed curves within the coordinate plane were also compared using the statistical tool SMATR.

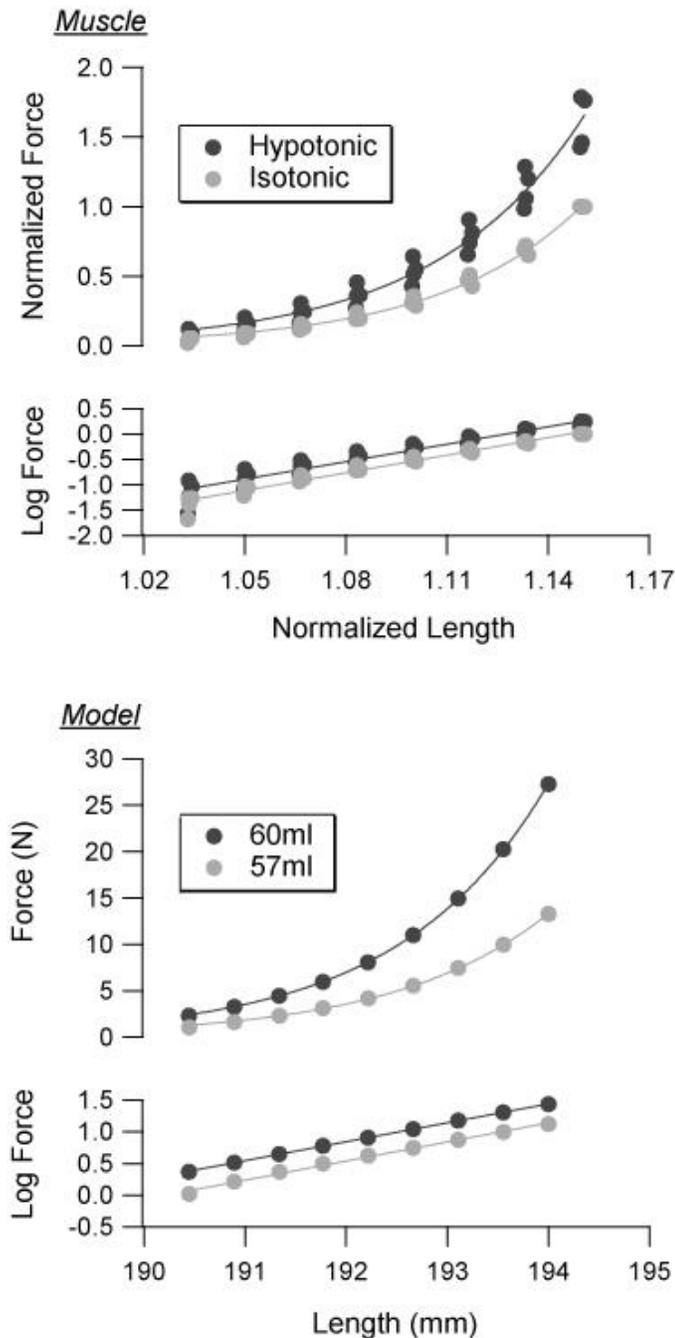

## RESULTS AND DISCUSSION

Increasing muscle volume by 40% resulted in 69% increased tension across all muscle lengths studied (fig. 1). The slopes of log-transformed lines for muscle were not significantly different before and after the osmotic perturbation, indicating that increases in tension occurred via a change in the zero-force length, or rest length, of the muscles, rather than by a change in the form of their length-tension curves. Significant differences in the location of the curves within the coordinate plane revealed by the statistical tool SMATR confirmed this interpretation.

The physical model displayed muscle-like length-tension properties which arose from the interaction of the helical sleeve and the fluid-filled bladder. Increasing the internal fluid volume of the fluid

bladder shifted the zero-force length of the model in a manner identical to that described for muscle.

horizontal axis in the untransformed data. Adapted from [1].

**Figure 1:** Tension produced by passive muscle (n=4) and the physical model before and after fluid volume increase. In both, volume increase caused a vertical shift in the log-transformed length-tension relationship without a significant change in slope. This is the equivalent of a leftward shift along the

Geometric analysis of the model revealed that the volume of space available within the sleeve decreased as a function of length. This occurred as the comprising fibers became aligned with the long axis of the model. Large increases in model tension with stretch occurred only once the internal volume of the helical sleeve approached the constant, incompressible volume of the fluid-filled bladder. At this length, reorientation of the sleeve was inhibited by the incompressible bladder, and further lengthening was made more difficult. We suggest that a similar mechanism contributes to the highly non-linear length tension profile of passively stretched muscle. At short muscle lengths, reorientation of collagen fibers allows the tissue to extend at low stress, but at long lengths this motion is inhibited by the incompressibility of muscle fibers.

## CONCLUSIONS

Our results indicate that fluid acts as a mechanical component of muscle, influencing the passive tension generated in response to stretch. Alterations to muscle fluid volume are shown to alter passive tension, and this same behavior is replicated by a simple physical model of muscle morphology. Our results provide empirical support for existing mathematical models of muscle which incorporate incompressible fluid into their design [2,2], and suggest that activities or pathologies that alter muscle fluid content will influence muscle mechanics.

## INTRODUCTION

Variability is inherent within all biological systems. Human movement appears to have an optimal amount and structure (temporal organization) of variability and disease states tend to cause deviations from this point [1]. It has been suggested that the structure of variability provides insight into system organization and motor control. Previous studies have demonstrated that the structure of force variability is altered in healthy, older adults and individuals with disease, which led investigators to suggest analysis of variability may be applied as a diagnostic biomarker [1-3]. However, the analysis of force variability is currently limited because it only provides a global understanding of skeletal muscle mechanics when measured with conventional clinical tools. Quantification of individual muscle force can refine our understanding of musculoskeletal mechanics and motor control.

Intramuscular pressure (IMP) is the fluid pressure generated within skeletal muscle and is a direct reflection of individual muscle tension [4]. Measurement of IMP has the potential to advance innovative strength assessment techniques. Currently, the variability of IMP is not well characterized. Therefore, the purpose of this investigation was to characterize the structure of the IMP variability during ramped isometric contractions. We hypothesized that the IMP variability would be less than the force variability and that this variability would have a less regular time series structure compared to force variability.

## METHODS

**Subjects:** Sixteen healthy adults (6 females; mean  $\pm$  SD age:  $42 \pm 18.9$  years; BMI:  $25 \pm 4.7$  kg/m<sup>2</sup>) with no history of neurologic or musculoskeletal disease

participated in this study after providing informed consent.

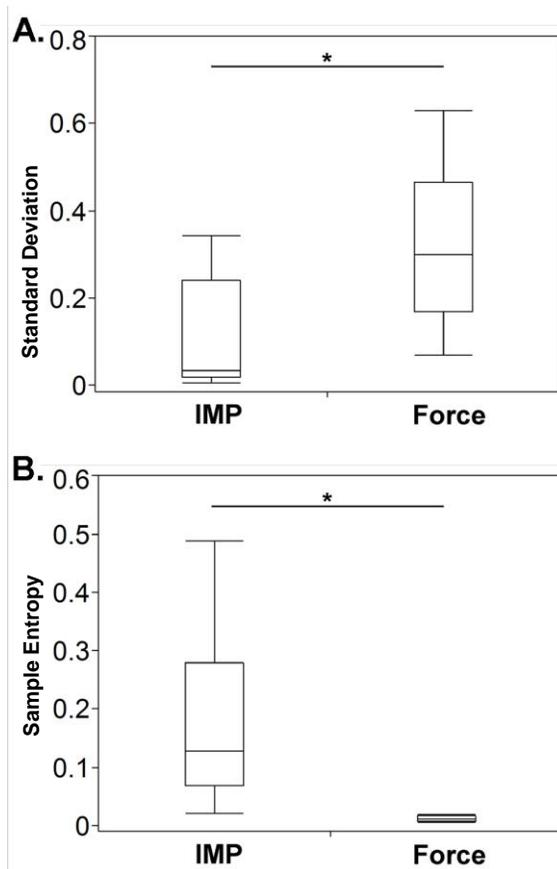

**Experimental set-up:** While subjects were supine, the right ankle was raised until the foot was perpendicular with the shank was parallel to the ground and held in that position with straps placed around the lower leg. A foot strap was secured around the metatarsals and secured to an external load cell (SM-100, Interface Inc., Scottsdale, AZ) in line with the load cell axis and perpendicular to the ankle rotation axis. A fiber optic pressure sensor (FOP-M260, FISO Technologies Inc., Quebec, Canada) was inserted into the tibialis anterior (TA) under ultrasound guidance using a 22-gauge IV catheter. The catheter was oriented toward the distal TA tendon through the skin at a 30° angle until the tip was mid-depth in the TA superficial compartment. The needle was withdrawn and the IMP sensor was advanced through the catheter lumen into the muscle. Force and IMP were simultaneously acquired (2500 Hz) using custom software (LabVIEW, National Instruments, Austin, TX).

**Protocol:** Subjects performed three maximal voluntary contractions (MVC) from which the greatest value was selected. Subjects then performed ramped isometric contractions to 50% MVC at rates of 5, 10, and 15% MVC/second guided by visual feedback. Fifteen trials were performed at each contraction rate, with at least 30 seconds of rest between trials to prevent fatigue.

**Data Analysis:** The unfiltered raw IMP and force time series from the start of force generation to peak force were analyzed using a custom MatLab program (The Mathworks, Inc., Natick, MA). The standard deviation (SD) was used to quantify the amount of

variability present in the force and IMP; a higher SD suggests that the signal has a greater amount of variability. Sample entropy (SampEn) was used to measure the regularity in the IMP and force time series [5]. A more regular time series will have a SampEn closer to zero, while a completely irregular time series will have a SampEn that approaches infinity.

**Statistical Analysis:** Separate repeated measures ANOVAs were performed in JMP software (SAS Institute Inc., Cary, NC) with an alpha value of 0.05. The rate of force development was the independent variable and the force or IMP SD and SampEn were the dependent variables for the respective ANOVA.

**Figure 1:** **A)** The standard deviation and **B)** sample entropy of the mechanical measure main effects during the ramped isometric contractions (N=14). \* indicates  $p < 0.05$ .

## RESULTS AND DISCUSSION

Fourteen subjects had evaluable data and were included in the final analyses. The mechanical measure main effect revealed that the force SD ( $0.35 \pm 0.13$ ) was higher than the IMP SD ( $0.11 \pm 0.25$ ;  $p < 0.001$ ; Figure 1A), suggesting that there is more variability in the force signal. For the SampEn, there was a mechanical measure main effect displaying that the IMP SampEn ( $0.19 \pm 0.16$ ) was higher than the force SampEn ( $0.01 \pm 0.01$ ;  $p < 0.001$ ). These outcomes suggest that the IMP has a less regular time series than the force. There was not a significant rate of force development main effect or interaction for both the SD and SampEn ANOVA ( $p > 0.05$ ).

These outcomes demonstrate that the IMP of healthy individuals has less variability and a more complex physiological time series signal than force. Moreover, the rate of force development did not appear to influence the SampEn or SD. These outcomes suggest that IMP is highly flexible and can adapt to task demands. Thus, since the structure of variability provides insight into system organization, IMP may be a more accurate reflection of individual muscle motor control than force. Future investigations should seek to quantify the alterations in IMP variability in populations with clinical disorders in order to determine the diagnostic capability of IMP.

## INTRODUCTION

Tendon and whole muscle transfers are conducted to restore lost motor function. Orthopedic surgeons perform a free functional muscle transfer (FFMT) of the gracilis from the lower limb to the upper limb to regain elbow flexion following an injury to the brachial plexus. The donor muscle often loses one or more grade of muscle strength in the process [1,2]. It is believed that this strength loss may be due to improper tensioning of the muscle during surgery, resulting in sarcomere lengths that are inadequate to achieve the required muscle force production [2].

To increase force production in transferred muscles, a better understanding of in vivo human muscle sarcomere length and other muscle properties are needed. Collection of gracilis muscle properties during surgery, specifically in vivo sarcomere lengths at different joint angles and the associated forces, will provide additional knowledge that may help to improve future computational models and simulations of FFMT surgeries. *We hypothesize that gracilis sarcomere length is on the descending limb of the force-length curve.*

## METHODS

For this study, data were collected during FFMT surgeries. Six subjects (1 female) with an average BMI of  $26.1 \pm 3.3$ , aged  $39 \pm 17$  years consented to participate in the study. Data were collected once the gracilis was isolated under two conditions: tendon attached and tendon transected.

*Tendon attached:* With the gracilis tendon still attached, biopsy clamps were used to collect muscle tissue samples. Joint angles were varied to achieve different muscle fiber lengths (Table 1). After tissue fixation, three fiber bundles were separated from the biopsy samples and placed on glass slides, then three laser diffraction measurements were performed to determine mean sarcomere length for each sample (n=9/sample).

**Table 1:** Joint configurations (JC) for the limb positions used to evaluate changes in sarcomere length.

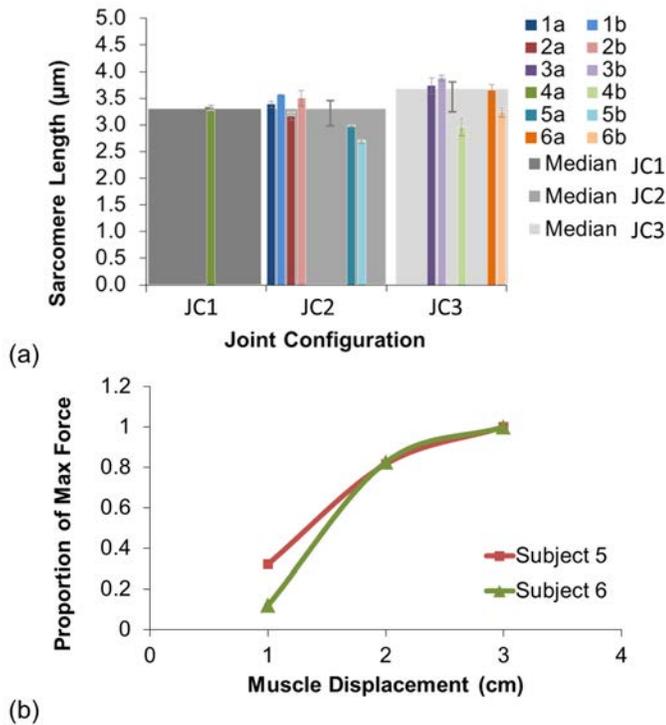

JC	Hip Rot. (°)	Hip Abd. (°)	Hip Flexion (°)	Knee Flexion (°)
JC1 (n=1)	60	45	45	120
JC2 (n=6)	40	30	45	90
JC3 (n=5)	40	30	45	0

*Tendon transected:* The distal aspect of the gracilis tendon was attached to a custom linear actuator with a clamp used to change muscle length. The same device recorded isometric muscle force production using a load cell (WMC-100, Interface Inc., Scottsdale, AZ), and LabVIEW (National Instruments, Austin, TX). Muscle activation was achieved through stimulation of the obturator nerve and force was recorded during isometric tetanic contractions at three different muscle lengths.

Due to surgical time constraints, data from only two subjects were collected with isometric force measurements recorded at three muscle lengths. To compare the subjects, data were normalized to the maximum force value (Fig. 1(b)).

## RESULTS AND DISCUSSION

*Tendon attached:* Sarcomere length ranged from 2.69-3.88 $\mu\text{m}$  (Fig. 1(a)). Median sarcomere length for JC1 and JC2 was 3.27  $\mu\text{m}$ . Median for JC3 increased to 3.65 $\mu\text{m}$  as illustrated by the grey bars behind sample means (Fig. 1(a)).

**Figure 1:** (a) *Tendon attached:* Sarcomere length from two biopsies per subject (indicated by 1a and 1b) was measured by laser diffraction. Mean is displayed with colored bars for each sample. Error bars represent standard error of mean. (b) *Tendon transected:* Median sarcomere length evaluated for each joint configuration (JC) is indicated by the grey bars with error bars for the 1<sup>st</sup> and 3<sup>rd</sup> interquartile range.

The measured range of sarcomere lengths (3.27 to 3.65 $\mu\text{m}$ ) at different JC, suggests the gracilis operates, at least in part, on the descending limb of the force-length curve, assuming an optimal sarcomere length of 2.8 $\mu\text{m}$  [3]. This study agrees with data from previous human studies evaluating the upper extremity and the soleus in the lower extremity [4,5].

*Tendon transected:* The isometric tetanic force production followed similar trends for each subject, increasing with each 1cm of muscle displacement

(Figure 1(b)). The increased value seen for Subject 5 at the start value is likely due to additive pretension on the linear actuator. More experiments need to be performed with improved tendon clamping techniques to gain a better understanding of the underlying muscle physiology. It was difficult to ensure the muscle was in its physiological position when starting force measurements.

## CONCLUSIONS

These novel force and sarcomere length data provide insight into the architecture of the gracilis muscle, suggesting it operates on the descending limb of force-length curve. The experimentally obtained patient-specific parameters obtained in this study can be used to reduce the assumptions made in computational simulations of force production. The results can be used to improve musculoskeletal modeling and guide future patient-specific models to advance surgical interventions such as tendon and muscle transfers.

## INTRODUCTION

Children with cerebral palsy (CP), the most common pediatric movement disorder, routinely develop muscle contractures, *i.e.*, muscle excursion limitations that reduce joint range of motion. Unfortunately, their biological basis is poorly understood. Skeletal muscles are composed of myofibers, arranged in parallel and series and made up of basic contractile units: sarcomeres. Serial sarcomere number can increase or decrease under conditions of stretch or slack, respectively. During childhood development, longitudinal growth occurs by sarcomere addition in series. Children with CP have a decreased serial sarcomere number and over-stretched sarcomeres [1, 2], implying reduced ability to add the sarcomeres needed for growth.

Muscle stem cells, *i.e.*, satellite cells, are indispensable for postnatal development, repair and regeneration of skeletal muscles. This stem cell pool is reduced by ~70% in contractures [3]. It is thus possible that, due to reduced muscle stem cell number, inadequate sarcomere addition occurs, leading to muscular contractures. Here we use transgenic mice ( $Pax7^{CreER/+}$ ;  $Rosa26^{DTA/+}$ ), capable of inducible satellite cell ablation, to directly test the hypothesis that adequate satellite cell number is required to add the sarcomeres needed to recover from a contracture.

## METHODS

$Pax7^{CreER/+}$ ;  $Rosa26^{DTA/+}$  ( $Pax7$ -DTA), were used for experiments (N=10, aged 8 weeks) such that treatment with tamoxifen would induce a reduction of satellite cell number by Diphtheria toxin via Cre-Lox recombination but not with a vehicle control.

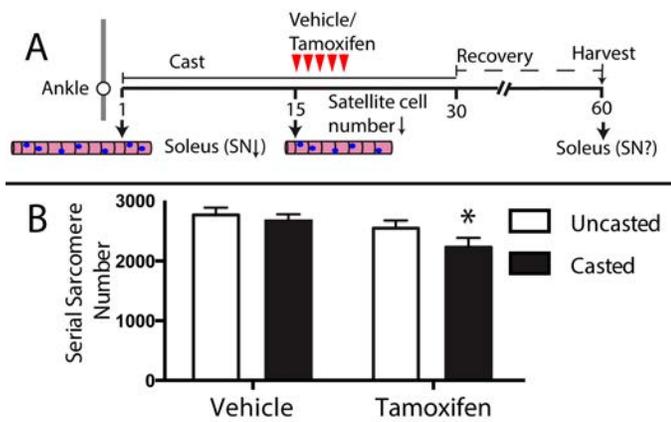

The right hindlimb was casted in plantarflexion for 2 weeks so that the soleus would lose serial sarcomeres, then treated with tamoxifen or vehicle and allowed to recover for a month after cast removal (Fig. 1A). After a month, maximal dorsiflexion range permissible on the casted side was measured from images and mice were sacrificed and muscles were harvested and used fresh, fixed or frozen.

Flow cytometry was used on fresh quadriceps and gastrocnemius muscles to quantify the number of satellite cells ( $\alpha7$ -integrin<sup>+</sup>/NCAM<sup>+</sup>/CD31<sup>-</sup>/CD45<sup>-</sup>). Serial sarcomere number, myofiber length and sarcomere length were measured in fixed soleus muscles. Collagen content, myofiber areas and muscle area fraction was also calculated from the previously frozen soleii.

## RESULTS AND DISCUSSION

Tamoxifen-treated  $Pax7$ -DTA mice had a significant reduction (~80%) in satellite cell number compared to the vehicle control group ( $p < 0.05$ ), fortuitously similar to that seen in children with CP.

Soleus serial sarcomere number was significantly lower on the tamoxifen-casted side, compared to the contralateral side ( $p < 0.05$ ) while the vehicle control casted side and the contralateral side were similar (Fig. 1B). Soleus sarcomere length was similar in both groups between the casted and uncasted sides. Correspondingly, soleus fiber length was significantly shorter on the tamoxifen casted side compared to the contralateral side, while serial sarcomere number on the vehicle control casted side was similar to the contralateral side.

**Figure 1:** Experimental protocol and muscle architecture. A) Mice were in a plantarflexion cast to reduce soleus serial sarcomere number (SN), then treated with either tamoxifen or vehicle-control, cage remobilized for a month and muscles harvested. Serial sarcomere number of the soleus was compared between the groups and sides after the recovery period.

Maximal dorsiflexion angle was similar immediately post-cast. However, at the end of the recovery phase, the tamoxifen-treated casted group was significantly lower compared to the vehicle-treated casted group (Fig. 2A,  $p < 0.05$ ). Importantly, maximal dorsiflexion angles in the tamoxifen-group, *i.e.*, extent of recovery from contracture, was

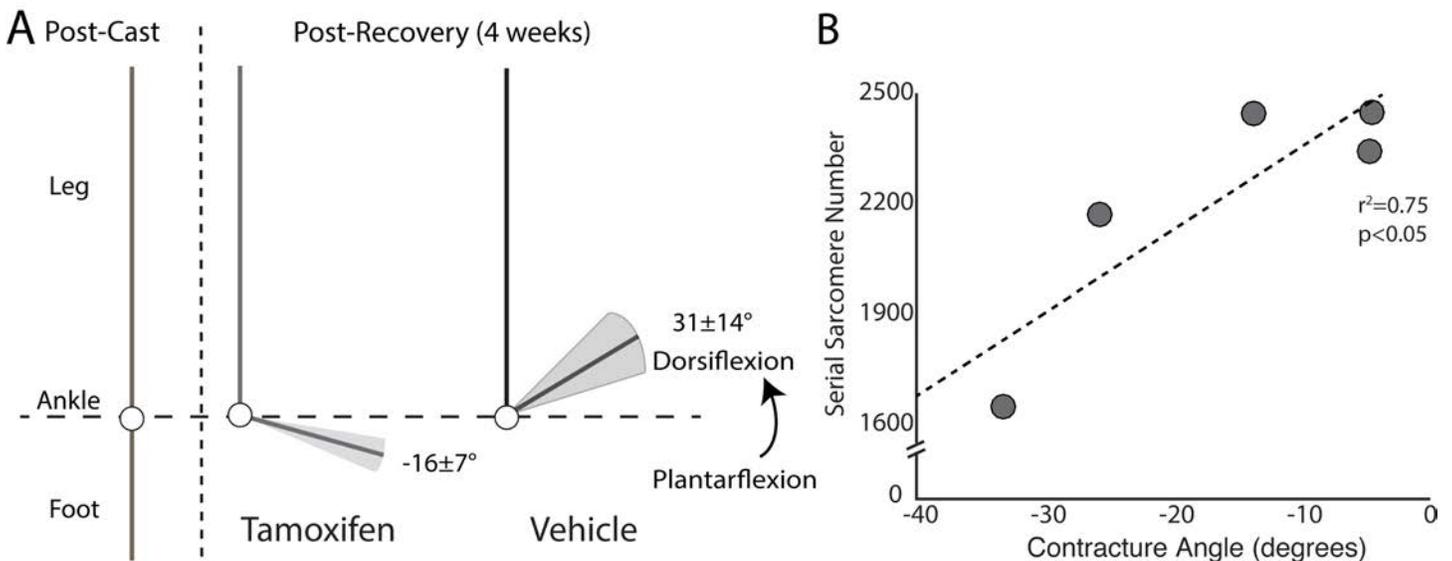

strongly associated with soleus serial sarcomere number (Fig. 2B,  $p < 0.05$ ,  $r^2 = 0.75$ ). Myofiber areas, muscle area fraction and collagen content were not significantly different between the groups and sides.

## CONCLUSIONS

Here we used a transgenic mouse model to show that recovery from skeletal muscle contracture requires satellite cell-mediated sarcomere addition and that contracture severity is related to serial sarcomere number/fiber length rather than changes in collagen content or in muscle area fraction. These results in a model system test the idea that children with cerebral palsy suffer contractures due to impairment of longitudinal muscle growth because of reduced satellite cell number.

## INTRODUCTION

Legged locomotion research has primarily been interested in the study of steady state behaviors – walking, running and hopping. Several groups have taken a modelling and simulation approach, including some previous work in our lab, to study such behaviors [1]. However, humans – or animals in general – don't locomote in a flat world at constant speed. They need to be able to reject perturbations quickly and safely.

Bipedal birds achieve this by a proximo-distal gradient in their motor control strategy [2]. However, it's less clear what happens at the individual muscle level – especially in humans. Furthermore, the details of the neural control strategy (*i.e.*, reflex feedback vs feedforward contributions) are not well understood.

Modelling is a powerful approach to tackle this problem as the neuromechanics can be explicitly specified. Previous studies of simulated hopping using a model with a muscle *only*, driven by feedback and feedforward neural commands show that positive force feedback leads to improved response to perturbation [3]. However, most animals have tendons that can mechanically buffer unexpected perturbations and potentially limit injurious muscle strains [4]. We hypothesize that reflex feedback in conjunction with tendinous series elasticity can allow a compliant muscle-tendon system to recover from perturbations both rapidly and safely.

## METHODS

We developed a mathematical model of a cyclically stimulated muscle-tendon unit (MTU) (Figure 1). It consists of a massless Hill-type muscle model with a parallel elastic element (PEE) – that together forms the contractile element (CE) – and a nonlinear spring that models the tendinous tissues (series elastic element (SEE)).

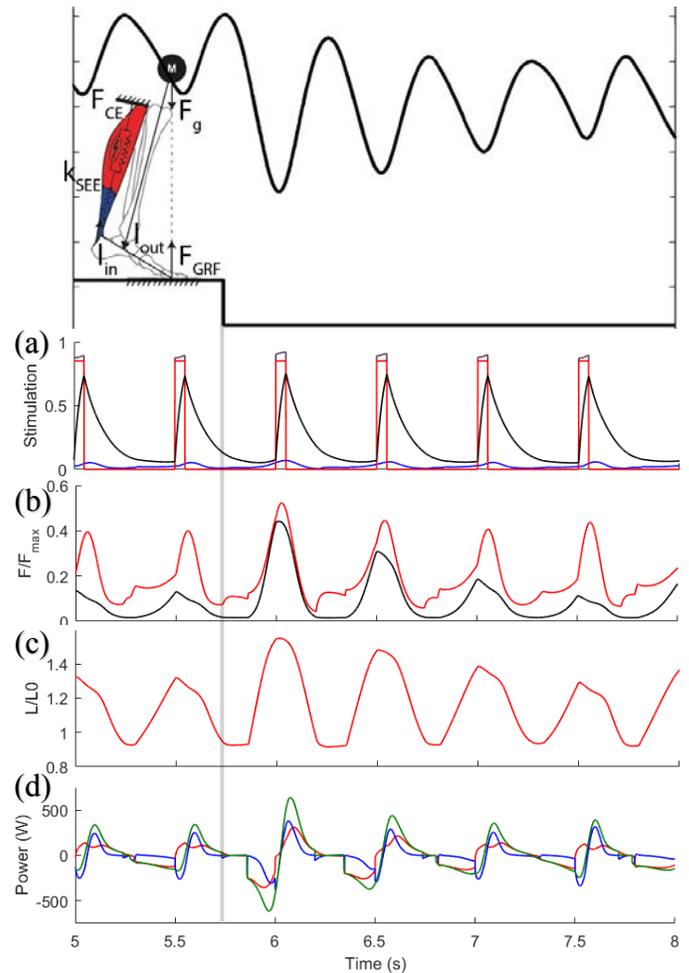

Figure 1: Time series data of (a) **Feedforward, Feedback, Total Stimulation and Activation** (b) **Total and Passive CE Force** (c) **CE Length** and (d) **MTU, CE and SEE Power** for Feedforward Fraction (FF) 0.85 and Positive Force Feedback (PFF) gain  $15 \times 10^{-5} \text{ N}^{-1}$

In the current model, a combination of positive force feedback (PFF) and feedforward (FF) signals stimulate the CE:

$$u(t) = FF(t) + (1 - FF(t)) \cdot \beta \cdot F_{CE}^{\Delta t}$$

where  $FF(t)$  is a square wave with 10% duty cycle and frequency of 2 Hz,  $\beta$  is the feedback gain and  $F_{CE}^{\Delta t}$  is the CE force that is fed back with a physiological time delay of 20 ms.

This stimulation gives rise to an activation  $a(t)$ , which in turn gives rise to active force in the CE in addition to the passive force from the PEE. This total force actuates a point mass in a gravitational field through a mechanical advantage. We apply a perturbation after 10 cycles of hopping to the MTU by virtually moving the ground by  $-5\text{cm}$  ( $\sim 20\%$  MTU slack length). We then allow the model to return to steady hopping. We determine settling time as the time point where the difference in peak total energy levels of the system are within 1% of the energy injected into the system. We calculate metabolic cost based on the velocity of the CE, scale it by activation, integrate it and divide that by body mass and total time to get a mass specific average metabolic rate [5]. To address the hypothesis, we simulated the system at many combinations of feedforward fraction (0-1.0) and positive force feedback gains ( $0-1.8 \times 10^{-6}$ ).

## RESULTS AND DISCUSSION

Increased feedback gain or feedback fraction did not necessarily improve settling time. In fact, whether increasing the feedback percentage or feedback gain, the system first gets slower and then faster at returning to steady hopping (*i.e.*, moving vertically or horizontally across Fig. 2(a)). Interestingly, there are many solutions in the parameter space where settling time is lower (2-5 hops) than the pure feedforward case (6 hops – top left corner of contours in Fig. 2).

Increasing either the feedback fraction or increasing feedback gain, resulted in shorter CE strains during recovery from perturbations (Fig. 2(b)). Compared to the pure feedforward case, CE strains are reduced by up to  $\sim 10\%$  in cases with high feedback. Thus, positive force feedback potentially acts as a safety mechanism that allows the muscle to maintain shorter and thus safer operating lengths in response to sudden perturbation.

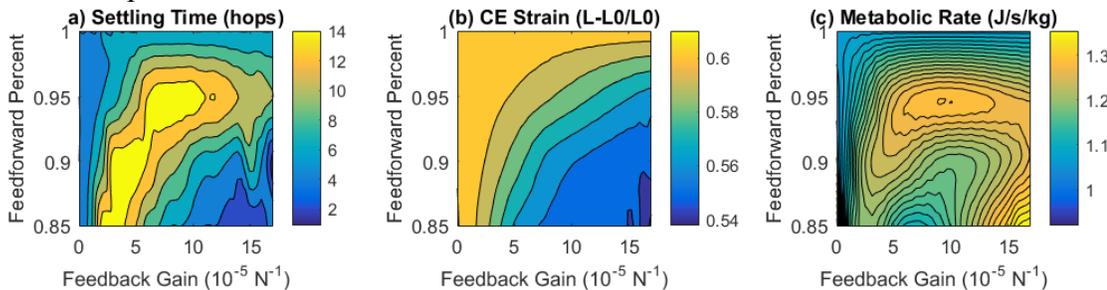

Figure 2: Contours as a function of feedforward (FF) contribution and positive force feedback (PFF) gain for (a) Settling time, (b) Peak strain of CE after perturbation and (c) Mass specific average metabolic rate.

In general, metabolic cost was higher for systems with feedback when compared to purely feedforward control strategies (Fig. 2(c)). For example, the metabolic rate was 20% higher at 0.95 feedforward fraction and  $9 \times 10^{-5} \text{ N}^{-1}$  force feedback gain than the purely feedforward case (1.3 W/kg and 1.1 W/kg). Increased metabolic demand of feedback based neuromuscular control strategies was a result of more reliance on active rather than passive muscle force contributions (Fig 1(b)).

## CONCLUSIONS

Optimally tuned positive force feedback in the context of series compliance within a muscle-tendon unit can facilitate recoveries from unexpected perturbations that are both fast and safe. However, the reduced settling times and safer operating lengths of the contractile element come with a fundamental tradeoff of increased metabolic cost. We have begun to test the predictions of this simple model by examining the behavior of individual muscle-tendon units in both humans (using ultrasound imaging) and on the benchtop (using sonomicrometry) during perturbed cyclic contractions. Insights from these experiments will be used to guide the design of next generation lower-limb robotic devices capable of seamless adjustment to environmental variation.

## INTRODUCTION

A minimal amount of research exists in the literature pertaining to quantification of athletic capabilities in the performing arts. Dancers in particular undergo substantial amounts of physically demanding and technical training from a young age. The distinct, aesthetic focus of jumps and leaps in most stylistic choreography results in hyper-plantarflexion and stretch-shortening cycle (SSC) action primarily about the ankle-joint. The SSC is characterized by the active lengthening of the muscle-tendon unit (MTU), which stores elastic strain energy that is subsequently utilized during active shortening of the MTU for enhanced concentric (CONC) performance. Previous findings have suggested that trained athletes who participate in ballistic movements benefit both biomechanically and physiologically from the SSC [1]. Other evidence has shown that dancers possess significantly greater maximal voluntary isometric plantarflexion strength as well as musculo-articular stiffness of the triceps-surae complex than untrained controls [2]. Participation in dance might therefore result in morphology adaptation to the lower leg and contribute to performance. Due to ankle joint dominance in most dance movements, a hopping model might best reflect the SSC capabilities of dancers. Therefore, the purpose of this study was to compare SSC performance during different hopping conditions between dancers and untrained controls. Our hypothesis was that dancers would hop higher and achieve significantly greater relative force and power values when compared to untrained controls.

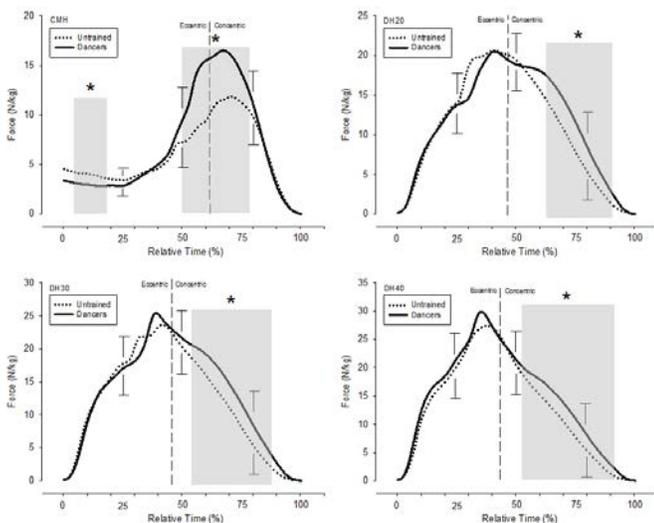

## METHODS

Twenty healthy, college-aged females participated in the study with no musculoskeletal injury,

neuromuscular disease, or lower limb injury within the past six months. Dancers ( $n = 10$ ; age =  $19.7 \pm 1.3$  yrs; height =  $163.9 \pm 6.6$  cm; body mass =  $62.0 \pm 10.3$  kg; dance training =  $17.0 \pm 1.2$  yrs) were required to currently be training at least three times per week. Untrained controls ( $n = 10$ ; age =  $19.5 \pm 1.1$  yrs; height =  $166.0 \pm 6.8$  cm; body mass =  $69.6 \pm 14.5$  kg) were physically inactive and did not have any background in endurance training, strength training, or dance. Subjects completed four types of hops on a custom-made sled at an inclination of  $20^\circ$  with the knees tethered just proximal of the patella to ensure that the knee joint could not contribute to hopping performance. The sled was equipped with dual force plates at the base, which provided force measurements. A potentiometer was fixed to the top of the sled-carriage, which calculated displacement and thus hopping height measurements. Subjects performed three countermovement hops, and three drop hops at 20cm (DH20), 30cm (DH30) and 40cm (DH40) and were instructed to hop as high as possible during each trial. Two-minute rest intervals were provided between trials. Subjects' greatest hop height was chosen for further analysis and comparison between groups. Forward dynamics were used to obtain a velocity-time curve, allowing for calculation of power from the product of force and velocity. Individual hopping trials were re-sampled to 500 samples using  $\Delta\text{time} = \# \text{ of original samples}/500$ . All force and power measurements were expressed relative to subjects' body mass. Average force- and power-time curves were then generated for each group from each hopping trial and used for further comparison. Displacement-time curves were used in order to define the transition from the eccentric (ECC) phase to the CONC phase.

## RESULTS AND DISCUSSION

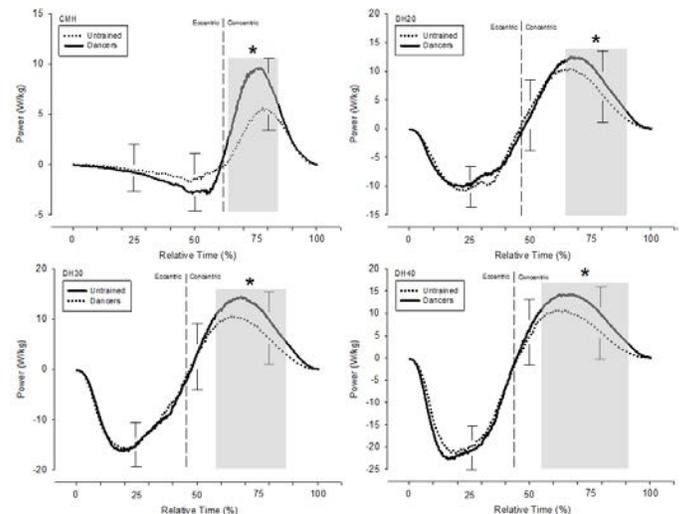

Dancers hopped significantly ( $p \leq 0.05$ ) higher than untrained controls during the CMH ( $0.17 \pm 0.03$  m;  $0.13 \pm 0.03$  m), DH20 ( $0.22 \pm 0.04$  m;  $0.17 \pm 0.03$  m), DH30 ( $0.24 \pm 0.05$  m;  $0.17 \pm 0.05$  m) and DH40 ( $0.25 \pm 0.05$  m;  $0.18 \pm 0.05$  m). Dancers had significantly greater relative force during the end of the ECC phase and beginning of the CONC phase than untrained controls during the CMH (Fig. 1). Dancers had significantly greater relative force during DH20, DH30 and DH40 in comparison to untrained controls in the CONC phase (Fig. 1). Dancers also had significantly greater relative power than untrained controls during the CMH, DH20, DH30 and DH40 in the CONC phase (Fig. 2). Relative force and power measurements were significantly related to hop height during all hopping conditions.

**Figure 1.** Comparison of average force-time curves during all hopping conditions between groups.

The main findings of this investigation provide evidence that participation in dance might result in enhanced SSC performance. Dance involves high volumes of ankle-specific SSC movements during unilateral leaps. Analysis of the gran jeté has shown dancers to perform with small take-off knee angles and large take-off peak power measurements nearing

6,000W [3]. These results are in support of our hypothesis that dancers emphatically use the ankle-joint to transfer power during dance-specific movements.

**Figure 2.** Comparison of average power-time curves during all hopping conditions between groups.

## CONCLUSIONS

In conclusion, the current data indicate that biomechanical variables significantly influence dancers' SSC performance, which may be due to muscle-tendon specific adaptations from years of complex movement synchronization. While not the focus of most training for dancers, supplemental plyometric and resistance training might further develop SSC capabilities and ultimately dance performance.

## INTRODUCTION

Comprehensive motion analysis methodology has been an integral part of the orthopaedic surgical decision-making and outcomes evaluation in the clinical setting for over 50 years. Joint kinematics, kinetics, and electromyographic data have been used to assess and document gait pathomechanics for informed treatment decision-making in the clinical setting. Following treatment, repeat assessments have provided objective documentation of treatment outcomes. This paradigm has facilitated development of new strategies for treatment of gait pathology especially in persons with cerebral palsy. As technology has improved, there is an increased opportunity to determine viable solutions for ongoing issues in clinically based motion analysis. This symposium will combine researchers and clinicians from both the ASB and the GCMAS (Gait and Clinical Movement Analysis Society) to a) delineate ongoing clinical challenges and b) discuss viable solutions to these challenges. We will present clinical issues and their current solutions in some cases and clinical issues that still require creative biomechanical solutions in other cases. In all examples, the symposium will combine a detailed understanding of the clinical question that requires viable implementation options in the clinical setting. It is our goal to develop collaborations between the GCMAS and the ASB so that we can ultimately improve clinical treatment outcomes. The symposium will cover the following topics:

## GAIT AND CLINICAL MOVEMENT ANALYSIS SOCIETY – Kenton Kaufman

The Gait and Clinical Movement Analysis Society (GCMAS) is a multi-disciplinary organization of physicians, allied health professionals, engineers,

biomechanists, and scientists working together to advance scientific knowledge, technical capabilities, and clinical practice in the field of human movement. It was formed in 1995 to improve functional outcomes and quality of life for individuals with any movement disorder at any age. GCMAS members use the latest technology and professional knowledge to measure, evaluate, and understand human movement, provide a forum for professional interaction and exchange of ideas, promote education, stimulate research, and disseminate current knowledge and best practices to enhance human movement and health. Given the cross-disciplinary nature with the ASB, it is hoped that ASB members will consider attending the GCMAS annual meetings. Gait and Posture is the official journal of the GCMAS. More information can be found at <http://www.gcmas.org/>

## UNDERSTANDING THE RELATIONSHIP BETWEEN IMPAIRMENT AND FOOT/ANKLE FUNCTION DURING GAIT IN CHARCOT-MARIE-TOOTH DISEASE – Sylvia Öunpuu

Charcot-Marie-Tooth (CMT) disease is a progressive peripheral neuropathy that impacts gait. The impairments vary depending on phenotype but generally include progressive muscle weakness starting at the foot and ankle muscles. CMT may lead to any one or a combination of deformities such as cavus, claw toes, and limited or excessive passive dorsiflexion range of motion. The impact on gait includes a wide variety of pathology that may include a flail foot, weight bearing on the lateral foot during stance, or toe walking. The complex interaction between cavus deformity, plantar flexor contracture and simultaneous weakness, have implications for surgical correction

of the painful cavus foot. Improved measurement of ankle and foot function during gait is needed to understand the underlying impairments and the possible risks of orthopaedic treatment options. This data will help develop evidenced based treatment indications and ultimately improved outcomes. The typical findings in CMT will be discussed along with our ongoing questions about how to document and understand the relationships that produce foot and ankle function. Other challenges in terms of measuring foot function will be briefly mentioned. We will end with an open discussion with the audience to help clarify the clinical questions and begin to define possible solutions.

### **PATELLAR INSTABILITY: WHAT SHOULD WE MEASURE TO GUIDE TREATMENT? – Jason Rhodes**

Patellar instability is the clinical syndrome due to morphologic abnormalities in the patellofemoral joint where the patella is prone to recurrent lateral dislocation. Most patients with patellar instability are young and active individuals, especially females in the 2nd decade. This presentation will focus how 3D gait analysis is used in pre-operative surgical planning for treatment of patellar instability. Issues with accuracy and repeatability in dynamic coronal and axial kinematic measurements will be presented and discussed. Pre and post-operative cases will be presented to show benefits for this work up to determine needs for different osteotomies and patellar realignment procedures. We will end with an open discussion with the audience to help clarify the clinical questions and begin to define possible solutions.

### **NEUROMUSCULAR CONTROL DURING GAIT IN CEREBRAL PALSY – Kat Steele**

Individuals with cerebral palsy (CP) have impaired movement due to a brain injury near birth. Dynamic electromyography during walking provides insight into when muscle synergists and antagonists are contracting. It is not uncommon in persons with CP to measure muscle activity that is early, prolonged, and out of phase in comparison to typically developing reference data. How does the clinician interpret this information to better understand appropriate surgical intervention?

Understanding how neuromuscular control is altered in CP can provide insight into pathological movement. Electromyographic data from children with CP will be presented, including a discussion of new techniques to quantify patient-specific changes in neuromuscular control to inform treatment planning. Individuals with CP use a simplified control strategy during gait compared with unimpaired individuals. We will explore how these results are similar to synergies during walking among adult stroke survivors, suggesting similar neuromuscular control strategies between these clinical populations

### **TORSIONAL DEFORMITIES AND THE KNEE FLEXION AXIS – Kenton Kaufman**

One of the important roles of clinical motion analysis is documentation of the transverse plane joint motion during gait. A significant part of this procedure is to correctly identify the knee flexion extension axis through identification of the medial and lateral femoral condyles. This is critical as this axis also defines hip rotation and is integral in femoral de-rotation osteotomy decisions. Motion-capture marker misplacement has previously been identified as the largest source of between-laboratory kinematic variability – accounting for up to 75% of the overall variance. Poor identification of the knee axis results in not only error in hip rotation but results in coronal plane knee artifact during maximal knee flexion in swing phase. This is also important in the assessment of maximum knee flexion during landing in the assessment of ACL readiness to return to sport. Examples of motion data for patients with torsional deformities and post ACL reconstruction patients will be presented to illustrate this challenge. This will be followed by a presentation that will outline an efficient algorithm to correct the knee flexion axis post-hoc.

The GCMAS gratefully acknowledges the support ASB for this opportunity.

# EFFECTS OF PASSIVE AND POWERED ANKLE-FOOT PROSTHESES ON MUSCLE ACTIVATION PATTERNS DURING LEVEL-GROUND WALKING

<sup>1</sup> Jana R. Jeffers, <sup>1</sup> Caroline D. Wilson, and <sup>1,2</sup> Alena Grabowski

## INTRODUCTION

To accomplish the mechanical tasks required for walking, lower limb muscles are active at different points in the stride [1]. In healthy adults walking at a steady speed over level ground the hip extensors, knee extensors and ankle dorsi-flexors are most active during the beginning of stance and at the end of the leg swing phase [1]. The ankle plantar-flexors are active during mid to late stance when the leg is producing propulsive power to redirect and accelerate the center of mass into the next step [1].

When people with a unilateral transtibial amputation walk on level ground using a passive-elastic (ESAR) prosthesis, they exhibit asymmetric muscle activation magnitudes and durations between their affected leg (AL) and unaffected leg (UL) [2]; the muscles of the AL produce lower peak and average activation, and the muscles of the UL produce higher peak and average muscle activation compared with the same muscles of non-amputees [2]. Powered ankle-foot prostheses have been developed that normalize the metabolic cost and biomechanics of level-ground walking for people with a leg amputation [3]. However, the effects of powered prostheses on muscle activation patterns remain unknown.

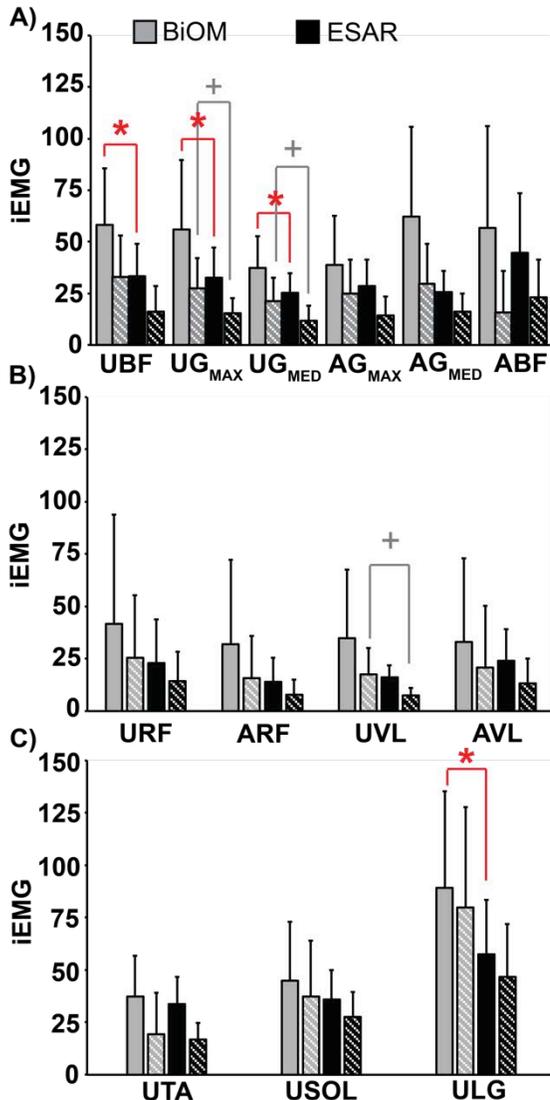

Thus, we investigated changes in muscle activation of people with a unilateral transtibial amputation using an ESAR and powered ankle-foot prosthesis during level-ground walking. We hypothesized that integrated electromyography (iEMG) would be lower in all muscles of the UL and higher in all muscles of the AL with use of the powered ankle-foot prosthesis compared to use of an ESAR prosthesis.

## METHODS

Ten otherwise healthy adults (6M, 4F, age 42±11 yrs., height 1.7±0.08 m, biological mass without a prosthesis 77.3±14.8 kg) with a unilateral transtibial amputation gave their written informed consent to participate in this study according to the VA and Colorado Multiple Institutional Review Board.

Subjects walked 1.25 m/s on a dual-belt force-measuring treadmill (Bertec Corp., Columbus, OH) using their own ESAR prosthesis and the BiOM T2 powered prosthesis (BiOM, BionX Medical Technologies Inc., Bedford, MA) for at least 30 seconds while we collected ground reaction force and surface EMG data at 1000 Hz (Noraxon, Scottsdale, AZ). We collected EMG bilaterally from the biceps femoris long head (BF), gluteus maximus ( $G_{MAX}$ ), gluteus medius ( $G_{MED}$ ), vastus lateralis (VL), and rectus femoris (RF), and from the UL lateral gastrocnemius (ULG), soleus (USOL), and tibialis anterior (UTA). We used a 4<sup>th</sup> order recursive butterworth filter with a cutoff frequency of 30 Hz on ground reaction force data and determined heel strike and toe off events with a 20 N vertical ground reaction force threshold. Using a custom Matlab (Mathworks, Natick, MA) script, we band-pass filtered at 10-495 Hz, rectified, and RMS-averaged with a 50ms window the raw EMG data. We then normalized EMG to the maximum signal magnitude for each muscle over a stride while using the ESAR prosthesis. We integrated the smoothed and normalized EMG (*iEMG*) data for each muscle over stance (*iEMG<sub>stance</sub>*) and an entire stride (*iEMG<sub>stride</sub>*). We averaged iEMG for at least 5 strides for each subject. We used dependent t-tests to determine prosthetic device effects on iEMG and set significance at  $p < 0.05$ .

## RESULTS AND DISCUSSION

**Figure 1.** Average  $iEMG_{stride}$  (solid) and  $iEMG_{stance}$  (hashed)  $\pm$ S.D. for A) hip extensors, B) knee extensors, and C) ankle flexors/extensors. U is the unaffected leg and A is the affected leg \* indicates significant difference in  $iEMG_{stride}$  and + indicates significant difference in  $iEMG_{stance}$  between prostheses.

$iEMG_{stride}$  (Fig. 1) increased with use of the BiOM compared to the ESAR prosthesis in UBF by 74% ( $p < 0.05$ ),  $UG_{MAX}$  by 71% ( $p < 0.05$ ), ULG by 55% ( $p < 0.05$ ), and  $UG_{MED}$  by 47% ( $p < 0.005$ ). We found no significant effect of foot type on AL  $iEMG_{stride}$  (Fig. 1). Similarly, with use of the BiOM compared to ESAR  $iEMG_{stance}$  (Fig. 1) increased for  $UG_{MAX}$  by 77% ( $p < 0.05$ ),  $UG_{MED}$  by 78% ( $p < 0.005$ ), and UVL by 128% ( $p < 0.05$ ). We found no significant effect of foot type on AL  $iEMG_{stance}$  (Fig. 1).

Contrary to our hypothesis,  $iEMG$  was greater in most UL muscles and not different in AL muscles with use of the BiOM compared to use of the ESAR prosthesis. The greater  $iEMG_{stride}$  and  $iEMG_{stance}$  in the UL could be due to the increased prosthetic mass of the BiOM or an increase in stride length. On average, the BiOM had 1.6 kg greater mass than an ESAR prosthesis. Net metabolic cost (J/s) presumably reflects  $iEMG$  and increased by 7% when 1.7 kg of mass was added to a passive prosthesis during walking in people with a unilateral transtibial amputation [4]. Thus, it is possible that the additional mass of the BiOM compared to the ESAR prosthesis could account for increases in  $iEMG$ . However, because the BiOM provides stance-phase power to the user during the second part of the stance phase [3], it is unclear how added mass and power differentially affect muscle activation patterns. Additionally, subjects increased stride length 5% (0.07m) starting with the AL heel strike and 1% (0.02m) starting with the UL heel strike when walking with the BiOM compared to the ESAR prosthesis, which could increase muscle activation [5].

## CONCLUSIONS

With use of the BiOM powered prosthesis compared to a passive-elastic prosthesis, subjects had greater stride and stance phase muscle activity in their UL biceps femoris, gluteus maximus and medius, lateral gastrocnemius, and vastus lateralis. These differences are likely due to biomechanical changes when walking with the BiOM. Future studies are warranted to examine the relationship between joint kinematics, kinetics and muscle activity when walking with a powered compared to passive ankle-foot prosthesis.

## INTRODUCTION

People with lower limb amputation have higher energetic costs during walking [1] and walk with increased asymmetry [2] compared to people without amputation. These deficits likely occur because of the functional loss of the plantarflexor muscles, which contribute 80-85% of the total mechanical power generated during the gait cycle [3]. To address this deficit, recent research has focused on the design of devices capable of supplying additional power for push-off. These powered ankle prostheses can increase preferred walking speed, reduce energetic cost and reduce some gait asymmetries in persons with transtibial amputations [4]. It is unclear how much power is required to alleviate the high energetic cost of walking or to minimize asymmetries. While we might attempt to match the work of the intact limb, a prosthetic ankle system experiences losses through the interface (socket) and functions across only one joint, rather than replicating the biarticular nature of the gastrocnemius. Therefore, the purpose of this study was to determine how the amount of power supplied through an ankle prosthesis impacted energetic cost and temporospatial symmetry.

## METHODS

Five individuals with unilateral transtibial amputation (average  $\pm$  SD, height:  $180.0 \pm 0.05$  cm, mass  $96.24 \pm 13.43$  kg, and age:  $46.2 \pm 13.81$  years) were fitted with BiOM T2 powered ankle prosthesis (BIONX Medical Technologies, Inc., Bedford, MA) by a certified prosthetist. Each participant walked on the treadmill with self-selected speed (average  $\pm$  SD,  $1.18 \pm 0.08$  meters/second). Participants were tested the six power conditions of the BiOM controller module (0%, 25%, 50%, 75%, 100%, and prosthetist-chosen).

A 20-camera infrared motion capture system (Motion Analysis, Santa Rosa, CA) was used to acquire three-dimensional marker data at 120Hz. Reflective markers were attached follow by 6 degrees of freedom marker set. Visual 3D (C-Motion, Inc., Germantown, MD) was used to calculate joint kinematics and step length in the sagittal plane from the marker data. We used a portable gas analyzer (K4b<sup>2</sup>, Cosmed, Rome, Italy) to measure the levels of oxygen intake and carbon dioxide output. These respiratory measurements were used to convert the metabolic power using the Brockway equation [5].

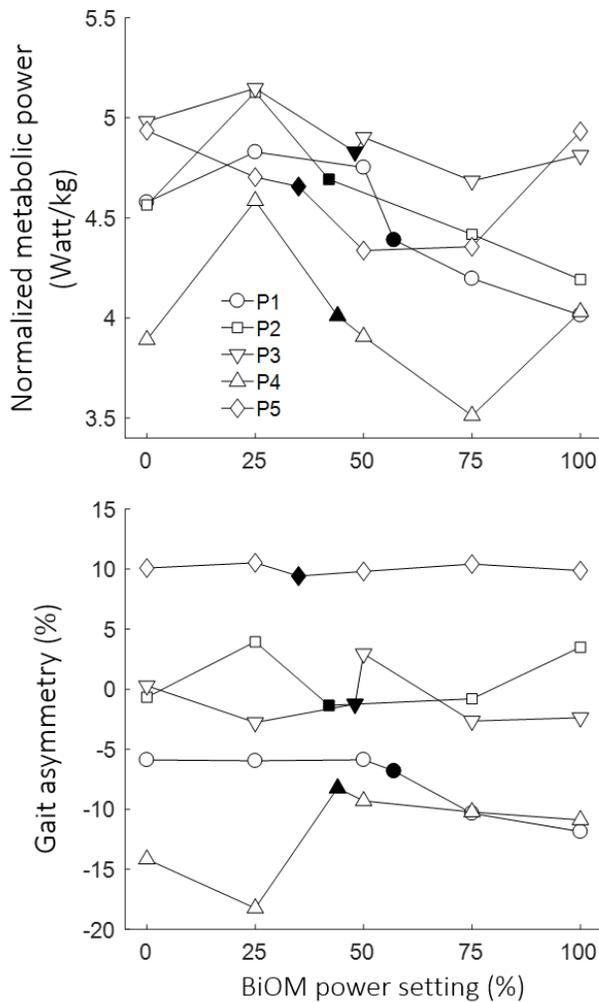

Participants were acclimatized for 10 minutes with the prosthetist-chosen power setting conditions on the treadmill. Then, participants walked in each BiOM power condition until respiratory signals reached steady-stated. The condition order was randomized. Step lengths and metabolic power were measured during 3 minutes. Steady-state metabolic powers were normalized by the body weight. The amputated side step lengths were normalized by the intact side step lengths. Gait asymmetry was quantified using an equation (Eqn. 1) proposed by Robinson et al. using amputated step length ( $l_a$ ) and intact step length ( $l_i$ ) [6].

$$Asymmetry = \frac{2(l_a - l_i)}{(l_a + l_i)} \times 100 \quad (1)$$

## RESULTS AND DISCUSSION

As BiOM power increased, metabolic power decreased for participants (Fig. 1). For two of these participants (P3, P4 and P5) metabolic power increased when the prosthesis power was above 75%. Unlike the metabolic power, there were variable changes in gait asymmetry. Participant 5 increased amputated step length and had more symmetric gait

with increased power. However, participant 6 decreased amputated step length and had less symmetric gait. Of the participants who had a symmetric gait in the 0% power condition (P2 and P3), either increased or decreased gait asymmetry. Participant 5 had larger step lengths on amputated side throughout all power conditions and had minimum changes.

**Figure 1:** Normalized metabolic power (top) and gait asymmetry (bottom). Prosthetist settings were represented with filled symbols. In the gait asymmetry, the value greater than 0 represents amputated side has longer step lengths compared to intact side.

The difference in gait asymmetry with different prosthesis power conditions may be because each individual use different motor adaptive strategies. For example, participants who had decreased step

lengths on the amputated side may have decreased strength or recruitment of residual muscles or had more muscle co-contraction to maintain the balance and this may lead to having more gait asymmetry. Contrarily, a participant who had larger step length on the amputated side with decreased metabolic power (P4) would have benefited from the power of prosthesis.

This suggests that using an optimally tuned powered prosthesis has the potential to decrease metabolic power and improve gait symmetry. Future research will be required to understand the underlying mechanisms by which muscle function changes with the different level of prosthetic power and correlate changes in muscle function with changes in metabolic power and gait asymmetry. In addition to the level of power, different power application during stance phase should also be considered to evaluate how these combinations can produce outcomes.

## CONCLUSIONS

Using a powered ankle prosthesis can reduce the metabolic cost of walking. However, the changes in gait asymmetry were variable between participants. Evaluating metabolic power and gait asymmetry can give guidance to develop an optimally powered prosthesis. This process must consider subject-specific factors to determine the optimal tuning parameters for each individual.

## INTRODUCTION

In the United States alone, 1.7 million individuals have had a foot or leg amputation [1]. Following transtibial amputation, a gel liner coupled with a prosthetic socket is utilized to maintain ambulation for patients. Pistoning commonly occurs when the prosthetic device translates vertically with respect to the residual limb due to the suspension of the limb [2]. Understanding the limb-to-socket interface is essential for creating a well fit prosthetic device. A few studies have used motion capture to quantify aspects of limb movement within the socket, however a comprehensive assessment of deformation across multiple individuals does not exist [3-4]. To obtain a complete understanding of the limb-device interface, data on how the gel liner deforms and movement of the limb with respect to the prosthesis is a necessity.

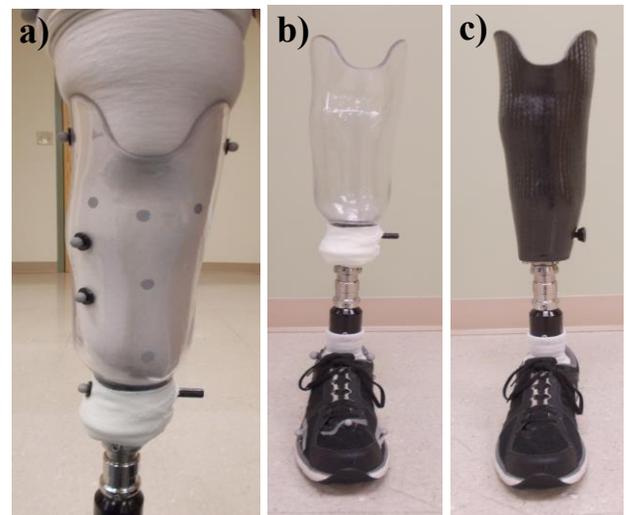

The objective of this work was to determine both longitudinal and circumferential displacements of the gel liner and movements of the prosthetic device relative to the gel liner. We hypothesized that larger localized displacements and strains would occur in the distal region of the liner due to pistoning.

## METHODS

Participants included eight transtibial amputees 57.9 +/- 8.2 yrs.; 6 female, 2 male, including one female bilateral amputee. All amputations occurred at least one year prior to the study and were due to traumatic injury, diabetes, or infection. None of the participants needed the use of an assistive device. All participants were seen within six months by a certified prosthetist who deemed their current prosthesis had a proper alignment and fit. All used the equivalent prosthetic

suspensions; a gel liner interface with pin/lock mechanism.

A duplicate socket was manufactured out of a clear thermoplastic material. The duplicates were developed to match the alignment and fit of the participant's prosthetic socket. This allowed reflective thin-disc motion capture markers to be positioned on the gel liner, below the clear prosthetic (Fig 1a). A kinematic assessment compared their gait between the original device and the clear socket to confirm no differences existed. Using motion capture, kinematic data were obtained so residual limb motions within and relative to the socket could be computed.

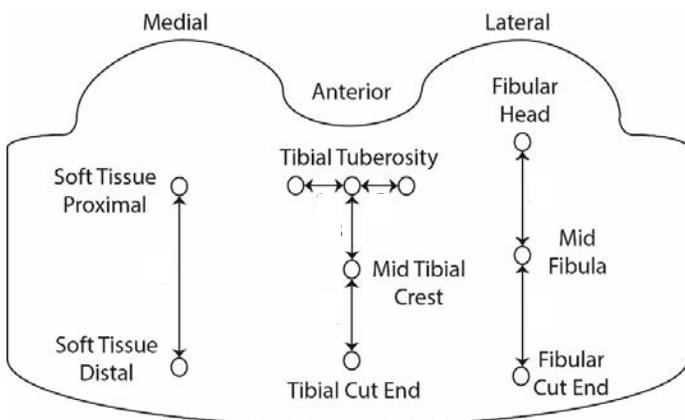

**Figure 1:** a) Clear prosthetic device with markers, b) Clear socket assembly c) Current prosthesis.

Four parameters were quantified: 1) displacement of the gel liner, 2) strain of the gel liner, 3) displacement of the prosthetic socket relative to the limb, and 4) rotation of the prosthetic socket relative to the limb. With these data sets, movements of the gel liner within the socket and relative to the socket were

calculated (Fig 2). Data were analyzed over five gait cycles. Within the four quantified parameters, a one-way ANOVA with Tukey's Post Hoc evaluated statistical differences in anatomical locations with respect to the parameter of interest.

## RESULTS AND DISCUSSION

Highest displacements on the gel liner were observed at the distal fibula (5.93 mm) distal tibia (5.83 mm) and medial side (6.34 mm). When the seven displacements of the liner were compared across each other, the distal measures were statistically different than proximal measures with p values of  $p < 0.05$ . Greatest strains occurred in the proximal tibia (10%), distal tibia (11%) and distal fibular regions (11%). Comparing across all gel liner strain locations the distal measures were significantly different than the proximal data  $p < 0.05$ . Lateral and medial anatomical landmarks had the largest prosthetic socket displacements relative to the limb. When compared across all relative movement measurements the lateral and medial data were larger than all others,  $p < 0.05$ . On average, the greatest relative displacement of  $30.7 \pm 11.4$  mm was observed in the medial proximal soft tissue region, followed by the fibular head with  $27.3 \pm 10.7$  mm. Angular rotation along the anterior, lateral and medial regions of the prosthetic socket relative to the limb showed on average  $5.3 \pm 3.6$ ,  $5.2 \pm 3.5$ , and  $5.4 \pm 3.9$  degrees respectively. The angular rotation data did not yield statistically significant differences in the three anatomical regions.

**Figure 2:** Location of anatomically placed markers beneath the clear socket. Displacements and strains were computed between the arrows in the figure.

Results overall confirmed that higher displacements and strains were observed distally as compared to proximally across participants. The reason for this increased distal displacement and strain is related to the suspension method. At the base of the gel liner, a pin system locks to the prosthetic socket, leg and foot. During gait, particularly the swing phase, an elongation of the gel liner occurs due to the suspended weight. Our displacement data are comprehensive in that six regions in the longitudinal direction, two in the transverse direction, three regions of rotation of the prosthetic relative to the leg and relative displacement of the prosthetic to the leg have been determined. Currently, no other data set is available with this number of measures on this large of sample. This mechanics-based information, can inform prosthetists of limb movement within the prosthetic socket and lead to socket or gel liner design changes in the efforts to minimize discomfort, and skin wounds for patients.

## CONCLUSIONS

Our data indicate that the distal interface region is problematic for prosthetic users. To achieve these larger distal displacements either the liner is sliding with respect to the skin or the liner is “sticking” to the skin and shearing tissues below. Either way, a shear force is produced, either at the skin surface or in deeper tissues. Future research will use finite element methods to explore these two scenarios to provide insight into tissue damage common to the distal region of the residual limb.

## INTRODUCTION

Rehabilitation of service members with lower extremity amputation is a critical aspect of returning them to the highest level of function possible. Injured service members were often highly active prior to injury and typically wish to return to activities that demand a high level of performance [1]. Specialized rehabilitation programs at Military Treatment Facilities (MTFs) in conjunction with advanced prosthetic devices allow service members with amputation to pursue their goals. At Naval Medical Center San Diego (NMCS D), the typical rehabilitation course for patients with amputation is broken into four phases: Phases I and II consist of immediate post-op healing and pre-prosthetic training, Phase III introduces prosthetic gait training, and Phase IV initiates higher-level devices and activities as the service member prepares to return to duty or separate from the service [2].

To date, no study has evaluated the improvements in temporal spatial parameters such as velocity, cadence, and step length at specific time points throughout a service member's entire rehabilitation process at an MTF. Temporal spatial parameters are highly related to functional ability and are important when evaluating a patient's ability for activity participation. The purpose of this study is to evaluate the progression of temporal spatial parameters throughout rehabilitation for service members with a unilateral transtibial amputation (TTA). This data can be used to validate the rehabilitation model at an MTF and help give quantitative guidelines and reference data for clinicians in determining course of care for patients with a unilateral transtibial amputation.

## METHODS

A total of 97 patients with a unilateral TTA underwent rehabilitation at NMCS D from 2008-2016 and were studied in the Gait Analysis Laboratory as part of their routine clinical care. Retrospective review excluded patients with contralateral involvement, traumatic brain injury (TBI) affecting gait, and/or less than three gait studies over the course of care. A total of 32 patients fit the inclusion criteria with an average age of  $26.4 \pm 5.0$  years at the time of baseline study. Patients' baseline studies occurred as soon as they were able to ambulate without an assistive device and correlated with early Phase III. Subsequent studies were conducted at six weeks, three months, six months, and one year post baseline. The six week study was performed at approximately the midpoint of Phase III while the three month study was near the conclusion of Phase III. The six month study occurred toward the end of Phase IV, while the one year study was conducted before the patient disengaged from active rehabilitation at the MTF.

Patients were studied in the Gait Analysis Laboratory at NMCS D using a modified Helen Hayes marker set, a 12 camera Eagle Camera system (Motion Analysis Corp., Santa Rosa, CA, USA), and 4 force plates (AMTI, Watertown, MA, USA). Data were processed in Visual 3D (C-Motion Inc., Germantown, MD, USA) and analyzed using R (R Foundation, Vienna, Austria). Temporal spatial variables of interest included velocity (m/s), cadence (steps/min), affected and unaffected step length (m), affected and unaffected stance times (% gait cycle), and step width (m). In addition, Symmetry Index (SI) was calculated for step length

and stance times [3]. Rehabilitation often focuses on minimizing asymmetries, although they are not necessarily functionally detrimental to the patient [4]. Multiple one-way ANOVAs were performed to evaluate a main effect of time with  $p < .05$ , followed by Games-Howell post-hoc tests to determine where significant differences occurred.

## RESULTS AND DISCUSSION

All 32 patients with unilateral TTA were male with an average height of  $1.77 \pm 0.06$  m and an average weight of  $82.1 \pm 17.4$  kg at baseline. Temporal spatial data is reported in Table 1. There were no significant changes in their step width ( $p = .41$ ), affected stance time ( $p = .91$ ) or step length SI ( $p = .58$ ) at any time point. There were significant changes in velocity ( $p < .001$ ), cadence ( $p < .001$ ), affected and unaffected step length ( $p < .001$ ,  $p < .01$ ), unaffected stance time ( $p < .001$ ), and stance time SI ( $p < .01$ ). Velocity and cadence significantly increased at all times compared to baseline (all  $p < .01$ ) and significantly increased at six months and one year compared to the six week time point ( $p < .05$ ). Affected step length significantly increased at all times compared to baseline ( $p < .01$ ) and was also greater at the one year study compared to the six week study ( $p < .01$ ). Unaffected step length increased at three months compared to baseline ( $p < .05$ ). Finally, stance time SI significantly improved at three months compared to baseline and six weeks ( $p < .05$ ) but by 1 year had significantly worsened ( $p < .05$ ).

## CONCLUSIONS

This is the first study to publish rehabilitation outcomes for service members with unilateral TTA

across the duration of rehabilitation at an MTF. Service members had significantly increased velocity, cadence, and step lengths throughout care. Walking velocity matches that of non-injured males by the three month study mark [5]. Compared to baseline, patients are significantly improved both at the end of Phase III of rehabilitation but also have further improvements at the end of Phase IV. This is significant in that they are no longer doing gait specific tasks as part of their rehabilitation course of care, having shifted to high level activities that allow for sport or duty reintegration. Interestingly, stance time SI is the only measure where a significant improvement is seen at the end of Phase III of rehabilitation and regresses over the rest of care. This measure may be acutely sensitive to the part of rehabilitation where active gait retraining is occurring. While all patients progressed through the rehabilitation program, some patients likely had more physical therapy visits than others and thus is a limitation of the study. Future research will look at any physical therapy “dosage” effects to provide additional guidelines for the rehabilitation program.

## INTRODUCTION

Individuals with unilateral lower limb loss are at increased risk for developing knee osteoarthritis (OA) within the intact (contralateral) limb [1]. While the exact mechanism(s) underlying this phenomenon are currently unknown, it is plausible, even likely, that large or unusual loads placed on the intact knee joint may contribute to the “wear and tear” model of OA development and progression [1]. Features of the knee adduction moment (KAM) and the knee flexion moment (KFM) have been previously associated with cartilage degeneration [2,3]. The progression of knee joint mechanics during early prosthesis use is of particular interest because it is important to know when during the rehabilitation process the gait and joint mechanics have “stabilized”. Individuals who have undergone ACL repair, a population with increased risk of OA development similar to limb loss, have been found to exhibit increased contralateral limb loading over time [4]. However, to our knowledge, there have been no longitudinal assessments of biomechanical variables related to OA initiation/progression in individuals with unilateral lower limb loss.

Therefore the purpose of this study was to examine changes in knee joint kinetics of individuals with unilateral lower limb loss as a function of time from independent ambulation. We hypothesized that knee joint moments would increase over time.

## METHODS

Nine male service members with unilateral lower limb loss from traumatic injury (three transfemoral, six transtibial) completed gait analyses at 3 distinct time points: 0, 2, and 6 months after initial ambulation (defined as able to walk 50ft

independently without assistive devices) (Table 1). All participants provided informed consent to procedures approved by the Walter Reed National Military Medical Center Institutional Review Board. Participants walked at a self-selected speed and cadence. Kinematic data were captured using a 23-camera motion capture system (Vicon, Oxford, UK; 120Hz) and kinetic data were captured using six force platforms embedded in a walkway (AMTI, Watertown, MA, USA; 1200Hz). Joint marker placements were completed by one of two trained investigators. Marker position and ground reaction force data were smoothed using a 4<sup>th</sup>-order dual-pass Butterworth filter with cutoff frequencies of 6 Hz and 50 Hz, respectively. Knee joint kinetics were calculated by 6DOF inverse dynamics using Visual3D software (C-Motion, Germantown, MD, USA).

A one-way repeated measures ANOVA ( $\alpha = 0.05$ ) tested for the effect of time on the peak, impulse, and loading rate of the KAM, and peak KFM, with a Bonferonni correction in post-hoc testing. Walking speed and stride length were included to determine if they should be covariates. Effect sizes of 0.01, 0.06, and 0.14 were interpreted as small, medium, and large according to guidelines for  $\eta_p^2$ .

## RESULTS AND DISCUSSION

There was a significant effect of time on stride length ( $p = 0.01$ ,  $\eta_p^2 = 0.42$ ), but not on self-selected walking speed ( $p = 0.13$ ,  $\eta_p^2 = 0.23$ ). After adjusting for multiple comparisons, there were no significant pairwise differences for stride length (all  $p \geq 0.07$ ). Therefore, speed and stride length were not included as covariates in the ANOVA.

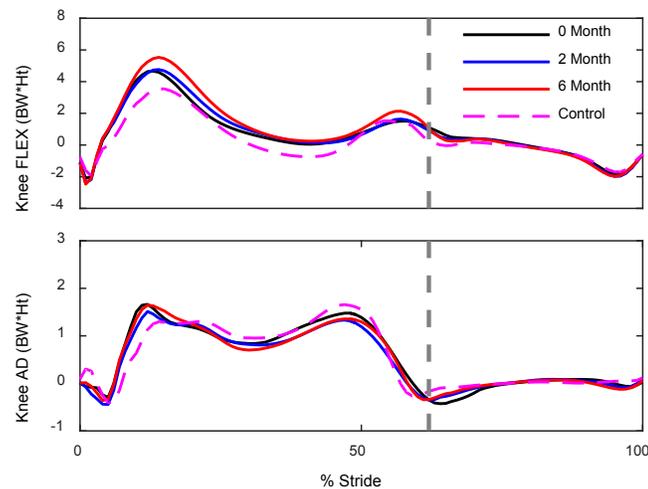

Waveforms of the average KAM and KFM at all time points are presented in Fig. 1. There were no

effects of time on peak ( $p = 0.40$ ,  $\eta_p^2 = 0.11$ ), impulse ( $p = 0.80$ ,  $\eta_p^2 = 0.03$ ), or loading rate ( $p = 0.41$ ,  $\eta_p^2 = 0.10$ ) of the KAM, or peak KFM ( $p = 0.11$ ,  $\eta_p^2 = 0.24$ ) (Fig. 2).

The findings reported herein suggest there is not a substantial, acute adaptation of the intact leg to walking with a prosthetic limb. Thus, if an individual walks with large or unusual knee joint loads throughout their rehabilitation, they may continue to walk with large or unusual loads long-term, potentially increasing their risk for developing knee OA in the intact limb.

## CONCLUSIONS

Recently ambulatory individuals with limb loss did not change the major features of the KAM or KFM of their intact knee joint over the first six months of

**Figure 1:** Mean knee joint moments in the sagittal (top) and frontal (bottom) plane during walking at self-selected speed. Stride begins and ends at heel strike. Vertical dashed lines indicate toe-off. Data from a non-limb loss group are included for reference (pink dashed).

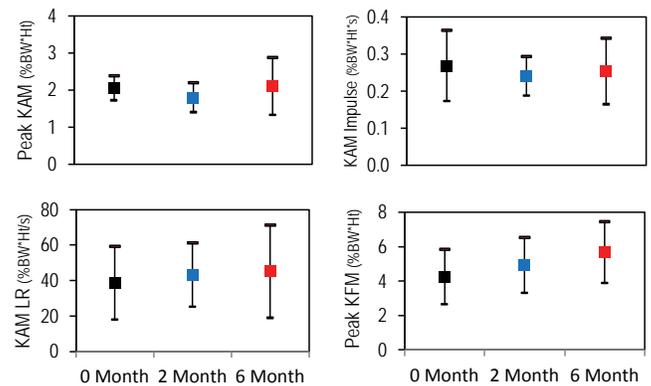

independently walking with a prosthesis. We speculate that these individuals will maintain this loading behavior until there is a reason to change, such as development of pain in the intact knee joint. Therefore, characteristics of knee joint loading early in the rehabilitation process may be relevant for knee OA risk, and should be considered as targets for therapy prior to the initiation of the disease. Future work should address potential longitudinal adaptations that occur after the first six months of independently walking with a prosthesis and the effects of loading on future joint health.

## INTRODUCTION

Persons with lower limb amputation (LLA) often walk with compensational movement strategies involving a prominent reliance on the trunk and pelvis [1]. Resulting increases in trunk and pelvic motions compared to able-bodied individuals have been associated with an elevated risk for low back pain (LBP; [2,3]). In the frontal plane, larger trunk range of motion (ROM) and peak lateral flexion (on the prosthetic side, specifically) among persons with vs. without LLA are often assumed to be a result of an active/learned neuromuscular movement strategy to compensate for weak (or missing) musculature in the residual limb [4]. Identifying the extent to which trunk and pelvic motions change or evolve over time following amputation, particularly beginning at time of initial ambulation, could provide additional insight into contributing factors and, ultimately, guidance for rehabilitation strategies to mitigate deleterious consequences of such motions. Thus, the purpose of this study was to characterize features of trunk and pelvic motion in the frontal plane among persons with LLA as a function of time after amputation. We hypothesized the overall magnitude of mediolateral trunk and pelvic motion would increase with increasing time of ambulation, suggesting a learned proximal movement strategy.

## METHODS

Thirty-two males with unilateral LLA (Table 1) completed gait analyses at 5 distinct time points: 0, 2, 4, 6, and 12 months after initial ambulation (defined as able to walk 50ft independently without assistive devices). Participants walked overground across a 15m level walkway at 3 controlled speeds (completed in a randomized order): Froude2 (mean=0.96 m/s), Froude3 (mean=1.20 m/s), and

Froude4 (mean=1.44 m/s). Full-body kinematics were recorded by tracking (120Hz) reflective markers using a 23-camera motion capture system (Vicon, Oxford, UK). All participants provided informed consent to procedures approved by the Walter Reed National Military Medical Center Institutional Review Board. Note, participants were not required to wear the same prosthetic components throughout, though only 4 of the 32 changed between similar passive energy storage and return feet (all ten with transfemoral amputation wore microprocessor or mechanical knees).

**Table 1.** Mean (SD) participant demographics, obtained at visit t=0, for persons with unilateral transtibial (TT) and transfemoral (TF) amputation. All amputations were the result of traumatic injuries.

	TT (n=22)	TF (n=10)
Age (yr)	27.1 (6.0)	28.5 (6.2)
Stature (cm)	178.5 (4.0)	177.9 (7.8)
Body Mass (kg)	84.2 (11.1)	83.9 (10.8)

Mediolateral trunk and pelvic ROM, and peak trunk lateral flexion in prosthetic limb stance, were computed for each walking speed within Visual3D (C-Motion, Germantown, MD, USA). The trunk was modeled as a single rigid segment, defined proximally by the acromia and C7 vertebrae, and distally at the T10 spinal level. All segmental kinematics were defined in the global coordinate system (relative to vertical). Because not all participants completed all five time points (mean=3, range 2-5), mixed-model repeated measures analyses of variance (ANOVA) were used to compare trunk ROM and peak lateral flexion by group (TT vs. TF) and time, and their first-order interaction. All statistical analyses were performed using SPSS (Version 21, IBM Corp., Armonk, NY, USA), with statistical significance determined when  $p < 0.05$ .

## RESULTS AND DISCUSSION

There were no differences in pelvis ROM by time ( $p>0.09$ ) or between groups ( $p>0.56$ ) at any speed. However, both trunk ROM and peak lateral flexion in prosthetic limb stance decreased (all  $p<0.024$ ) over time (Figure 1), wherein the 0 and 12 month time points were significantly different. At Froude2 and Froude4, these did not differ between groups ( $p>0.28$ ). At Froude3, however, there was a significant interaction between visit and group ( $p=0.014$ ); trunk ROM and peak lateral flexion decreased among persons with TF but not TT amputation, primarily due to the larger values at  $t=0$  among persons with TF amputation.

In contrast to our hypothesis, mediolateral trunk ROM and peak lateral flexion in prosthetic limb stance decreased with increasing time after initial ambulation, regardless of walking speed, most notably within the first 2 months of ambulation among persons with TF amputation. Such a trend suggests mediolateral movements of the trunk and pelvis may be more of a near-term reaction to walking with a prosthesis than a proactive movement strategy learned over time. However, these individuals were also participating in extensive rehabilitation throughout this one-year period and, thus, these changes may also reflect physical therapy and other gait training techniques. Nevertheless, the magnitudes of these motions remain larger than persons without LLA (see gray shaded areas in Figure 1), as well as compared to values reported elsewhere from individuals with LLA who are generally evaluated greater than 12

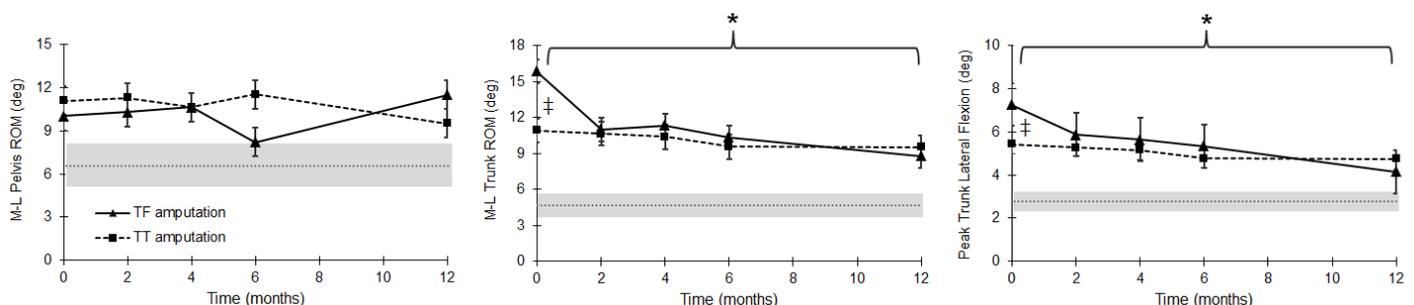

months post amputation [1,5]; suggesting these motions may continue to change over time. Future work should therefore longitudinally evaluate trunk and pelvic motions for extended durations to capture longer-term changes, particularly when these individuals are no longer receiving frequent rehabilitative care. In summary, data reported here identifies, for the first time, temporal relationships of mediolateral trunk motions within the first year of ambulation among persons with LLA. These data have longer-term implications for the surveillance of LBP onset and recurrence, and may help identify important biomechanical factors in its causation.

## INTRODUCTION

Athletes with bilateral transtibial amputations compete in events that span a broad range of running speeds. However, to date the biomechanics of only two such athletes have been reported across running speeds [1-3]. Furthermore, it is uncertain if the exhibited biomechanical changes with altered running speed are inherent to athletes with bilateral transtibial amputations, or if they are due to the characteristics of their running-specific prostheses (RSPs) (i.e. stiffness and height). Therefore, the purpose of our study was to quantify how prosthetic stiffness, height, and running speed affect the biomechanics of athletes with bilateral transtibial amputations. We hypothesized that prosthetic stiffness, but not height, would affect biomechanics across running speeds, and that faster running speeds would mitigate the influence of prosthetic stiffness on all tested biomechanical parameters.

## METHODS

Five male athletes with bilateral transtibial amputations gave informed written consent according to the COMIRB and USAMRMC Human Research Protection Office prior to participation. Each athlete performed fifteen sets of running trials lasting 10 strides each on a 3D force measuring treadmill (Treadmetrix, Park City, UT). Each set of trials began at 3 m/s and each successive trial was incremented 1 m/s until the athlete reached top speed. For each set of trials, athletes used a different prosthetic model, stiffness, and height combination. Prosthetic models included the Freedom Innovations Catapult FX6, Össur Cheetah Xtend, and Ottobock 1E90 Sprinter. Prosthetic stiffness conditions were that of the manufacturer recommended and  $\pm 1$  stiffness categories.

Prosthetic height conditions were the International Paralympic Committee's maximum competition height [4] and  $\pm 2$  cm.

We measured ground reaction forces (GRFs) (1000 Hz) throughout each trial and filtered them using a 4<sup>th</sup> order low-pass Butterworth filter (30 Hz). We used the filtered data to calculate the biomechanical variables that influence leg stiffness [2, 5] and running speed [6] from each trial. We determined prosthetic stiffness (kN/m) ( $k_{RSP}$ ) [5], then used it and calculated overall leg stiffness ( $k_{leg}$ ) to compute residual limb stiffness ( $k_{res}$ ) (Equation 1).

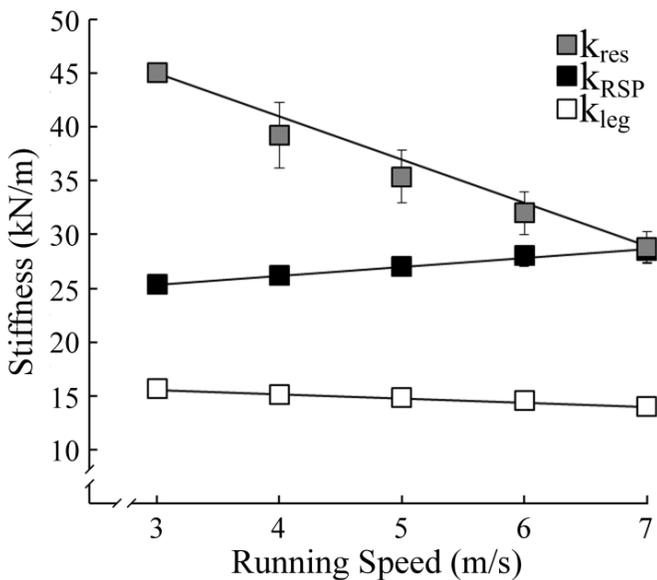

$$\frac{1}{k_{leg}} = \frac{1}{k_{res}} + \frac{1}{k_{RSP}} \quad (\text{Eq. 1})$$

We used linear mixed models to assess the influence of prosthetic stiffness, height, and running speed on each biomechanical variable. We set significance at  $p=0.05$ .

## RESULTS AND DISCUSSION

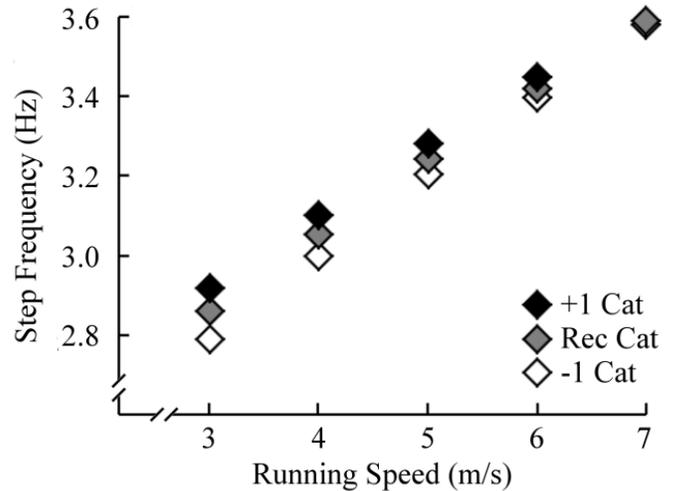

Prosthetic stiffness (kN/m) increased with faster running speeds ( $p<0.001$ ) (Fig. 1). Prosthetic stiffness, height, and running speed all affected biomechanics. Specifically, with stiffer prostheses athletes exhibited greater peak and stance average vertical GRFs ( $p<0.001$ ), increased overall leg stiffness ( $p<0.001$ ), decreased residual limb stiffness ( $p<0.001$ ), decreased ground contact times ( $p<0.001$ ), and increased step frequency ( $p<0.001$ ) (Fig. 2). Increased prosthetic height resulted in lower peak and stance average vertical GRFs ( $p<0.001$ ), as well as longer contact times and step lengths ( $p<0.001$ ). Running speed was inversely associated with overall leg stiffness and residual limb stiffness ( $p<0.001$ ) (Fig. 1).

In contrast to our previous study [5], participants demonstrated an inverse relationship between prosthetic and residual limb stiffness (Fig. 1). Moreover, with increased running speed the influence of prosthetic stiffness was reduced for stance average vertical GRF ( $p < 0.001$ ), residual limb stiffness ( $p = 0.020$ ), contact time ( $p < 0.001$ ), step frequency ( $p = 0.004$ ) (Fig. 2), contact length ( $p = 0.019$ ), the angle swept by the leg spring ( $\theta$ ) ( $p = 0.001$ ), and peak center of mass displacement ( $p < 0.001$ ). No other prosthetic stiffness and running speed interactions achieved significance.

**Figure 1.** Average ( $\pm$ SE) overall leg ( $k_{leg}$ ), prosthetic ( $k_{RSP}$ ), and residual limb ( $k_{res}$ ) stiffness at each running speed and across all prosthetic configurations. Some error bars are hidden behind symbols.

We reject our initial hypothesis because both prosthetic stiffness and height influenced biomechanics across running speeds. We accept our second hypothesis since faster running speeds mitigated the effect of prosthetic stiffness on biomechanics. Furthermore, our participants generally increased both stride length and frequency to achieve faster running speeds. However, for a few trials, some participants improved speed beyond 7 m/s by decreasing stride length and rapidly increasing stride frequency.

**Figure 2.** Average elicited step frequency across prosthetic models and running speeds while using running-specific prostheses at the recommended and  $\pm 1$  stiffness category (Cat) for a 70 kg subject. Step frequency =  $0.315 \text{ speed} + 0.042 \text{ stiffness (kN/m)} - 0.005 \text{ speed} \cdot \text{stiffness (kN/m)} + 1.258$ .

## CONCLUSIONS

Prosthetic stiffness, height, and running speed affect the biomechanics of athletes with bilateral transtibial amputations. Furthermore, the effect of prosthetic stiffness on biomechanics is reduced at faster running speeds, indicating that prosthetic stiffness has a greater influence on distance running than on sprinting performance for athletes with bilateral transtibial amputations.

## INTRODUCTION

The ankle joint is the primary power generator for able-bodied runners [1,2]. After amputation this joint is replaced with a mechanical prosthesis that may not fully replace the biological limb's function. Running-specific prostheses (RSPs) are usually modeled as a two-segment rigid body model where the ankle joint is defined by a single point on the keel, which is assumed to be rigid [3]. Consequently, mechanical energy analyses using such a model assume that all of the RSP power and work would be generated at that single point.

However, the RSP most likely does not generate its power and perform work at one point as the keel flexes throughout its length. Oversimplifying a biomechanical model can induce errors in the analysis and any interpretations drawn from such analysis. A multi-segment model can estimate power and work generation at various points throughout the RSP keel, providing a more comprehensive understanding of RSP keel dynamics during running. Identifying how and where the RSP keel generates power and performs work will improve modeling techniques for biomechanical analyses and can inform on prosthesis alignment, training, and RSP designs.

The purpose of this study was to improve our understanding of mechanical energy production in RSPs. We aimed to identify whether RSPs absorb and generate power and perform work throughout the keel at different running speeds. We hypothesized that (1) RSPs absorb and generate power and perform work throughout the keel, (2) RSPs do not absorb and generate power or perform work evenly throughout the keel, and (3) running

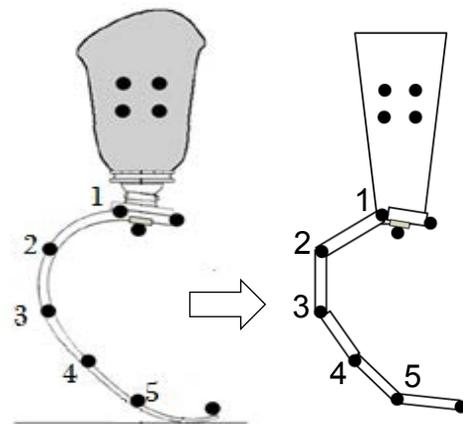

speed would not affect keel power and work performance.

## METHODS

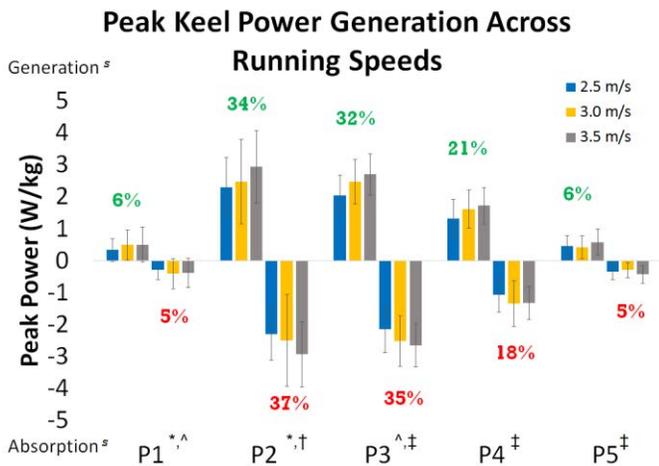

Eight males with unilateral transtibial amputation wore their own RSPs to run overground at 2.5, 3.0, and 3.5 m/s.

10 motion capture cameras (Vicon) captured kinematic data at 200 Hz while 10 force platforms (Kistler) captured ground reaction force data at 1000 Hz. A 6-segment RSP model with 5 joints (Fig. 1) was used to estimate mechanical energy throughout the RSP keel. Joint powers and work were calculated at each joint (Fig. 2-3) via inverse dynamics using Visual3D (C-Motion).

A two-factor (Joint x Speed) repeated measures ANOVA determined peak power and total work differences with  $\alpha=0.05$ .

**Figure 1:** Marker placement on RSP keel and resulting 6-segment model. Power and work were calculated at points 1-5.

**Figure 2:** Average peak joint powers at each keel point (P1-P5) across speeds. Error bars represent  $\pm 1$ SD. Percentages represent average percent of peak power generated (green) and absorbed (red) by each point across all speeds. Symbols (\*, ^, †, ‡) indicate points that differ from each other ( $P < .05$ ). *s* indicates significant speed effects ( $P < .03$ ).

## RESULTS AND DISCUSSION

*Hypothesis 1 Accepted:* RSPs absorb and generate power throughout the keel, not at one point. Each point on the keel performed work during each running speed condition.

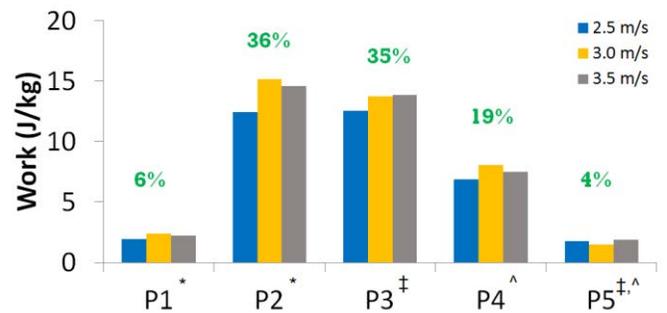

*Hypothesis 2 Accepted:* RSPs do not absorb and generate power or perform work evenly throughout the keel. Points significantly differed from each other in their power absorption and generation (see Fig. 2) and total work performed (see Fig. 3). Points 2, 3, and 4 absorbed and generated 85-90% of the keel power and performed 90% of the total work.

*Hypothesis 3 Accepted:* Total work did not change with speed; No interaction effect (Point x Speed) was observed for either power or work indicating the relative power and work output for each keel point did not change with speed.

*Hypothesis 3 Rejected:* Peak power absorption and generation increased with speed (see Fig. 2).

Past data conflict on whether RSP “ankle” joints produce less or more power and work compared to intact ankle joints [3,4]. Our data indicate that RSPs generate power throughout the keel, and not at one

## Total Work Performed Throughout the Keel

**Figure 3.** Total work performed at each keel point (P1-P5) across speeds. Average percent of work performed by each point across all speeds is shown. \*, ‡, and ^ indicate points that significantly differ from each other ( $P < .05$ ).

point. Modeling RSPs with a single “ankle” joint could induce errors in inverse dynamics analyses and lead to misinterpretations of RSP function.

Altering RSP designs to generate power and work evenly throughout the keel or optimize power generation at one point may lead to greater overall performance. Additionally, different prosthetic alignments may allow runners to optimize RSP power and work generation throughout the keel.

## CONCLUSIONS

Different RSP keel regions absorb and generate different magnitudes of power and perform differing amounts of work. Understanding RSP mechanics requires knowledge of kinematics and kinetics throughout the keel, not at only one point.

## INTRODUCTION

The regulation of angular momentum is important for maintaining balance during gait [1]. For example, individuals who have a history of falling have difficulty controlling angular momentum during fall recovery as compared to those without a history of falling [2]. In addition, the ankle plantarflexors are critical in the regulation of angular momentum [3,4] and fallers have a reduced peak ankle moment during fall recovery [2].

Individuals with a transtibial amputation (ITTA) are characterized by the functional loss of the ankle plantarflexors and have greater ranges of angular momentum during walking [5], which helps explain their greater risk of falling [6] and altered movement strategies. However, whole-body angular momentum has not been examined in ITTA during running.

Understanding movement coordination to provide propulsion, support and balance during running is important in evaluating running performance. Thus, the purpose of this study was to quantify whole-body angular momentum in people with and without transtibial amputations during running. We hypothesized that ITTA using running-specific prostheses (RSPs) would have greater ranges of whole-body angular momentum in all three anatomical planes during running compared to able-bodied individuals.

## METHODS

Five male runners with a unilateral transtibial amputation (mean  $\pm$  SD: height = 1.78  $\pm$  0.09m, mass = 82.9  $\pm$  16.5 kg) and five able-bodied (AB) male runners (mean  $\pm$  SD: height = 1.83  $\pm$  0.06m, mass = 81.3  $\pm$  9.39 kg) participated in the study. Each participant with an amputation ran with their

prescribed RSP. RSP mass and inertial properties were measured for each participant [7]. Participants ran continuously along a 100m track at 3.0 m/s. Speed was monitored using laser sensors during a 25m straightaway. Kinematics were collected at 200Hz using a ten-camera motion capture system and a full-body marker set.

Kinematics were filtered using a fourth-order Butterworth filter with a cutoff frequency of 6 Hz. Whole-body angular momentum ( $\vec{H}$ ) was calculated from body kinematics using a 15-segment model in Visual3D using the following equation:

$$\vec{H} = \sum_{i=1}^n [(\vec{r}_i^{COM} - \vec{r}_{body}^{COM}) \times m_i(\vec{v}_i^{COM} - \vec{v}_{body}^{COM}) + I_i \vec{\omega}_i]$$

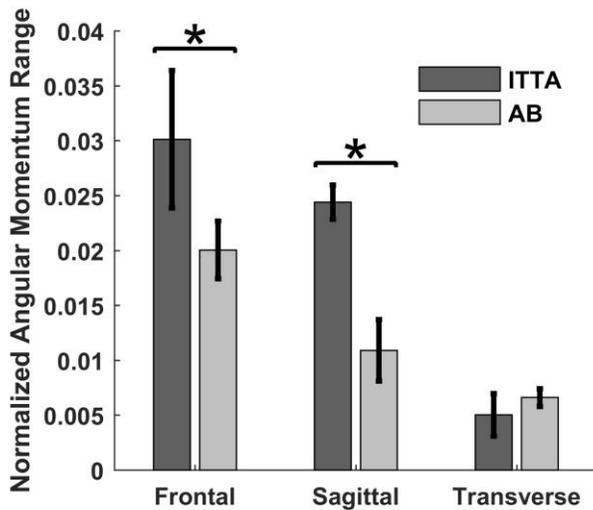

where  $\vec{r}_i^{COM}$ ,  $\vec{v}_i^{COM}$ , and  $\vec{\omega}_i$  are the position, velocity, and angular velocity of the  $i$ th segment respectively;  $\vec{r}_{body}^{COM}$  and  $\vec{v}_{body}^{COM}$  are the position and velocity of the center of mass of the whole body respectively; and  $m_i$  and  $I_i$  are the mass and inertia matrix of the  $i$ th segment respectively.  $\vec{H}$  was normalized by participant height, mass, and running speed. Comparisons for overall range of  $\vec{H}$  (peak-to-peak amplitude) between AB and ITTA were calculated using t-tests ( $\alpha=0.05$ ).

## RESULTS AND DISCUSSION

Sagittal and frontal plane  $\vec{H}$  ranges for ITTA were significantly greater ( $p < 0.001$  and  $p = 0.038$ , respectively) compared to AB individuals (Fig. 1), which is consistent with prior studies of walking [5]. Range of  $\vec{H}$  in the transverse plane was not significantly different between groups ( $p = 0.131$ ).

The net external moment equals the time rate of change of  $\vec{H}$ . Thus, greater values of  $\vec{H}$  suggest that ITTA may have difficulty recovering from

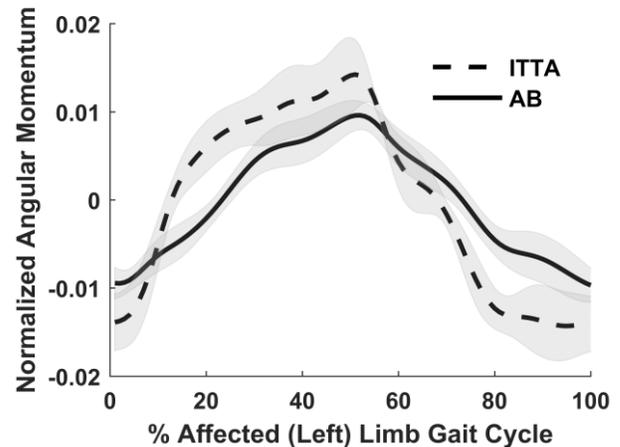

unexpected perturbations in the sagittal and frontal planes during running, as a greater external moment is required to restore the  $\vec{H}$  of the body to zero. In addition, ITTA have reduced muscular control at the ankle due to the loss of the plantarflexors, which are critical for balance regulation [3,4]. Thus, ITTA have a reduced capability to quickly modulate the external moment in response to a perturbation.

**Figure 1:** Normalized whole-body angular momentum range  $\pm$  one standard deviation in ITTA and AB individuals during running at 3.0 m/s. ‘\*’ indicates a significant difference between groups

Mediolateral ground reaction forces (GRFs) and vertical GRFs factor into frontal plane  $\vec{H}$  through their contributions to the external moment about the body center of mass. A reduction in mediolateral GRFs in the affected limb of ITTA [8] resulted in a reduction in its negative external moment generation toward the affected limb. Thus, the frontal plane  $\vec{H}$  trajectory had a greater positive slope (toward the intact limb) during prosthetic limb stance (~0-33% of the gait cycle, Fig. 2). Larger vertical GRFs during intact limb stance (~50-83% of the gait cycle) [8] contribute to a larger negative external moment (toward the affected limb). These asymmetric GRFs in ITTA result in a greater range of frontal plane  $\vec{H}$  relative to AB participants.

Reduced mediolateral GRFs resulting in an increase in frontal plane  $\vec{H}$  range may provide rationale for prosthetic design considerations. RSPs are typically designed for sagittal plane motion on flat surfaces (like a track). However, restoring mediolateral GRF generation in RSPs could improve their application

**Figure 2.** Average frontal plane whole-body angular momentum ( $\pm$  1 standard deviation indicated by the shaded area) for the ITTA and AB participant groups running at 3.0 m/s

to uneven surfaces like natural trails, where frontal plane balance is more challenging to maintain.

## CONCLUSIONS

Greater ranges of whole-body  $\vec{H}$  in the frontal and sagittal planes for ITTA during running highlight altered running strategies for ITTA due to the loss of the plantarflexors and subsequent changes in GRFs. Regulating  $\vec{H}$  in the frontal plane by altering prosthesis design to better incorporate mediolateral force control may improve the ability of ITTA to regulate dynamic balance during running.

### INTRODUCTION

The symposium, co-organized by the ASB and the Society for Integrative & Comparative Biology (SICB), aims to foster dialogue between the societies and to stimulate interchange between human-centered and comparative biomechanics fields. The theme of the symposium is the use of the ‘comparative’ approach to uncover biomechanical principles. The symposium will span both terrestrial and aquatic biomechanics. Exchange of technical approaches between fields will also be discussed. Finally, the symposium will showcase examples where the application to humans may not be immediately obvious, but that inspire *unexpected* scientific advances!

Symposium schedule:

Introduction – Jonas Rubenson & Elizabeth (Beth) Brainerd – 10 mins

Avian Model of Exotendons – Suzanne Cox – 15 mins

Mouth Expansion in Catfish Using XROMM – Aaron Olsen – 15 mins

Biomechanics of Strange Fishes (that don’t swim) – Brooke Flammang - 15 mins

Comparative Terrestrial Locomotion: Insights into Human Biomechanics and Biorobotics– Andrew Biewener – 15 mins

Speaker Q & A panel – 20 mins

### ROBOBIRD: AN AVIAN MODEL FOR PASSIVE-ELASTIC EXOTENDONS – Suzanne Cox, Gregory Sawicki & Jonas Rubenson

Limb orthoses, including exoskeletons, are externally worn braces or devices used to improve locomotor deficits, aid rehabilitation or augment human locomotor performance<sup>1</sup>. While robotic and passive exoskeletons have been shown to improve locomotor performance<sup>1</sup>, the limitations of human experimentation have left many important questions unanswered. More specifically, how does exoskeleton design influence muscular-tendon function<sup>2</sup>, and, in turn, locomotor performance?

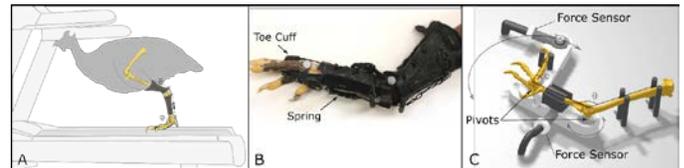

Figure 1: A) Experimental setup B) Exotendon design C) Jig for exotendon moment quantification

Here we present pilot data on a limb orthosis for a bipedal avian model (*Numida meleagris*; Fig 1A-C) that replicates the functionality of current human passive ankle-foot orthoses. In our design, the spring path spans the ankle and metatarsophalangeal (MTP) joints, mirroring the path of several digital flexors and supplementing elastic energy storage during stance phase (Fig 1B). Flexion of the phalanges acts as a natural clutch, disengaging the device during the swing phase. Using intact limb specimens, unaided joint moments at the MTP and ankle (without the exotendon) were subtracted from aided moments to quantify contribution of the exotendon across the span of limb configurations

(Fig. 1C). On combining these data with kinematic analyses of a bird running on a treadmill (n=1; Fig 1A) with and without the exotendon, we observed a 5-10% exo-tendon contribution to the moment at the MTP joint during stance phase (Fig 2). These initial experiments show promise for *in vivo* applications to study neuro-mechanical responses to exotendon augmentation and rehabilitation.

## UNCOVERING MECHANISMS OF MOUTH EXPANSION IN CATFISH USING X-RAY RECONSTRUCTION OF MOVING MORPHOLOGY – Aaron Olsen & Elizabeth Brainerd

The heads of ray-finned fishes contain over 20 mobile skeletal elements, interconnected by a morphologically and functionally varied set of articulations that allow a high degree of mobility. The interconnections among these skeletal elements form a series of coupled mechanisms that can transform input forces at a few elements into rapid expansion of the entire buccal cavity. However, how these mechanisms move and function in three dimensions and how their motion relates to their constituent joints remains unknown. To answer these questions we collected three-dimensional *in vivo* kinematics of seven interconnected cranial bones in channel catfish (*Ictalurus punctatus*)

during suction feeding using X-ray Reconstruction of Moving Morphology (XROMM). We then fit single-joint and multibody models of varying degrees of freedom (DoFs) to the *in vivo* kinematics. As expected, higher DoF models consistently have lower model errors, making it difficult to distinguish between models that have lower error because they better represent the true motion constraints and models that have lower error because they overfit errors. To resolve this, we compare the errors of models fit to the *in vivo* kinematics to the errors of models fit to simulated kinematics. We show how simulated kinematics can be used to establish null expectations for *in vivo* model fitting errors to distinguish between better-fitting and overfitted models. These results contribute to our basic understanding of how articular morphology relates to skeletal motion and demonstrate a model fitting approach applicable to a wide range of musculoskeletal systems.

## BIOMECHANICS OF STRANGE FISHES THAT DON'T SWIM – Brooke Flammang

There is tremendous morphological and ecological diversity among the approximately 33,000 known species of fishes; this is particularly apparent when looking at their fins. While fishes do use their fins for swimming, fin exaptations for walking or adhering are not uncommon. For example, the blind cave loach, *Cryptotora thamicola*, walks with a salamander-like diagonal-couplet lateral sequence gait. This is accomplished in part by its tetrapod-like pelvis, which unique to other fishes, has an ilium. As a result, *Cryptotora* can support its body

on land for walking and climbing. The functional morphology and biomechanics of this fish may provide insight into the fin-to-limb transition and the origin of tetrapods. Second, remoras are fishes that have evolved a unique adaptive ability: an adhesive disc formed from dorsal fin elements that allows them to attach reversibly to actively deforming wetted bodies of varying roughness and compliance that move at high speed. The adhesive disc is a hierarchical structure, in which the lamellae, spinules, fleshy outer lip, and cranial vessels all contribute to the generation of suction and friction for initial attachment and long-term hold. Continued research on the mechanisms and the material properties of these structures is leading towards a bioinspired adhesive device that will be useful in medicine, ecology, and defense.

### **BIOMECHANICS OF MAMMALIAN AND AVIAN TERRESTRIAL LOCOMOTION: INSIGHTS INTO HUMAN BIOMECHANICS AND BIROBOTIC DESIGN – Andrew Biewener**

Comparative studies of mammalian and avian locomotion provide important insight into the neuromuscular mechanics of movement. The *in vivo* function (fiber strain, force and neural activation) of limb muscles in relation to joint mechanics, recorded across a range of locomotor behaviors, reveals how force and work are modulated in relation to neural activation across movement tasks. Studies of avian bipeds and mammalian quadrupeds suggest the existence of a proximo-distal gradient in muscle function and control. Whereas proximal muscles function to modulate limb work through

feedforward control, distal muscles utilize intrinsic F-L and F-V muscle properties reinforced by reflexive feedback to respond to perturbations for stability during running. Distal muscle-tendon units emphasize economy of muscle force generation and tendon elastic energy recovery, rather than work modulation. Postural changes in limb function dramatically affect musculoskeletal loading patterns, and musculoskeletal features of limb function can be implemented in biorobotic design for legged locomotion. Finally, *in vivo* assessment of muscle function also provides an opportunity to validate Hill-type muscle model predictions, which are frequently used to model and evaluate human movement in normal and pathological conditions. By evaluating the predictive accuracy of Hill-type muscle models, features of the model can be adjusted to improve performance. Improvement in the accuracy of time-varying force produced by muscle models can, in turn, improve their application to studies of human muscle function related to movement performance, rehabilitation and aging.

## INTRODUCTION

Work involving arm elevation, especially at or above the shoulder level (or, overhead work), is an important risk factor for occupational shoulder musculoskeletal disorders [1]. Overhead work can be unavoidable in some workplaces, yet involves substantial exposure to overexertion, which account for nearly half of shoulder injuries with lost workdays reported in the U.S. [1].

Use of an assistive device can be an effective approach to reduce physical demands involved in overhead work. Earlier, we found that a Wearable Assistive Device (WADE) could substantially reduce upper arm and shoulder loads in overhead work [2]. We recently evaluated a new WADE (EksoBionics Inc., USA), an upper-extremity exoskeletal “Vest” that generates variable forces to support the upper extremities. While this device also reduced shoulder loads, our focus here was to assess potential adverse impacts related to the “loading pathway”, specifically whether use of such a device might increase low-back loading.

## METHODS

Twelve participants (6F & 6M) completed an experiment in which low-back loads were assessed with and without the WADE. Participants completed simulated drilling and light assembly tasks in the experiment. All participants provided informed consent, following procedures approved by Virginia Tech Institutional Review Board.

Training was first provided for the participants to learn the drilling task (see [3] for a task description). In a separate data collection session, three independent variables were experimentally manipulated in a full-factorial design: 1) Vest Intervention (with vs. without); 2) Work Task [drilling (Drilling<sub>LIGHT</sub>), drilling with additional load 2.27 kg (Drilling<sub>HEAVY</sub>), and Wiring]; and, 3) Work

Height [shoulder (SH) vs. overhead height (OH)]. For a given experimental condition, participants completed two trials of each simulated work task. Participants were instructed to complete the trial as quickly and as accurately as possible, and rest periods were provided between conditions.

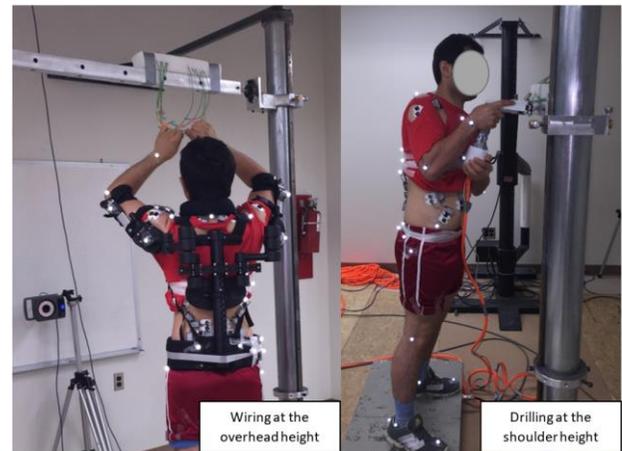

Figure 1. Illustration of drilling and wiring tasks at two work heights.

Muscle activity was monitored using surface EMG (TeleMyo Desktop DTS, Noraxon) over 14 accessible muscles in the lower lumbar region. Initial procedures were completed to calibrate an EMG-based model that estimated spinal loads (see [4] for details). Segmental body kinematics were recorded using surface markers. From the noted model, outcomes measures of peak and mean anteroposterior shear forces ( $F_{AP}$ ) and compressive forces ( $F_{COMP}$ ) were obtained, at the L5/S1 level. Separate mixed-factor ANOVAs were used to evaluate the influences of Gender, Vest, Task, and Height on these measures ( $p < 0.05$ ).

## RESULTS AND DISCUSSION

Peak and mean  $F_{AP}$  were significantly ( $p$ -values  $< 0.01$ ) affected by *Task*, and interaction effects of *Task*  $\times$  *Height* and *Task*  $\times$  *Vest* (Figure 2 Top). Peak

$F_{AP}$  decreased by  $\sim 27\%$  with the vest during shoulder-height work, however it was in general not substantially influenced by vest use.

Peak and mean  $F_{COMP}$  were significantly affected by *Task*, and interaction effects of *Height*  $\times$  *Vest* and *Task*  $\times$  *Vest* ( $p$ -values  $< 0.02$ ; Figure 2 Bottom). Use of the vest reduced peak and mean  $F_{COMP}$  forces respectively by  $\sim 15\text{-}16\%$  and  $\sim 16\text{-}18\%$  during the drilling task at shoulder height. Potential explanations for this decrease are: (1) the mass ( $\sim 6.5\text{kg}$ ) of vest and/or torso flexion created lumbar flexion moments, offsetting extension moments from the drilling task, and (2) participants needed less effort to stabilize their trunk (e.g., reduced co-contraction) because of the rigid and supportive structure of the vest. Further analyses will be needed to investigate these potential mechanisms.

In the current work, some beneficial effects of the vest were demonstrated in terms of low-back loads, though only after a rather short period of task

simulation. Hence, it is unknown whether or to what extent such effects will be maintained (or even increase) over a longer-term period. In addition to reducing shoulder loads, overall the exoskeletal vest led to reduced or comparable low back loads (i.e., both compression and shear lumbosacral reaction forces), especially during the drilling task. Thus, use of such technology may be an effective approach to reduce the physical demands and injury risk involved in overhead occupational tasks.

**Disclaimer:** EksoBionics and The Boeing Co. financially supported this research. While contributing to the study design, they were not involved in data analysis, interpretation, or decision for publication.

## INTRODUCTION

Upper limb disorders are common in grocery store cashiers, perhaps due to unique exposures. Cashiers have the highest rate of cumulative trauma disorders among all grocery store workers, accounting for up to 35% of all workplace injuries in the retail sector (1). Cashier work tasks involve repetitive movements and prolonged maintenance of awkward postures, such as arm elevation (2). Arm postures are likely influenced by the cashier environment, and certain workstation configurations and packaging containers may alter the physical demands of cashiers (3), increasing their risk for injury.

The purpose of this study was to examine the influence of cashier workstation height, packaging type, workload intensity, and side on arm elevation to delineate postural demands in cashiers.

## METHODS

Fifteen experienced cashiers (7 males, 8 females, age =  $21.5 \pm 1.9$  years) free of self-reported upper-extremity or back injury within the past year participated. The study protocol was approved by the University of Waterloo Research Ethics Board; all participants provided written informed consent.

A simulated cashier station was created for data collection, with dimensions and adjustability matching those of a standard cashier workstation. Participants performed 36 grocery scanning and packing trials. Workstation height (high, medium, low), packaging type (bin, reusable bag, plastic bag), and workload intensity (6 items, 20 items) were systematically tested in a full factorial design.

Motion of the torso and upper limbs was tracked with 8 VICON MX20 (Vicon Motion Systems, Oxford, UK) optoelectronic infrared cameras and reflective markers were placed on the skin near anatomical landmarks per ISB standards. Thoracohumeral angles were calculated for both arms and amplitude probability distribution functions (APDF) created to examine levels of arm elevations for each trial. The amplitudes of the 10<sup>th</sup> percentile, 50<sup>th</sup> percentile, and 90<sup>th</sup> percentile were extracted for each trial and arm.

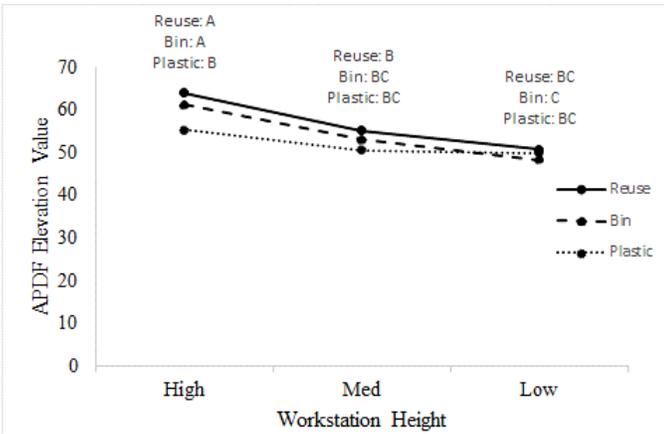

A mixed effect repeated measures ANOVA with a post-hoc Tukey HSD analysis for gender, intensity, packaging type, and workstation height evaluated the main and interaction effects of each parameters on the different APDF percentiles. Paired t-tests determined bilateral differences (all tests at  $p < 0.05$ ).

## RESULTS AND DISCUSSION

Packing type and workstation height interacted to influence right arm posture at the 90<sup>th</sup> percentile APDF value, considered to be “peak” workload (Figure 1). At the high workstation height, the highest elevation values were for the reusable bags (63.9°), then bins (61.2°) and then plastic bags (55.3°). However, the low height using the bins required the lowest levels of peak arm elevation (48.2°). Moreover, the combinations of reusable bags and low height required similar elevations levels as the combination of plastic bags and medium height, at 50.7° and 50.6°, respectively.

There were also main effects of both packaging type and workstation height for both arms at the 50<sup>th</sup> and 90<sup>th</sup> percentiles. In general, reusable bags required significantly higher arm elevations than both the

bins and plastic bags. Regarding workstation height, the greatest arm elevations occurred while packing at the high heights, followed by the medium height, and then the low height, as expected.

**Figure 1: Interaction of packaging type and workload height for right arm elevation. Levels sharing a letter are not significantly different ( $p < 0.05$ ).**

The differences in arm elevation levels between the different packages are consistent with the geometric profiles of each packaging type. Plastic bags have a low profile, as well as an optional lower bagging area that often cannot be used with the larger reusable options. Bins and reusable bags are taller than plastic bags, with reusable bags being the tallest (1). The main effect of packaging type on arm elevation suggests that reusable bags create the greatest postural demands for the shoulder for cashiers, and the interaction with height, particularly at the highest intensity elevations (90<sup>th</sup> percentile) highlights the need to adjust the workstation to coincide with packaging type to reduce demanding arm postures.

Arm elevation increased with workstation height in the current study, which is a commonly reported phenomena (4). It follows that increasing workstation height would result in greater arm elevations during work. The increased arm elevation

required with workstation height increases and high profile packaging containers, combined with the weighted grocery items, can increase muscular demand (5). This increased muscular demand can initiate muscle fatigue and decreased glenohumeral stability, and instigate shoulder impingement, which is a precursor to many shoulder musculoskeletal disorders (6).

Finally, the right arm had greater arm elevation postures than the left arm. This is likely a consequence of the workstation configuration; groceries were placed to the right of the participant and packaged on the left, resulting in a higher work demand for the right arm. These results indicate that cashiers may benefit from rotation through stations with mirrored layouts.

## CONCLUSIONS

For grocery store cashiers, packaging type and workstation height influence arm postures. The reusable bags and high workstation height required the greatest postural demand, suggesting that when using reusable packaging, workstations should be adjusted to the lowest height, and that lower profile reusable bags should be encouraged.

# AN INVESTIGATION OF CERVICAL SPINE KINEMATICS IN VARIOUS TABLET READING POSTURES

Ethan Douglas and Kaitlin Gallagher

University of Arkansas, Fayetteville, AR, USA  
email: [kmg014@uark.edu](mailto:kmg014@uark.edu)

## INTRODUCTION

In the past five years, tablet ownership in the United States has risen from 4% to almost 50% [1]. Despite recent research associating higher neck flexion angles and muscle activity with handheld computers [2,3], ergonomic standards for these devices do not exist. Previous studies on tablet reading posture have either kept an upright trunk or not assessed different trunk angles when sitting. A survey of high school students reported that seated with a tablet in the lap and a semi-reclined trunk (the hips in front of the shoulders) was the second most common adopted tablet reading position [4]. One recent study examined the effect of a semi-reclined reading position on neck posture and found that increased trunk rotation led to higher neck flexion levels than upright seated positions, but lower neck extensor muscle activity [3]. This study only assessed external measurements of the neck, and so the biomechanical effect of trunk rotation on the cervical spine kinematics is unknown. The purpose of this study was to examine the effect of trunk rotation on cervical spine lordosis and intervertebral joint angles while viewing a tablet computer.

## METHODS

Twenty participants (11 female, weight  $71.1 \pm 11.2$  kg; height  $174.1 \pm 10.2$  cm) aged 18-34 ( $21.3 \pm 1.2$  years) were recruited to participate in this study. The inclusion criteria for participation in this study were no previous neck or spine injury, no chronic headaches, no allergy to rubbing alcohol and have not been exposed to any of the following within the past two years: lumbar spine x-ray, upper GI tract x-ray, barium enema x-ray, or any CT scans. For female participants, an additional inclusion criteria was no chance of pregnancy.

All radiographs were taken by a licensed technician. A lead marker was placed on the right tragus to estimate the head's center of mass. The first image was looking straight ahead (neutral), followed full flexion. Radiographs were then taken with the

participant reading a tablet (iPad2) in their lap in three different postures: 1) Upright seated 2) Semi-reclined ( $20^\circ$  with respect to vertical) 3) Reclined ( $45^\circ$  inclination with respect to vertical) (Figure 1).

Figure 1. Tablet reading positions. (Left to right: Upright, Semi-reclined, Reclined).

All measurements were manually taken by the experimenter using ImageJ and custom MATLAB code. Measurements taken were centroid cervical lordosis (CCL), (represents the lower cervical lordosis angle from C7 to C3 [5]), skull angle with respect to the horizontal, skull-C1, C1-C2, and C2-C3 joint angles, and gravitational moment arm. All measurements were analyzed using one-way repeated measures ANOVAs ( $\alpha=0.05$ ) with a within-factor of position (Neutral/Upright/Semi-reclined/Reclined). Tukey's HSD tests were run to analyze significant main effects.

## RESULTS AND DISCUSSION

There was a main effect of position for CCL ( $p<0.0001$ ), moment arm ( $p<0.0001$ ), C1-C2 ( $p<0.001$ ), C2-C3 ( $p=0.0014$ ), and Skull angle ( $p<0.001$ ). There was no main effect of position for the Skull-C1 angle.

CLL angle became increasingly more flexed when viewing the tablet with an upright trunk compared to the semi-reclined ( $p<0.0001$ ) and reclined trunk ( $p<0.0001$ ) positions. The gravitational moment arm of the head was largest when reading the tablet with an upright trunk compared to the semi-reclined

( $p=0.0248$ ), and reclined ( $p=0.0071$ ) positions (Table 1). The moment arm for the reclined position was not significantly different from neutral. Compared to neutral, the C1-C2 angle was more flexed in the C1-C2 ( $p<0.0001$ ), semi-reclined ( $p=0.0032$ ) and reclined ( $p=0.0010$ ) position. There were no significant differences between C1-C2 for three positions. C2-C3 was also more flexed in the semi-reclined ( $p=0.0008$ ) and reclined ( $p<0.0257$ ) position compared to neutral. The upright position was not different from any of the positions. The skull angle with respect to the horizontal was more flexed than neutral in all positions ( $p<0.001$ ); however, the head experienced the least amount of flexion in the reclined position ( $p=0.0421$ ).

The gravitational moment arm was highest when the person was reading with the upright trunk posture, which agrees with previous findings [2]. Our results also follow previous results demonstrating that the head is more in line with the horizontal in the reclined position versus the semi-reclined and upright sitting positions[4], decreasing the moment arm. Sitting in a reclining position could have some benefits for decreasing the required muscle activation to support the head.

The potential risks of a reclined posture can be seen in the lower cervical spine. While moment arms decreased with trunk rotation, the CCL angle increased. This result is in line with previous work that showed head-to-trunk flexion was greatest in this posture compared to reading a tablet off the lap with an upright posture [3]. Many cervical erector spinae muscles originate inferior to C7 and insert on the upper cervical spine. A larger CCL angle could increase the passive tension applied to the muscles

and ligaments, change where these muscles operate on the force-length curve for active tension development and alter their muscle moment arm.

While the CCL saw increased flexion with the reclined position, there were no subsequent compensations in the upper cervical spine. The intervertebral joints were only slightly more flexed compared to neutral, and the skull-C1 angle was the same for all positions. With the lower cervical spine more flexed with small changes in the upper cervical spine posture, the normal cervical lordosis still will not be maintained. There was also a large variability in the intervertebral joints (Table 1). Participants might adopt different strategies within the cervical vertebrae to achieve similar neck flexion angles. Future work should further investigate this variation in intervertebral joint angles with neck flexion.

# FINGER FLEXOR TENDON AND SUBSYNOVIAL CONNECTIVE TISSUE MOTION WITH EXTERNAL MECHANICAL PRESSURE AND PARTIAL OCCLUSION

Amanda Farias Zuniga<sup>1</sup>, Calvin Tse<sup>2</sup>, Peter Keir<sup>1</sup>

<sup>1</sup> Department of Kinesiology, McMaster University, Hamilton, Canada

<sup>2</sup> Rehabilitation Sciences, University of British Columbia, Vancouver, Canada  
email: fariasza@mcmaster.ca

## INTRODUCTION

Carpal tunnel syndrome (CTS) is a highly prevalent neuropathy resulting from median nerve compression, and manifesting into neurological symptoms affecting the hand and wrist. The subsynovial connective tissue (SSCT) is a collagenous network surrounding tendons and the median nerve in the carpal tunnel, and serves to facilitate independent motion between tunnel contents. Cumulative injury to finger flexor tendons and the adjacent SSCT has been postulated as a precursor to CTS development [1]. Moreover, women are more likely to develop CTS [2], suggesting that sex, among other factors, may be a risk factor in CTS development.

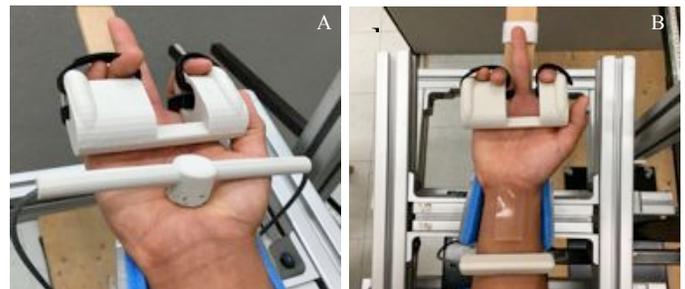

Previous investigations have suggested that externally applied pressure to the hand and forearm increase carpal tunnel pressure, subsequently increasing gliding resistance between carpal tunnel contents [3]. Additionally, acute ischemia has been shown to elicit transient CTS symptoms, altering the fluid environment within the tunnel and affecting the viscoelastic properties within [4], ultimately effecting tendon motion.

The current investigation examined the relationship between flexor digitorum superficialis (FDS) tendon–SSCT relative motion with external pressure applied to the hand and forearm, and with local ischemia through brachial (cuff) compression. We hypothesized that each of the compression conditions would increase tendon-SSCT shear strain as measured by their individual tissue displacements

## METHODS

FDS tendon and SSCT motion in 19 healthy subjects (10 men; age= 23 ± 2.2 years) were

measured at baseline and in three experimental conditions: palmar compression (Figure 1A), forearm compression (Figure 1B), and partial ischemia (via brachial arteriovenous occlusion)(Figure 2). Palmar and forearm compression were achieved through custom force applicators using external weights resulting in 5 kg of compression. Participants performed repeated cycles of finger flexion-extension in each experimental condition and at two speeds (0.75 and 1.25 Hz), while tendon-SSCT motion was observed using a Vivid q BT10 sonographic imaging system (GE Healthcare, WI, USA). Colour Doppler imaging was used to measure FDS tendon and SSCT velocities. To compare tendon-SSCT relative displacement, tissue velocities were filtered and integrated to calculate FDS tendon displacement, SSCT displacement, FDS-SSCT relative displacement, and Shear Strain Index (SSI) ( $FDS_{Disp}-SSCT_{Disp}$ ) /  $FDS_{Disp}$ ). This technique using colour Doppler imaging has been validated against cadaveric displacements as an effective method for evaluating tendon-SSCT relative motion [5]. Repeated Measures ANOVAs were performed for each variable and separated by session, and Bonferroni-corrected post-hoc t-tests performed on significant effects.

**Figure 1:** Palmar (A) and forearm (B) force applicators with 5kg weight secured via steel cables.

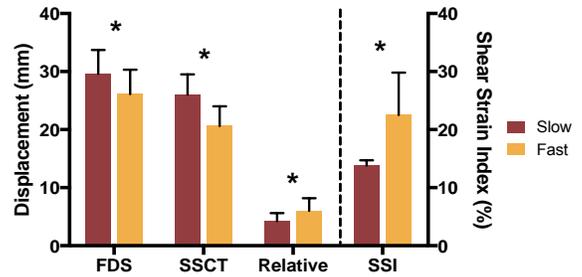

**Figure 2:** Partial ischemia condition with manual blood pressure cuff placed around upper arm and pressure gauge to monitor compression level.

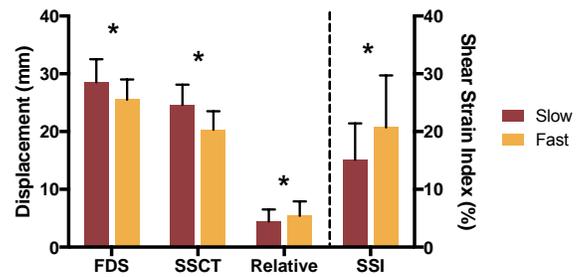

## RESULTS AND DISCUSSION

A significant main effect of compression was found for FDS displacement ( $p < 0.05$ ), with forearm compression resulting in significantly less tendon displacement compared to baseline. Velocity of finger movement during compression significantly affected FDS displacement ( $p < 0.001$ ), SSCT displacement ( $p < 0.001$ ), tendon-SSCT relative displacement ( $p < 0.001$ ) and SSI ( $p < 0.001$ ), whereby fast finger movement decreased tendon and SSCT displacement, and increased tendon-SSCT relative displacement and SSI (Figure 3).

Under partial ischemia, there was a small but significant main effect of ischemia on SSCT displacement ( $p < 0.05$ ) such that ischemia decreased SSCT displacement. Furthermore, fast movement velocity significantly decreased FDS displacement ( $p < 0.001$ ) and SSCT displacement ( $p < 0.001$ ), while tendon-SSCT relative displacement ( $p < 0.01$ ) and SSI ( $p < 0.001$ ) were greater in the fast movement condition (Figure 4). Although not a main objective, further investigation suggests differences in SSCT and FDS displacement under partial ischemia may be explained by sex. A significant Sex  $\times$  Speed interaction effect was observed for both SSCT and FDS displacement under ischemia. For instance, in men, FDS displacement decreased under slow finger movement and increased with fast movement, while FDS displacement in women decreased under both movement speeds. Further post-hoc analysis will aim to explain these sex differences.

**Figure 3:** Tissue displacement and shear strain index (SSI) for slow and fast movement velocities during the palmar and forearm compression session.

**Figure 4:** Tissue displacement and shear strain index (SSI) for slow and fast movement velocities during the partial ischemia session.

## CONCLUSIONS

Our investigation shows compression and partial ischemia alters FDS tendon and SSCT displacement. Some results suggest greater risk for tendon-SSCT shear injury, particularly under partial ischemia. Faster movement velocities resulted in greater relative tendon-SSCT displacement *in vivo*, an observation previously made in cadaver studies. Preliminary analyses suggest an avenue for sex-related differences in tendon mechanics. This investigation aims to improve the current understanding of mechanisms underlying CTS, specifically related to mechanical compression and ischemia and may be helpful in developing ergonomic interventions.

## Applied hand-rung forces after a ladder perturbation

Erika Pliner and Kurt Beschoner  
University of Pittsburgh, Pittsburgh, PA, USA  
email: beschorn@pitt.edu

### INTRODUCTION

The majority of fatal falls are to lower levels with ladders accounting for the plurality of these falls [1]. Improved understanding of falling dynamics is critical for developing preventative strategies. For example, previous research on stair fall dynamics have been used to inform handrail design [2]. A significant gap in the ladder fall literature is the magnitude of hand-rung forces applied after a ladder perturbation. The translation of these results will assist in determining whether rung designs enable the force generation required to recover from a ladder perturbation. Furthermore, the interaction between the upper and lower body kinetics during falling are not well understood. This understanding is important since reestablishing the feet back onto the ladder rungs is an important part of recovery process [3]. The purpose of this study is to quantify hand-rung forces during climbing and determine the impact of upper and lower-body responses on these forces.

### METHODS

Thirty-five (13 females) participants climbed a custom-designed, vertically fixed ladder 30 times. Participants experienced a simulated ladder misstep perturbation during six of the climbs (3 per climbing direction) [4]. Onset of perturbation corresponded to the timing of when a person is most likely to experience a slip [3]. Kinetic data was collect from eight unidirectional load cells (2000 Hz) placed on the eighth and ninth rungs (two on the ends of each rung to collect horizontal and vertical forces). Participant safety was ensure with a fall arrest system, and informed consent and IRB approval was obtained prior to testing.

Four hand placement responses from the hand that moved during the perturbation or the hand that was next to move (moving hand) were observed: HP2 – moved two rungs from initial position; HP1 – moved one rung from initial position; HP0 – elevated and returned to initial position; HPN – did not move.

Three foot placement responses were observed after the perturbation: FP2 – both feet reestablished foot placement with the rung(s); FP1 – one foot reestablished foot placement with a rung; FP0 – neither foot reestablished foot placement with a rung. The time window used for all analyses started with the perturbation onset, and the end of the perturbation was defined based on harness forces and downward displacement of the body [4].

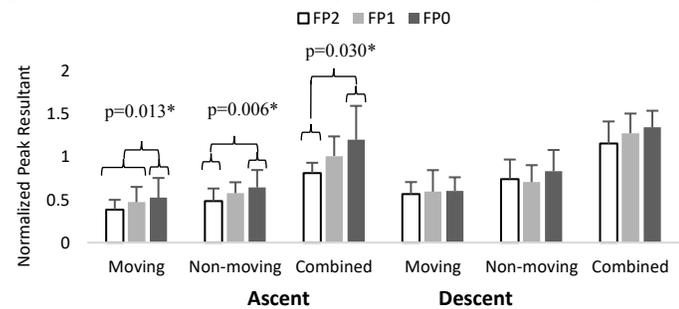

The peak horizontal, vertical, and resultant forces applied to rungs 8 and 9 were calculated for the moving hand and the hand that did not move (non-moving hand) during the falling event. The peak forces were only determined if either hand ended or was located on rungs 8 or 9. The separated and combined rungs forces where only assessed if both hands were on these rungs. Peak forces were normalized by body weight. In addition, the angle of the resultant force with respect to the vertical was determined to assist in the characterization of resultant forces applied to a ladder rung.

Repeated-measure ANOVA methods were used with the moving hand, non-moving hand, and combined hands peak resultant force as the dependent variables. The independent variables were subject number (random), gender (confounding), and hand and foot placement response. All analyses were conducted separately for ascent and descent. A Tukey HSD post hoc was run on significant hand and foot placement response effects.

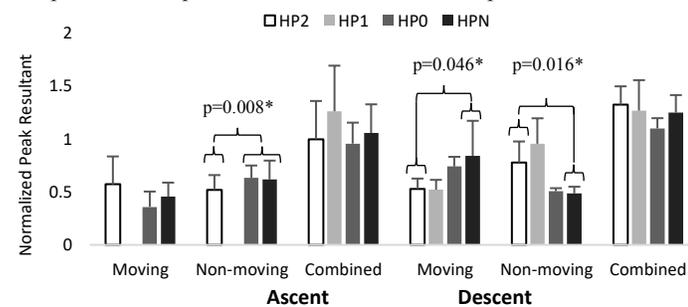

### RESULTS

The non-moving hand peak forces and resultant force angle were greater than those of the moving hand. The combined resultant forces were slightly larger than the subject's body weight for ascent and about 20% larger than their body weight for descent. The combined resultant force angle was about the average resultant force angle from both hands (Table1).

Resultant peak forces were affected by hand and foot placement responses for ascending and descending ladder perturbation recoveries. During ascent, the moving hand had greater peak force for the FP0 compared to the other two foot placement responses. Similarly, the non-moving hand and combined hands had greater peak forces for FP0 than FP2 (Fig.1). In addition, the non-moving hand had greater peak forces for HP0 and HPN compared to HP2 (Fig.2). During descent, applied peak forces were similar across foot responses and varied across hand responses for the moving and non-moving hands. Specifically, the moving hand generated greater force levels for HPN than HP2. The opposite effect occurred with the non-moving hand generating a greater force for HP2 compared to the HPN response.

**Figure 1:** Normalized peak resultant forces applied to the rungs across foot placement responses after ascent and descent perturbations.

**Figure 2:** Normalized peak resultant forces applied to the rungs across hand placement response after ascent and descent perturbations

## DISCUSSION

Peak resultant forces per hand varied between 47% and 75% of participant body weight (BW). These results add context to previous work that investigated

the peak force persons could generate across different handhold designs. Specifically, we would not anticipate hand forces to be a limiting factor when grasping a horizontal cylindrical rung since the achievable forces on this design are approximately 94%-117% BW [5]. However, hand forces may be a limiting factor when grasping a vertical cylinder (68%-72% BW) or vertical plate (50%-55% BW) [5]. While force distribution varied across the moving and non-moving hand for hand placement responses, the overall combined hand force was similar across hand placement responses. This suggests that the applied forces from the upper body are similar regardless of hand placement response. During ascending ladder perturbations, greater forces were applied to the rungs when neither foot reestablished foot placement with the ladder rung(s). Thus, participants that do not utilize their lower body to recover after a ladder perturbation may need to compensate with a greater upper body response.

## CONCLUSIONS

This study reinforces previous research suggesting that a horizontal cylinder is sufficient to facilitate the generation of hand forces used in response to a ladder perturbation. In addition, this study gives insight on how different hand and foot placement responses facilitate recovery after a ladder perturbation. Overall, these results can be used to support safer ladder handhold designs, and increase the understanding on the interaction between upper and lower body kinetics during falling.

## INTRODUCTION

Sport helmets are designed based on surrogate headforms used for impact testing. For ice hockey, the Canadian Standards Association currently requires all testing to be done on the CEN EN 960 standard headform <sup>[1]</sup>, built to the dimensions of a 50<sup>th</sup> percentile male <sup>[2]</sup>. However, head shapes can vary substantially across users of the same head circumference size. This may explain in part why individuals with similar head circumference favour different hockey helmet models and adjustment settings <sup>[3]</sup>. Of greater concern, poor helmet-to-head fit may reduce helmet effectiveness <sup>[4]</sup>.

The objective of this study was to compare the head shapes of two 50<sup>th</sup> percentile male headforms and a subset of the male sample from Greencorn (2017).

## METHODS

3D models of 23 adult male heads and 2 medium sized headforms (CEN EN 960 and NOCSAE) were created using a 3D acquisition protocol. Human subjects in this study were adult Caucasian males (ages 20-32) who exclusively wore medium sized helmets; these subjects will hereafter be referred to as medium heads. 3D acquisition was completed using photogrammetry, a technique that constructs 3D models from overlapping images. A series of digital images were taken of the subjects at multiple angles, and the software AutoDesk ReMake™ was used to render the pictures into 3D models.

Data analysis was completed by comparing three 2D slices taken from the 3D models. First, the 3D models were oriented to have the centre of the Frankfurt Plane (transverse plane passing through the inferior borders of the bony orbit and the upper

margins of the auditory meatus) positioned at the origin. Next, slices were taken at 50mm (Plane 1), 65mm (Plane 2) and 80mm (Plane 3) above the Frankfurt Plane. Principal Component Analysis was performed on Planes 1, 2, and 3 of all subjects to determine the largest components of head shape variability. Z-scores were determined and ranked for each of the three greatest principal components (i.e. PC1, PC2, and PC3) of Planes 1, 2, and 3. Independent samples t-tests were run to compare the average radius of the medium heads to the average radius of the headforms in each of the three planes.

## RESULTS AND DISCUSSION

The ranks of the Z-scores of the CEN EN 960 and NOCSAE headforms demonstrate substantial differences from the median score for most principal components and planes; these ranks are presented in Table 1. PC1 represents difference in scale (or average radius), PC2 represents difference in length to width ratio, and PC3 represents difference in front and back head width. These principal components account for 8-72% of total variability in each plane.

A 50<sup>th</sup> percentile head shape was expected to have Z-score ranks between 8 and 17. For PC1 of all planes, both the CEN EN 960 and NOCSAE headforms ranked within the top 5 scores, thus falling at an end of dataset. This corresponded to the headforms' smaller average radii compared to the medium heads. Across PC2 of all planes, both headforms ranked in the bottom 5 scores, suggesting the headforms are wider and shorter (i.e. more circular) than the rest of the sample. For PC3, CEN EN 960 ranked 18<sup>th</sup>, 15<sup>th</sup>, and 2<sup>nd</sup> for Planes 1, 2, and 3, respectively; Planes 1, 2, and 3 of NOCSAE ranked 13<sup>th</sup>, 12<sup>th</sup>, and 7<sup>th</sup>, respectively.

PC1 indicated that headforms are smaller than the mean of the medium heads: this suggests that headforms may replicate a human cranium without accounting for the thickness of the superficial tissues of the head. The Z-score rankings for PC3 suggest both headforms are near or within the median for the difference in front and back head width at Planes 1 and 2. At Plane 3, both headforms ranked high, indicating a wider front and narrower back; these rankings may reflect incongruency between the medium heads and headforms in this aspect of head shape variability.

Superimposing the average radius of the two headforms with the average radius of the 23 medium heads at Plane 2 in Cartesian and Polar coordinates (Fig 1a and b) revealed significant differences between the average radius of the headforms (n=2) and average radius of medium heads (n=23) at Plane 2 (p=0.019) and Plane 3 (p=0.021), but not at Plane 1 (p=0.065).

## CONCLUSIONS

Despite the small sample size, substantial differences in head shape dimensions from headforms were detected. In particular, significant

differences were found between the mean head radius of two 50<sup>th</sup> percentile adult male headforms and a sample of human subjects. In general, Principal Component Analysis demonstrated neither headform represented a median subject in the three greatest components of head shape variability. The headforms do not represent the median head size of the sample of medium heads. The findings of this study may have implications on future headform design, as sport helmet certification standards require testing on a representative human headform. Further study is in progress to collect a larger sample pool.

## INTRODUCTION

Tendon moment arm is an important musculoskeletal parameter that simultaneously determines muscle mechanical advantage while imposing constraints on muscle function. Despite its relevance to muscle and joint functional capacity [1], variability in moment arm measurements that is attributable to the technique used to measure moment arms limits our understanding of the implications of moment arm for movement capacity.

There are two dominant methodological paradigms for *in vivo* measurement of tendon moment arms: 1) geometric methods that quantify the distance between the tendon line of action and joint center (or axis) of rotation and 2) tendon excursion methods based on the Principle of Virtual Work that take moment arm to be equal to the tendon travel per unit joint rotation. While geometric assessments of moment arm using magnetic resonance (MR) imaging have many advantages [2], tendon excursion measurements that employ ultrasound imaging are attractive alternatives because of their low cost and ease of application. Therefore, the purpose of this study was to compare the moment arms obtained using tendon excursion from ultrasound images to those determined using the geometric technique applied to MR images in the same subjects.

## METHODS

Achilles tendon moment arms were quantified using different techniques in 19 healthy-young males ( $27 \pm 4$  years) in this IRB-approved study. MR images were acquired at neutral ankle position ( $0^\circ$ ),  $10^\circ$  plantarflexion, and  $10^\circ$  dorsiflexion using a 3T scanner (Siemens Trio). Subjects were supine with knees extended and were instructed not to contract their muscles during scanning. The sagittal-plane images acquired in the plantarflexed and dorsiflexed

positions were used to locate the center of tibiotalar rotation, and tendon moment arm was calculated as the shortest distance between tendon line of action and the center of rotation on the neutral-position image [1].

To measure tendon excursion during ankle rotation, the distal muscle-tendon junction of medial gastrocnemius was tracked using B-mode ultrasonography (Aloka 1100; transducer: SSD-625, 7.5 MHz and 39-mm scan width) while the foot was rotated from  $10^\circ$  dorsiflexion to  $10^\circ$  plantarflexion at  $10^\circ\text{s}^{-1}$  in an isokinetic dynamometer (Biodex System 3) [2]. To test the effects of tendon tension on these measurements, subjects performed these plantarflexions while (a) passive, (b) maximally contracting the plantarflexors, and (c) maintaining constant tendon force equal to 30% of the maximum isometric tendon force in neutral position by matching desired torques computed using moment arm versus joint angle relationships previously reported [3].

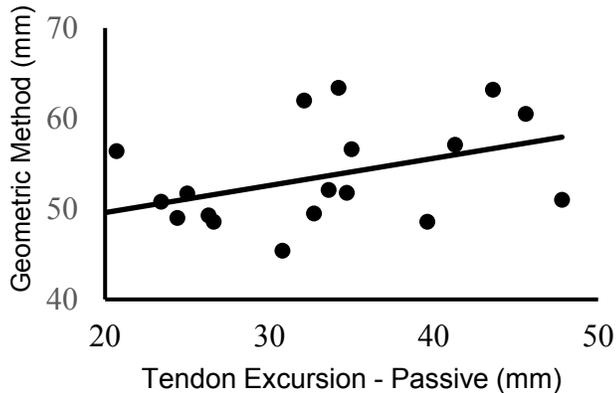

Moment arms derived from tendon excursion were compared to those determined from the geometric technique using regression analysis.

## RESULTS AND DISCUSSION

All variations of the tendon excursion method yielded smaller moment arms than those determined using the geometric method. Further, there were very weak to moderate correlations across subjects between each tendon excursion moment arm measurement and the moment arm from the geometric method, with  $R^2 = 0.21$ ,  $0.08$ , and  $0.07$  for conditions (a)-(c) as described above. The strongest correlation ( $R^2 = 0.21$ ;  $p = 0.052$ ) with the geometric method was found when tendon excursion was measured during passive ankle movement (Fig. 1).

Geometric method moment arms averaged across subjects ( $53 \pm 6$  mm) agreed with previously reported geometric method values ( $52 \pm 4$  mm) [2]. Moment arms from tendon excursion were about 30% smaller and exhibited twice the variability as geometric method values, also comparing favorably to moment arms measured previously using similar methods [2].

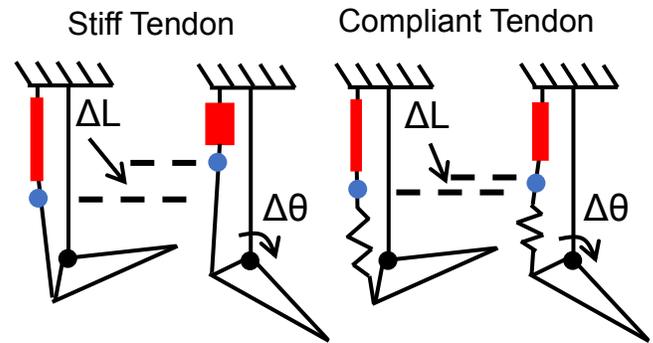

When applied *in vivo*, tendon excursion methods are likely confounded by tendon compliance and an inability to maintain constant tendon tension. When the assumption that the tendon is inextensible [4] is violated and the tendon stretches and relaxes during movement, tendon excursion will underestimate tendon moment arm (Fig. 2). A very stiff tendon or one in which tendon tension is constant will maintain its length and all tendon excursion observed will be attributable to joint rotation. A compliant tendon with varying tension, however, will appear to exhibit less excursion as its length changes, leading to a measurement artifact and an apparently smaller moment arm.

**Fig. 1** Achilles tendon moment arms measured using geometric and tendon excursion methods showed a moderate positive correlation ( $R^2 = 0.21$ ;  $p = 0.052$ ).

The current findings do not agree with a prior report of a strong correlation ( $R^2 = 0.94$ ) between Achilles tendon moment arms in a similar study of the geometric and tendon excursion methods applied in the same subjects [2]. Our sample size was more than twice as large as that of the previous study ( $N = 19$  vs.  $N = 9$ ), which may explain the discrepancy. We performed linear regressions with all combinations

of 9 subjects selected from our sample of 19 subjects ( ${}_{19}C_9 = 92,378$  combinations). These regression models yielded a maximum  $R^2$  value of 0.92, and 11% of the correlations were strong ( $R^2$  greater than 0.50).

**Fig. 2** Moment arms computed as tendon excursion with respect to joint angle ( $\Delta L / \Delta \theta$ ) will be sensitive to tendon compliance and variation in tendon tension. A very stiff tendon will not produce this artifact, but it will be seen when a compliant tendon stretches and relaxes, resulting in an apparently smaller moment arm.

## CONCLUSION

Achilles tendon moment arms calculated using tendon excursion measured *in vivo* do not appear to be strong surrogate measures for moment arms measured using the geometric method. Moment arms measured using tendon excursion may reflect the mechanical properties of the tendon and an inconsistent application of tendon tension throughout movement. It is important to note, however, that measures of tendon excursion in themselves (due to tendon length changes and joint rotation) may be useful for the insights they provide into muscle fiber length changes during movement.

# ARE ULTRASOUND-BASED ESTIMATES OF ACHILLES TENDON KINEMATICS CONSISTENT WITH THE EXPECTED BEHAVIOR OF A PASSIVE ELASTIC TISSUE IN SERIES WITH MUSCLE?

## INTRODUCTION

The Achilles tendon (AT) is an important passive elastic structure that facilitates safe and economical human locomotion, and whose behavior informs the development of assistive technologies and rehabilitative interventions. However, quantifying AT kinematics and kinetics *in vivo* is challenging, leading to inconsistent estimates of length change, stiffness and hysteresis in literature [1]. Ultrasound imaging offers one way to non-invasively estimate AT kinematics *in vivo* during human movement, but critical questions remain about which ultrasound methods are most accurate, and if/when each method yields physiologically plausible AT estimates [2]. Two questions motivated this study: (I) Do commonly used ultrasound tracking methods yield similar estimates of AT length change? (II) Are these estimates consistent with the expected behavior of a passive elastic tissue acting in series with a contracting muscle?

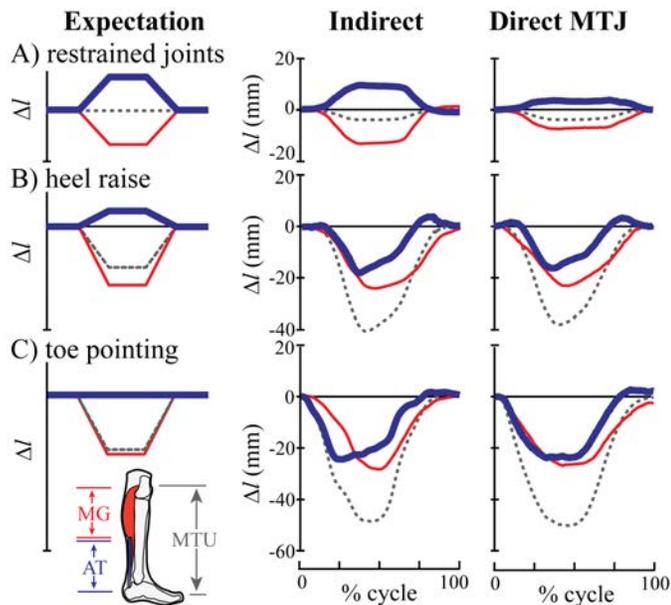

## METHODS

Three healthy subjects ( $20 \pm 2$  years,  $75 \pm 10$  kg) performed various movement tasks, during which unilateral lower-limb kinematics (100 Hz, Vicon) and ground reaction forces (1000 Hz, Bertec) were collected synchronously with B-mode ultrasound (~60 Hz, 50 mm depth, Telemed). Subjects provided informed consent prior to participation. To address question (I), we compared AT length change estimates from two commonly used ultrasound methods. For the first method, termed *Indirect*, the ultrasound probe (7 cm linear transducer) was placed on the medial gastrocnemius (MG) muscle belly to track muscle fascicle length changes. Fascicle length was corrected for pennation angle to estimate total muscle length

change. AT length change was then approximated indirectly as the difference between the overall muscle-tendon unit (MTU) length change (estimated from a regression equation using knee and ankle joint angles [3]) and muscle length change. For the second method, termed *Direct Muscle-Tendon Junction (MTJ)*, the ultrasound probe was placed over the MG-AT MTJ. Using optical motion capture and a custom-fixture attached to the probe to track its position, AT length change was more directly estimated as the linear distance between the calcaneus marker (AT insertion) and MTJ. MG muscle length change was also approximated using this method, by subtracting AT from MTU length change (from [3]).

To address question (II), subjects completed three simple tasks in which empirically-estimated AT length changes could be compared to the expected behavior of a passive elastic tendon acting in series with muscle. Tasks were chosen to test combinations of high/low MTU force and large/small MTU length changes. Tasks: (A) Restrained joint calf contractions were performed while seated with a rigid bar affixed above the knees, restricting ankle and knee rotation. Expectation: Small MTU length change and high MTU force would result in substantial AT lengthening, equal and opposite to MG shortening. (B) Heel raises involved contracting the calf muscles while standing to rise onto the toes. Expectation: Large MTU length change and high MTU force would result in AT lengthening. (C) Toe pointing required subjects to hold their foot in the air and plantarflex their ankle. Expectation: Large MTU length change and low MTU force would result in minimal AT length change. Each cycle began/ended with the MG relaxed and the foot in neutral position (i.e., perpendicular to shank).

## RESULTS AND DISCUSSION

**Figure 1:** AT (thick blue), MG (thin red) and MTU (dashed gray) length changes for one subject during 3 tasks. Data averaged over 5 cycles.  $\Delta l$  = change from relaxed length.

AT length change estimates were strongly correlated between the Indirect and Direct MTJ tracking methods. We found correlation coefficients of  $r = 0.82 \pm 0.06$ ,  $r = 0.89 \pm 0.09$ ,  $r = 0.75 \pm 0.21$  for tasks A, B, and C, respectively (N=3, Figure 1). AT length change estimates were qualitatively consistent with the expected behavior of a series elastic tissue during task A, which involved

minimal changes in MTU length. However, AT length changes were drastically different from expectations for tasks B and C, in which the MTU underwent substantial shortening.

## CONCLUSIONS

Preliminary findings suggest that Indirect and Direct MTJ methods yield similar estimates of AT kinematics for the tasks tested. However, estimated AT kinematics were highly inconsistent with the expected behavior of a passive elastic tissue in series with muscle. In this ongoing study we seek to understand the reasons for and implications of this inconsistency.

# DO TRICEPS SURAE MUSCLE DYNAMICS GOVERN NON-UNIFORM ACHILLES TENDON DEFORMATIONS?

William H. Clark and Jason R. Franz

University of North Carolina and North Carolina State University, Chapel Hill, NC, USA  
email: jrfranz@email.unc.edu web: http://abl.bme.unc.edu

## INTRODUCTION

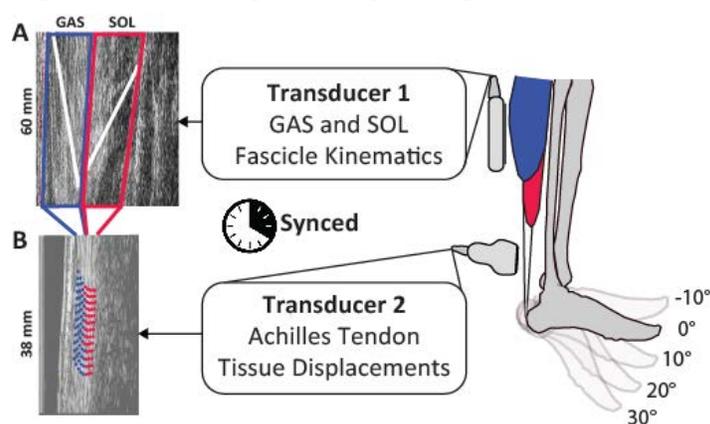

The Achilles tendon (AT) consists of distinct bundles of tendon fascicles arising from the gastrocnemius (GAS) and soleus (SOL) muscles that may act as mechanically independent structures [1]. Indeed, we have shown that these “sub-tendons” exhibit non-uniform displacement patterns during walking, which may reflect sliding between adjacent tendinous structures [2]. While the mechanisms governing these non-uniform displacement patterns have remained allusive, recent computational model predictions implicate differential GAS versus SOL muscle dynamics as a biomechanical candidate [3]. In that study, removing differential GAS versus SOL muscle forces reduced model-predicted tendon non-uniformity by 85%. Thus, here, we implemented a novel dual-imaging approach to investigate triceps surae muscle dynamics as a determinant of non-uniform AT tissue displacements during ramped isometric contractions. We hypothesized that superficial versus deep differences in AT tissue displacements would be accompanied by (and correlate with) anatomically consistent differences in GAS versus SOL muscle shortening.

## METHODS

We have thus far collected data for 8 subjects (age:  $25.4 \pm 5.9$  years, mass:  $71.0 \pm 6.2$  kg, height:  $1.8 \pm 0.1$  m, 3 females and 5 males). Subjects performed three ramped maximum voluntary isometric contractions (MVICs) at each of five ankle joint angles spanning  $10^\circ$  dorsiflexion to  $30^\circ$  plantarflexion in a dynamometer (Biodex System 4 Pro), with the knee flexed to replicate that near the push-off phase of walking. We synchronized two linear array ultrasound transducers to simultaneously record GAS and SOL fascicle kinematics with tissue displacements in their associated tendinous structures (Fig. 1). A 60 mm Teleded Echo Blaster 128 transducer (LV7.5/60/128Z-2) placed over the

medial gastrocnemius and soleus of subjects’ right leg recorded cine B-mode images at 61 frames/s. Simultaneously, a 38-mm transducer (L14-5W/38, Ultrasonix Corporation, Richmond, BC) operating at 70 frames/s recorded ultrasound radiofrequency (RF) data from a longitudinal cross-section of the right free AT, distal to the SOL muscle-tendon junction and secured via a custom orthotic. Subjects’ right foot was barefoot throughout the experiment to facilitate proper placement of the AT transducer. Finally, motion capture tracked right ankle and knee joint kinematics and the positions and orientations of both probes.

Available MATLAB routines based on an affine extension to an optic flow algorithm quantified time series of GAS and SOL fascicle lengths and pennation angles (UltraTrack, [4]), which we combined to compute longitudinal muscle lengths. A custom 2D speckle-tracking algorithm estimated localized displacements of AT tendon tissue, which we averaged in two equally sized tendon depths - superficial and deep - corresponding to tendon tissue

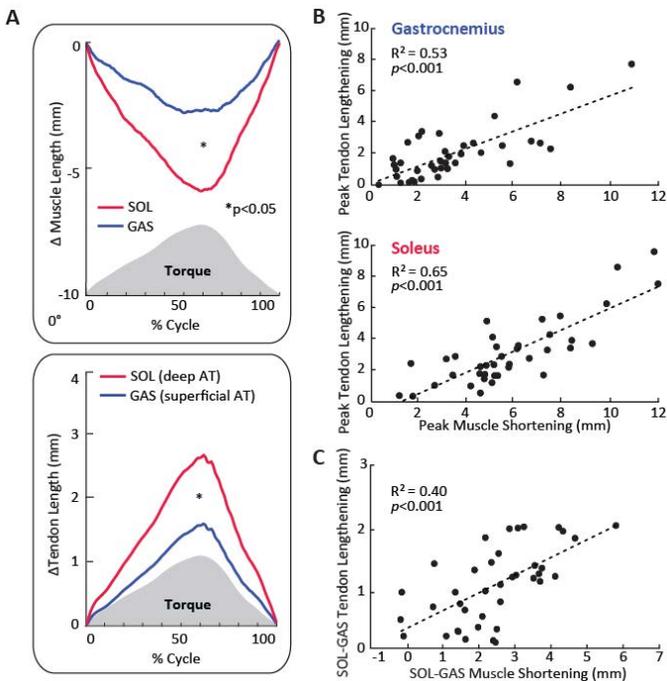

**Figure 1.** Simultaneous ultrasound imaging of the gastrocnemius (GAS), soleus (SOL), and free Achilles tendon. (A) Fascicle lengths and pennation angles derived from cine B-mode images. (B) Custom speckle-tracking of localized Achilles tendon tissue displacements.

thought to arise from GAS and SOL, respectively [2]. A repeated measures ANOVA tested for significant main effects of ankle angle and muscle/tendon (i.e., GAS vs. SOL) on peak muscle shortening and peak tendon lengthening. Finally, we calculated Pearson's correlation coefficients between: (i) GAS and SOL muscle shortening and lengthening in their associated regions of the AT, and (ii) muscle non-uniformity (i.e., GAS versus SOL) and tendon non-uniformity (i.e., superficial versus deep).

## RESULTS AND DISCUSSION

Peak isometric plantarflexor torque decreased progressively from dorsiflexion to plantarflexion across the range of angles tested ( $p < 0.01$ ). For all conditions, SOL shortened by an average of 73% more than GAS during force generation (Fig. 2A). This was accompanied by, on average, 53% more lengthening in the deep versus superficial region of the AT (Fig. 2A). The magnitude of GAS and SOL muscle shortening during force-generation positively

**Figure 2.** (A) Group average muscle shortening and tendon lengthening for the  $0^\circ$  condition. (B) Correlations between peak GAS or SOL muscle shortening and lengthening in their associated regions of the AT. (C) Correlation between superficial versus deep differences in AT lengthening and GAS versus SOL differences in muscle shortening. Both correlations are pooled across all conditions. Asterisks (\*) indicate  $p < 0.05$ .

correlated with lengthening in their associated regions of the AT ( $p < 0.05$ ) (Fig. 2B). Moreover, and consistent with our hypothesis, superficial versus deep differences in AT lengthening positively correlated with anatomically consistent differences in GAS versus SOL muscle shortening ( $p < 0.05$ ) (Fig. 2C). Finally, the strength of these latter correlations exhibited a dependence on plantarflexor torque generation; increased ankle dorsiflexion, conveying an increase in plantarflexor torque generating capacity, elicited stronger correlations between muscle non-uniformity and tendon non-uniformity (e.g., up to  $R^2 = 0.76$  at  $10^\circ$  dorsiflexion,  $p < 0.01$ ).

## CONCLUSIONS

We present *in vivo* evidence that triceps surae muscle dynamics may precipitate non-uniform displacement patterns in the architecturally complex Achilles tendon. Moreover, we present a novel dual-imaging approach to empower simultaneous *in vivo* assessment of muscle and tendon toward an improved mechanistic understanding of triceps surae behavior. Our findings may have important implications for understanding age-associated changes in AT displacement patterns [5], which we suspect alter the muscle contractile behavior of older adults. Specifically, we have proposed that a proliferation of collagen cross-linking and adhesions between adjacent sub-tendons in the AT can unfavorably couple GAS and SOL muscle-tendon dynamics during walking in older adults.

## INTRODUCTION

The Achilles tendon is the largest in the body and plays a critical load-bearing role during walking and running. This tendon has a unique architecture that comprises three subtendons that twist around each other and are each derived from a muscle of the triceps surae. Recent dynamic ultrasound studies have revealed that these subtendons slide past each other during ankle motion, as nonuniform tendon displacements have been observed in both passive and eccentric loading trials [1].

In a recent study, a 3D finite element model (FEM) of the Achilles with its subtendons was developed to explore the mechanisms of this nonuniform displacement [2]. This model showed that inter-subtendon sliding and differential passive muscle force conditions lead to the largest disparity in subtendon displacement. In that study, tendon was modeled as a Neo-Hookean material for simplicity. It is unknown how a more accurate constitutive model containing directional material properties of the collagen fibers in the twisting subtendons would affect simulated displacements. The first goal of this study is to incorporate a transversely isotropic constitutive formulation [3] into the Achilles tendon FEM to elucidate the effect of the material model on displacement nonuniformity.

In addition to *in vivo* displacement measurements, ultrasound can be used to measure local mechanical properties, which can be used to estimate muscle and tendon slack lengths. Recent studies have compared slack lengths of the triceps surae muscles [4] and the medial gastrocnemius and Achilles tendon [5] and found that they occur at different ankle angles. While the individual subtendons were not measured, muscle-tendon and inter-muscle

differences in slack length suggest that these subtendons could also be slack at different ankle angles. Tendon is assumed to be at slack length at the start of finite element simulations, but these differences may be important to consider when modeling Achilles motion. Thus, the second goal is to examine the potential role in displacement nonuniformity of differential subtendon slack lengths by incorporating a pre-tensioning parameter into the material model.

## METHODS

The creation of a free tendon FEM of the Achilles has been previously described in detail [2]. Achilles 3D geometry was constructed from segmented UTE MR images and divided into subtendons based on dissection and MRI of triceps surae locations [Fig. 1A]. Frictionless contact interfaces were assigned between subtendons. To simulate dorsiflexion, a 25° rotation was prescribed to the distal end of the tendon, while the proximal end was constrained to move only proximal-distally. Nodal stiffnesses were applied to the proximal end to simulate passive muscle forces and tuned, in the Neo-Hookean model, to reproduce displacements observed with ultrasound [1].

Simulations were repeated with identical geometry and boundary conditions for tendon modeled as Neo-Hookean and transversely isotropic materials with strain energy density functions:

$$W^{N-H} = C(I_1 - 3) \text{ and } W^{TrIso} = C(I_1 - 3) + W_3(\lambda)$$

Where  $W_3$  defines the relationship between the Cauchy stress ( $\sigma$ ) and the stretch ( $\lambda$ ) along the tendon fiber direction [3]. The stretch is a function of the right Cauchy-Green deformation tensor and vectors defining the fiber directions [Fig 1A], which

were defined using computational fluid dynamics [6]. The stress is in piece-wise exponential form:

$$\lambda \frac{\partial W_3}{\partial \lambda} = \sigma(\lambda) = \begin{cases} L_1 \left( e^{L_2(\lambda - \lambda_{beg})} - 1 \right), & \lambda_{beg} < \lambda < \lambda^* \\ L_3 \lambda + L_4, & \lambda > \lambda^* \end{cases}$$

Where  $\lambda^*$  is the stretch when  $\sigma$  becomes linear, and  $\lambda_{beg}$  is the stretch at the beginning of the simulation. Transversely isotropic simulations were run with  $\lambda_{beg} = 1$  for all subtendons (no pre-tension case). Pre-tension was applied by shifting  $\lambda_{beg}$  (and  $\lambda^*$ ) by a given value, informed by estimated angle of slack length [Fig. 1B]. Differential displacement was compared between Neo-Hookean and transversely isotropic with and without pre-tension by measuring the displacement at the proximal end of each subtendon [Fig. 1C].

## RESULTS AND DISCUSSION

In both the Neo-Hookean and transversely isotropic simulations, the soleus subtendon experienced the largest distal displacement, and the lateral gastrocnemius experienced the least. However, displacements were more nonuniform in the model with transversely isotropic material [Fig. 1C].

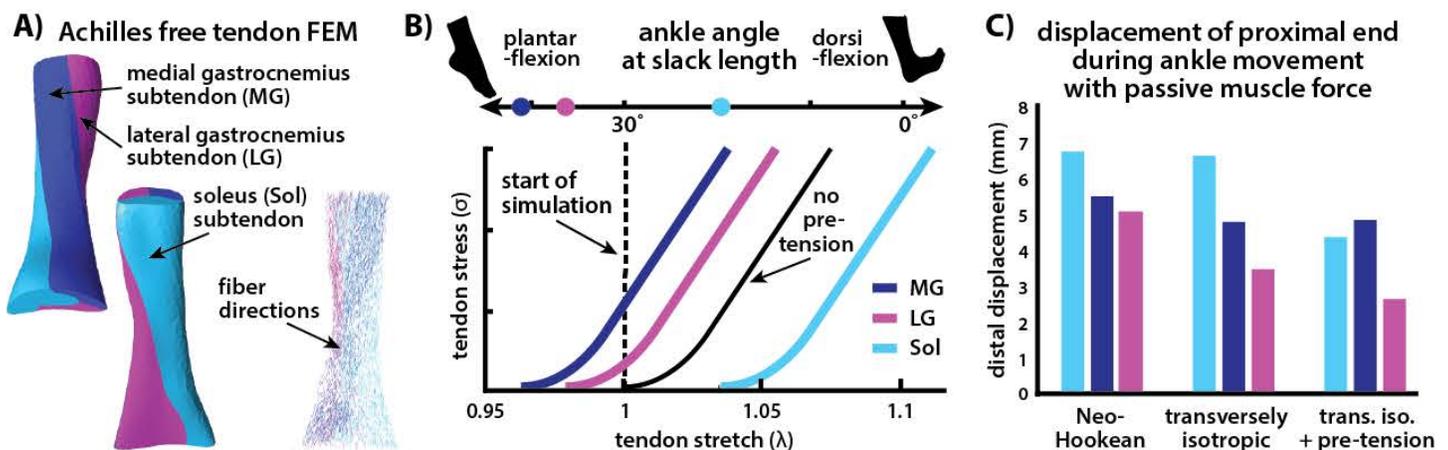

Based on muscle and tendon measurements [4,5], the ankle angle at slack length was estimated for the subtendons ( $\angle_{MG} = 42^\circ$ ,  $\angle_{LG} = 37^\circ$ ,  $\angle_{Sol} = 21^\circ$ ). The joint angle at the start of the simulation

occurred at a tendon stretch of 1 ( $\lambda_{beg}$  with no pre-tension), and the tendon stress-strain curves for the subtendons were adjusted accordingly for pre-tension ( $\lambda_{beg, MG} = 0.035$ ,  $\lambda_{beg, LG} = 0.02$ ,  $\lambda_{beg, Sol} = -0.035$ ) [Fig. 1B]. The displacements of the subtendons with pre-tension were different from the no pre-tension case in both the order and the amount of disparity. With pre-tension, the medial gastrocnemius experienced the most displacement, but displacements were more uniform compared to simulations without pre-tension [Fig. 1C].

The directional material model resulted in greater subtendon displacement non-uniformity, so the contribution of differential passive muscle forces may be less than previously estimated and require further tuning [2]. Since inclusion of pre-tension altered the displacement profile of the Achilles, future modeling efforts would benefit from more accurate measurements and incorporation of the angle-specific material properties in the subtendons.

# ASSESSING NON-UNIFORM STIFFENING OF THE ACHILLES TENDON USING SURFACE WAVE ELASTOGRAPHY

<sup>1</sup> Muhammad Salman, <sup>2</sup> Karim G Sabra

<sup>1</sup> University of Engineering and Technology, Lahore, Pakistan

<sup>2</sup> Georgia Institute of Technology, Atlanta, GA, USA

<sup>1</sup>email: [msalman3@uet.edu.pk](mailto:msalman3@uet.edu.pk)

<sup>2</sup>email: [karim.sabra@me.gatech.edu](mailto:karim.sabra@me.gatech.edu)

## INTRODUCTION

Currently, noninvasive cost-effective techniques are not available that can quantify in-vivo non-uniform degradation of tendon's mechanical and structural properties associated with localized tendon injuries. This study will demonstrate the applicability of our novel cost-effective surface-wave elastography (SURF-E) method for quantifying spatial variations of tendon mechanical and structural properties in a much broader range of tendon stiffness with various positions and anatomical level than currently available elastography methods do such as Ultrasound (US) and MRI.

## METHODS

Ten healthy men (age:  $22 \pm 5$  years, height:  $175 \pm 9$  cm, body mass:  $72 \pm 8$  kg) were tested with no signs of neuromuscular diseases. The study was approved by the Institutional Review Board (IRB) of the Georgia Institute of Technology. The ankle joint was set to three different values  $70^\circ$ ,  $80^\circ$  and  $90^\circ$  by the help of a goniometer (Fig. 1a). In order to have the data repeatability, leg was restrained in a fixture around calf (Fig. 1b) by the help of a strap and a tong clamp.

Figure 1: a) Ankle angle set by goniometer, b) Fixture around calf, c) Achilles Tendon setup with LDV and shaker rod.

Achilles tendon was marked by five anatomical landmarks each 1cm apart starting from the datum line parallel to the proximal of calcaneus bone (Fig. 1c). Three sections of AT starting from 1 cm above the datum line were quantified for elastic stiffness. The datum line was actuated by an electrodynamic mini-shaker (model 4810, Brüel & Kjær, Nærum, Denmark) to generate band pass filtered frequency (5 Hz-1000 Hz) impulses. Four LDV sensors (PDV 100, Polytec, Irvine, CA, USA) shone along a 5-6 cm long thin retro-reflective adhesive tape (3M). The tape was attached over the tendon from the datum line and 6 cm along the axis of the Achilles tendon. Subjects performed three series of brief contractions for each ankle angle. The measurements were made in a randomized order. The laser elastography measurements were performed on these ten subjects using the similar procedure as described in details in Salman & Sabra [1] and previously validated using soft gel samples [2].

## RESULTS

Fig. 2 consists of four plots obtained from one of the ten subject's data analysis for a  $70^\circ$  ankle angle (dorsiflexion). Fig. 2a is the power spectrum of the four LDV sensors and the shaker excitation. It is clear that the signal ranges from 10 Hz to 500 Hz. The higher the excitation frequency, the lower is the wavelength which gives more localized mechanical properties. Fig. 2b is the application of cross correlation signal processing filter for the four LDV sensors which shine 1 cm apart from each other. The maximum point of these correlation vectors shows that the sensor signal is matched perfectly with the excitation source signal.

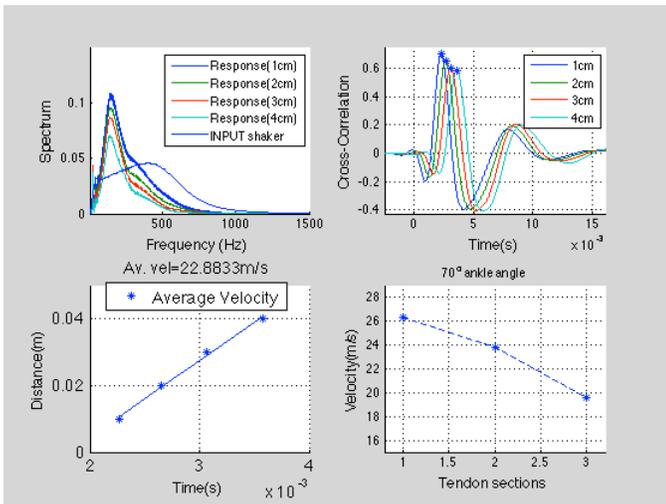

Figure 2(Data analysis of a subject at 70° ankle angle) a)Power spectrum of the sensor and shaker, c) Cross-Correlation signal processing filter, d) Linear fit of four max. peaks in fig. 2c, e) Spatial velocity variation of the AT.

When these peaks are linearly fit they give the slope of an average shear wave velocity as shown in Fig. 2c. When the difference of these peaks is taken we get the velocity slopes which are the spatial velocity variations of the AT as shown in Fig. 2d. Fig. 3 is the the result analysis of ten subjects at three ankle positions. Fig. 3a shows a decreasing trend in the shear wave velocity along the AT. Since wave propagation velocity is the criteria of stiffness of the AT, therefore section I of AT, proximal to calcaneus bone, is at a higher velocity value as compared to the section II and section III which are near the calf muscle. Fig 3b shows the mean of shear wave velocity at three ankle positions.

## DISCUSSION

The measured velocity values in Fig. 3a ranges from (38--10m/s) show that this technique is an objective way to quantify the stiffness of the AT unlike the other techniques such as Ultrasound (US) and MRI techniques which can provide a simple estimate of AT's overall stiffness. High standard deviation in Fig 3a for 70° ankle position as compared to the other two shows the variability of stiffness of AT under high loading. Fig 3b verifies that at low ankle angle, AT becomes stiffer and so does the wave velocity accordingly.

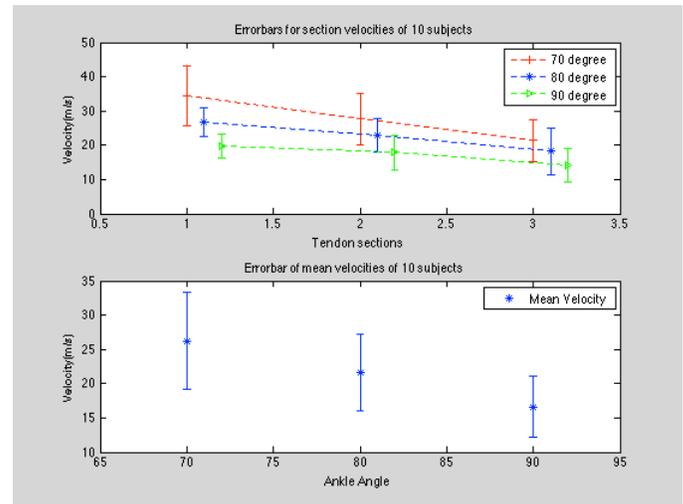

Figure 3 (Data analysis of 10 subjects) a)(Top) Spatial velocity variation of AT at three ankle positions. b)(Bottom) Mean of shear wave velocity along the AT.

## CONCLUSIONS

Developing a low-cost, single LDV-based SURF-E modality as an alternative to using expensive US scanner would broaden the acceptance and clinical usage of transient elastography methods for AT's diagnosis and monitoring the mechanical recovery of injured ATs. SURF-E method would assist the injury risk assessment and patient-specific selection of treatment plans for tendinopathy as well as the monitoring of the efficiency of therapeutic exercise programs which would diminish health care costs associated with the exponentially increasing number of AT injuries. As another advantage, SURF-E method can be performed in near real-time (<3 s) and thus could readily be used to monitor the evolution of the AT.

# IN VIVO TENDON STRESS IS PREDICTED BY NON-INVASIVE WAVE SPEED MEASUREMENT

Jack Martin, Scott Brandon, Emily Keuler, James Hermus, Matthew Allen, and Darryl Thelen

## INTRODUCTION

Understanding tendon tissue loading is crucial to the investigation of musculoskeletal disorders. Unfortunately, assessing *in vivo* loading remains challenging – direct measurements are highly invasive [1], and modeling approaches rely on assumptions of muscle coordination and tissue geometry [2]. We have recently developed a novel non-invasive technique for estimating tendon loads from wave propagation measures. Considering tendon as a tensioned beam, we hypothesized that shear wave speed in tendon should be directly dependent on axial stress [3]. A subsequent *ex vivo* study [3] clearly demonstrated this relationship, showing a strong correlation between tendon stress and squared wave speed (mean  $r^2 = 0.98$ ). We subsequently invented a simple accelerometer-based approach for tracking *in vivo* tendon wave speeds [4]. The purpose of the current study was to investigate the relationship between wave speed and tendon stress for the human Achilles and patellar tendons *in vivo* during isometric contractions.

## METHODS

**Wave tracking.** We constructed a shear wave tensiometer to generate and track transient shear waves in the Achilles and patellar tendons (Fig 1A). Waves were generated using a piezoelectric actuated (Thorlabs PK4JQP1, Newton, NJ, USA), 3D-printed tapper. The tapper was strapped ~7cm superior to the calcaneus for the Achilles tendon and slightly superior to the tibial tuberosity for the patellar tendon. Tendons were tapped in the transverse direction (20 $\mu$ m displacement) at 50Hz, with each tap sending a transverse (shear) wave along the tendon. Two single-axis accelerometers (PCB Piezotronics 352C23/NC, Depew, NY, USA) were positioned over the tendon 10mm and 20mm inferior (Achilles) or superior (patellar) to the

tapper. Transverse acceleration of the tendon was sampled from each accelerometer at 50kHz. Wave speed was calculated using lag in wave arrival time between the two accelerometers (Fig 1B) after each tap, so that wave speed data were collected at 50Hz.

**Figure 1:** A) Schematics of wave speed measurement method for the Achilles and patellar tendons. B) Example shear waves recorded via skin-mounted accelerometers.

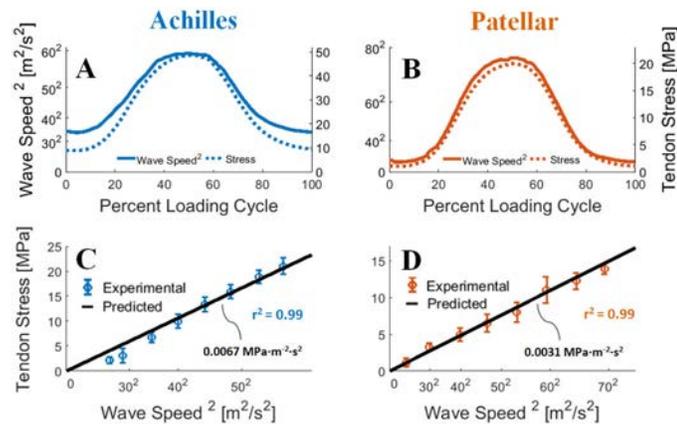

**Isometric testing.** Five subjects (3M, 2F) performed isometric contractions cyclically for 8 seconds at 3 rates (0.5, 1.0, 2.0Hz). For Achilles tendon testing, subjects sat in a chair with their ankle dorsiflexed 10 degrees and their knee at 20 degrees flexion. They then pushed against a force plate with a rod positioned under the head of their first metatarsal to control the ankle moment arm. For patellar tendon testing, subjects sat on a bench with their knee at 90 degrees flexion, and pulled against a cable with an in-series load cell. The cable was attached to a brace positioned just above their ankle.

**Analysis.** Tendon stresses were estimated based on measured forces, joint moment arms, tendon moment arms, and tendon cross-sectional areas. Using ultrasound imaging, tendon cross-sectional areas were measured and tendon moment arms were estimated as the perpendicular distance from the trans-epicondylar axis to mid-thickness of the tendon. Wave speed data were low-pass filtered at 20Hz. Correlation between tendon stress and squared wave speed was assessed using the coefficient of determination. A paired t-test ( $\alpha = 0.05$ ) was used to determine whether linear fit slopes were significantly different between the

Achilles and patellar tendons. Inter-subject variability was assessed using the coefficient of variation of fit slopes between subjects. Predicted stresses were calculated using tendon/subject-specific fits of stress versus squared wave speed. Data from all loading rates were pooled for this analysis.

## RESULTS AND DISCUSSION

Tendon wave speeds ranged from ~20-80 m/s in the Achilles tendon and ~10-100 m/s in the patellar tendon through the loading cycles across the 5 subjects. Peak stresses ranged from ~20-100 MPa in the Achilles tendon and ~12-35 MPa in the patellar tendon. There was excellent temporal agreement between squared wave speed and tendon stress (Fig 2A/B). Squared wave speed was highly correlated with tendon stress across all subjects (Achilles:  $r^2 = 0.94 \pm 0.06$ ; patellar:  $r^2 = 0.98 \pm 0.01$ ). Linear fit slopes (Achilles:  $0.013 \pm 0.006 \text{ MPa} \cdot \text{m}^{-2} \cdot \text{s}^2$ ; patellar:  $0.0036 \pm 0.0015 \text{ MPa} \cdot \text{m}^{-2} \cdot \text{s}^2$ ) were significantly different between tendons ( $p < 0.001$ ; e.g., Fig 2C/D), and showed moderate inter-subject variability (Achilles:  $c_v = 0.42$ ; patellar:  $c_v = 0.46$ ).

**Figure 2:** A/B) Ensemble mean squared wave speed and tendon stress across all subjects and loading rates. C/D) Predicted tendon stress and binned mean  $\pm$  standard deviation of experimental stress vs. squared wave speed for a representative subject.

These data confirm that the relationship between wave speed and tendon stress observed *ex vivo* holds for the *in vivo* case for both Achilles and patellar tendons. Additionally, this study has established the feasibility of measuring wave speed

at a high rate (50Hz) using skin-mounted accelerometers, making the technique usable for dynamic activities like walking, running, and jumping. Moreover, this study demonstrates the ability to calibrate subject-specific tendon stress-wave speed relationships using simple isometric exertions (e.g., Fig 2C/D). Further experimental and computational study is ongoing to determine the extent to which tendon cross-sectional area, length and architectural features can influence wave speed.

Tendon loading predictions using our shear wave tensiometer have numerous potential applications in biomechanics. First, this technology could be useful in assessing coordination patterns without using cumbersome motion capture and inverse dynamics techniques. Second, direct measurements of tendon stress would be highly useful for validating musculoskeletal models. Finally, and perhaps most impactful, is the potential to use tendon stress measures to diagnose impairments, plan treatments, and track recovery following rehabilitative and surgical interventions.

## CONCLUSIONS

This work has demonstrated the exciting potential for non-invasively tracking tendon wave speeds and using these data to accurately predict tendon stresses *in vivo* during dynamic activity. Future work will aim to better understand the inter-tendon and inter-subject differences observed here, and to apply the technique to important clinical and research applications.

# HIGH-ACCELERATION TRAINING DURING GROWTH INCREASES OPTIMAL FIBER LENGTHS IN AN AVIAN BIPEDAL MODEL

<sup>1</sup> Matthew Q. Salzano, <sup>1</sup> Suzanne M. Cox, <sup>1</sup> Stephen J. Piazza, <sup>1</sup> Jonas Rubenson

## INTRODUCTION

Previous research has shown that fiber lengths of the vastus lateralis and gastrocnemius are longer in human sprinters than in distance runners and untrained controls [1]. Longer fascicle lengths have also been associated with better performance within a group of trained sprinters [2]. In these groups, longer fiber lengths may increase muscle power and work production (independent of PCSA) by reducing fiber strain and relative velocity and thus minimizing force-length-velocity effects.

However, it is unknown if the longer fascicle lengths associated with better sprinting ability are primarily due to genetic variation or if they result from sprint training. Fascicle lengths have been shown to increase in response to stretch [3] but studies examining effects of running training are limited. One study of marathon training showed a decrease rather than an increase in gastrocnemius fiber lengths [4].

The purpose of this study was to determine if optimal muscle fiber lengths are affected by high acceleration running/jumping training during growth, when muscle plasticity may be greatest. We explored this question using a bipedal animal model, guinea fowl, that are fast-growing and amenable to training. We hypothesized that acceleration training during the animals' growth period would result in longer fascicle lengths compared to those measured in a sedentary control group.

## METHODS

Guinea fowl (*Numida meleagris*) were obtained from a regional breeder (Guineafarm, OH). At 4 weeks of age, guinea fowl were split into an Exercise Group (EG; n=15) and Sedentary Group (SG; n=15). The EG were housed in a large, dual-circle pen (each 1.85 m in dia.; ~5.3 m<sup>2</sup>) with ample room for running and perching. The SG were housed in smaller pens (~1

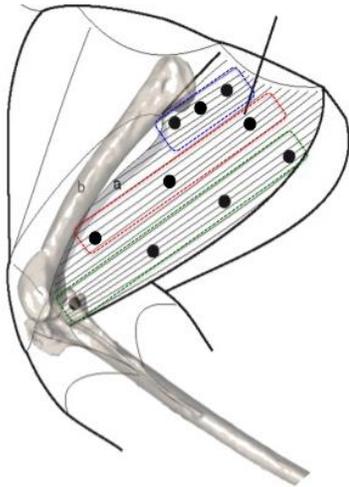

m<sup>2</sup>) to limit movement. Birds were given food and water *ad libitum*.

Along with opportunities for spontaneous movement, the EG were exercised in two ways. An automated boom (Fig. 1) swept through the pen for 10 min h<sup>-1</sup> for 12 h per day to encourage movement. Birds were also manually exercised for 30-40 min per day for 5 days per week in which the animals accelerated in short-duration bouts of running. The SG received no external motivation for movement. The exercise protocol lasted from 4 weeks of age to 14 weeks, when birds were sacrificed. Specimens were imaged using standard x-ray for segment lengths and dual x-ray absorptiometry (DXA) for body composition. Specimens were then dissected to separate the lower limbs. Left limbs were frozen for subsequent measurement of muscle wet mass. Right limbs were fixed in 5% formalin, with joint angles set to approximate the mid-swing phase of running.

The iliotibialis lateralis pars postacetabularis muscle (ILPO; Fig. 1), a large hip and knee extensor was the focus of this study. The ILPO was chosen for initial analysis because it is a major muscle used for locomotion and has been shown to undergo substantial muscle strain during running [5]. The fixed ILPO was dissected free from the limb and photographed for measurement of fascicle pennation angle. Cranial, middle, and caudal portions were sectioned off (Fig. 1), and placed into 30% nitric acid for digestion. Digested muscles were then placed in glycerol for at least one day before small bundles of fibers were transferred to slides. Fiber lengths were measured by digitizing the fiber from high-resolution images. Laser diffraction was used to measure at least 3 different sarcomere lengths across the length of the fibers. Finally, optimal fiber lengths were calculated from the average measured sarcomere lengths per section and the known optimal sarcomere length (2.36 μm) of guinea fowl [5]:

$$L_0 = (2.36/S_L) \cdot FL$$

where  $L_0$  is the optimal fiber length (mm),  $SL$  is the average sarcomere length ( $\mu\text{m}$ ) and  $FL$  is the measured fiber length (mm).

**Figure 1.** Schematic of the ILPO muscle and the cranial (blue), middle (red) and caudal (green) muscle sections and  $SL$  measurements (dots).

## RESULTS AND DISCUSSION

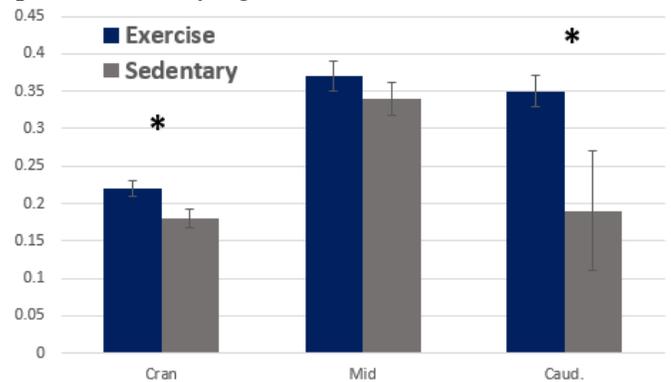

The groups had similar body masses initially (4 weeks-old), but EG body mass was 10% lower than SG by week 6 and throughout the remainder of the experiment ( $p < 0.05$ ). Body composition (percent lean mass) was similar between groups. EG had overall leg lengths 2% shorter than that of SG.

Preliminary tests ( $N = 5$ ) revealed that wet muscle mass, PCSA, pennation angle and  $SL$  were not different between groups. Serial sarcomere number and  $L_0$  were not statistically different between the groups, but showed a trend for increases in the cranial ILPO fibers of the EG ( $p = 0.07$ ).

When normalized to leg length, however, the EG had significantly greater serial sarcomere numbers and longer cranial and caudal  $L_0$  compared to the SG (Fig. 2). These results agree with previous results showing sarcomerogenesis in response to stretch training [3]. However, they contradict findings from a study of endurance training in humans [4] in which shorter

muscle fibers resulted in the gastrocnemius muscle. We interpret this result from differences in the type of training and the functional roles of the muscles studied. Endurance training may lead to adaptations for economical force production favoring short-fibered muscles such as the gastrocnemius. The high-acceleration training in the EG was, on the other hand, hypothesized to lead to longer  $L_0$  that reduces fiber strain and velocity. These activities likely mimicked human sprint-type training as opposed to endurance training.

In conclusion, these findings offer among the first evidence that sprint training during growth may contribute to the observed differences in fiber lengths between sprinters and non-sprinters and between sprinters of varying abilities.

## INTRODUCTION

It is widely known that the architectural properties of skeletal muscle, including optimal fascicle length ( $l_{fo}$ ) and physiologic cross-sectional area (PCSA), have considerable influence on muscle's ability to generate force and facilitate movement [1]. Because of muscle's hierarchical organization, it is essential to consider architecture across length scales in order to understand these structure-function relationships. While traditional imaging modalities, such as ultrasound and magnetic resonance imaging (MRI), are used extensively to study muscle structure at the fascicle and whole-muscle level, respectively, non-invasive methods of *in vivo* imaging at the length scale of the sarcomere have not been available until recently. Thus, current sarcomere structure data come from cadaveric studies or invasive imaging methods that disrupt muscle tissue and may be limited in their applicability to healthy musculature.

A novel imaging system has been developed that relies on the second harmonic generation (SHG) properties of myosin and a minimally invasive microendoscopic needle to access sarcomeres without the need for incisions or muscle removal [2]. This technology offers an opportunity to image sarcomeres in healthy, living subjects without disrupting muscle structure, and, when combined with traditional imaging methods, provides a comprehensive view of muscle architecture.

The purpose of this study is to use a combination of imaging modalities to provide what we believe are the first *in vivo* measurements of optimal fascicle length in the tibialis anterior (TA) muscle. We have collected image data of TA architecture across length scales using MRI, ultrasound, and *in vivo* SHG microendoscopy to determine  $l_{fo}$  and PCSA of the TA muscle in healthy adults.

## METHODS

Three healthy adult subjects with no history of lower limb injury were recruited for this study (age:  $27.7 \pm 10.8$  years, M/F: 2/1, height:  $172.7 \pm 13.4$  cm, weight:  $66.5 \pm 9.4$  kg). Axial magnetic resonance images of the lower limb were gathered using a 3T Siemens (Munich, Germany) Trio MRI Scanner with a 2D multi-slice sequence and spiral gradient echo. The TA was segmented within the image sequence using an in-house segmentation software created in MATLAB (MathWorks, Natick, MA). TA volume was measured from the 3D surface that was generated by connecting the segmentation contours across image frames.

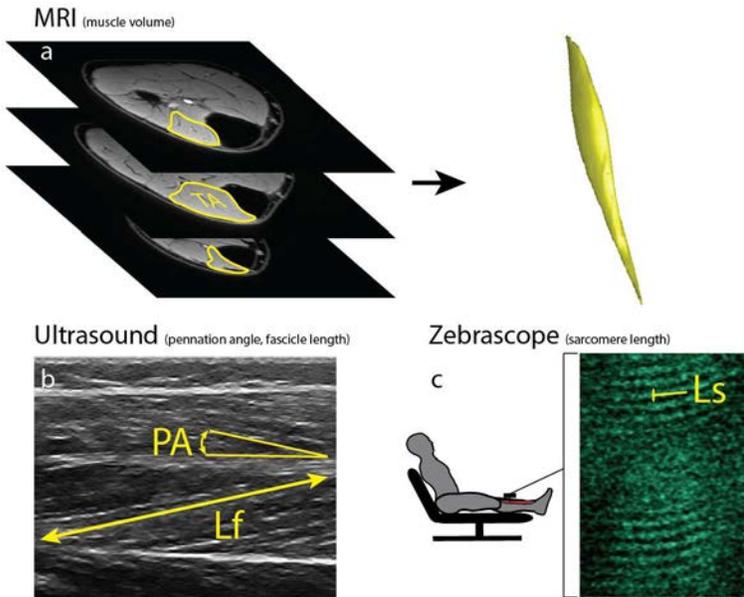

Muscle fascicle architecture was imaged using a Teleded LS128 ultrasound system with a 60 mm, 7 MHz flat transducer (TELEMED Medical Systems, Milano, Italy). Three panoramic ultrasound image scans were taken of the TA along its path of action from origin to insertion on the dominant leg of each subject. During imaging, the ankle was held at an angle of  $20^\circ$  plantarflexion using a custom brace. Image frames of each panoramic scan were stitched together to produce three complete ultrasound images of the TA in longitudinal cross section for each subject. Muscle pennation angle was measured as the angle between the observed fascicle direction and the internal aponeurosis direction. Muscle fascicle length was measured as the distance along the path of the muscle fascicles between the observed edge of the TA and the internal aponeurosis. Measurements were made in the proximal, middle, and distal third of the muscle length on both the anterior and posterior side of the internal aponeurosis. These measurements were averaged across the three images to determine the pennation angle and fascicle length for each subject [3].

*In vivo* sarcomere length measurements were made using the ‘Zebroscope’ SHG microendoscope system (Zebra Medical Technologies, Mountain View, CA). A high-power laser provided 200 fs pulses of 1030 nm wavelength light, which interacted with the myosin-containing bands of the sarcomere to produce SHG signal. A fiber-optic cable and microendoscopic needle delivered the excitation light into the TA with the ankle joint held at 20° plantarflexion. The needle was oriented within the muscle belly such that the endoscope lens plane was parallel to the TA fascicle direction. The resulting SHG signal was used to produce images of the TA sarcomeres, which allowed for the direct measure of sarcomere length for each subject.

Measured muscle architecture parameters were used to compute  $l_{fo}$  and PCSA.  $l_{fo}$  was computed according to the following equation:

$$l_{fo} = l_f / l_s * 2.7 \mu\text{m}$$

where  $l_f$  is the fascicle length measured from ultrasound imaging, 2.7  $\mu\text{m}$  is the optimal sarcomere length for humans [4], and  $l_s$  is the measured sarcomere length. PCSA was then calculated according to the following equation:

**Figure 1:** (a) Segmentation of the TA in MRI images to produce 3D volume, (b) Measurement of pennation angle (PA) and fascicle length (Lf) in ultrasound images of the TA, (c) Acquisition of *in vivo* SHG images and sarcomere length (Ls) measurement

$$PCSA = V / l_f$$

where  $V$  is the muscle volume measured from MRI.

## RESULTS AND DISCUSSION

At 20° of plantarflexion, pennation angle of the TA was measured at  $8.75 \pm 0.90^\circ$ . The TA fascicle length was measured to be  $6.56 \pm 0.22$  cm and sarcomere length was measured at  $2.83 \pm 0.16 \mu\text{m}$ . The mean TA volume was  $144.8 \pm 30.5 \text{ cm}^3$ . Based on these measurements,  $l_{fo}$  was calculated at  $6.3 \pm 0.5$  cm and PCSA was found to be  $23.0 \pm 5.1 \text{ cm}^2$ .

The values reported here agree well with previously reported architecture measures from cadaveric studies. For the TA, Ward et al. report an optimal fascicle length of  $6.83 \pm 0.79$ . The PCSA reported here is significantly larger than that reported by Ward et al. ( $10.9 \pm 3.0 \text{ cm}^2$ ) due to the larger muscle volume in the healthy subjects compared to the cadaveric specimens [5]. This is consistent with the findings of Handsfield et al [6].

## CONCLUSIONS

This work presents the first reported values of optimal fascicle length computed from *in vivo* muscle architecture measurements of healthy, living subjects and provides important insight regarding the force-length behavior of the TA. Future work will aim to confirm our reported values through the inclusion of additional subjects in our study, consider muscle architecture measurements across ankle joint range of motion, and correlate  $l_{fo}$  and PCSA with measured strength and gait capacities of the TA.

## INTRODUCTION

Lower limb trauma (LLT) impairs walking stability [1]. As a result, individuals with LLT often adopt a cautious gait pattern which includes a greater step width. Individuals with LLT also display a greater lateral margin of stability ( $MOS_{ML}$ ) when walking which is related to the force required to move the center of mass outside of the base of support [2]. While this strategy helps maintain the center of mass within the base of support by resisting perturbing forces, the stabilizing effect can also resist intended movements, reducing maneuverability. Thus, we investigated how the cautious gait pattern of individuals with LLT affects their ability to execute lateral walking maneuvers. We hypothesized that individuals with LLT would maintain a wider step width and greater  $MOS_{ML}$  throughout a lateral transition and this would result in poorer transition performance.

## METHODS

Fifteen able-bodied controls and 13 individuals with varying levels of LLT completed 6 trials of a virtual obstacle course at 0.9 m/s (Fig. 1A). The obstacle course consisted of navigating an avatar through a series arches in one of 4 lanes projected on the screen, with the goal of hitting as few arches as possible (Fig. 1B). We tested 2 conditions: “Anticipation” where the transition direction was visible ahead of time and “Reaction” where the transition direction was not visible until exiting the current arch set. We calculated the step width and  $MOS_{ML}$  just prior to and across the transition (Fig. 1C). We also quantified the number of unsuccessful transitions where they collided with one of the arches as a measure of maneuverability. To simplify the analysis and focus on the impact of lower limb trauma, we reduced the dataset by pooling the data from

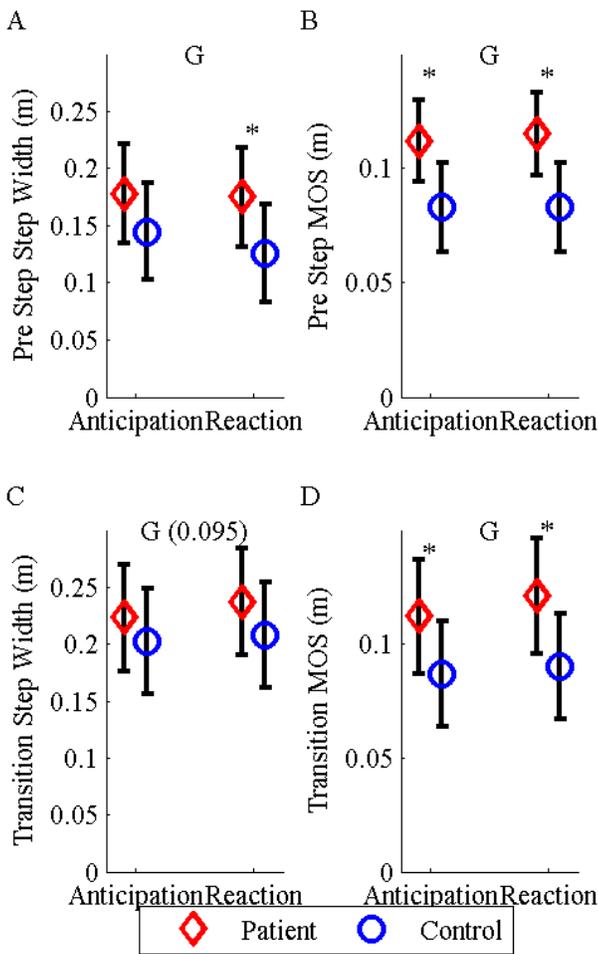

both directions and only analyzing the more challenging 2-lane transitions. To analyze the effect of LLT on stability and maneuverability we ran a 2-factor (Group x Condition) ANOVA and *post hoc* t-test with Bonferonni-Holm corrections for multiple comparisons with significance defined as  $p < 0.05$ .

**Figure 1:** A) Patient walking in the VR system, B) Pelvis trajectory during typical obstacle course trial, C) Diagram of the transition task.

## RESULTS AND DISCUSSION

As hypothesized, there was a significant Group effect for both step width ( $p=0.003$ ; Fig. 2A) and  $MOS_{ML}$  ( $p < 0.001$ ; Fig. 2B) during the Pre Step with individuals with LLT maintaining a wider step width and greater  $MOS_{ML}$ . The findings were similar for the values across the transition with a trend towards a significant Group effect for step width ( $p=0.096$ ; Fig. 2C) and a significant Group effect for  $MOS_{ML}$  ( $p=0.001$ ; Fig. 2D) both with the LLT group being greater than controls. This suggests that individuals with LLT prioritize stability and maintain a cautious gait pattern even when preparing for and performing lateral maneuvers.

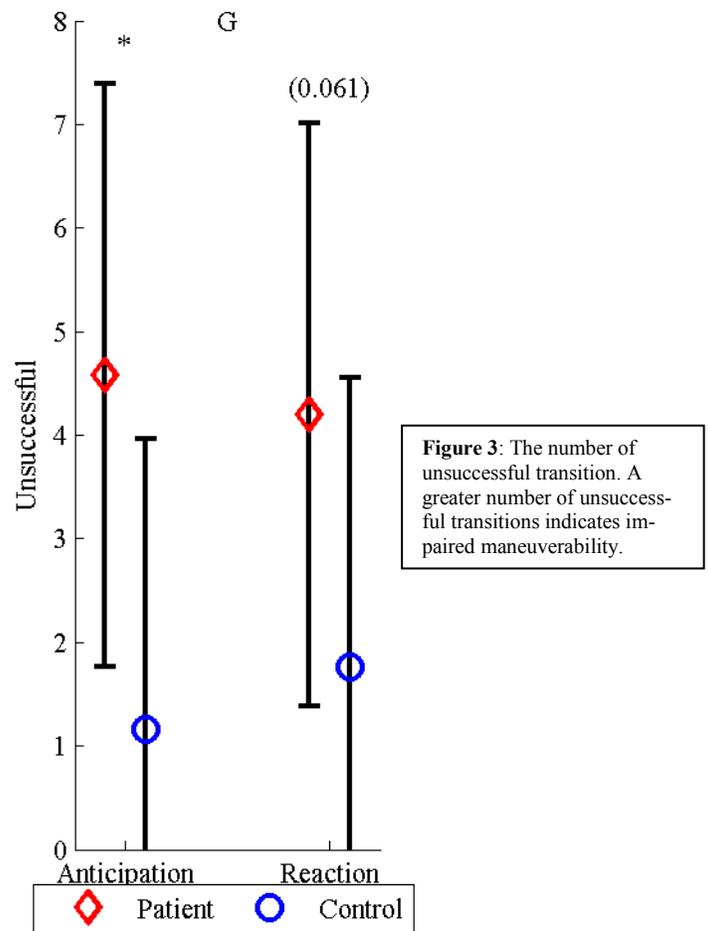

**Figure 2:** Step width and lateral margin of stability (MOS) during the Pre Step (A-B) and across the transition (C-D), respectively.

Further, in support of our hypothesis, there was a significant Group effect for the number of unsuccessful transitions with individuals with LLT performing more poorly than controls ( $p=0.001$ ; Fig. 3). This suggests that the greater priority on stability and reliance on the cautious gait patterns likely impairs transition performance and maneuverability.

## CONCLUSIONS

The individuals with LLT prepared for and transitioned with a wider step width and greater  $MOS_{ML}$ . This suggests that individuals with LLT prioritize stability and retain their cautious gait pattern to the detriment of their maneuverability. By improving individuals' stability and balance confidence through the use of interventions and training, we may be able to reduce patients' reliance on a cau-

tious gait pattern and allow them to develop a more efficient and adaptable gait that can change to meet the specific demands of the environment.

**Figure 3:** The number of unsuccessful transition. A greater number of unsuccessful transitions indicates impaired maneuverability.

## INTRODUCTION

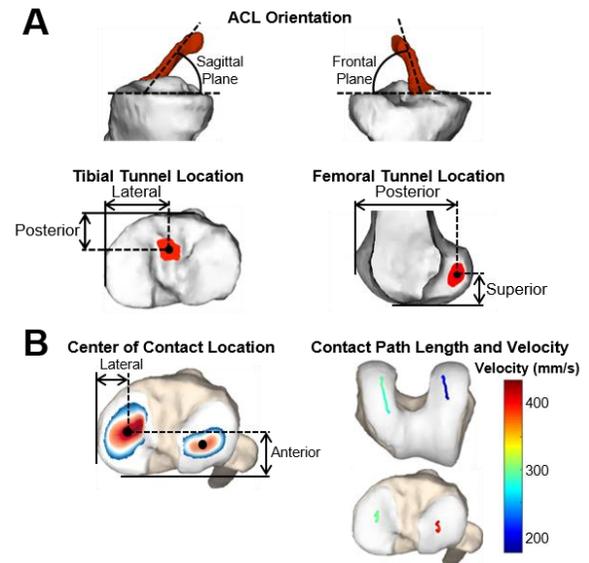

Subtle asymmetries in tibiofemoral (TF) kinematics have been detected in ACL reconstructed (ACLR) knees [1,2]. These altered kinematics may produce a shift in cartilage contact regions, which is theorized to initiate osteoarthritis [3]. Additionally, altered TF cartilage contact has been correlated to cartilage damage grade and progression [4,5]. Thus, restoring normal contact patterns with ACLR could prevent early cartilage degradation.

A recent study found that graft tunnel placement impacts TF kinematics during quasi-static lunges, with an antero-proximal femoral tunnel linked to greater anterior translation, medial translation, and internal rotation of the tibia [6]. However, the implications of these altered kinematics on cartilage contact are not well understood. Accordingly, our objective was to investigate the links between TF cartilage contact and ACL graft geometry during a loaded flexion-extension task using dynamic MRI.

## METHODS

The bilateral knees of 18 subjects that underwent a primary unilateral, isolated ACLR were tested (9 M, 24.8±5.7 yrs, 78.9±16.5 kg, 20.2±8.7 months post-op, 9 PT grafts). Bilateral, high-resolution MR images were collected and segmented to create bone, cartilage, and ACL geometries for the ACLR and healthy knees. The location of the ACL femoral and tibial attachments and the orientation of the ACL relative to the tibial plateau were measured bilaterally (Fig. 1A). Non-native ACL graft geometry was characterized by subtracting the healthy from the reconstructed metrics.

During the dynamic MRI protocol, subjects lay supine in the MR scanner with their leg attached to an inertial loading device designed to induce eccentric quadriceps loading at peak knee flexion.

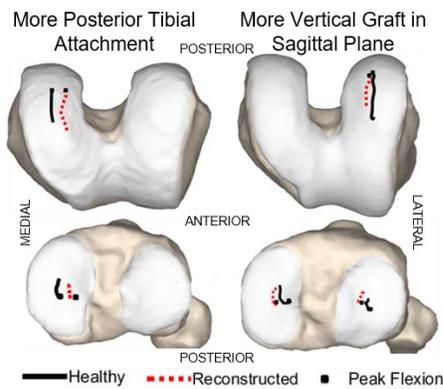

**Figure 1:** A. ACL geometry metrics B. Contact metrics. The sliding length and velocity were computed by subtracting the femur path length and velocity from that of the tibia.

Subjects performed cyclic knee flexion-extension at 0.5 Hz for 5 min while dynamic volumetric images were continuously acquired [7]. Images were retrospectively sorted and reconstructed into 60 frames over the motion cycle. Cartilage contact was characterized by optimally registering the bone and cartilage geometries to the image sets at each frame and computing the overlap of the femur and tibia cartilage. We then extracted the location of the center of contact (COC) on the medial and lateral tibial plateaus at peak flexion (Fig. 1B). Computing the COC location with this method has a maximum error of 0.49mm in the lateral direction and 0.25mm in the anterior direction [8]. We also computed the relative difference (femur subtracted from tibia) in the COC path length and velocity, which have been used as measures of contact sliding length and velocity [4]. Contact asymmetries were determined by subtracting the healthy from the reconstructed metrics. We performed a multiple linear regression analysis to determine the ability of non-native ACL geometry to predict the asymmetry in contact metrics. When a

significant relationship was found ( $p < 0.05$ ), we used the coefficient of the regression model ( $\beta$ ) to determine the sensitivity of each contact metric to non-native graft placement.

## RESULTS AND DISCUSSION

Tibial posterior attachment location and sagittal graft orientation predicted asymmetries in cartilage contact location and sliding length (Fig. 2). A more posterior tibial attachment was linked to a more lateral COC ( $\beta = 0.72$  mm/mm) and greater sliding length ( $\beta = 1.7$  mm/mm) in the medial compartment. A greater sagittal plane angle was linked to a more medial COC on the medial tibia ( $\beta = 0.14$  mm/deg) and decreased sliding length in the lateral compartment ( $\beta = -0.19$  mm/deg).

**Figure 2:** Tibia and femur COC paths for representative subjects with only significant differences shown. More posterior tibial attachments predicted more lateral contact and greater sliding length, as seen by the longer reconstructed femur COC path. More vertical grafts corresponded to more medial contact on the medial tibia and decreased lateral compartment sliding length, as seen by the shorter reconstructed femur COC path.

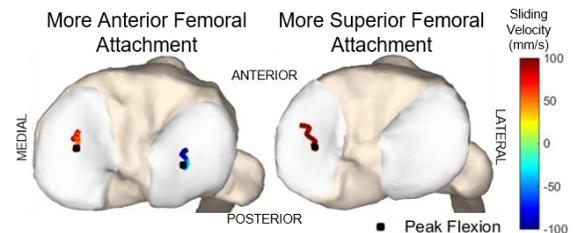

Femoral superior and posterior attachment locations predicted asymmetric sliding velocity magnitudes (Fig. 3). A more anterior femoral attachment was related to greater sliding velocity in the medial compartment ( $\beta = 60$  (mm/s)/mm) and lower sliding velocity in the lateral compartment ( $\beta = -22$  (mm/s)/mm). A more superior femoral attachment was linked to greater sliding velocity in the medial compartment ( $\beta = 22$  (mm/s)/mm).

Our findings suggest that non-native ACL graft placement may contribute to altered cartilage loading in ACLR knees. Recent studies by DeFrate et al. [6] have shown that ACL grafts placed antero-

proximally on the femur, relative to native, tend to be more vertical in the sagittal plane and are linked with greater anterior tibia translation, medial tibia translation, and internal rotation. Similarly, we found links between femoral attachments, sagittal graft angle, and abnormal cartilage contact. The largest contact sensitivity was indicative of substantially greater sliding velocity in the medial compartment in subjects with an abnormally anterior femoral attachment. It was previously found that an increase in sliding velocity of 10 mm/s correlates to approximately a 1 point increase in cartilage damage grade (on a 5 point scale) [4]. Hence, our findings suggest that the early progression of osteoarthritis seen in this population could arise from abnormal contact due to a non-native graft femoral attachment.

## CONCLUSION

This study elucidates links between ACL graft geometry and asymmetric cartilage contact. These findings suggest that altered cartilage loading can potentially be restored through graft placement, which may be important to consider when planning ACLR procedures to restore normative mechanics.

**Figure 3:** Bilateral differences in sliding velocity for representative subjects with only significant differences shown. Anterior femoral attachment was linked to increased medial compartment sliding velocity and decreased lateral compartment sliding velocity. A more superior femoral attachment predicted greater medial compartment sliding velocity.

## INTRODUCTION

A 2009 report estimated that osteoarthritis (OA) affected approximately 27 million US adults at that time [1]. In-shoe lateral sole wedging has been proposed as a low cost measure to address varus knee malalignment and associated medial knee OA (MKOA). While one review [2] concluded there was a ‘strong scientific basis for applying wedged insoles in attempts to reduce osteoarthritic pain of biomechanical origin’, another [3] concluded that the use of lateral wedges for MKOA was not supported. Potential benefit derived from lateral wedging has been linked to reduction in the external knee adduction moment (EKAM), with concomitant reduction in medial condylar loading. While some mechanistic study findings have supported this link, others report mixed or contradictory results [4].

Most previous studies of lateral wedging have investigated only one level of wedging - most frequently a 5° lateral wedge. As part of a more comprehensive investigation that incorporates weight bearing MRI of the knee joint, our study explored the effects of incremental increases of lateral wedging on EKAM. In comparison with a non-wedged (neutral) insole, we studied three different levels of wedging at two walking speeds.

## METHODS

We report initial results from all participants recruited to date (n=4, male, 63±6.7 years) in a study that has a target enrollment size of 20. All research procedures were approved by the Institutional Review Board. All participants presented symptomatic, predominantly medial knee osteoarthritis, as confirmed by physical examination and a standing frontal radiograph. Exclusions to

enrollment included: presence of advanced knee OA; history of lower extremity joint replacement or osteotomy; knee surgery in the preceding 6 months; intra-articular viscosupplementation or corticosteroid injection in the preceding 4 months; use of wedged insoles in the preceding 4 months. For each participant, one knee was assigned as the index knee based on the clinical and radiological severity.

All participants were tested in a pair of standardized walking shoes (New Balance MW577), selected according to self-reported shoe size. Four sets of custom insoles were prepared by a professional pedorthist. The base insole was constructed of 5/16” thick neoprene (Spenco®), Spenco Medical Corp., Waco, TX). The neutral (‘N’) insole consisted only of the neoprene layer. Lateral wedging of 3°, 6°, and 9° was added using 1/8” and 1/4” cork layers applied to the full width tapering to zero thickness medially. Lengthwise, wedging was applied from the heel to the metatarsal heads.

Participants were fitted with a custom 42-marker Helen-Hayes kinematic marker set. Marker trajectories were captured using a 12-camera motion analysis system sampling at 120 Hz (Motion Analysis Corp., Santa Rosa, CA). Force data was recorded with two force plates sampling at 2520 Hz (Bertec Corp., Columbus, OH) mounted in the floor.

Initial testing was performed with the neutral insoles. Participants were then asked to walk across the length of the laboratory, first at a “stroll” speed, then at a “brisk” speed. Speeds were self-selected based on verbal cues indicating respectively ‘leisurely walking’ and a faster walk, as if to catch a bus. The average speed of 5 trials for each speed was collected using optical timing gates at the beginning and end of the walk. The subsequent testing order for

footwear condition (N/3°/6°/9°) was randomized. After a brief period of acclimation to each wedge condition, the participant was asked to walk at the ‘stroll’ and ‘brisk’ speeds established during the initial trials, using an audible metronome set to match the cadences to assist in reproducing those baseline speeds. Walking trials were accepted for analysis subject to the following criteria: (1) timing gate speed within  $\pm 5\%$  of targeted speed; (2) kinetic data recorded for the complete stance phase on either or both limbs. Besides the metronome, verbal cueing was provided to facilitate meeting these criteria. At least 3 trials were collected for each limb for each condition.

All kinematic and kinetic post-processing was performed using Cortex (Motion Analysis Corp.) & Matlab (MathWorks, Inc., Natick, MA) software. Marker trajectory data was smoothed using a 6 Hz Butterworth low-pass filter. EKAM profiles were calculated using the Cortex software’s kinetic model and normalized to body weight. The EKAM measure analyzed was the normalized EKAM impulse, calculated as the time integral of the normalized EKAM curve throughout stance.

Data for the index knee were analyzed in this report. Statistical analyses were performed for both speeds, using analysis of variance with lateral wedge level as a repeated factor. Pairwise comparisons were used to test for outcome differences in wedged conditions from the neutral condition. Within wedge conditions, paired t-tests were used to analyze the effect of walking speed. Significance level ( $\alpha$ ) for all statistical testing was set at 0.05.

## RESULTS AND DISCUSSION

In the ‘stroll’ speed, we observed a significant effect ( $p=0.023$ ) of wedge condition, such that EKAM impulse was reduced by the increasing wedge (Fig. 1). At this speed, pairwise testing indicated that EKAM impulse was significantly lower than for the neutral insole for all wedge angles. No significant effect of wedging ( $p=0.383$ ) was found for ‘brisk’ speed, although pairwise testing indicated the EKAM impulse was lower for 3° than N. Mean EKAM impulses were lower for ‘brisk’ than ‘stroll’ speed, significantly at the N and 3° conditions. An

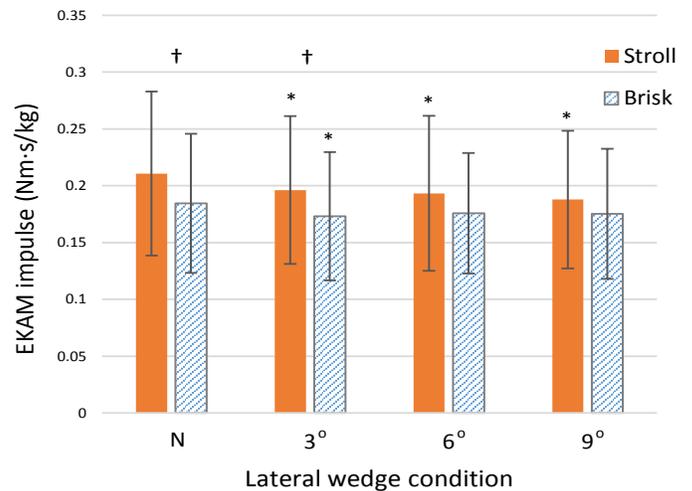

Figure 1: Impulse of normalized knee adduction moment for two walking speeds and 4 wedge conditions. \*: Significant difference of wedge condition from ‘N’, within speed condition; †: significant difference between speeds, within wedge condition.

effect of decreasing EKAM impulse with increasing speed has been reported previously [5].

## CONCLUSIONS

In the ‘stroll’ walking speed, these preliminary results support the hypothesis that incremental lateral wedging monotonically reduces EKAM. At the accelerated speed, the results suggested the presence of a limiting or ceiling effect of lateral wedging on EKAM. Ongoing work will combine these results with a parallel weight bearing MRI investigation of knee joint condylar contact in this cohort, to more clearly describe the biomechanical effects of lateral wedging in MKOA patients.

## INTRODUCTION

Osteoarthritis (OA) is a degenerative joint disease, reported to account for 1% of total deaths worldwide [1]. OA is often caused by increased joint stress and affects the medial knee joint compartment most frequently. The end-stage treatment for OA is total knee replacement (TKR), whereby natural tissues are removed. Although, clinical outcomes are generally satisfactory, a restriction for certain activities, instability, pain, and unmet patient expectations may result.

The Atlas™ implant (Fig. 1), fixed subcutaneously alongside the medial aspect of the joint, is designed to offload the medial compartment of the knee, without violating the natural tissues. This may halt the debilitating symptoms associated with OA progression.

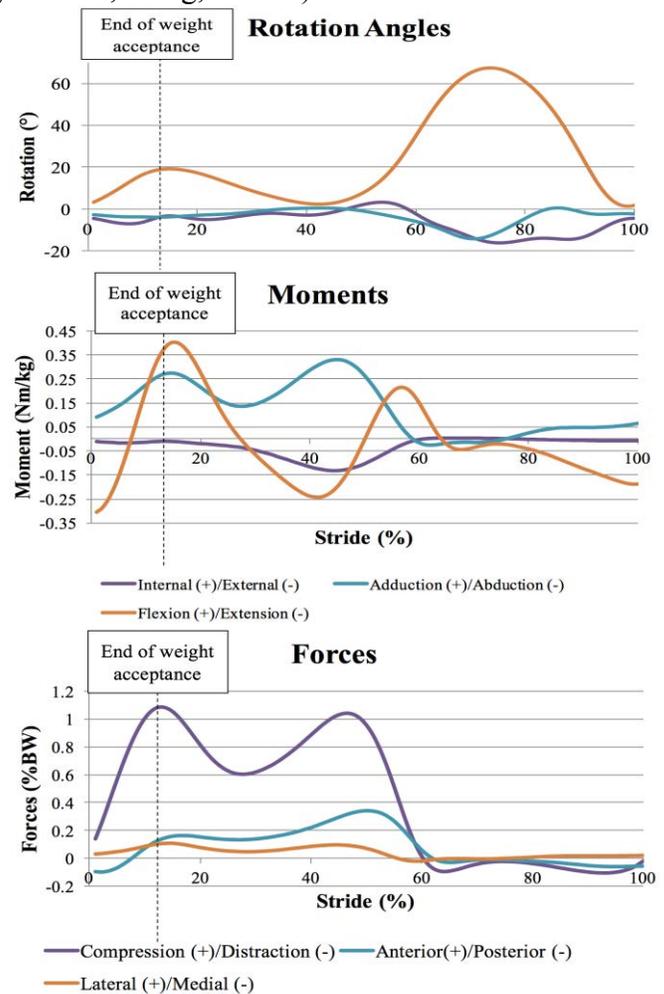

**Figure 1:** The Atlas™ implant fixed to the medial distal femur and proximal tibia.

The aim of this investigation was to study the effect of the Atlas™ knee implant on knee joint contact stress.

## METHODS

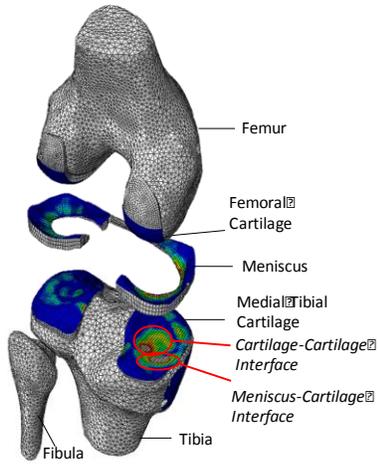

A three-dimensional previously-validated cadaver-specific finite element (FE) knee model [2] was used in this study. Computer aided design models of the Atlas™ components were virtually fixed to the medial aspect of the knee model to simulate

treatment of medial knee OA. To evaluate the knee joint stress distribution within the medial compartment in response to the Atlas™ implant, the model was driven by the loading experienced during the gait cycle (Fig. 2) of a healthy subject with similar anthropometric data as the cadaver (male, 50 years old, 65 kg, 1.65 m).

**Figure 2:** Knee joint angles, forces and moments during the gait cycle of level walking.

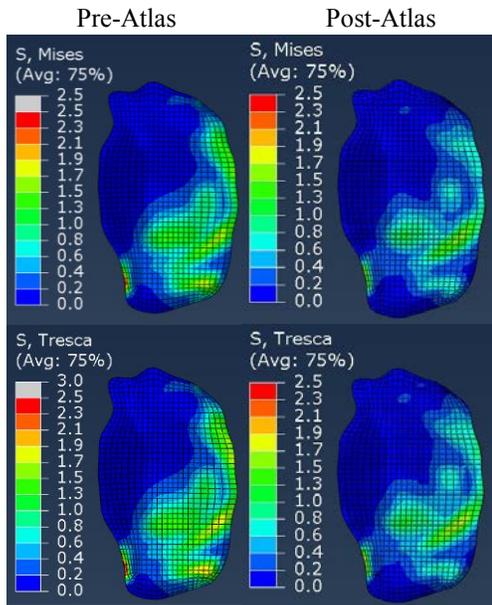

Note that varus thrust is maximum at 20° of knee flexion and 15% of the gait cycle, at the end of weight acceptance (Fig. 2). Peak Tresca and von Mises stress were computed in the medial knee compartment with and without the Atlas™ implant at different points of stance phase.

**Figure 3:** Exploded view of the FE knee model, showing stress distribution on the tibial cartilage and meniscus- cartilage interface were compiled for the quasi-static FE analyses (Fig. 3).

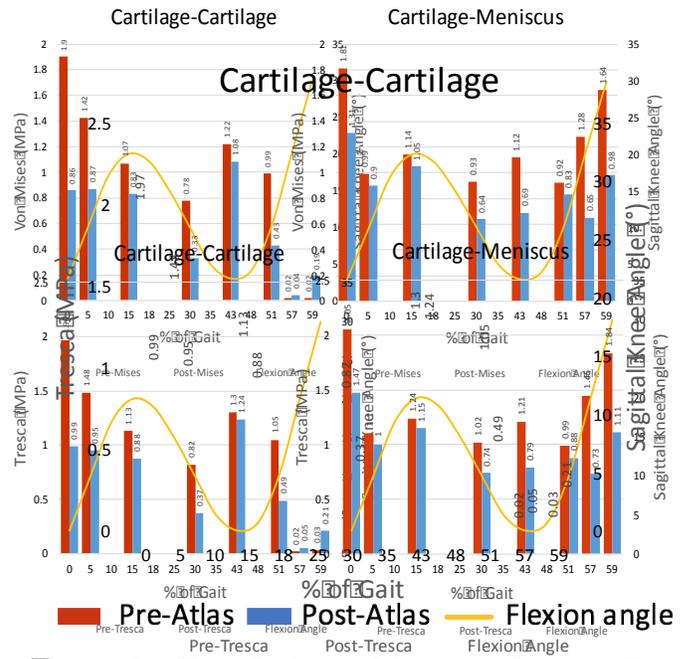

## RESULTS AND DISCUSSION

Figure 4 shows von Mises and Tresca stress values in the medial tibial cartilage, with and without the Atlas™ implant, at end of weight acceptance.

**Figure 4:** (Top) von Mises and (bottom) Tresca stress values on the medial tibial cartilage at the end of weight acceptance.

Peak von Mises and Tresca stress values, with and without the Atlas™ implant, across the stance phase of gait, are compiled in Figure 5.

**Figure 5:** (Top) Peak von Mises and (bottom) Tresca stress values in the medial tibial cartilage at different points of the gait cycle pre- and post- Atlas™. The corresponding knee flexion angle is shown in yellow.

A cadaveric-specific knee FE model was used to compare peak stress values in the medial tibial cartilage with and without the Atlas™ implant at different points during the stance phase of gait. Consistent reductions in peak von Mises stress values, ranging from 11.5% to 56.6% and 9.1% to 49.2%, were noted in the cartilage-cartilage and meniscus-cartilage regions, respectively. Consistent reductions in peak tresca stress values, ranging from 4.6% to 54.9% and 7.3% to 49.7%, were noted in the cartilage-cartilage and meniscus-cartilage regions, respectively.

## CONCLUSIONS

Results of this study show the capability of the Atlas™ implant to offload the medial knee compartment. The clinical significance is that the Atlas™ implant could help delay OA progression, and delay the need for a knee replacement.

## INTRODUCTION

Obesity is a risk factor for onset of knee osteoarthritis (OA) [1]. Studies using 3D motion capture have reported the gait pattern of individuals with obesity [2]. However, the articular cartilage contact characteristics of the knee joint in obese individuals are still unclear. In this study, we aimed to use a validated dual fluoroscopy imaging system (DFIS) with a subject-specific magnetic resonance (MR) cartilage model to investigate the articular cartilage contact kinematics in obese individuals with knee pain.

## METHODS

Eighteen obese individual with knee pain (age:  $42.4 \pm 9.4$  yrs; body height:  $1.64 \pm 0.09$  m; body mass:  $106.2 \pm 11.9$  kg; body mass index (BMI):  $39.5 \pm 2.5$ ; 15 females, 3 males) with knee pain (visual analog scale:  $63.8 \pm 17.4$  out of 100) were recruited for the fluoroscopic gait analysis. The study protocol was approved by the Institutional Review Board and each subject provided written informed consent. The painful knee of each individual was MR scanned (Philips, Achieva, Eindhoven, The Netherlands) using a Proton Density-Weighted (PDW), Spectral Attenuated Inversion Recovery (SPAIR) sequence. The knee MR images were used to construct the subject-specific bone and cartilage surface models. Each individual was then asked to walk on a treadmill at 1.5 mph (0.67 m/s) and the painful knee was imaged by DFIS (Philips, BV Pulsera, Eindhoven, The Netherlands). Knee positions during the stance phase of the gait cycle were obtained through a 2D to 3D registration procedure. The femoral and tibial cartilage models were mapped to the corresponding bone models at each position. The

cartilage contact was represented by overlapping of the tibial and femoral cartilage surfaces, and the centroid of the overlapped surfaces was defined as the cartilage contact point [3]. The contact points during the stance phase of the gait cycle were described by contact location on the tibial plateau, and the contact and deviation angles on the femoral condyles (Figure 1) [3]. The excursion of contact locations was determined by subtracting the maximum from the minimum during the stance phase of the gait cycle. Paired t-test was used to determine the statistical difference between medial and lateral contact locations. Pearson's correlation analyses were performed to assess the relationship between the excursion of contact locations and BMI/pain status. The alpha level was 0.05.

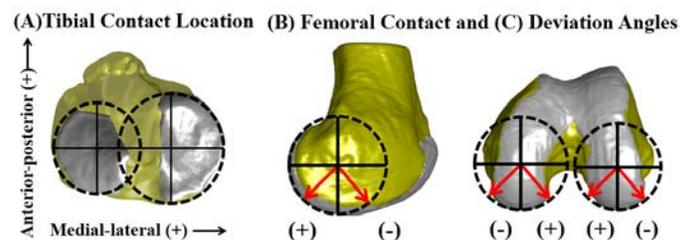

Figure 1. (A) The cartilage contact location on the tibia plateau. The medial-lateral axis is defined first as a line connecting the centroids of the two circles fit to the medial and lateral tibial plateau surfaces. The anterior-posterior axis is created perpendicular to the medial-lateral axis and the long axis of tibia. (B) Femoral contact angle in the sagittal plane is based on the geometric center of each condyle. Positive values indicate the contact point is in the posterior condyle. (C) The deviation angle is in a plane perpendicular to the sagittal plane. Positive values indicate the contact point is in the inner portion of the condyle [3].

## RESULTS

The tibial cartilage contact points in the medial compartment were more anteriorly and medially located compared to the contact points in the lateral compartment during the stance phase of gait (Figure 2A, 2B). The femoral contact angle in both the medial and lateral condyles during the stance phase followed the knee flexion angle, and the medial condyle had a smaller contact angle throughout the stance phase (Figure 2C). The medial condyle had a greater femoral deviation angle than the lateral condyle throughout the stance phase (Figure 2D).

In terms of the excursion of the contact location during the stance phase of gait, the anterior-posterior tibial contact point translated more in the medial compartment than in the lateral compartment (Table 1). Additionally, the femoral contact angle for the medial condyle had a larger excursion compared to the lateral condyle (Table 1). In the correlation analyses, no significant association was found between excursion and BMI or knee pain.

Table 1. Excursion of the tibial and femoral contact locations during stance phase.

	Medial	Lateral	P-value
<b>Tibial anterior-posterior (mm)</b>	7.8 ± 3.2	5.2 ± 1.8	0.003

## DISCUSSION

This abstract reported the articular cartilage contact characteristics of eighteen obese individuals with knee pain during the stance phase of the gait cycle. The major tibial contact point translation was in the anterior-posterior direction. The larger anterior-posterior translation in the medial compartment may be helpful to distribute the compressive stress over different areas of the tissue. However, more shear stress may be experienced in the medial plateau during the stance phase of gait when compared to the lateral compartment. This may damage the medial plateau cartilage as shear stress is thought to be a major contributor to the formation of osteoarthritis. In terms of femoral contact angles, the offset implies that the distribution of the contact locations is

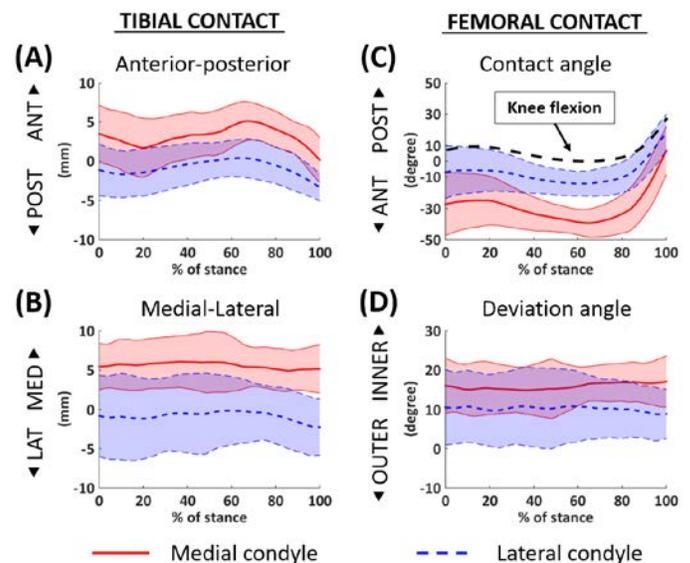

Figure 2. Tibial and femoral articular cartilage contact characteristics. Cartilage contact on tibial plateau along the anterior-posterior direction (A) and medial-lateral direction (B). Cartilage contact angle (C) and deviation angle (D) on femoral condyle.

different between the medial and lateral condyles. The positive femoral deviation angles indicate that both medial and lateral contact points were located in the cartilage on the inner portion of the femoral condyles. Further, the contact characteristics could not be better explained either by BMI or knee pain.

This is the first study, to our knowledge, to investigate the articular cartilage contact mechanism in obese individuals with knee pain. The difference between contact locations in the medial and lateral compartments may provide insights into the pathogenesis of knee osteoarthritis in individuals with obesity.

## INTRODUCTION

Femoroacetabular impingement (FAI) is a condition in which morphological abnormalities of the hip joint result in mechanical impingement of the joint causing pain and disability during activities of daily living such as gait [1]. Previous studies have shown that when compared to healthy controls, FAI patients exhibit altered hip joint loading patterns during the first half of the stance phase of gait [2] and that hip joint mechanics remain altered after hip arthroscopy [3]. Furthermore, the altered joint mechanics in patients undergoing hip arthroscopy possibly increase the risk of osteoarthritis (OA). Understanding the neuromuscular patterns that occur during gait both before and after hip arthroscopy in FAI patients may provide insight into the possible mechanisms that may potentially lead to hip joint degeneration.

The purposes of this study were to: 1) identify the differences in hip joint muscle force production during gait in subjects with FAI, both before and after hip arthroscopy and 2) determine the relationship between muscle forces and progression of hip joint cartilage abnormalities and composition (assessed with MRI) in FAI patients. We hypothesized that FAI patients would demonstrate abnormal muscle force production during gait both before and after hip arthroscopy and that these abnormal muscle forces would be related to disease severity and its progression.

## METHODS

Thirty-five participants were enrolled in this study. There were 10 FAI patients (40.3±8.7yrs, 7 males, 24.6±3.8kg·m<sup>-2</sup>) and 25 age and BMI matched

controls (CONT, 45.4±12.3yrs, 14 males, 23.7±3.5kg·m<sup>-2</sup>). FAI patients were tested both before and at 7.5±1.3 months after arthroscopic treatment with labral repair and osteochondroplasty. All participants performed 4 successful trials of walking at a self-selected speed, where speeds were controlled to be within 5% of the first successful trial. Static optimization, within OpenSim [4], was used to determine muscle force production, normalized body weight (BW), during the stance phase (initial contact to toe-off) of walking of the gluteus maximus, gluteus medius, gluteus minimus, sartorius, tensor fasciae latae, iliacus, psoas, adductor (magnus/brevis/longus), lateral (LH) and medial (MH) hamstrings, rectus femoris (RF) and the vastii (medius, lateralis and intermedius).

Each FAI patient underwent a hip MRI of the surgical limb using a 3T MR-scanner (GE MR750). Hip joint cartilage abnormalities, in both the acetabular and femoral cartilage regions were assessed before and after hip arthroscopy using a validated MR-based semi-quantitative method called Scoring Hip Osteoarthritis with MRI (SHOMRI) [5] and were summed together to provide a total cartilage score. In addition, T<sub>1ρ</sub> and T<sub>2</sub> mapping [6] of the acetabular and femoral cartilage was performed before and after surgery.

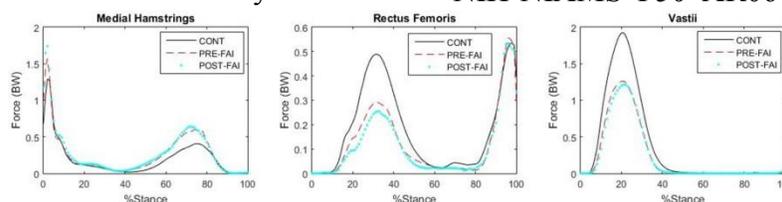

Peak muscle forces in the first and second halves of the stance phase of gait were assessed using one-way ANOVAs and Mann-Whitney U-tests (non-normally distributed data), with a Bonferroni correction of p≤0.004 (0.05/12 muscles). Paired t-tests (p≤0.004) were used to assess differences in muscle force production, T<sub>1ρ</sub> and T<sub>2</sub> mapping (p<0.05) in FAI patients before and after hip arthroscopy. Spearman's (r) and Pearson's (P)

correlations were used to assess for associations between changes in MH, RF and vastii muscle forces with cartilage abnormalities and T<sub>2</sub> mapping in FAI patients, respectively.

## RESULTS AND DISCUSSION

There were no significant differences ( $p > 0.05$ ) in age, BMI or walking speeds between the FAI and CONT groups. Compared to CONT, after hip arthroscopy, the FAI patients exhibited increased MH (FAI:  $1.86 \pm 0.39$  BW; CONT:  $1.41 \pm$  BW;  $P < 0.001$ ), decreased RF (FAI:  $0.29 \pm 0.19$  BW; CONT:  $0.55 \pm 0.25$  BW;  $p = 0.003$ ) and decreased vastii (FAI:  $1.24 \pm 0.36$  BW; CONT:  $2.03 \pm 0.73$  BW;  $p = 0.004$ ) muscle forces during the first half of stance (Fig. 1). Prior to hip arthroscopy, the FAI patients exhibited trends of reduced RF ( $p = 0.02$ ) and vastii ( $p = 0.01$ ) muscle forces during the first half of stance compared to CONT. No differences in muscle forces ( $p > 0.05$ ) were exhibited between the FAI patients and CONT during the second half of stance both before and after hip arthroscopy. In addition, no differences exist in muscle forces during gait or T<sub>1ρ</sub> mapping ( $p > 0.05$ ) within FAI patients after hip arthroscopy. After hip arthroscopy, FAI patients exhibited increased anterior femoral T<sub>2</sub> relaxation times ( $\Delta 2.68 \pm 2.21$  ms,  $p = 0.006$ ). Within FAI patients, a reduction in vastii muscle force was associated with an increased change in the anterior femoral T<sub>2</sub> relaxation time ( $P = -0.70$ ,  $p = 0.03$ ) after hip arthroscopy. No associations between muscle force and cartilage abnormalities were observed.

In the current study, FAI patients demonstrated increased MH, reduced RF and vastii muscle forces during the first half of the stance phase of gait after hip arthroscopy. After hip arthroscopy FAI patients exhibited reduced knee extensor moments during gait compared to controls [4], which may be related to decreased knee extensor force production after hip arthroscopy as shown in the current study. It is

**Figure 1:** Muscle force profiles for the controls and femoroacetabular impingement (FAI) patients during gait.

unclear if these results indicate a role of vastii activation in the pathomechanics of FAI-associated hip OA, or if this represents a simple association as patients reduce vastii activation as an analgesic mechanism to reduce joint compression forces. The increased MH forces exhibited by FAI patients after hip arthroscopy during the first half of stance may cause increased knee flexion and may be a compensatory mechanism of a possible reduced ability to flex the hip joint. Increased vastii muscle force after hip arthroscopy may be a protective mechanism against hip joint degeneration and suggests that quadriceps strengthening may be an important factor in FAI rehabilitation programs. Also, the results of the current study indicate that T<sub>2</sub> mapping may be more sensitive in assessing cartilage degeneration than morphological based cartilage assessments.

## CONCLUSIONS

FAI patients exhibited abnormal muscle forces during the first half of the stance phase of gait. More specifically, vastii strength after hip arthroscopy may affect articular cartilage health. These parameters should be investigated with longer follow-ups and larger cohort sizes.

# MUSCLE CONTRACTILE PROPERTIES IN MICE WITH LGMD2i MUSCULAR DYSTROPHY

<sup>1</sup> Jordan Rehwaldt, <sup>1</sup> B. Dan Rodgers, and <sup>1</sup> David Lin

<sup>1</sup> Washington State University, Pullman, WA, USA  
email: davidlin@wsu.edu

## INTRODUCTION

Muscular dystrophies are particularly debilitating muscle degenerative diseases that compromise myofiber integrity. Interestingly, comprehensive assessments of muscle contractile function in dystrophic animals are surprisingly lacking, and without this essential baseline information, it is extremely difficult to understand how the disease affects motor behavior or to assess whether a novel therapy is effective.

A mouse model for limb girdle muscular dystrophy 2i (LGMD2i) has been developed recently (the P448L mouse) [1], enabling a comprehensive understanding of the disease and the potential development of therapeutics. The objective of our study was to characterize the fundamental contractile properties of the medial gastrocnemius (MG), including force-length (F-L), and force-velocity (F-V) properties. Not only will these data provide a baseline for assessing disease pathogenesis, they will identify novel markers of contractile dysfunction that could prove valuable to drug development efforts. Furthermore, they can elucidate the underlying causes of deficits in motor behavior.

## METHODS

All procedures were pre-approved by the Institutional Animal Care and Use Committee (IACUC) at Washington State University. Experiments were performed on young adult mice (6-7 months old): 5 female wild-type (WT), 5 male WT, 4 female P448L and 6 male P448L mice.

Measurements of *in situ* contractile properties of the MG in a bath at 37°C were made using a whole mouse test system (Aurora Scientific) while operating in either length control mode for isometric contractions or force control mode for isotonic

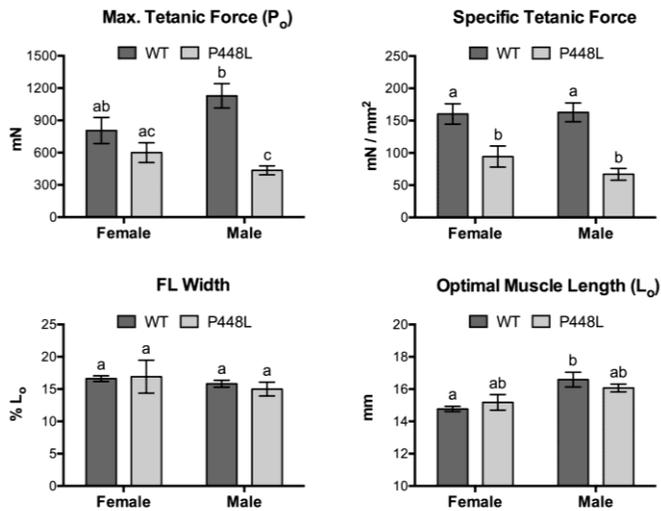

contractions. F-L properties were estimated from isometric contractions at seven randomized lengths. F-V properties were estimated from contractions with at least 6 isotonic loads (usually 9).

For the F-L data, the analysis included estimates of  $L_o$ , maximal isometric force ( $P_o$ ) and the width of the F-L curve (an indicator of sarcomere inhomogeneity [2], which could occur from structural deficiencies due to the muscular dystrophy). For the F-V data, we estimated maximal shortening velocity ( $V_{max}$ ), normalized maximal power ( $P_{max}$ ), and optimal velocity ( $V_{opt}$ , the velocity at which maximal power occurs). Comparisons were made across all four animal groups using a two-way ANOVA with genotype (P448L and WT) and sex as independent variables and with Tukey's post hoc analysis. Significance was reported at  $P \leq 0.05$ .

## RESULTS AND DISCUSSION

The  $P_o$  was significantly smaller in male P448L mice compared to WT mice in both absolute units (mN; 61% smaller) and when normalized by physiological cross-sectional area (PCSA) (*i.e.*, specific tension; 59% smaller) (Fig. 1). For the female mice, the absolute force was not different between groups, but specific tension was significantly smaller (41%) in P448L mice. These results were a reflection of the larger muscles in female P448L mice relative to WT mice. For both measures, there were no sex differences in either the P448L or WT mice. These results suggest that maximal isometric tetanic contractility is impaired in P448L mice.

Polynomial curves fitted to the normalized F-L data of each animal were used to estimate force-length width, which was found to be similar between all groups (Fig. 1). This result indicated that sarcomere inhomogeneity was not a prevalent feature of LGMD2i mice.

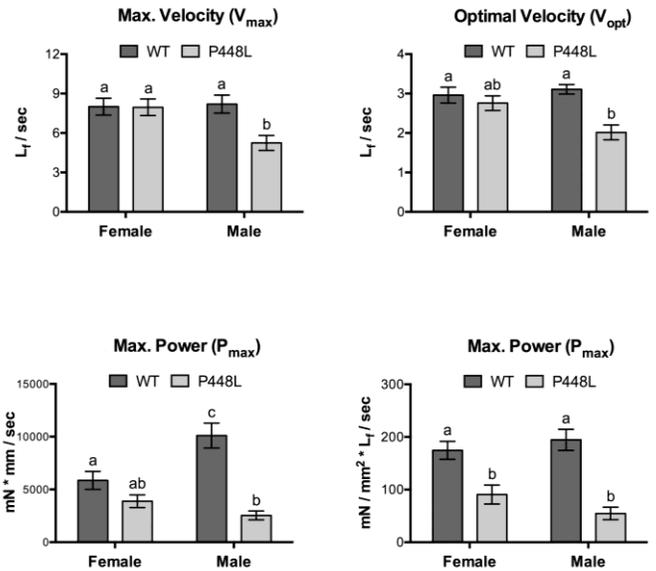

**Figure 1.** Comparison of F-L properties in P448L and WT mice with sex as a factor.

Hill's Equation was fitted to the normalized F-V data and normalized power-velocity (P-V) data of each mouse. From these fits, we could estimate the dynamic contractile properties. Normalized  $V_{max}$  was 36% slower in male P448L mice compared to WT (Fig. 2). Similarly, male-matched comparisons of normalized  $V_{opt}$ , was 35% slower (Fig. 2C). However, no differences were detected in either measures when comparing female groups. These results are again indicative of sexual dimorphism.  $P_{max}$  was lower in P448L males compared to WT mice in both absolute units (75% lower) and when normalized by both fiber length ( $L_f$ ) and PCSA (72% lower) (Fig. 2). Power generation was also lower in P448L female mice (absolute  $P_{max}$  by 34%, normalized  $P_{max}$  48%), though females only differed significantly in normalized  $P_{max}$ . There were no sex differences in normalized  $P_{max}$  in either strain of mice. These results are consistent with the isometric measurements, which were lower in P448L mice, albeit the differences were again greater in P448L males.

## CONCLUSIONS

We quantified the *in situ* contractile properties of the mg in young adult P448L mice, a novel model of LGMD2i. We found that:

**Figure 2.** Comparison of F-V and P-V properties in P448L and WT mice with sex as a factor.

- Normalized isometric force and power were all significantly smaller in P44L mice compared to sex-matched wild-type mice. These differences were consistent with the replacement of contractile fibers by passive tissue.
- The shape of the active force-length relationships were similar in both groups, regardless of sex, indicating preservation of homogeneous sarcomere structure in P448L mice.
- Sex differences were mostly noted in the F-V curves as maximal and optimal velocities were significantly slower in P448L males, compared to wild-type, but not in P448L females. This suggests that the dystrophic phenotype progresses more quickly in P448L males.

## INTRODUCTION

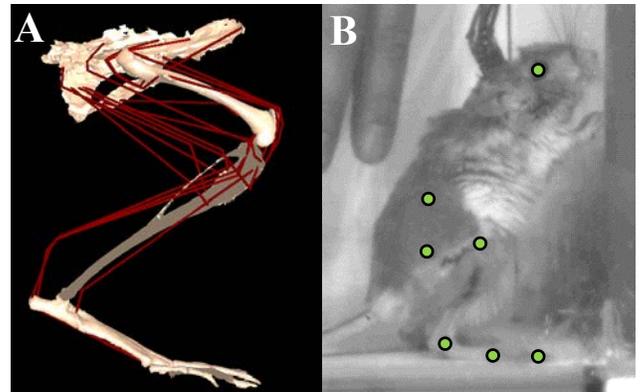

Forward dynamic simulations of detailed musculoskeletal models are powerful tools for investigating human movement [1]. Combined with experimental data, these tools provide a strong framework for informing clinical practice and improving rehabilitation outcomes. These techniques have broad application and can assist clinicians treating a wide range of populations.

However, existing limitations must be overcome to unlock the unrealized potential of these approaches. To date, generic models are still widely used to study and inform various clinical populations. Advances in rehabilitation methods show that best outcomes are achieved when clinical programs are tailored to a patient's unique needs and pathological condition. Similarly, the use of subject-specific musculoskeletal models is necessary to increase their clinical effectiveness. Researchers have begun to address the limitations inherent in generic models by developing approaches for scaling generic model parameters (e.g., muscle strength, limb masses) [2].

In addition to the aforementioned parameters, the characteristics defining individual muscle-tendon units (MTUs) may need to be tuned to individual patients, especially within populations known to exhibit changes in MTU properties (e.g., aging). In this study, we present a first step in determining the influence that individual MTU properties have on modeling and simulation outcomes, by using an ideal animal model (kangaroo rats) to test the sensitivity of Hill-type muscle parameters on jumping simulation outcomes. Of specific interest is the influence of tendon stiffness, which has been shown previously to greatly influence MTU performance [3].

## METHODS

A detailed musculoskeletal model of the right hind limb of a kangaroo rat (*D. deserti*) was developed from 3D bone scans and muscle dissection (Fig. 1A). A planar model was generated by importing bone scans into SIMM (Musculographics, Inc.) to create five segments that are articulated via seven joints. A total of 21 Hill-type musculotendon actuators were used to represent the major hind limb muscles. Muscle-tendon paths were based on dissection and verified using empirical moment arm data (collected using the tendon-travel method). Tendon parameters were obtained from a generic human model available in OpenSim [2].

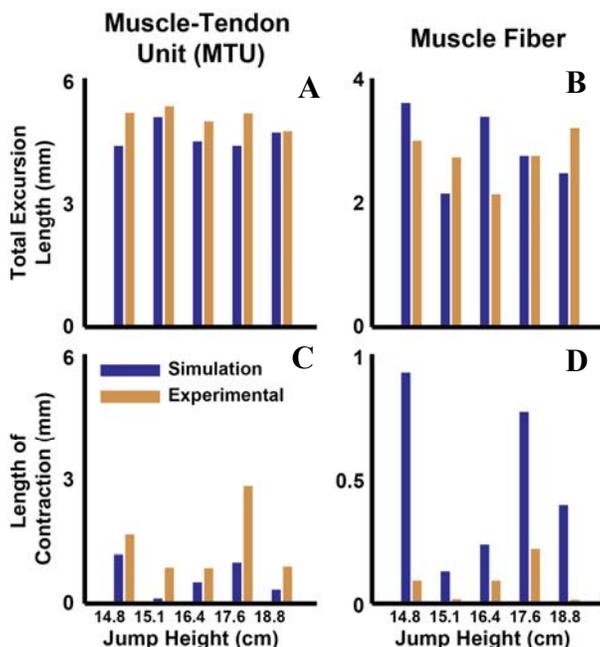

**Figure 1:** A) Kangaroo rat (*D. Deserti*) hind limb musculoskeletal model. MTU are represented by red (grey) lines. B) Experimental jumping setup. Green (grey) circles represent markers used to calculate joint angles.

The model was placed within a dynamic optimization framework where each muscle tendon actuator was excited using a parameterized double-Henning pattern (6 parameters/actuator). An optimal tracking cost function was used to generate forward dynamics simulations that reproduced experimental joint angles during jumping (Fig. 1B).

Five simulations were generated, representing a single representative animal jumping over increasing obstacle heights (20, 25, 30, 35, and 40 cm). MTU and muscle fiber length trajectories of the Gastrocnemius were obtained from each simulation and used for analysis. To evaluate the capabilities of the Hill-type muscle actuators and their sensitivity to tendon parameters, simulated muscle data were compared to experimental MTU and muscle fiber lengths obtained during each jump using sonomicrometry. Muscle excitation timing was also compared to experimentally collected EMG data to verify the feasibility of the optimal simulations.

## RESULTS AND DISCUSSION

In all jump heights, the optimization framework successfully reproduced the major features of the jumping motion with root mean square (RMS) differences between simulated and experimental joint angles averaging <10.5 degrees in all cases. Although total excursion (lengthening + contraction) and contraction only MTU length changes were similar between the simulated and experimental results, the simulations consistently underestimated MTU length changes (Fig. 2A,2C).

**Figure 2:** Comparisons of total excursion (A,B) and contraction (C,D) lengths for the entire MTU and only muscle fibers.

Total excursions of contractile lengths were variable across simulations (Fig. 2B), likely due to their sensitivity to slight variations in excitation timing during the countermovement phase of the jump. On the other hand, following the countermovement where most of the MTU and fiber contraction occurs, simulated fiber contractions were much greater than those observed experimentally (up to 10% of optimal fiber length, Fig. 2D). The low experimental results are consistent with human jumping studies that suggest ankle extensor muscles act isometrically during the movement [3,4].

## CONCLUSIONS

Relative to human Achilles tendon, kangaroo rat tendons are likely to be stiffer, which would result in relatively higher fiber contractile lengths [5]. Despite this our preliminary data show that, even using a human-based tendon model, simulations may overestimate fiber contractile lengths during jumping. Inaccurate estimations of fiber excursions can limit the utility of detailed musculoskeletal models and simulations in clinical practice and more work is needed to characterize subject-specific variation in tendon properties. Our experimental and simulation framework allows us to test various aspects of muscle-tendon interaction and future simulations specifically detailing the sensitivity of muscle fiber excursion to tendon properties will help determine appropriate parameters for subject-specific human models.

## INTRODUCTION

Following traumatic knee injury, biomechanical changes in joint loading and chondrocyte metabolism lead to deterioration of articular cartilage and symptomatic presentation of osteoarthritis (OA, [1]). Exercise after traumatic knee injury could alter magnitude and distribution of knee loading necessary to maintain joint health and exacerbate post-traumatic OA. A medial meniscal transection (MMT) rat injury model is often used to evaluate therapeutic interventions on the development of OA following injury [2]. This model allows us to experimentally test OA causes and potential interventions, however, the ability to accurately measure kinematics has been a barrier to relating disease progression to behavioral assays in rats [3]. 3D X-ray Motion Analysis (XMA) using dual-plane, high-speed digital radiography allows accurate measurement of joint kinematics in rats and circumvents skin movement artifact errors common to external marker-based systems [3].

Assessing accurate kinematics with 3D cartilage microstructure and composition allows for a more comprehensive understanding of disease markers and their behavioral presentation in OA pathogenesis. This study tests the effect of an exercise intervention on joint kinematics and cartilage health in a rat knee MMT model of OA. We hypothesized exercise intervention would amplify markers for knee OA disease and cause greater changes in compensatory gait kinematics.

## METHODS

14 male Lewis rats (weight:  $304 \pm 57$  gm) underwent MMT surgery in their left hindlimbs and

were randomly assigned to 1) a non-exercise (NON, N=7) or 2) an exercise (RUN, N=7) group. Rat exercise training consisted of treadmill running 30 minutes per day, 4 days per week at 0.2 m/s. A sham surgery was performed on 6 additional control rats where the MMT was not performed.

Rats were evaluated 8 weeks post-surgery for hind-limb joint kinematics during treadmill locomotion (0.5 m/s) using a high-speed 3D X-ray motion analysis system (100 Hz). Rats were euthanized following testing and 3D bone surface models were generated from whole bone CT scans and aligned with high-speed radiographic images to quantify *in vivo* kinematics (XROMM Autoscooper, Providence RI; Maya, Autodesk). 3D microstructure and composition of the tibial plateau cartilage and subchondral bone were quantified using contrast enhanced microcomputed tomography, EPIC-uCT (50um resolution).

## RESULTS AND DISCUSSION

Hip abduction at midstance is shown to be significantly greater in the RUN rats relative to the sham group ( $p=0.005$ ), whereas NON rats demonstrate increased abduction only at midstance ( $p=0.036$ ) (Fig 1B). RUN rats also demonstrated greater knee varus alignment compared to the sham group at toe-off ( $p=0.036$ ) (Fig 1C). RUN rats showed increased contralateral limb stance support relative to NON and sham groups. Reduced stance time on the injured hindlimb in RUN rats compared to the other groups also revealed a compensatory gait pattern of favoring the injured limb. Increased hip abduction, knee varus alignment, and contralateral limb support time are reflective of gait in persons with mediotibial OA [1], which is also

indicated by an increased exposed bone surface area to the medial tibial plateau in the RUN rats (Fig 2).

Destabilizing the knee joint via meniscal transection alters mechanical stresses to the underlying articular cartilage. Increased degeneration indicated by decreased thickness to the proximal cartilage surface (Fig 2) and higher exposed bone values to medial 1/3 of the mediotibial plateau (Table 1) reflect concentrated force distribution to the area [3] and disrupted joint homeostasis. Attenuation measurements obtained from EPIC-uCT, which are indicators of cartilage health, further support this finding. Increased cartilage attenuation in exercise rats inversely correlates to decreased proteoglycan content and thus an inability to provide sufficient hydrostatic pressurization to resist the mechanical forces that lead to OA progression.

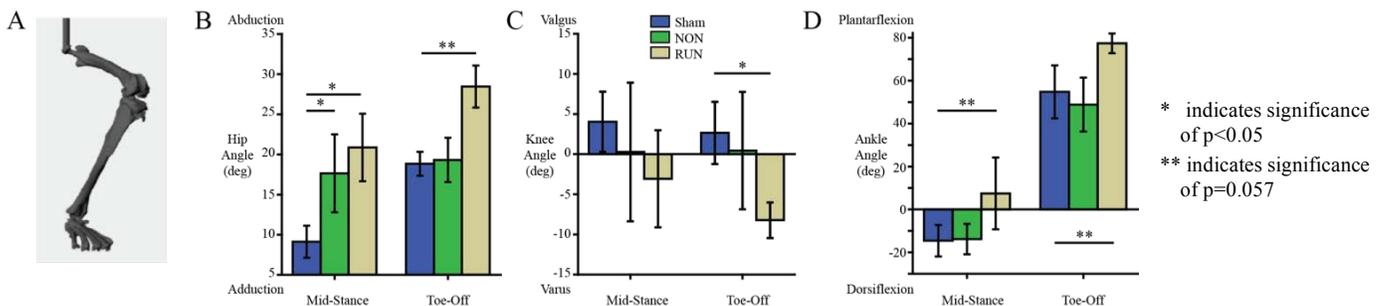

## CONCLUSIONS

The cascading effects of disrupted homeostasis on the cellular level in OA is supported by our measurement of tissue level degradation and changes in gait kinematics. Increased cartilage degeneration, subchondral bone thickening, and

osteophyte formation demonstrated in RUN rats are consistent with end-stage OA. Gait compensations through decreased single limb support time by the injured hindlimb to account for this accelerated OA progression present kinematic gait deviations in RUN rats through varus knee alignment and hip abduction. In contrast, less cartilage degeneration and increased cartilage thickness and volume in NON rats, would suggest a slower progression of OA. Kinematics evaluation at earlier measured time points to assess gait modifications is forthcoming. Quantifying animal behavior with joint structural changes across these time points will be critical for revealing the causal relationship between tissue-level OA markers and changes in gait kinematics. The MMT rat appears to be an effective OA model for evaluating behavioral interventions in combination with cellular therapeutics offering new opportunities to improve current treatment options and disease prevention.

email: kshorter@umich.edu

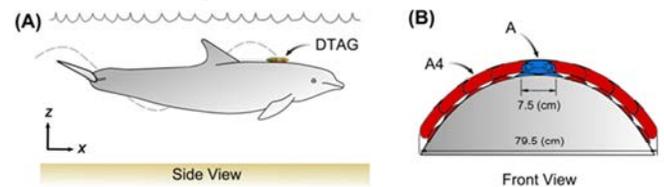

## INTRODUCTION

Maneuverability is vital for animals that must actively hunt highly maneuverable prey. Complex movements are required to out-manuever the prey, which may include rapid changes in velocity and turning radius [1]. There are, however, limitations to maneuverability that are inherent to the animal due to size and dynamic state. For swimming animals, maneuverability is heavily dependent on stability in a fluid environment, which in turn is related to morphological structure [2]. While maneuverability is essential to the success of the animal in the wild, it is difficult to quantify as the marine environment restricts direct observation of these animals during their daily routines. In this study we will investigate the effect of drag loading on the maneuverability of bottlenose dolphins (*Tursiops truncatus*) in a controlled experimental environment. Animal dynamics during a prescribed cornering task were measured and then quantified using a combination of camera-based position measurements, and dynamic information collected from the animal with a bio-logging tag. We expect that additional drag loading will slow the animal down and result in increased maneuverability.

## METHODS

**Experimental set up:** Four dolphins were trained to swim laps around a 750 m<sup>2</sup> (~40 m in diameter) artificial lagoon for ~10 min. During the trials the animals self-selected swimming speeds and four marine mammal specialists stationed around the lagoon used a “point” cue to indicate when the animal should turn and continue swimming to the next turn. The bottom left corner of the lap was selected for the cornering analysis; data 5 m before and after the midpoint of the turn were used to quantify maneuverability. Fig. 1 shows the three drag loading conditions examined: control (C), tag (A), and the tag with added drag loading (A4). In

the A4 condition drag elements increased the tag cross-sectional area by ~800%, resulting in a large increase in drag.

**Figure 1:** Illustration of the dolphin swimming with the tag and the physical elements used to increase drag loading.

**Hardware/Calibration:** Camera data from a GoPro Hero3+ mounted above the lagoon were used to track the animals when visible at the surface. Camera data were calibrated and then hand-tracked to give position, velocity, and acceleration measurements. To supplement camera data, a DTAG3 bio-logging tag was used to measure dynamic information from the animals. Tag sensors include an accelerometer, gyroscope, and magnetometer (all tri-axis), as well as a thermometer, pressure sensor and hydrophones. The tag was attached to the dolphins using four silicone suction cups, mounted ahead of the dorsal fin, oriented with the hydrophone towards the front of the animal. Before the data was used in localization processing, it was calibrated using custom Matlab toolboxes. The study protocol was approved by the University of Michigan Institutional Animal Care and Use Committee and the animal specialists and staff of Dolphin Quest.

**Madgwick Orientation Filtering:** Orientation estimate (pitch, roll, and heading) at the tag was calculated using an algorithm adapted from the method presented in [3]. This method obtains an orientation estimate of the earth frame relative to the sensor frame, through a weighted sum of the gradient-descent optimization of accelerometer, magnetometer and gyrodrometer-based orientation measurements.

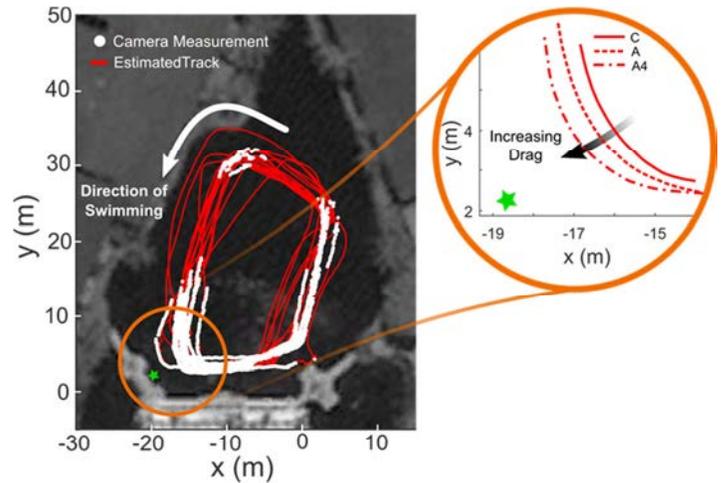

**Specific Acceleration Estimate:** Accelerometers measure both specific acceleration created by animal motion and gravitational acceleration. Specific acceleration can be isolated from the measurement by removing the gravitation component using the orientation estimate generated above and the known magnitude and direction of the gravitational acceleration.

**Velocity Filtering:** We employ a modified Kalman filter to improve the horizontal velocity estimate of the animal. Specific acceleration estimated from tag data and external velocity measurements calculated from camera data were combined to provide a more accurate velocity estimate than can be calculated from tag data alone.

**Pose-Graph Localization and GTSAM:** Numerically integrating the filtered velocity yields an initial track of the tagged animal. The track is enhanced through pose-graph localization, implemented with the optimizations on the second generation Incremental Smoothing and Mapping (iSAM2) technique, as part of the GTSAM toolbox [4]. The initial track estimate is decomposed into odometry components, and both track and odometry are inserted into a GTSAM graph, along with video-based position measurements of the animals as ground-truth location measures. Process and measurement noise estimates were defined empirically. The graph is optimized using the GTSAM-based Levenberg-Marquardt optimizer, and yields the final track estimate.

## RESULTS AND DISCUSSION

Data from a representative animal are presented here, with ~30 min of swimming and ~60 cornering events analyzed. Figure 2 presents a representative track estimate along with the camera position measurements (white points) during the A4 condition. The bottom left corner was selected for analysis because the high density of camera based position measurements resulted in the best track estimates. As drag was increased (A and A4), the animal's speed and acceleration around the corner both decreased significantly, Table 1. However, because of the reduced speed the animal was able change heading more rapidly in response to the "point" that initiated the cornering event. This resulted in a decrease in the radius of curvature as drag was increased, Fig 2 and Table 1.

**Figure 2:** Lagoon, camera measurements and estimated track for a representative animals (A4). Detail of the average position for one animal during all conditions.

**Table 1:** Individual animal cornering parameters.

	C	A	A4
Speed - $ \vec{v} $ (m/s)	3.6 (0.7)	3.2 (0.6)	1.8 (0.8)
Acceleration - $ \vec{a} $ (m/s <sup>2</sup> )	2.4 (0.7)	4.1 (1.5)	2.8 (1.4)
Radius - $\rho$ (m)	5.4 (2.3)	4.5 (1.1)	3.6 (0.7)

## CONCLUSIONS

These results demonstrate the potential of this unique experimental environment to examine the swimming biomechanics and maneuverability of dolphins during extended swimming tasks. Similar to terrestrial mammals, dolphins do not perform tight turns at their highest speeds [1]. During the experiment the dolphins decreased overall velocity and acceleration in response to drag loading. But, we observed an increase in maneuverability during the cornering task, with the slower speeds allowing the animal to make sharper turns following the cue. These results support our expectation that maneuverability would increase with added drag loading. Future work will involve processing data from three additional animals, and the development of constraints to control the velocity of the animal in order to further examine the how added drag loading affects the swimming biomechanics of bottlenose dolphins.

email: clpeterson@vcu.edu

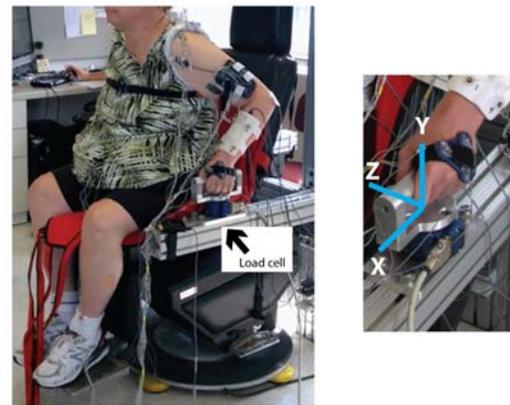

## INTRODUCTION

Pain is prevalent in adults with tetraplegia. The shoulder is the most common location of upper limb pain and is associated with additional losses in function and community mobility. Weight-relief lifting, a movement to lift body weight from the wheelchair seat, must be routinely performed by individuals with spinal cord injury to effectively prevent pressure ulcers, but imparts significant loads on the upper limbs. The triceps play a critical role during weight-relief lift in individuals with paraplegia, who experience lower glenohumeral contact forces relative to individuals with tetraplegia.<sup>1</sup> Individuals with C5 or C6 tetraplegia typically have weak or no residual triceps function. However, active elbow extension can be restored via tendon transfer, a surgical procedure that reassigns the insertion tendon of a non-paralyzed muscle to the insertion site of the paralyzed triceps. The purpose of this study was to compare tendon forces in the rotator cuff during weight-relief lifting in individuals with tetraplegia who have undergone tendon transfer to individuals with tetraplegia without tendon transfer. Rotator cuff tendon forces were compared because rotator cuff disease is the most common cause of shoulder pain in tetraplegia. Tendon forces cannot be directly measured *in vivo* during movement. Thus, musculoskeletal modeling and forward dynamics simulations that replicated the kinematics and kinetics generated by human subjects were analyzed to estimate tendon forces.

## METHODS

Individuals with tetraplegia were recruited for participation (Table 1). The experimental protocol was approved by the Institutional Review Board of Northwestern University. Maximum voluntary joint moments generated by primary upper limb muscle groups were recorded via a load cell interfaced with

a Biodex Multi-Joint System, Pro. For weight-relief trials, subjects were transferred to a chair positioned between two adjustable hand rails. A load cell was interfaced with a custom built handrim to record kinetics during weight-relief lifting trials (Fig. 1). Rigid clusters of non-collinear infrared markers were secured to the thorax, acromion, upper arm, forearm, and hand segments. Kinematics and kinetics were recorded at 74 Hz and 1000 Hz, respectively. Subjects completed six weight-relief lift trials in which they were instructed to lift their body weight using their upper limbs to the best of their ability, to a degree sufficient to relieve pressure under the buttocks, and to hold the lift for five seconds.

**Figure 1:** Experimental setup during weight-relief lift trials; kinematics and kinetics were recorded.

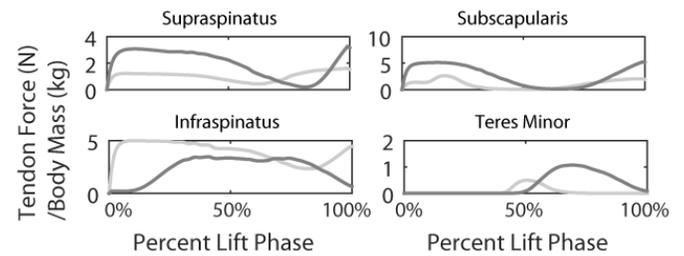

Two representative individuals with tetraplegia were selected for modeling and simulation based on their injury level and ability to achieve a lift; one with bilateral biceps-to-triceps transfers (Male, 29 years, cf., Table 1, light gray shading) and one with some residual triceps function (Female, 36 years, cf., Table 1, light gray shading). A musculoskeletal model of the nonimpaired upper limb<sup>2</sup> was adapted to model the biceps-to-triceps transfer based on surgical descriptions. Maximum elbow extension strength for the individuals with and without tendon

transfer were 20% and 27% of the maximum isometric elbow extension strength of the nonimpaired model, respectively. The model was driven by 26 Hill-type musculotendon actuators. Maximum force-generating capacity of the upper limb model was scaled to limb strength as measured via maximum joint moments. Forward dynamics simulations that reproduced the kinematics and kinetics recorded from the two participants during the lifting phase were developed using an optimization approach. A simulated annealing algorithm<sup>3</sup> was used to determine muscle excitations that minimized the difference in the simulated and experimental joint angles and handrim forces. Muscle forces were multiplied by the cosine of the pennation angle to estimate tendon forces.

## RESULTS AND DISCUSSION

Rarely an individual with C5 tetraplegia can achieve a weight-relief lift.<sup>4</sup> For the subject in our study, the biceps-to-triceps transfer provided similar elbow extension strength as an individual with C6 tetraplegia with some residual triceps function; in both of these individuals elbow strength was sufficient to lift. Our simulation analysis indicates these two subjects used different muscle coordination patterns to achieve the same task. When normalized to each subject's body mass, peak tendon forces in the individual with residual triceps function were higher relative to the individual with biceps-to-triceps transfer in three of the four muscles of interest: the subscapularis, supraspinatus, and teres minor (Fig. 2). Peak tendon force in the infraspinatus was greater in the individual with biceps-to-triceps transfer (Fig. 2). Overall, relative forces (normalized to maximum isometric force) in the rotator cuff for both subjects were very high, exceeding a previous report in tetraplegia.<sup>1</sup> The relative forces in our study were greater because our model was scaled to represent the strength of the individuals with tetraplegia we

assessed. While van Drongelen et al. did not scale the strength of their model, they found greater relative forces in the rotator cuff in subjects with tetraplegia relative to paraplegia or in nonimpaired subjects.<sup>1</sup> Overall, in our study, peak tendon forces resulting from the weight relief task ranged between 70% and 90% of maximum isometric muscle force, when normalized to subject-specific strength. Peak tendon force in supraspinatus reached 120% for the individual with tendon transfer because passive force was generated.

**Figure 2:** Tendon forces in tetraplegia during lift with (light) and without tendon transfer (dark).

## CONCLUSIONS

Tendon transfer can provide weight-relief lifting ability. However, limited elbow extension strength in individuals with tetraplegia, regardless of whether elbow strength is restored via transfer or residual after injury, results in high tendon forces in the rotator cuff.

## INTRODUCTION

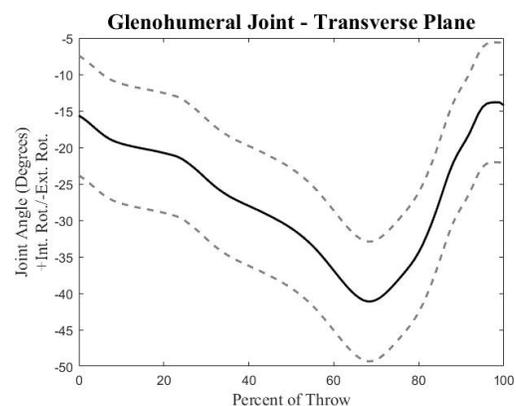

Since 2001, over 550,000 able-bodied athletes joined organized lacrosse teams in the United States [1]. Similarly, wheelchair lacrosse, founded in 2009, has grown in popularity amongst adaptive athletes. Despite this, there has been no research investigating the biomechanics of the wheelchair lacrosse athletes, particularly about the unique mechanisms for injury the sport may present. Kibler et al. found that a 20% reduction in kinetic energy from the hip and trunk requires a 34% increase in rotational velocity of the shoulder to impart the same force at the hand [2]. Most wheelchair athletes have lower extremity impairments reducing or eliminating their ability to generate forces from the hip and trunk. The resulting increased demands of the shoulder and upper extremity (UE) is highly concerning in a population whom rely on their UEs for mobility and completion of activities of daily living. Investigation of the increased UE demands experienced by manual wheelchair lacrosse players is required to identify additional mechanisms for injury. This will enable the implementation of preventative measures, thereby reducing the risk of injury. This study characterized upper extremity biomechanics during an overhead throw in wheelchair lacrosse athletes.

## METHODS

Five wheelchair lacrosse players with a mean age of 47.4 years ( $\pm 14.9$ ) participated. Subjects used their own sport wheelchair when possible, a 41-inch standard lacrosse stick, and a no-bounce lacrosse ball. Thirty-one passive markers were placed on the subject. Motion data was collected at 240 Hz using a 19 camera Vicon T-Series motion capture system. Subjects were instructed to begin without prior

propulsion of the wheelchair and perform a maximal velocity overhand throw. Three trials from each subject were used for analysis. A custom upper extremity kinematic model [3] was applied, via MATLAB, to determine the three-dimensional glenohumeral (GH), elbow, and wrist joint angles. The start and end of the throw were identified based on definitions used with able-bodied lacrosse players [4] modified for use with wheelchair athletes. Joint angles were time normalized and averaged over the duration of the throw. Group averages were determined for the peak joint angle, and joint range of motion in all three planes for the GH, elbow and wrist joints. Joint angular velocities and accelerations were calculated by taking successive derivatives of the joint angle data; average peak values were obtained.

## RESULTS AND DISCUSSION

**Figure 1:** Group average (solid) and standard deviations (dotted) of transverse plane glenohumeral joint angle.

The average peak elbow flexion angle ( $115^{\circ} \pm 18.8^{\circ}$ ), and GH external rotation ( $41.1^{\circ} \pm 8.2^{\circ}$ ) are similar to reported values observed in able-bodied lacrosse players of  $100.5^{\circ}$  and  $47.5^{\circ}$ , respectively [5]. Also, the overhead lacrosse throw relies on trunk rotation and extension more than GH external

rotation compared to an overhead baseball throw [5]. This is concerning as many manual wheelchair users may compensate for their inability to produce large degrees of trunk motion with the UEs. Simultaneous high degrees of GH joint abduction and external rotation, as seen here, can lead to tears and recurrent anterior dislocations of the GH joint, with sufficient repetitions [6, 7]. In addition, concurrent high degrees of elbow flexion, also seen here, and biceps activation have been shown to transfers high levels of stress to the glenoid labrum [6]. This is further compounded as the arm reaches its peak external rotation and begins to internally rotate rapidly (Figure 1), while remaining near peak GH abduction. This combined action increases the risk of a labrum tear, which would greatly reduce GH joint function [6].

During the acceleration phase of the throw there are multiple high joint accelerations occurring simultaneously, including 6097 deg/s<sup>2</sup> of wrist flexion, 6888 deg/s<sup>2</sup> of GH joint internal rotation, and 9041 deg/s<sup>2</sup> of elbow joint supination. While these values do not approach those experienced by professional baseball pitchers, they are of still of concern. First, they are occurring simultaneously, stressing multiple structures of the shoulder at the same time. Second, an adult manual wheelchair user likely already has some overuse wear, and is more susceptible to pain and injury development.

## CONCLUSIONS

Overhead throw biomechanics were successfully characterized for 5 wheelchair lacrosse athletes. The

results highlight several potential risk factors. There is already a known high prevalence of pain and pathology development in manual wheelchair users. As many wheelchair athletes are dependent on their upper extremities for mobility it is important to understand these injury mechanisms so steps may be taken to minimize risk of occurrence. Research is underway to compare biomechanics, and muscle activation patterns, of this population to able-bodied lacrosse and wheelchair lacrosse players during overhead and side-arm throws. This information will assist governing bodies in creating rules and regulation necessary to protect wheelchair lacrosse athletes from unnecessary risk of pain and injury.

## INTRODUCTION

There are an estimated 124,000 children under the age of 21 whom use a wheelchair in the United States (U.S.) [1]. Approximately 10,000 individuals sustain a spinal cord injury (SCI) each year in the U.S., with about 20% occurring in those under 20 years of age [2]. SCI often results in physical limitations affecting functional mobility; thereby, making individuals reliant upon wheelchairs.

In adults with SCI, shoulder pain and degenerative changes may develop prematurely due to overuse. A high prevalence of shoulder pain and injury has been observed in adult manual wheelchair users (MWC), with up to 73% of paraplegics reporting upper extremity (UE) pain [3]. However, it should not be assumed that the developing child experiences the same loading demands or is exposed to similar risk factors for injuries as adults. Children are not physically proportionate to adults; therefore, simple scaling of adult dynamics information will not give an accurate representation of the demands of pediatric wheelchair mobility. Due to longer-term wheelchair use in those with pediatric-onset SCI, UE pain and injuries may occur earlier in the lifespan, and severely limit independence, function, and quality of life. Despite this, there is limited research of pediatric wheelchair mobility [4]. Evaluation of pediatric wheelchair mobility is essential to determine differences from adults. This exploratory work aimed to characterize pushrim biomechanics during pediatric manual wheelchair propulsion.

## METHODS

Ten pediatric manual wheelchair users with SCI, and an average age of  $11.5 \pm 4.7$  years (ranging from 6.5 to 19.5 years), participated. Subjects were

diagnosed at least one year prior to the study; average time since injury was  $3.3 \pm 2.1$  years. SCI levels ranged from C3 to T10. The average height and weight was 150.5 cm ( $\pm 28.9$  cm) and 47.7 kg ( $\pm 24.0$  kg), respectively.

**Figure 1:** Representative subject in her personal wheelchair with passive markers on her upper extremity and the wheel axle of the SmartWheel.

Subjects propelled their MWCs along a 15 m level tile walkway using a self-selected speed and propulsion pattern. Markers placed on the subject's third metacarpal joints, and acromions, and on the wheel axle were used for analysis. A 14-camera Vicon MX motion capture system collected bilateral kinematic data at 120 Hz and simultaneously a SmartWheel system collected dominant side 3D force and moment data at the hand-handrim interface at 240 Hz. Up to fifteen stroke cycles per subject were analyzed. To eliminate acceleration and deceleration effects, the first two and last two strokes of any one trial were excluded.

The markers on the acromion process and wheel axle were used to determine the fore-aft (XPOS) and vertical (YPOS) positions of the shoulder relative to the wheelchair axle [4]. The hand and axle markers were used to determine the angle relative to top dead center at which the hand was located on the handrim. The stroke cycle was divided into the contact and recovery phases, with

the contact phase subdivided into the initial contact, propulsion, and release periods [5]. The maximum rate of rise of the resultant force was determined by differentiating the resultant force curve with respect to time, and finding the peak value. Fractional effective force (FEF) was calculated as the percent of the tangential force that contributed to the resultant force.

## RESULTS AND DISCUSSION

### *Temporal-Spatial Parameters*

Subjects propelled at an average speed of 1.17 m/s (+/- 0.28 m/s), covering an average of 1.21 m (+/- 0.19 m) per stroke cycle. Average fore-aft position of the shoulder relative to the wheel axle was aft 59.8 mm (+/- 45.1 mm). Although there is a large variation, this indicates the shoulder is forward of the axle during most of the stroke cycle. The average vertical position of the shoulder relative to the wheel axle was 646 mm (+/- 87 mm). This positively correlated with subject height ( $R^2 = 0.85$ ), as has been found in adults [4]. At initial handrim contact and handrim release, the average angular location of the hand relative to top dead center was 24.6° (+/-15.7°) counter-clockwise, and 52.0° (+/-11.5°) clockwise, respectively. The average transition point between the contact and recovery phases was 36.1% (+/-8.2%) stroke cycle, ranging from 21.0% to 60.8%. While the value falls within the range commonly reported for adult manual wheelchair users of 30 – 50% stroke cycle, there were three subjects with an average stroke cycle transition at 30% of the stroke cycle or less. This may decrease the amount of time available to impart force to the handrim, requiring the child to increase the applied force which adult guidelines discourage.

### *Kinetic Parameters*

As with adults, the pediatric manual wheelchair users experienced braking effects in most, if not all, of their stroke cycles. On average the braking moment about the wheel axle was imparted during 0 - 4.7% (+/- 3.7%) (initial contact period) and 33.7% (+/- 2.5%)–36.1% (release period) of the stroke cycle. Average maximum resultant handrim force over the stroke cycle was 43.5 N (+/- 20.8 N); however, this value ranged widely from 13 N to 116

N. Literature on adult manual wheelchair users, propelling at approximately the same speed, have reported higher average peak resultant forces, between 54.3 N (+/-18.9 N) and 75.5 N (+/-33.2 N), with similar variability [3,5]. The average rate of rise of the resultant force was 1549.3 N/s (+/-939 N/s), again with subjects experiencing values ranging from 337 N/s to 6653 N/s. Adult literature has reported smaller values, with averages and standard deviations between 915 (+/-401) [3] and 1461 (+/-555). The average maximum FEF was 70% (+/- 20%), which is only slightly outside of the adult range of 71% – 80.2% [5].

## CONCLUSIONS

Clinical practice guidelines recommend manual wheelchairs users keep peak forces, rate of rise of force and braking moments to a minimum in order to reduce pain and injury. However, these guidelines were developed for adults, and may not be appropriate for children. Further investigation is required on the impact of the similarities and differences between adult and pediatric MWC discussed here, as well as their correlation to joint biomechanics, stroke patterns, and subject characterizations (time since injury, injury level, etc.). Deeper knowledge of pediatric manual wheelchair biomechanics is essential for understanding the root cause of pain and injury development in order to preserve UE extremity function and joint integrity over their lifespan.

## INTRODUCTION

There are currently 3.2 million wheelchair users in the United States, with the vast majority using manual wheelchairs [1]. Of these manual wheelchair users (MWCUs), 253,000 are the result of a spinal cord injury [2]. Because of the consistently high muscle demand on the upper limbs during manual wheelchair propulsion, shoulder pain and injury are prevalent in MWCUs which often leads to a decreased quality of life [3]. Recent studies have analyzed the relationship between a MWCUs' propulsion hand path pattern (Fig. 1) and the upper extremity demand and found that semi-circular (SC) and double-loop patterns (DL) require less muscle power, and therefore are more favorable from an energetics point of view [4,5]. However, it is not known if the less favorable propulsion patterns are more likely to result in shoulder pain over time compared to the more favorable propulsion patterns.

The objective of this study was to determine whether specific propulsion patterns correlate with the development of shoulder pain in MWCUs with paraplegia. We hypothesized that subjects who use the more favorable DL or SC patterns would be less likely to develop shoulder pain over time.

**Figure 1:** The four propulsion patterns are arcing (AR), single loop (SL), double loop (DL), and semi-circular (SC) [4].

## METHODS

Experimental kinematic data from 18 subjects with paraplegia were analyzed at three times: baseline (BL), 18 months after baseline, and 36 months after baseline (17 men; age at BL:  $34.6 \pm 7.0$  yrs; time from injury at BL:  $8.5 \pm 7.0$  yrs). Participants propelled their own wheelchair on a stationary ergometer for a 40-second trial at a comfortable, self-selected speed with data collected during the last 10 seconds. Kinematic data from the wheel, trunk and upper extremities were recorded using a 4-scanner CODA motion analysis system at 100 Hz and were time normalized for each cycle and averaged across cycles. Force data were collected using an instrumented wheel (SmartWheel, 200 Hz) and used to identify the contact and recovery phases of the propulsion cycle using a threshold of 5 N.

Propulsion pattern was identified by the trajectory of the third metacarpophalangeal joint projected onto the handrim plane, and a multiple-rater system was used to subjectively categorize each subject's propulsion pattern (Fig. 1). Additionally, net radial thickness (NRT) and total radial thickness (TRT) were calculated for each trial to quantitatively describe each subject's propulsion pattern [6]. Participants were asymptomatic for shoulder pain at baseline and were classified as having developed shoulder pain if they experienced an increase of  $\geq 10$  points on the Wheelchair User's Shoulder Pain Index at either the 18-month or 36-month follow-up assessment.

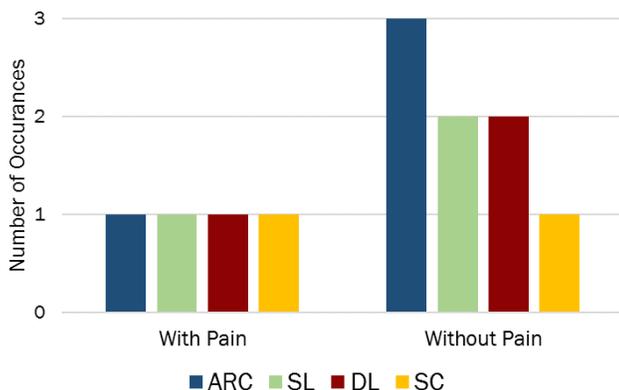

To determine whether the development of shoulder pain was related to propulsion pattern, a generalized linear mixed-effects model was used. The fixed effects included propulsion pattern grouping, NRT, and TRT. The random effect was subject with each

having three observations (time points). Fixed effects had a significant influence on the pain score if their coefficients had a p-value less than 0.05.

## RESULTS AND DISCUSSION

Neither NRT, TRT, nor the pattern classification showed a significant relationship between propulsion pattern and pain. Thus, our hypothesis that subjects using a more under-rim propulsion pattern (DL or SC) would be less likely to experience shoulder pain was not supported.

Contrary to what we expected, subjects who did not develop shoulder pain did not use the more favorable patterns (DL and SC) more than the others. Rather, these subjects used the AR and SL patterns more frequently, though not by a significant amount (Fig. 2, Table 1). This result is interesting as the AR and SL patterns tend to require the highest and second highest upper extremity demand over the full cycle, respectively [4]. Additionally, for those who developed pain and did not change patterns over time (Fig. 2), each used a different hand pattern. A potential limitation in this study is that we used muscle power as a surrogate for upper extremity demand which may not be indicative of the biomechanical mechanisms that lead to pain. Also, the lack of statistical significance could be due to too few subjects developing pain relative to the total number of subjects. Future work will be directed at increasing the sample size.

**Figure 2:** Propulsion pattern of subjects who used a stable pattern over time, including those who did and did not develop upper extremity pain.

Subjects who did change their propulsion pattern over time also varied widely in their preferred propulsion pattern (Table 1). Six subjects had at least two different propulsion classifications during the baseline, 18-month, and 36-month data collections. Of these six, only one subject developed pain. However, this subject changed from a SL to DL pattern and ultimately developed shoulder pain.

**Table 1:** Propulsion pattern used by subjects who changed their pattern over the 36-month period.

Subject	Baseline	18	36	Pain (Y/N)

## CONCLUSIONS

These results suggest that although specific propulsion patterns require less upper-extremity demand than other patterns, the specific pattern used by an individual may not propagate or mitigate shoulder pain. Future work should analyze additional subjects and biomechanical quantities that may be biomarkers for the development of shoulder pain in MWCU.

## INTRODUCTION

Many patients with low back pain (LBP) may benefit from wearing a lumbar belt (LB) [1], but the mechanisms involved are not fully understood. Two perspectives can be considered, involving pain-related psychological mechanisms and biomechanical mechanisms.

Wearing a LB can produce immediate pain relief which in turn may reduce pain-related fears and catastrophizing, but this has never been formally tested. Biomechanically, a LB can also provide a stiffening effect, leading to a smaller lumbar range of motion (ROM) [2], and decreasing stress on lumbar structures. Our earlier work studied the effect of two flexible LBs (extensible; non-extensible) on lumbar ROM in healthy subjects [2]. These results need to be extended to subjects with LBP.

This study aimed to investigate how wearing an extensible belt (EB) or a non-extensible belt (NEB) affects pain intensity, pain-related psychological variables, and biomechanical (ROM) variables during maximal trunk flexion in subjects with LBP as well as healthy controls (ROM only).

## METHODS

**Subjects.** Non-obese healthy controls (n = 20) and subjects with LBP (n = 40), equally divided by sex, participated. The subjects with LBP had lumbar or lumbosacral pain (with or without radicular pain) for at least 4 weeks.

**Lumbar Belts.** The EB and NEB were chosen based on their functionality at workplace (flexibility and comfort) [2] and had the same dimensions. The tension of the LBs was adjusted at 8.0 kPa, in the

standing upright posture, as measured with a Force Sensing Resistor sensor [2].

**Experimental Conditions.** Starting from the upright posture (knees extended) and following the pace of a metronome, the subjects bent forward maximally (4 s), remained relaxed in that fully-flexed posture (4 s), returned to the upright posture (4 s) and stood quietly (4 s). The task was repeated 5 times, consecutively. The angular kinematics of the trunk was measured with three inertial sensors attached over the sacrum (pelvis), just above the LB (~T9-T10) and at the T1-T2 vertebral level [2]. The ROM of the pelvis ( $ROM_{PE}$ ), lumbar ( $ROM_{LU}$ ) and thoracic spine ( $ROM_{TH}$ ) (Fig. 1) was computed for each quartile (INTERVAL) of the trunk ROM.

**Pain-related variables (subjects with LBP only).** Before performing any flexion trial, pain intensity (0-10 scale) was measured, with and w/o LB. After each flexion trial (with and w/o LB), fear of pain (100 mm visual analog scale) and pain catastrophizing (6-item scale) were also recorded.

**Statistical analyses.** For ROM variables computed for the flexion phase only, 3-way ANOVA for repeated measures (GROUP: healthy vs LBP; CONDITION: no belt (NB) vs with EB vs with NEB; INTERVAL: 0-25 vs 25-50 vs 50-75 vs 75-100% of total trunk ROM) were performed.

## RESULTS AND DISCUSSION

Wearing a LB significantly decreased pain intensity, fear of pain and pain catastrophizing, although the type of the LB did not affect the scores (Fig. 2).

With regard to ROM variables, no GROUP × CONDITION interaction was found, showing the same effect of wearing a LB in both groups. Total

$ROM_{LU}$  for the patient group ( $57.8 \pm 13.1^\circ$ ) was smaller than that for the control group ( $63.6 \pm 12.0^\circ$ ) although the effect was not statistically significant ( $p = 0.072$ ). In contrast,  $ROM_{TH}$  was significantly higher ( $p = 0.027$ ) in the patient group ( $-2.4 \pm 8.2^\circ$ ) compared to the control group ( $-6.6 \pm 6.4^\circ$ ), suggesting compensation between trunk segments.

Total  $ROM_{LU}$  was significantly larger (by  $6-7^\circ$ ) in the NB condition than in both EB and NEB conditions. This was partly compensated for with more  $ROM_{TH}$  (by  $2^\circ$ ) in the EB and NEB conditions.

CONDITION  $\times$  INTERVAL interactions ( $p < 0.001$ ) were seen for  $ROM_{PE}$ ,  $ROM_{LU}$  and  $ROM_{TH}$  (Fig. 3), revealing that wearing either LB had an effect on the movement of the different trunk segments, and that these effects changed over the intervals. The LB reduced the lumbar movement during interval 1 (Fig. 3, middle), which was partly compensated by an increase in  $ROM_{TH}$  (Fig. 3, right). In the final interval (interval 4), however, there was more lumbar movement in the two LB conditions than in the NB condition (Fig. 3, middle), but less pelvic movement (Fig. 3, left).

## CONCLUSIONS

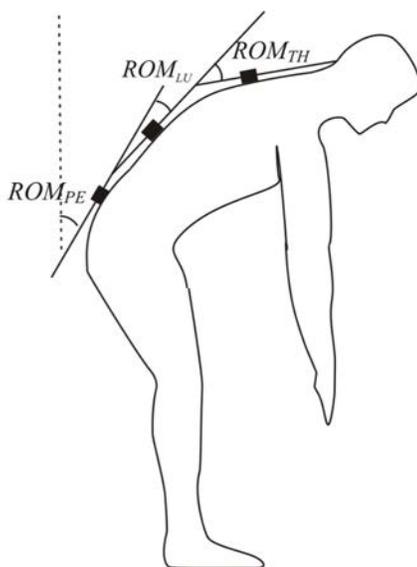

Wearing a LB can produce immediate pain relief as well as reduced pain-related fears and catastrophizing, which may help in initiating a gradual re-exposure to physical work activities (disability prevention perspective), or in helping a worker maintain these activities (secondary prevention perspective), following a LBP episode. Such flexible LBs (EB, NEB) also reduce the lumbar ROM in subjects with LBP in the same way as healthy controls. This effect is compensated for by ROM changes of adjacent trunk segments (pelvis, thorax) during trunk flexion. Whether these compensations are detrimental remains unknown.

## INTRODUCTION

A number of research studies have demonstrated the negative health consequences associated with prolonged sitting [1,2]. This has prompted scientists and clinicians to advocate for workers to perform office related tasks while standing, that would be typically done in sitting [4].

In contrast, prolonged standing has been shown to be a risk factor for low back pain (LBP) development [3]. Approximately 50% of asymptomatic individuals are susceptible to acute LBP development during prolonged standing [4,5]. As a result, these findings have led to an emphasis on the importance of movement and varying postures throughout the day with the use of sit to stand workstations. These workstations have shown increased popularity in recent years, demonstrating decreased sedentary behavior, diminished fatigue and greater comfort [6].

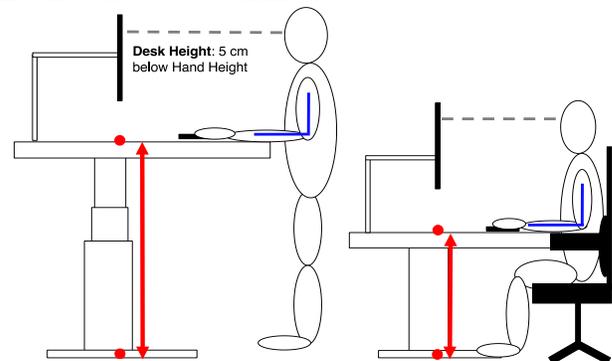

The Canadian Standards Association (CSA) Guideline for Office Ergonomics, states that when performing a light office task such as typing, while sitting or standing, the workstation should be set 5 cm below the workers' hand height with elbows bent at 90°, with the monitor placed at or slightly below eye level [7].

Aside from moving the desk when transitioning from sitting to standing, there is a lack of literature regarding the necessary adjustments to other equipment associated with the workstation. A previous analysis has demonstrated that when moving from sitting to standing and following CSA Guidelines, monitor height must be adjusted to keep the monitor at eye level [8]. This suggests that differences in spine posture alignment may exist between sitting and standing. Therefore, the purpose of this study was to evaluate posture in sitting and

standing while adhering to CSA Guidelines. If differences do exist, this study will support changes to office ergonomics guidelines to incorporate monitor adjustments when using sit to stand workstations.

## METHODS

Sixteen participants (8 female and 8 male) were recruited between the ages of 18 and 25 years old. Participants completed 2 different conditions: 1) Sitting Constrained; in which the participants' chair, desk and monitor heights were adjusted according to current CSA seated work guidelines (Figure 1). 2) Standing Constrained; the participants' desk and monitor heights were adjusted according to the current CSA standing work guidelines. In both conditions the participants were constrained to this setup with no freedom to adjust the equipment (Figure 1). Each condition lasted 15 minutes and during each condition participants were randomly assigned the following three standardized computer tasks for five minutes each: 1) Reading short stories on the monitor (READ), 2) Data entry into blank fields on the computer (FORM), and 3) Typing paragraphs as they appear on the screen (MAIL). Each task lasted 5 minutes.

**Figure 1:** Constrained Sitting and Standing workstation setup. Desk height was set to 5 cm below hand height, with the elbows bent to 90°, and the monitor placed at or slightly below eye level

Movement of the head, thoracic, lumbar spine, pelvis and monitor were tracked at 10 Hz using an optoelectronic motion capture system (Optotrak Certus, NDI, Waterloo, Canada). Eye Height relative to Monitor, Lumbar Spine Angle, Trunk Angle relative to vertical and Acromion Process (AC) to Hip distance were calculated as average values across each 5 minute individual task. Lumbar joint angles are expressed relative to individuals' standing postures. A three-way mixed model ANOVA assessed the influence of Condition (Sit vs. Stand), Task (READ, FORM, MAIL), and Gender on posture.

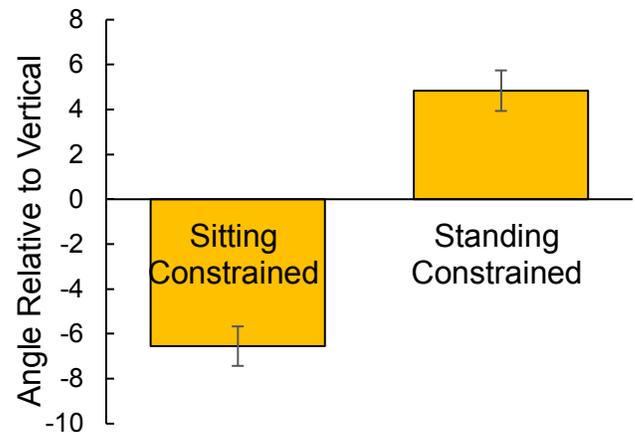

## RESULTS AND DISCUSSION

No significant differences were observed between eye height and monitor height across Condition ( $p = 0.181$ ), or across Task ( $p = 0.056$ ).

There was a significant main effect of Condition ( $p < 0.0001$ ) and Task ( $p = 0.008$ ) for Lumbar Spine Angle. Not surprisingly, there was significantly more lumbar spine flexion in the Sitting condition when compared to Standing. For the main effect of Task, READ resulted in significantly more lumbar flexion in comparison to FORM and MAIL.

A significant main effect of Trunk angle relative to vertical was observed for Condition ( $p < 0.0001$ ). When sitting, participants sat with their Trunk flexed relative to vertical. While standing participants stood with their Trunk extended relative to vertical. (Figure 2).

Significant main effects of Condition ( $p < 0.0001$ ) and Task ( $p = 0.033$ ) were observed for AC to Hip distance. When compared to Standing, the distance between the mid-point of the right and left acromion process to the mid-point of the right and left hip joint center was significantly less (Sitting;  $45.7 \text{ cm} \pm 2.7$ ; Standing  $48.0 \text{ cm} \pm 2.5$ ). For the main effect of Task, Acromion to Hip distance was significantly greater in FORM when compared to READ and MAIL.

**Figure 2:** Main effect of Condition for Trunk angle relative to vertical. A negative value corresponds to Flexion with respect to vertical while a positive value corresponds to Extension

## CONCLUSIONS

The results from this investigation demonstrate that lumbar spine alignment differences do occur between Sitting and Standing. The observed increased Trunk flexion relative to vertical and decreased distance between AC to hip combined with lumbar spine posture differences explain changes in monitor height when transitioning from sitting to standing and re-adjusting for CSA standards. Results from this investigation support the notion that monitor height adjustments relative to the work surface are necessary when utilizing sit to stand workstations.

## INTRODUCTION

About half of individuals with no clinically-diagnosed low back pain (LBP) will develop LBP when asked to stand continuously for two hours (PDs = pain developers). PDs have shown motor control alterations during standing [1] and are at an increased risk for developing clinical LBP in the future compared to controls (NPDs = not PDs) [2]. Dynamically measured vertebral motion can lend insight into potential mechanisms leading PDs to develop clinical LBP. This study's purpose was to use high-speed radiography to measure intervertebral contributions to lumbar curvature during pelvis-driven lumbar spine motion to determine if PDs and NPDs move their spines differently.

## METHODS

Fourteen participants (8 female) with no history of LBP between 21 and 35 years old performed two testing sessions: 1) standing screening and 2) radiography data collection. The standing session involved participants standing continuously for up to two hours. Prior to and every 15 minutes during the screening, participants reported the intensity of any LBP they experienced on a 100 mm visual analog scale. Any participants reporting pain intensities greater than 10 mm were classified as PDs, with others classified as NPDs [1]. During the radiography data collection, participants sat on an adjustable custom seat with lower limb supports. The seat had a 50 cm diameter hemisphere underneath the seat pan that allowed the seat to tilt freely in all directions and was placed on a rigid table. Participants were instructed to cyclically tilt the seat pan anteriorly (into lumbar extension) and posteriorly (into lumbar flexion) as far as possible while maintaining balance following directed familiarization and practice. Pulsed radiographic images (25 Hz) containing the anterior and posterior

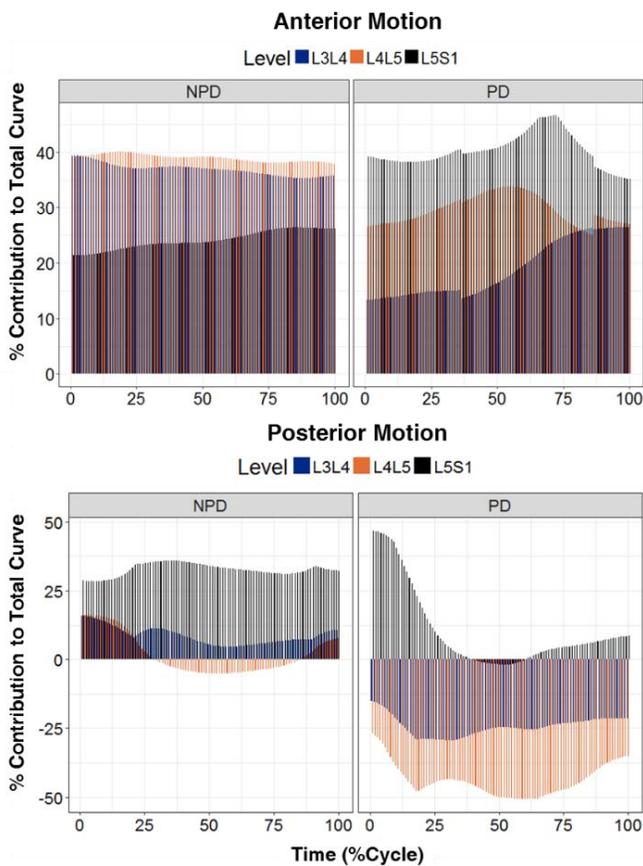

half-cycles were captured of L3 to S1 throughout the entire motions.

Radiographs were undistorted (XMA Lab, Brown University, Providence, RI), and underwent a Matlab-based (ver 2015b, Mathworks, Natick, MA) local contrast enhancement algorithm prior to digitization of four corners of each vertebral body from L3 to S1. Corners were used to compute time-varying sagittal-plane intervertebral joint angles for L3/L4 through L5/S1. Joint angles were expressed as a percentage of the total measurable curve by dividing the raw joint angle by the sum of the magnitudes of all joint angles in order to prevent numerical instability through division by small numbers. The mean contribution across the entire cycle and contributions at the peak total lumbar spine angle (L3-S1) were taken from each joint level for statistical comparisons. Data were stratified by direction of motion (anterior/posterior) and entered into a mixed-model ANOVA using a within factor of joint level (L3/L4 – L5/S1) and a between factor of pain group (NPD/PD). Effect sizes (Cohen's *d*) were calculated for each comparison and bootstrap sampled to produce a 95% confidence interval.

## RESULTS AND DISCUSSION

One male and five females were classified as PDs via the standing screening. Data for the one male PD was excluded as it was incomplete and diverged from the five female PDs. Contributions to lumbar angles were positive in anterior and posterior tilting for NPD and diverged for PD in posterior tilting (Fig. 1).

In the anterior direction (lumbar extension), NPDs and PDs had similar contributions across the entire cycle and also at peak lumbar angle for each joint level ( $p > 0.252$ ; Table 1). However, large effect sizes indicated that PDs may have had greater

**Figure 1:** Mean contributions to lumbar curvature during anterior and posterior tilting while seated on an unstable seat. Error bars omitted for clarity.

contributions coming from L5/S1 compared to L3/L4 ( $d$  95% CI: 0.91 – 1.10) in this direction (Fig. 1). In the posterior direction (lumbar flexion), PDs appeared to achieve spine flexion mainly through L5/S1, while NPDs appeared to achieve motion primarily through L4/L5 (Fig. 1). There was a main effect of pain group for the mean contributions where PDs had more spine flexion than NPDs in the posterior direction ( $p = 0.016$ ;  $d$  95% CI: 1.01 – 1.71)

**Table 1:** Relative intervertebral joint angle contributions as a percentage of measured lumbar curvature. Data are Mean  $\pm$  SD; positive numbers indicate that the intervertebral joint angle was in extension. Asterisks indicate significant effects of pain group in the posterior direction; different letters indicate main effects of joint level.

		Anterior			Posterior		
		L3/L4	L4/L5	L5/S1	L3/L4 <sup>A</sup>	L4/L5 <sup>A</sup>	L5/S1 <sup>B</sup>
<b>Mean*</b>	NPD	36.9 $\pm$ 13.9%	39.0 $\pm$ 5.5%	24.1 $\pm$ 14.8%	17.0 $\pm$ 29.2%	11.5 $\pm$ 32.9%	35.1 $\pm$ 6.2%
	PD	19.0 $\pm$ 19.7%	29.8 $\pm$ 22.3%	40.6 $\pm$ 22.3%	-24.4 $\pm$ 18.4%	-44.0 $\pm$ 11.8%	10.3 $\pm$ 31.5%
<b>During Peak</b>	NPD	34.6 $\pm$ 11.8%	39.5 $\pm$ 7.7%	25.9 $\pm$ 13.6%	11.0 $\pm$ 30.1%	5.9 $\pm$ 40.7%	36.1 $\pm$ 16.0%
	PD	13.6 $\pm$ 29.8%	27.9 $\pm$ 25.0%	37.6 $\pm$ 16.1%	-17.1 $\pm$ 26.8%	-41.6 $\pm$ 10.5%	14.1 $\pm$ 35.9%

with a similar trend in the contribution at peak lumbar angle ( $p = 0.087$ ;  $d$  95% CI: 0.74 – 1.32; Table 1). L5/S1 was also more extended than L3/L4 and L4/L5 in the posterior direction ( $p < 0.002$ ; Table 1).

## CONCLUSIONS

PDs and NPDs used different regions of their lumbar spines to tilt anteriorly and posteriorly while seated on an unstable chair. These results suggest that PDs adopted an L5/S1-dominant approach to attaining lumbar spine motion while NPDs did not localize motion to a given vertebral level as clearly. The more evenly distributed motion adopted by NPDs may prevent local stress concentrations in the facet joints and surrounding soft tissues and potentially reduce injury risk and pain development [3].

The unstable seat required motion to be driven from the pelvis, contrary to previous studies investigating the development of LBP in PDs, which were performed in standing postures [1]. This study provides evidence of altered spinal kinematics in PDs beyond standing; potentially indicative of generalized, deficient trunk muscle coordination [4]. The transfer of kinematic changes beyond prolonged standing lends further evidence that PDs represent people at an increased risk for developing clinical LBP [2].

# LANDING MECHANICS DURING A STOP JUMP IN INDIVIDUALS WITH LOW BACK PAIN AND LOW BACK INJURIES

<sup>1</sup> Alexa K Johnson, <sup>1</sup> Joshua D Winters, <sup>1</sup> Kathleen M Poploski, <sup>1</sup> Nicholas R Heebner, and <sup>1</sup> John P Abt

## INTRODUCTION

The clinical presentation of low back pain (LBP) is highly variable, therefore it has been recommended that the spine be included with the lower extremities when conducting clinical and movement analyses [1]. LBP is known to increase knee stiffness in runners [2], though information on how joint motion and loading rates may affect each other are unavailable. Likewise, the majority of research on LBP and low back injuries (LBI) has focused on back and trunk biomechanics, independent of the lower extremities. If those with LBP and/or LBI exhibit altered movement in the trunk, additional compensations may exist in the lower extremities, which may lead to the development of an injury in the lower extremity [2].

The purpose of this study is to determine if physically active individuals with a history of LBP or a LBI have altered landing mechanics in a double leg stop jump task, compared to healthy controls. We hypothesize that those with a history of LBP or LBI will have lower loading rates and different lower extremity sagittal plane kinematics at initial contact of a stop jump task, compared to healthy controls, and that such changes are related.

## METHODS

Thirty-five subjects, thirteen with a history of LBP (age  $26.7 \pm 4.1$  yrs; height  $69.5 \pm 1.9$  in; mass  $85.1 \pm 7.3$  kg), nine with a LBI (age  $28.1 \pm 3.6$  yrs; height  $70.8 \pm 2.0$  in; mass  $89.0 \pm 8.1$  kg) and thirteen healthy control subjects (age  $28.2 \pm 5.3$  yrs; height  $70.1 \pm 2.2$  in; mass  $85.8 \pm 9.9$  kg), completed a double limb stop jump. Subjects jumped forward onto two force platforms (Kistler Instrument Corp., Amherst, NY) from 40% of the subject's total body height. They were instructed to jump forward and then vertically as high as possible. Two practice trials were given and variables were averaged across three subsequent trials. Healthy control subjects reported no history of

back or lower extremity injuries, or back pain. The LBP group indicated they suffered from chronic LBP lasting at least 6 months and the first indication of pain reported was an average  $3.0 \pm 2.4$  years ago. The LBI group reported a physician diagnosed herniated disc or bulging disc in the lumbar section of the spine, with injury occurrence ranging from  $2.3 \pm 1.7$  years prior. All subjects reported no pain at the current testing session and were all currently highly physically active.

Raw vertical ground reaction forces (VGRF) were sampled at 1200 Hz and filtered using a fourth order low pass butterworth filter with a cutoff of 50Hz. A custom Matlab code (MathWorks, Natick, MA) was used to calculate loading rates from the VGRF. Peak loading rates were calculated from the onset of force, greater than 20N, to the initial peak VGRF and normalized to body mass. Subjects were outfitted with lower extremity reflective markers and an eight camera three dimensional motion capture system (Vicon Motion Systems Ltd, Centennial, CO) was used to collect bilateral sagittal plane kinematics at the hip, knee and ankle. Kinematic data were sampled at 200 Hz and marker trajectories were filtered using a Woltering filter with a predicted mean square error at 10mm. The plug-in gait model was used to calculate hip flexion at initial contact, knee flexion at initial contact and ankle flexion at initial contact.

Data were summarized using descriptive statistics including means and standard deviations. Analysis of variance was used to compare the mean bilateral peak loading rates, knee flexion at initial contact, hip flexion at initial contact, ankle flexion at initial contact and peak VGRF, between the three groups. A significance level of  $\alpha = 0.05$  was used and post-hoc comparisons were conducted using the Bonferonni adjustment for multiple comparisons. Pearson Correlation Coefficients ( $r$ ) between peak loading rates and lower extremity sagittal plane kinematics at initial contact and vertical ground

reactions forces, in each group were also completed. All data analysis was conducted using SPSS (SPSS 22 IBM Corp, Armonk, NY).

## RESULTS AND DISCUSSION

There were no significant differences in any sagittal plane lower extremity kinematics, VGRF, or peak loading rates between groups (Table 1.;  $p > 0.05$ ). In all groups VGRF were significantly correlated to peak loading rates,  $p < 0.05$ , which was expected as peak loading rates are calculated from the VGRF curve. On the right limb, peak loading rate was significantly correlated to knee flexion at initial contact in the LBP group ( $r = 0.61$ ;  $p = 0.026$ ) and to ankle flexion at initial contact in the LBI group ( $r = 0.75$ ;  $p = 0.019$ ). All other correlations were not significant. Although there are significant correlations between sagittal plane landing at initial contact and peak loading rates, they do not support our initial hypotheses as there were no group differences.

The correlation differences between right and left limbs, or possible limb dominance [3], could play into why we only saw significant correlations on the right side and not the left side. All but one subject, in the LBI group, were right limb dominant. This change in landing strategy between the LBP and LBI groups, from the control group, may be a compensatory strategy adopted due to pain or other mechanisms. If the shock from landing is not adequately distributed it may be an indicator for future injury [2]. Though, in a task in which landing

successfully is not the end goal, landing strategies and shock attenuation may change, as in this case the end goal is to vertically jump as high as possible.

## CONCLUSIONS

It appears that individuals with LBP and/or LBI are not loading different to that of healthy controls during the landing phase, in preparation for an explosive counter movement. The lack of differences may be due to the large between subject variability seen in different landing strategies displayed, and small sample sizes. Analyzing the take-off portion of the stop jump task may provide insight on how LBP and LBI may truly affect performance. Additionally, further research is needed to determine if landing strategies differ when subjects perform more impactful movements with a greater emphasis on shock absorption, like a single limb hop.

# Soft Tissue Increases Stability and Propulsion During Human Running

Samuel Masters and John Challis

email: sem361@psu.edu

## INTRODUCTION

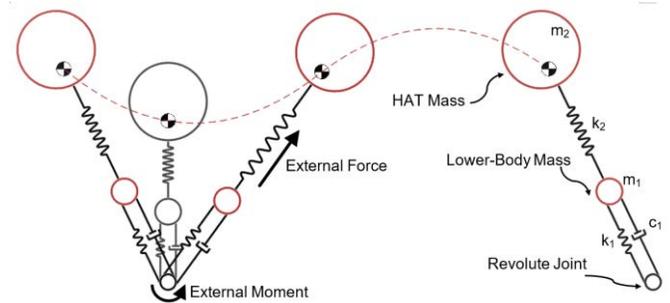

Soft tissue moves relative to the skeleton during human locomotion. This motion affect the energetics of human motion [1]. However, the effects of soft tissue motion have not been quantified on the whole-body center-of-mass (COM) control and stability during human running.

A two-body spring-loaded inverted pendulum (SLIP) controlled by a central pattern generator (CPG) can mimic the whole-body COM trajectory and ground reaction force (GRF) during running or hopping [2]. With finely tuned model parameters, this system is asymptotically stable with minimal control feedback. It was hypothesized that adding a soft tissue mass will increase stability and the running velocity of the SLIP model.

## METHODS

The SLIP model contained three masses, a spring connecting the upper body to the lower body, a spring-damper (S-D) connecting the lower body to the ground (Fig. 1), and a S-D connecting the lower body to a soft tissue mass. All S-D values were constant excluding the ground-spring interface. The ground-spring dampening was a function of the dampening coefficient, spring compression and velocity.

The SLIP was powered by an external moment at the spring-ground interface and a propulsive force (PF) that accelerated the whole-system COM. The propulsive phase of the gait cycle started when the SLIP was past vertical and ended when the spring connecting the ground to the lower leg approached its resting length. A tanh function was utilized in order to enforce a zero PF and external moment before and after the propulsive phase.

**Figure 1:** Two-mass SLIP model of running with a stance and flight phase. This figure does not include the soft tissue mass.

Vertical stance phase kinematics and GRFs from 10 college-aged male subjects running at  $3.1 \text{ m}\cdot\text{s}^{-1}$  were averaged and used to tune the parameters of the model. The COM vertical position and velocity were fitted with a sine wave to enforce smoothness and cyclical kinematics. All values of force were normalized with respect to body weight (BW). The weight of the lower and upper bodies were 0.165 BWs and 0.835 BWs, respectively. The soft tissue weight was approximately 61% (0.1 BW) of the lower BW.

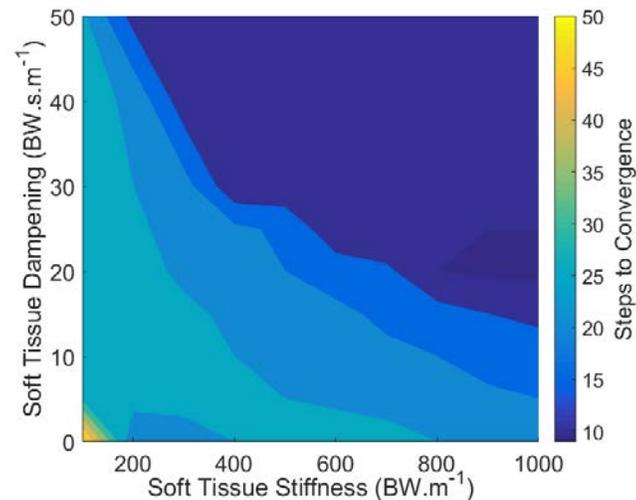

A particle swarm optimization was utilized to determine the best set of parameters. The S-D parameters were systematically incremented between 100-1000  $\text{BW}\cdot\text{m}^{-1}$  and 0-50  $\text{BW}\cdot\text{s}\cdot\text{m}^{-1}$ , and the SLIP was simulated until its step cycle converged to a period-one gait cycle. These simulations contained minimal control feedback. The angle of the leg increased or decreased proportional to horizontal running velocity.

Stability was measured by two methods. The first method measured the level of noise that induced failure in the SLIP. The magnitude of noise in the spring-ground stiffness was gradually increased until the SLIP fell over. Stability was also measured by increasing the lower spring stiffness value by 100% for a single step and counting the number of steps

until the COM velocity kinematics converged to  $10^{-3}$   $\text{m}\cdot\text{s}^{-1}$  of its period-one gait cycle.

The running speed of the period-one gait cycle for all S-D combinations were used as a measure of efficiency. The propulsion dynamics were the same for all S-D combinations, thus greater running speed was indicative of greater efficiency.

All measurements of performance were compared to a control SLIP. The control SLIP did not have soft tissue.

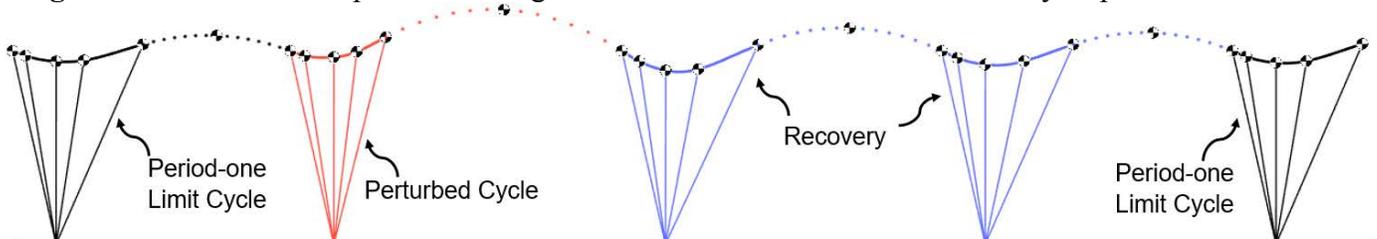

**Figure 2:** A contour plot of the number of steps the SLIP model took for each S-D combination following a perturbation to the spring-ground interface. Dark and light colors indicate greater and lesser stability, respectively.

## RESULTS AND DISCUSSION

The spring stiffness values for the lower and upper springs were  $217.9 \text{ BW}\cdot\text{m}^{-1}$  and  $211.1 \text{ BW}\cdot\text{m}^{-1}$ , respectively. The dampening coefficient for the ground-spring interface was  $23.6 \text{ BW}\cdot\text{s}\cdot\text{m}^{-1}$ . The PF and external moment magnitudes were  $4.15 \text{ BW}$  and  $2.57 \text{ BW}\cdot\text{m}$ .

**Figure 3:** Center of mass position during a simulated trial. Some of the recovery steps have been removed.

The S-D values of the soft tissue had a large effect on the propulsion dynamics of the period-one gait cycle. The SLIP running velocity was proportionally and inversely related to the soft tissue stiffness and dampening, respectively. The horizontal running speed ranged between  $1.9 \text{ m}\cdot\text{s}^{-1}$  and  $3.6 \text{ m}\cdot\text{s}^{-1}$ . The control SLIP ran at a horizontal speed of  $2.2 \text{ m}\cdot\text{s}^{-1}$ . The PF of the control SLIP would have to increase in order to match the running speed of the SLIP with soft tissue for most S-D combinations. This indicated that the SLIP with soft tissue was more efficient than the control SLIP.

Following a perturbation to the leg-ground stiffness, the SLIP with soft tissue performed better than the control SLIP for 94% of the S-D combinations (Fig. 2). The control SLIP took 29 steps before its gait velocity was within  $10^{-3} \text{ m}\cdot\text{s}^{-1}$  of its period-one gait cycle. The number of steps that the SLIP with soft tissue took was between 9 steps and 52 steps (Fig. 3). The bottom of that range occurred at high stiffness and dampening values.

About 98% of the S-D combinations resulted in a SLIP model that could withstand 2x the magnitude of noise relative to that of the control SLIP. The low and high end of the range occurred at zero dampening in the soft tissue. This indicated that a small amount of soft tissue dampening would be sufficient to guarantee greater robustness to noise in the terrain.

The SLIP with soft tissue performed better by all standards measured in this study. It was more stable and ran at greater speeds with the same CPG propulsion dynamics.

## INTRODUCTION

Functional differences among joints may help to coordinate overall leg function during locomotion. The leg may exhibit a proximal-distal gradient in joint mechanical function from power production to spring-like behavior [1]. During walking, human hips produce energy (like motors) and ankles absorb and produce energy (like springs) [2]. The knee exhibits several functions, including motor, energy-absorbing damper, and energy-transferring strut. Distinct joint functions sum together to result in the overall strut-like function of the leg during walking.

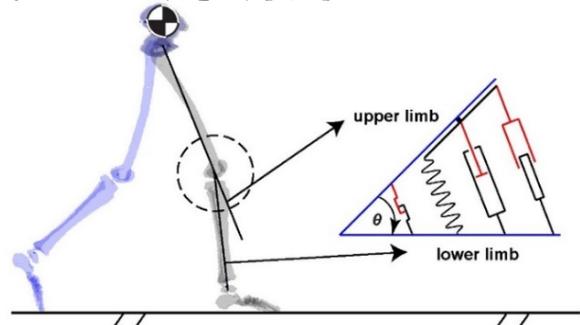

When running, legs exhibit overall spring-like function. Spring-like leg function can provide a degree of intrinsic dynamic stability, contributing to locomotion control. However, the contribution of joint functional differences to running leg function and stability is not well understood. We investigated the role of functional differences among leg joints on stability during running maneuvers by testing two hypotheses: (1) that humans exhibit a proximal-distal gradient in joint function during both constant-average-velocity (CAV) running and during sagittal-plane running maneuvers (stepping up and down); and (2) that humans select leg parameters (*e.g.*, stiffness and damping) that optimize intrinsic dynamic stability.

## METHODS

We used a 3-D motion tracking system with 10 cameras (VICON<sup>®</sup> 612, Oxford Metrics Ltd., Oxford, UK) to track whole body kinematics (120Hz, plug-in Gait marker set, 39 markers). We used three stationary force platforms embedded in the ground to record GRFs (3000Hz, 600×400mm, FP4060-NC, Bertec Corp., Columbus, OH, USA). We asked participants to run at a comfortable speed and asked them to perform three tasks (stepping up, CAV running, and stepping down.). Nine males (body mass=74.0±8.2kg, height=1.78±0.06m,

age=27.1±5.7yrs., leg length (greater trochanter to ground)=0.98±0.02m, mean±S.D.) participated.

To categorize leg joint (*i.e.*, hip, knee, and ankle) function, we developed strut, spring, motor, and damper indices (Fig. 1) [2, 3].

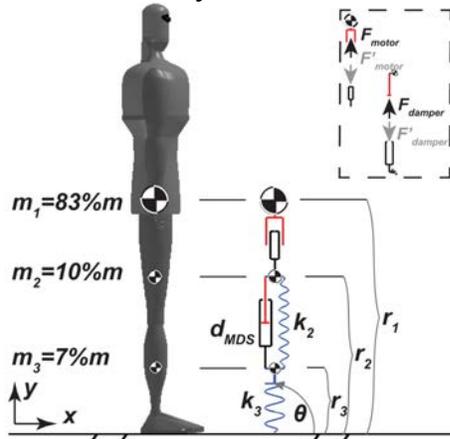

**Figure 1:** Diagram of a leg joint modeled by a strut, motor, spring, and damper in parallel.

The strut index is the dimensionless ratio between the power,  $P_{joint}$ , and moment ( $M_{joint}$ ). A strut index of 100% means a joint has no angular movement while only passing/bearing the moment between two segments; a strut index of 0 means that moments are associated with energy production or absorption. The motor, spring and damper indices characterized the nature of mechanical joint work: energy production, absorption followed by production, and absorption, respectively.

We used experimental data to construct and constrain a dynamic 2D Motor-Damper-Spring model (MDS) with alternate stance and flight phases [3]. The MDS is planar, with three segments: a proximal motor (analogous to the hip), an element with spring and damper in parallel (knee analog), and a distal spring (ankle/foot analog; Fig. 2).

We used forward dynamic simulations to estimate the number of steps achieved by the MDS model before falling on the ground. We quantified stability as the number of steps (# steps) before falling. We performed a sensitivity analysis over a wide

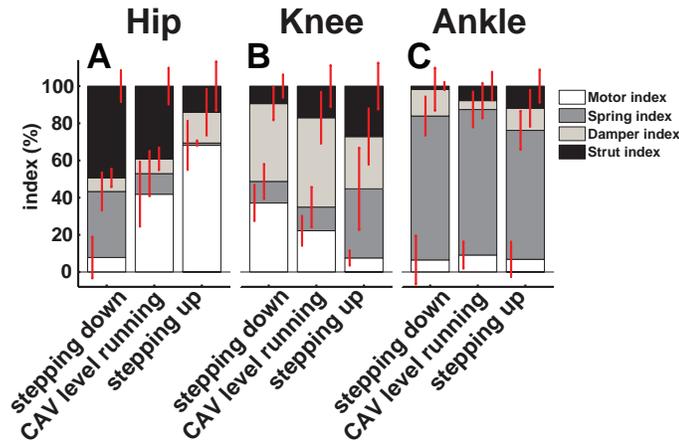

parameter space, and also constrained the model using parameters used by humans.

**Figure 2:** Schematic of MDS model.  $k$  is spring constant, and  $d$  is damping constant.

## RESULTS AND DISCUSSION

Consistent with our hypothesis, the hip acted as a “motor,” the knee as a “damper,” and the ankle as a “spring” (Fig. 3) during CAV running and maneuvers.

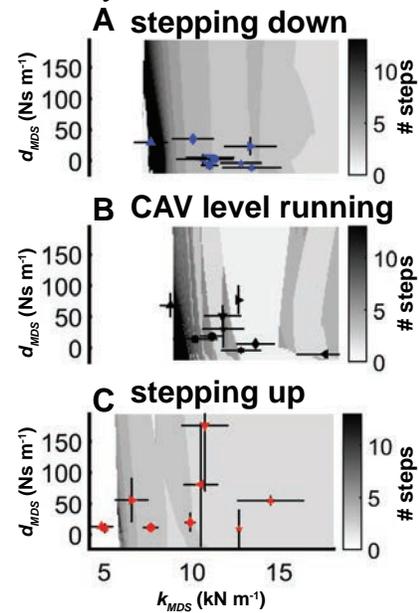

**Figure 3:** Joint functional indices during CAV level running and sagittal-plane maneuvers.

Maneuvers were associated with modest functional changes at the hip and knee joints, with small changes at the ankle joint (Fig. 3). The overall mechanical behavior of leg joints suggests that the MDS model (Fig. 2) is a reasonable representation of leg joint function during running.

The intrinsic dynamics of the MDS model resulted in sustained locomotion on level ground within narrow parameter ranges (Fig. 4; black regions). However, using parameters experimentally derived from humans, the model showed only short-term stability (Fig. 4; symbols). Parameters were

consistent across conditions rather than chosen to maximize stability.

**Figure 4:** Sensitivity analysis of MDS performance relative to stiffness ( $k_{MDS}$ ) and damping ( $d_{MDS}$ ) parameters. Superimposed symbols and STDEV lines represent parameters selected by humans (different symbols represent different participants).

## CONCLUSIONS AND IMPLICATIONS

During constant-average-velocity running and sagittal plane maneuvers, legs showed a proximal-distal gradient in function. The hip, knee and ankle acted as a motor, damper, and spring, respectively. Humans may not optimize intrinsic dynamic stability alone, but may instead choose mechanical and behavioral parameters appropriate for both CAV locomotion and maneuvers. Understanding the contribution of differential joint function to overall leg and body mechanics is an important neuromechanical question with potential implications for athletic training, rehabilitation, prosthetics, and legged robotics.

# **The energetics of the human foot across a range of running speeds**

The University of Queensland, School of Human Movement and Nutrition Sciences,  
Centre for Sensorimotor Performance, Brisbane, Australia, email: l.kelly3@uq.edu.au

## **INTRODUCTION**

The longitudinal arch (LA) of the human foot behaves in a spring-like manner during running. Compression of the LA during early stance allows mechanical energy to be stored in the stretched elastic ligamentous and tendonous tissues that span this structure. In late stance the LA recoils and the elastic structures shorten to return stored mechanical energy to the body. It has been suggested that this mechanism delivers between 8-17% of the mechanical energy required for each stride [1].

In contrast to the LA, the metatarso-phalangeal (MTP) joints are known to absorb mechanical energy during late stance. Thus it is possible that a proportion of the energy returned via LA recoil is actually absorbed at the MTP joints, rather than returned to the body [2].

The notion that positive work is performed about the LA simultaneously with negative work being performed about the MTP joints is somewhat problematic, as the same structures (ie plantar fascia and intrinsic foot muscles) are considered to be the primary source of the mechanical work being performed at both of these joints. Although the same tissue may have a localized effect of performing negative work about a distal joint whilst performing positive work about another proximal joint, it is the net behavior that will contribute to the overall energetics of the system. With this in mind, we suggest it may be more appropriate to consider the energetic function of the LA and MTP joints as part of an entire 'foot' system. Under this scenario the net-work performed by muscles and ligaments acting across both the LA and MTP joints, as well as the contributions of other soft tissues (plantar fat pads etc.) may be adequately captured to reflect the energetics of the foot as an entire system.

Therefore the aim of this study was to quantify the energetic profile of the foot during running and to determine if the foot can indeed be described as spring-like in nature when considering the combined influence of the LA and MTP joints in addition to the other soft tissue structures. We also sought to determine if this energetic profile remained constant across a range of running speeds.

## **METHODS**

Eight healthy participants ran on a force-instrumented treadmill at 2.2, 3.3 and 4.4 m.s<sup>-1</sup> in a counter-balanced order. Three-dimensional motion of fourteen reflective markers attached to the foot, electromyography (EMG) and ground reaction force (GRF) data were captured synchronously during each running trial, with motion data collected at 200 Hz and GRF and EMG data captured at 2000 Hz via a 14-bit analogue to digital converter.

Marker trajectories and GRF data were filtered with a recursive 20 Hz low pass, second order Butterworth filter, while EMG signals were high-pass filtered at 35 Hz using a recursive second order Butterworth filter.

A previously described multi-segment foot model was applied in order to describe rear-, mid- and forefoot motion during running [3]. Foot power was calculated using a unified deformable (UD) segment analysis [2] with the calcaneus applied as the reference segment. Thus foot power reflects the net power contribution of all structures acting distal to the calcaneus segment, including the plantar fascia, intrinsic and extrinsic foot muscles and the plantar fat pads. Negative and positive work performed during stance phase was calculated by applying a trapezoidal integration of joint power curves across the stance phase. In order to describe the spring-like qualities of the foot, a work ratio was calculated at each running speed by dividing the positive work

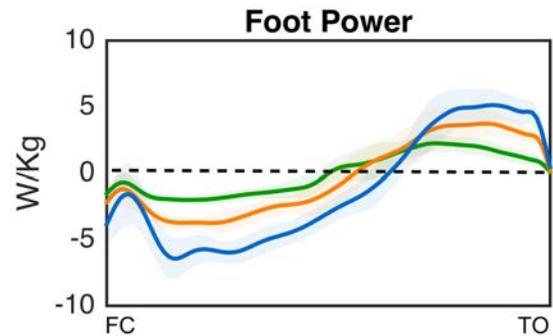

done by the absolute value of negative work during the stance phase.

Intramuscular EMG was recorded from the two largest intrinsic foot muscles, abductor hallucis (AH) and flexor digitorum brevis (FDB) using previously described techniques [4] to provide further insight into the active muscular contributions to the foot spring function. An EMG root mean square (RMS) signal envelope was calculated using a moving window of 50 ms and each signal was normalized to its peak RMS amplitude found across all conditions. Normalised mean EMG RMS amplitude was calculated during the stance phase for each stride cycle, allowing comparisons in magnitude of stance phase muscle activation between running velocities.

For each individual, the kinetic and EMG data was averaged across a minimum of 10 stride cycles to form individual means for each condition. A one-way repeated measures analysis of variance (ANOVA) was used to describe the influence of running velocity on foot energetics and intrinsic foot muscle activation.

## RESULTS AND DISCUSSION

The foot underwent a phase of negative work from early stance through to mid-stance, followed by positive work in late stance (Figure 1). The magnitude of negative work ( $-0.19 \pm 0.03 \text{ J.Kg}^{-1}$  2.2  $\text{m.s}^{-1}$ ,  $-0.29 \pm 0.04 \text{ J.Kg}^{-1}$  3.3  $\text{m.s}^{-1}$ ,  $-0.42 \pm 0.11 \text{ J.Kg}^{-1}$  4.4  $\text{m.s}^{-1}$ ) and positive work ( $0.18 \pm 0.06 \text{ J.Kg}^{-1}$  2.2  $\text{m.s}^{-1}$ ,  $0.23 \pm 0.10 \text{ J.Kg}^{-1}$  3.3  $\text{m.s}^{-1}$ ,  $0.26 \pm 0.10 \text{ J.Kg}^{-1}$  4.4  $\text{m.s}^{-1}$ ) increased with running velocity ( $P < 0.05$ ). Although a greater amount of negative and positive work was performed about the foot when participants ran faster, work ratio significantly declined with running speed ( $P < 0.05$ ). When running at the slower speed the foot behaved like a spring, returning 98% of the energy stored during early stance (work ratio  $0.98 \pm 0.25$ ). As running speed increased, the foot behaved increasingly like a spring-damper, returning 81% at 3.3  $\text{m.s}^{-1}$  (work ratio of  $0.81 \pm 0.29$ ) and 64% of the energy absorbed during early stance when running at 4.4  $\text{m.s}^{-1}$  (work ratio  $0.64 \pm 0.25$ ).

**Figure 1.** Group mean  $\pm$  SD foot power time series data calculated during stance when participants ran at 2.2 (green) 3.3 (red) and 4.4  $\text{m.s}^{-1}$  (blue). Both negative and positive work increased with running speed. Foot contact (FC) and toe off (TO)

Both AH and FDB muscles were active for the entire duration of stance phase, with the FDB muscle displaying a distinct peak in activation during late stance. Mean stance phase activity increased significantly with running speed for both AH ( $21.8 \pm 11.6 \%$ max,  $31.1 \pm 13.7 \%$ max,  $40.0 \pm 17.2 \%$ max) and FDB ( $22.5 \pm 8.4 \%$ max,  $34.8 \pm 12.4 \%$ max,  $46.9 \pm 16.2 \%$ max) indicating that the contribution of these muscles to power absorption and generation increases with running speed.

## CONCLUSIONS

As previously proposed, the foot does behave in a spring-like manner, although it appears that distal structures such as the plantar fat pads and metatarso-phalangeal joints may act to dampen a substantial proportion of the energy that is absorbed within the foot, especially at higher running speeds.

The underlying mechanism for why the foot behaves like a spring-damper at higher running speeds requires further investigation. However, we suggest that damping energy in mid- to late- stance may act to slow centre of pressure velocity and thus possibly improve the gear-ratio of the ankle plantar flexors.

# HIP ALIGNMENT, POSITION AT FOOT STRIKE AND PEAK HIP ADDUCTION ANGLE IN FEMALE RUNNERS

<sup>1</sup>Richard A. Brindle, <sup>1</sup>Clare E. Milner

<sup>1</sup>Drexel University, Philadelphia, PA, USA  
Email: brindle@drexel.edu

## INTRODUCTION

The peak hip adduction angle is a risk factor for the most frequently reported overuse injuries in female runners. Specifically, a large peak hip adduction angle is a risk factor for patellofemoral pain syndrome [1] and iliotibial band syndrome [2] in female runners.

Peak hip adduction angle differences between groups of female runners are often coincident with an offset in angle throughout the stance phase [2]. This offset in hip adduction angle throughout stance may be due to biomechanical differences at foot strike, or anatomical differences between runners. Specifically, a larger pelvis width to femoral length ratio (PW:FL) has been hypothesized to influence the peak hip adduction angle during running [3]. Additionally, the frontal plane position of the pelvis or thigh at foot strike during running may influence the hip adduction angle throughout stance.

Thus, the purpose of this study was to determine if anatomical or biomechanical differences exist between women with large or small peak hip adduction angle during running. We hypothesized that female runners with a large peak hip adduction angle would have a greater PW:FL, and different frontal plane hip, pelvis, and thigh angles at foot strike than those with a small peak hip adduction angle.

## METHODS

As part of an ongoing study, thirty-seven uninjured female runners between 18 and 45 years old participated ( $28 \pm 8$ yr,  $1.66 \pm 0.06$ m,  $62.2 \pm 7.4$ kg,  $23 \pm 10$  miles per week). Participants ran at least 10 miles a week for a year or more. Those with a history

of serious lower extremity injury were excluded. Each participant gave written informed consent.

An eight camera motion capture system and a synchronized force plate recorded marker position at 200 Hz and ground reaction forces at 1000 Hz. Initially, runners were screened for a rearfoot foot strike pattern. Participants changed into shorts and wore laboratory footwear. Retro-reflective markers were attached to both feet and shoes. Running velocity was standardized to 3.7m/s ( $\pm 5\%$ ), and monitored by two photocells connected to a timer. A static trial and five good running trials were collected, and then foot strike pattern was determined using strike index [3]. Of 37 runners screened, 30 were rearfoot strikers and continued in the study. Retro-reflective markers were then attached to the participants' pelvis and right thigh and running gait analysis procedures were repeated.

Hip joint angles and pelvis and thigh segment angles were determined using the joint coordinate system and segment coordinate systems, respectively. Foot strike was the point when vertical ground reaction force surpassed 20N. Anatomical measures were determined from the static trial. Pelvis width (inter-trochanteric distance) was divided by right thigh length (greater trochanter to lateral epicondyle) to calculate each participant's PW:FL.

For analysis, all thirty runners were ranked by their peak hip adduction angle. Dependent variables were averaged for ten runners with the largest peak hip adduction angles (large peak angle group) and ten runners with the smallest peak hip adduction angles (small peak angle group). Between-group differences were interpreted using Cohen's d effect size. Moderate ( $\geq 0.5$ ) or large effects ( $\geq 0.8$ ) which exceeded minimal detectable difference (MDD) were considered meaningful.

## RESULTS AND DISCUSSION

The purpose of this study was to determine if anatomical or biomechanical differences exist between female runners with large or small peak hip adduction angles. We hypothesized that the large peak angle group would have a greater PW:FL and different frontal plane hip, pelvis, and thigh angles at foot strike than the small peak angle group. Our hypotheses were partially supported by the results.

The large peak angle group had a larger peak hip adduction angle and adduction angle at foot strike than the small peak angle group (Table 1). This was expected as comparisons between groups with different peak hip adduction angles found an offset between the frontal plane hip angle ensemble curves throughout the stance phase of running, e.g. [2]. However, frontal plane hip angle at foot strike has not been reported previously in female runners. Thus, reducing hip angle at foot strike may be a way to decrease large peak hip adduction angles in female runners.

The larger hip adduction at foot strike in the large compared to the small peak angle group came from thigh adduction and not contralateral pelvic drop. Pelvis and thigh angle at foot strike have not been reported previously in female runners. These findings suggest that large peak hip adduction angle in female runners is due to thigh rather than pelvis position at foot strike. Thus, reducing thigh angle at foot strike may decrease large peak hip adduction angles in female runners.

The large peak angle group had a moderate effect for greater PW:FL than the small peak angle group. A previous study reported no difference in a similar measure between female runners with different peak hip adduction angles [4]. The large difference in peak hip adduction angle between groups in this study may explain why we found a difference in this ratio. The PW:FL may be useful to clinicians as a simple screening tool for the likely presence of a large peak hip adduction angle in female runners. These results are part of an ongoing study of determinants of the peak hip adduction angle in female runners.

## CONCLUSION

Women with large peak hip adduction angles during running have a more adducted hip and thigh at foot strike, and greater PW:FL than women with small peak hip adduction. Decreasing thigh adduction at foot strike could be a component of treatment for large peak hip adduction angles in female runners. PW:FL may be a useful clinical tool to screen for female runners who may have large peak hip adduction angles.

## **INTRODUCTION**

The overall incidence of running-related injuries has been found to be 19.4% to 79.3% of recreational or competitive runners who run a minimum of 5 km per training, race, or both. [1] Approximately 50% of all running-related injuries occur at the knee with nearly half of those involving the patellofemoral joint.[1] During running, peak shear stress at the knee occurs around midstance and is tangential to the vertical component of the ground reaction force. Increases in shear forces can potentially alter muscle activation patterns and impact joint stability. [5] High shear has been reported to be detrimental to bone health. [5] During human running, the individual stiffness values of the ligaments, bones, muscles and other musculoskeletal elements are typically integrated together as a simple spring-mass model.[2-3] Running velocity influences vertical stiffness and knee joint stiffness but its relationship with stride frequency (SF) has not been completely understood.[2-4] Luedke et al. in a study on high school runners revealed that runners with  $SF \leq 166$  steps/min were more likely to experience anterior knee pain than those with  $SF \geq 178$  steps/min.[6] The purpose of this study was to compare knee joint torsional stiffness and anterior tibial shear forces in recreational female runners with different stride frequencies.

## **METHODS**

Sixty-four healthy female recreational runners who ran at least 10 miles per week volunteered to participate in the study. Subjects were provided with standard neutral footwear (New Balance, Boston, MA). Gait analysis was conducted on an instrumented treadmill (Treadmetrix, ParkCity, UT). Retroreflective markers were placed on bilateral lower extremities using the modified Cleveland clinic marker set. A 30 second trial was collected using a 5-camera motion analysis system (Qualisys, Goteborg, Sweden) at 120 Hz as

participants ran at a matched pace 2.98m/s. Visual 3D motion analysis software (C-Motion, Germantown, MD) was used to process data. Joint angles were calculated as Cardan angles between adjacent local segments. The knee joint moments were calculated through inverse dynamics and transferred into the segment coordinate system and expressed as internal moments and normalized to body mass and height. Torsional stiffness at the knee (TK) was calculated as the slope of the line through the moment-angle curve from the point of initial contact to maximum knee flexion during the stance phase. Tibial shear (TS) at the knee was defined as the anterior component of the peak forces in the sagittal plane during stance normalized to body mass and height. Three groups of stride frequencies were created: low ( $\leq 164$ ), middle(166-174), high(176-186) steps per minute. Differences in sagittal plane TK and TS were compared utilizing ANOVA and post-hoc Tukey tests were performed for analyzing differences between the three stride frequency groups. SAS®software, Version 9.3 for Windows. Copyright © [2014] SAS Institute Inc., Cary, NC, USA was used for all statistical analysis with an alpha level of 0.05 being considered statistically significant.

## **RESULTS**

Fifty-four subjects were included in the analysis. (Mass:  $61.98 \pm 8.62$ kg, Height:  $1.65 \pm 0.06$ m, BMI:  $22.65 \pm 2.62$ , Age  $35.07 \pm 10.47$  years). Ten subjects were removed from the analysis as their values of either SF, TS or TK were outside of three standard deviations from the mean. There were significant differences between the SF groups when evaluating TS ( $p=0.03$ ) with the low SF group demonstrating the largest shear ( $9.06 \pm 1.41$ N) compared to the middle ( $8.95 \pm 0.95$ N) and high ( $8.06 \pm 1.19$ N) SF groups. Post hoc testing revealed that the low group was significantly different from the high group. A significant difference was also seen with TK

( $p < 0.01$ ) between the three SF groups with the low group exhibiting the highest TK ( $0.08 \pm 0.013 \text{ Nm}^\circ$ ) compared to the middle ( $0.075 \pm 0.01 \text{ Nm}^\circ$ ) and high ( $0.076 \pm 0.01 \text{ Nm}^\circ$ ) SF groups respectively. Further testing showed that the low SF group was different from the middle and high SF groups.

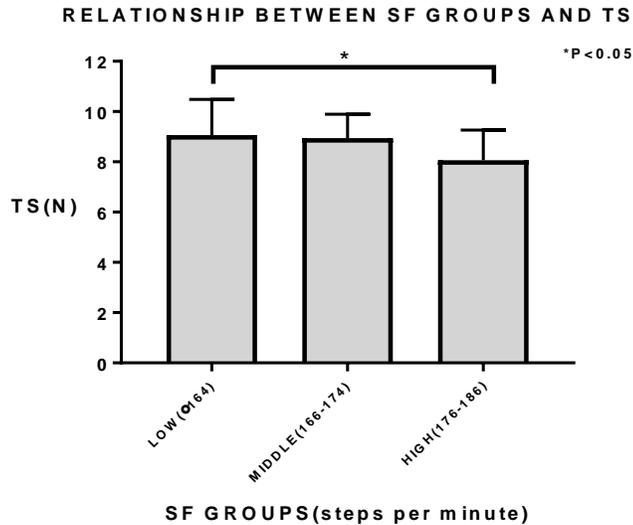

Figure 1: Bar graph demonstrating relationship between the three SF groups and TS.

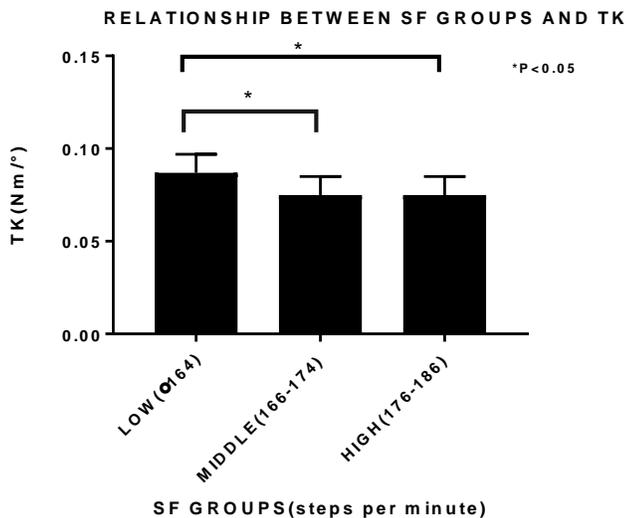

Figure 2: Bar graph demonstrating relationship between the three SF groups and TK.

## DISCUSSION AND CONCLUSIONS

A low stride frequency of less than 166 steps per minute results in an increase in tibial shear forces and concomitant increase in torsional stiffness at the knee joint. This correlates with previous studies which have suggested that low stride frequency leads to increased loading in the knee. Changes in

torsional stiffness could be the result of either increased moment or decreased knee ROM which results in an overall stiffer gait pattern, as the knee is a major contributor to leg stiffness during running.[2,4] Given that the pace was fixed between subjects in the current study, the current study was able to differentiate changes in stiffness and shear based on different stride frequencies. Given the primary role that stiffness plays in the neuromuscular control of movement as well as injury and performance, it is important to note factors that can contribute to its change. Joint stiffness at the knee has been implicated in overuse injuries and degenerative diseases. [3] For example, a more compliant knee joint will attenuate the load placed on the joint to a greater extent than a stiffer joint. Running with a more flexed knee (higher excursion) results in a more compliant knee and increased energy absorption. On further analysis, the current study also showed that the highest stiffness value of the knee joint was due to a relatively greater knee moment in the low SF group ( $1.92 \text{ Nm/kg}$ ) compared to the middle ( $1.67 \text{ Nm/kg}$ ) and high ( $1.65 \text{ Nm/kg}$ ) SF groups. This is likely to place increased compressive forces on the patellofemoral joint as well as on the tibiofemoral joint, thus partially explaining the increases in anterior shear forces. Lack of differences in knee flexion excursion could be attributed to a greater stride length especially in the low SF group which could alter the moment arm, orientation of the ground reaction force and muscle activation. We did not assess the role of muscle contraction and activation, which contributes to the joint moment. Future studies should investigate the role of increasing stride frequency on the ability to alter stiffness and shear in individuals with tibiofemoral joint pathology such as meniscus injuries or knee osteoarthritis.

## INTRODUCTION

The high prevalence of running related overuse injury (RROI) can be attributed largely to rapid increases in training load and inadequate recovery. A healthy runner may not recognize when modifications to a current training program are necessary until after they feel the pain and discomfort associated with “overtraining.” This pain and discomfort may cause a runner to inadvertently alter their running mechanics, causing abnormal loading on the joints and tissues that can eventually lead to injury. Therefore, we suggest that overtraining induces ‘cumulative fatigue’ that results in measurable changes in running gait mechanics prior to the onset of RROI.

Deviations in running mechanics resulting from acute fatiguing bouts have been suggested to cause abnormal loading on the joints and tissues and eventually, lead to injury [1]. To date, changes to running gait patterns resulting from fatigue have only been investigated during or after acute intense runs to exhaustion. Runners in these studies adopted gait characteristics associated with injury development as they reached volitional exhaustion. These characteristics may include increased ground reaction forces, tibial shock, joint stiffness [2, 3], and a decline in center of mass (COM) acceleration complexity [4]. A decline in movement complexity has been suggested to represent an unhealthy system that has a reduced capacity to respond to environmental perturbations [5]. It is unknown if injury-causing gait patterns observed after acute exhaustive runs also occur after more typical submaximal, recreational running bouts or after prolonged training periods of many submaximal running bouts. The purpose of this pilot study was to begin establishing a proof of concept that cumulative fatigue following a submaximal run and following a

prolonged running training period can be identified by a reduction in COM movement complexity. It was hypothesized that COM acceleration complexity would decline after a 30-min submaximal run and after three-weeks of increased running volume.

## METHODS

To date, 12 novice runners who have been running for less than two years, run a minimum average of 10 miles per week, and complete at least three runs per week were included in this study. All participants provided informed consent to participate in the study protocol approved by the IRB. Participants were instructed to reduce their training volume by at least 80% (i.e. training taper) the week prior to the first testing session. During the first testing session, participants completed a 30-min treadmill run at their preferred pace. A 3D accelerometer was secured to the proximal sacrum for which the Z-axis was aligned with the body’s longitudinal axis. The proximal sacrum was used as the estimated location of the participants COM and provided a bony landmark with low soft tissue artifact to mount the accelerometer. Acceleration data were recorded for 30 sec at 200 Hz during the 3<sup>rd</sup> min (pre-run) and 29<sup>th</sup> min (post-run) of the run. Participants rated their lower limb fatigue on a visual analog scale (FVAS; 10 = most fatigued) before and after the baseline treadmill run.

Participants were given a progressive three-week training program scheduled to begin the day after the baseline treadmill run performed in the lab. The program increased weekly mileage by 25% per week for three-weeks and was based on 3–6 runs per week. Participants were encouraged to run at their preferred training pace as long as the prescribed weekly running volume was met. A shoe-worn GPS pod was used to monitor the training adherence by recording

pace and distance per run. Participants returned to the lab the week following the conclusion of the training program to rate their lower-body fatigue and perform a five minute treadmill run at the same speed as the first testing session. COM acceleration was collected during the 5<sup>th</sup> minute of this run (post-train).

The resultant value of the raw COM acceleration data was calculated for each instant then filtered with a Butterworth low-pass filter with a 60Hz cut-off. Complexity of the resultant COM acceleration signal was calculated by multiscale entropy (MSE) [6]. The radius of similarity ( $r=0.001$ ) was determined by calculating 15% of the standard deviation of the original signal. Parameter  $m$  was set to a value of 2 and scale factors 1–8 were examined. The complexity index ( $C_r$ ) was calculated from the area under the MSE curve (sample entropy vs. time scale). Given the small sample size, Cohen’s  $d$  effect sizes were used to determine if the differences in  $C_r$  and FVAS between time points were meaningful.

## RESULTS AND DISCUSSION

Two participants did not complete the training protocol: one due to injury and illness, the other due to noncompliance. Three other participants experienced an injury and two others experienced illness but were able to adhere to the training protocol. The effect of pre-run vs. post-run FVAS was large ( $d=1.41$ ; Table 1) indicating meaningful fatigue perceived by the participants following the 30-min treadmill run. However, mean post-run FVAS was less than 5 on a 1–10 scale which suggests that the treadmill run did not elicit high degrees of lower limb fatigue. Therefore, despite a meaningful change in FVAS, the similarity in pre-run and post-run  $C_r$  was expected ( $d<0.01$ ; Table 1) given that the magnitude of the perceived fatigue was low.

The training protocol was designed to systematically increase the distance of individual sub-fatiguing runs as much as possible without causing injury. This

training program induced a cumulative effect on lower-body fatigue as indicated by greater FVAS post-train than pre-run ( $d=0.79$ ; Table 1). Contrary to the hypothesis, post-train  $C_r$  was moderately greater than that of pre-run and post-run ( $d>0.41$ ). There are two possible explanations for greater COM complexity after the training protocol: (1) running skill of these novice runners improved, increasing the capacity to respond to environmental constraints; or (2) the combination of a novice running pattern and cumulative fatigue following three weeks of intense running training cause COM complexity to increase outside the threshold for optimal health, a continuum that has been proposed by other authors [e.g. 7]. We are currently collecting data on more novice runners, a group of experienced runners, and a control group to provide support for either of these or other explanations. In addition, COM acceleration data is being collected for more than one minute of running to assess complexity over scale factors  $\geq 20$ .

## CONCLUSIONS

The implementation of an intense, three-week running training program increased perceived lower limb fatigue and may also be supported by a change in COM acceleration complexity. Monitoring COM complexity during prolonged running training may help to identify when rest or modifications are needed to avoid RROI development.

## INTRODUCTION

Most biomechanics research is conducted within a laboratory setting, either overground or on a treadmill. The recent introduction of wearable devices has allowed biomechanics research to move from the lab to the field. However, since most runners run outside, it is more ecologically valid to measure mechanics in natural environments.

Increased tibial shock (TS) has been associated with running injuries such as stress fractures. [1] It has also been shown that TS increases with fatigue during treadmill running. [2] However, these studies were conducted under tightly controlled conditions in terms of speed, surface, grade, etc. In addition, environmental influences, such as temperature and wind, are also controlled. These factors may contribute to the relationship between fatigue and TS. Fatigue also appears to play a role in strike pattern. Larson has reported that runners who used a midfoot (MFS) and forefoot strike (FFS) early in a race (10 km) changed to a rearfoot strike (RFS) pattern later in the race (32 km). [3]

Therefore, the purpose of this study was to determine if there is an association between footstrike pattern (FSP) changes and TS during a marathon. It was expected that FSP would shift posteriorly over the course of the race and that this shift would be associated with a larger TS increase rather than remaining at a given FSP.

## METHODS

254 runners enrolled in a marathon were recruited. Each subject was provided an inertial measurement unit (IMU) to be worn on their right leg during the marathon. Prior to the race, a mark was placed on the subject's distal, medial tibia, just above the ankle. (Figure 1) The subjects were instructed to place the device over that mark on race day. Additionally, they were taught how to properly affix

and tension the IMU with a strap around the lower leg. A mark placed on the strap was used as a guide. Each subject's device number was written on the outside of their right lower leg in order to identify them on videos taken in the field.

Figure 1: Example of IMU placement

Prior to the race, two areas where the course was level and would allow for optimal camera viewing were identified. Video data (240 Hz) were collected continuously at approximately the 10k and 40k marks in the race. During post-processing, the videos were assessed by study staff to identify subjects' FSP, when possible, at each location.

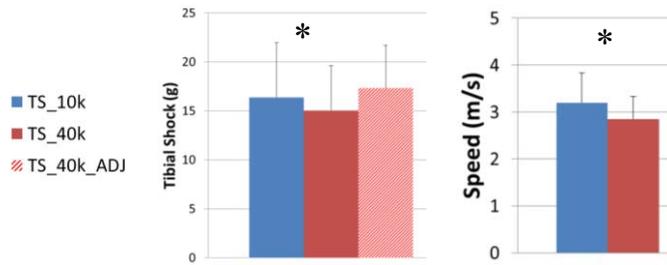

Acceleration data were sampled in 3 dimensions at 1,000 Hz during the entirety of the race. The resultant acceleration was calculated from the three axes. Tibial shock (TS) was measured as the peak resultant acceleration from each right step during running. TS was averaged for each subject over the 5k period surrounding each video capture point, as 5k split times were made available after the race. Acceleration due to gravity [ $g=9.81\text{m/s}^2$ ] was subtracted from TS resultant accelerations and used to normalize TS to units of gravity [g].

To avoid the confounding effect of pain on mechanics, subjects reporting pain  $>3/10$  on a numeric rating scale prior to the 40th kilometer of the race were excluded ( $n=16$ ). Additionally, runners without complete tibial shock data for the race were excluded ( $n=61$ ). Finally, those who were not identified in the videos at both race points were excluded ( $n=150$ ). This left 37 subjects with complete data which could be analyzed [24 males, 13 females; age= $44.4\pm 12.15$  yr].

Paired t-tests were used to compare TS early (TS\_10k) and late in the course (TS\_40k). As TS has previously been associated with speed ( $5.26 \frac{g}{m/s}$ ), [4] TS\_40k was adjusted for speed differences between the two points (TS\_40k\_ADJ) and compared to early in the race as well. Changes in FSP between the 10k and 40k locations were also tabulated.

## RESULTS AND DISCUSSION

TS\_40k was 13.4% lower than TS\_10k (Figure 2, left;  $p < 0.001$ ). However, speed at the 40k location was 13.7% lower than speed at the 10k location (Figure 2, right;  $p < 0.001$ ). After adjusting for speed, TS\_40k\_ADJ was 5.6% higher than TS\_10k, though this difference did not reach significance (Figure 1, left;  $p = 0.16$ ).

**Figure 2:** Left: Average tibial shock at 10k and 40k race points. Right: Average speed at 10k and 40k race points. Error bars represent standard deviations. \* indicate significant differences ( $p < 0.05$ ).

A summary of FSP and TS changes can be seen in Table 1. 78% of the runners analyzed were RFS, 19% were MFS and 3% were FFS at the 10km race point. Most RFS runners (33/37) retained their FSP throughout the race. These runners experienced a 3.35% increase in speed-adjusted TS.

**Table 1:** Footstrike Pattern at 10k and 40k race points. Total number of observations of each change, if any, recorded. Heavy shading indicates a posterior FSP shift. Light shading indicates an anterior shift. No shading indicates no shift.

10k	40k	n	Average TS_10k[g]	Average TS_40k adj[g]	Percent Diff.
FFS	FFS	1	13.51	12.90	-4.66%
MFS	MFS	2	19.91	19.70	-1.01%
MFS	RFS	5	17.15	18.32	6.59%
RFS	MFS	2	22.66	22.04	-2.75%
RFS	RFS	27	16.22	16.77	3.35%

Only five runners shifted to a more posterior strike pattern as we had hypothesized (all 5 MFS to RFS). This posterior shift in FSP was associated with a 6.59% increase in TS after adjusting for speed, the largest increase observed in our cohort. Two runners changed from a RFS to a MFS. On average these runners demonstrated a decrease in speed-adjusted TS, but only one runner decreased while the other increased. Interestingly, all three runners who maintained a FFS or MFS demonstrated lower speed-adjusted TS later in the race than they did early in the race.

Previous research utilizing a treadmill has shown an increase in TS after a period of exhaustive running, [2] consistent with our results within runners out in the field during an overground marathon race who started with, and maintained, a RFS. Further, the subset of runners that shifted to a more posterior FSP during the race demonstrated an increase in TS. This is also consistent with literature showing that a more posterior strike pattern is related to an increase in loading rates and impacts. Our smallest groups were the most interesting, demonstrating decreases in speed-adjusted TS. More data is needed to understand if this group truly represents what happens under these FSP conditions.

It should be noted that determination of FSP was restricted to one foot contact due to capture volume limitations. It is possible that the captured FSP may not accurately categorize the runner at each point.

## CONCLUSIONS

Tibial shock reduced over the course of the marathon, as did running speed. However, no difference was found when tibial shock was adjusted for speed. In most cases, runners either maintained footstrike angle or shifted posteriorly.

# CHANGES IN RUNNING MECHANICS DURING THE 2016 US OLYMPIC TRIALS MARATHON

<sup>1</sup>Iain Hunter, <sup>1</sup>Jared Ward, <sup>1</sup>Gill Fellingham, <sup>1</sup>James Tracy, and <sup>1</sup>Andrew Terry

<sup>1</sup>Brigham Young University, Provo, UT, USA  
email: iain\_hunter@byu.edu, web: <http://biomechanics.byu.edu/>

## INTRODUCTION

The 2016 US Olympic Trials Marathon (13 February 2016) resulted in a wide range of finish times perhaps due to the relatively high temperature. There was also a larger field than recent years due to a relaxed qualifying standard. Slower marathoners have greater changes to running mechanics than faster [1]. However, many of these changes are likely due to a slower pace near the end of the race among the slower runners. Other studies found that fatigue cannot be explained by running mechanics [2] and changes in running economy during marathon running cannot be explained by any single kinematic measurement [3].

The 2016 US Olympic Trials Marathon allowed for a unique opportunity for greater detail on the time course of changes in running mechanics comparing slower and faster runners. The course involved a four-lap “P” shaped loop permitting measurements eight times throughout the race. These measurements were approximately every five km.

Realizing that running mechanics do change throughout a marathon, we focused on whether these changes were due to changes in running speed or some other factors. We were also interested in whether the magnitudes of any observed changes in mechanics were correlated with race pace.

## METHODS

Seventy of the 108 finishers of the men’s race were analyzed. They qualified for the race by running under 2:19:00 for a full marathon or under 1:05:00 for a half marathon between 1 August 2013 and 17 January 2016. A Sony a7s ii was placed on each side of Figueiroa Road in between 27<sup>th</sup> and 28<sup>th</sup> Streets ([Course Map](#)). The cameras recorded at 120 Hz with a field of view that could capture at least one full

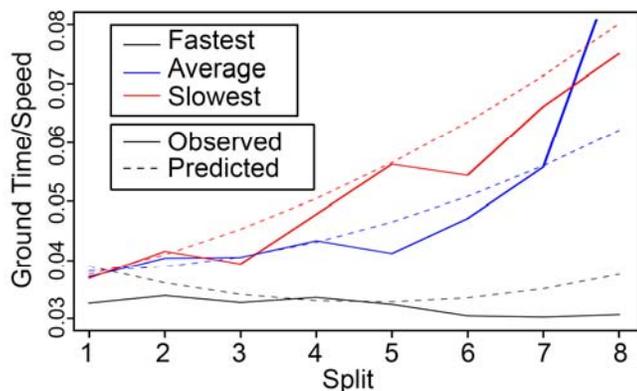

stride if they ran at least 2 meters from the camera. This allowed measurements of stride rate (SR) and ground time (GT). Stride length was also calculated based upon running paces provided through race results along with the measured SR. All variables were adjusted for running speed through the measurement zone.

We analyzed these data using a repeated measures mixed model in SAS 9.4 (SAS Institute, Cary, NC). As in multiple regression, this method allows estimation of fixed effects (GT/speed and SR/speed). GT/speed was divided multiplied by 100 to make the numbers more readable. The utility of the mixed model also accounts for the covariance structure within subject. Each runner has differences in biomechanics for a variety of reasons. Regressing these data in a traditional sense with multiple observations for each runner would violate assumptions of observation independence, as athletes’ technique measurements throughout the race are likely highly correlated. Adjusting for each athlete’s dependence in this way offers a more accurate estimation of fixed effects of interest along with information on interactions [4].

## RESULTS AND DISCUSSION

Individual GT/speed changes and SR/speed changes were strongly correlated with average race speed. Faster runners had smaller changes in GT/speed and SR/speed even after accounting for differences in running speed through the measurement section (Figure 1). SR and stride length are highly correlated and provided similar findings, so only SR will be discussed here since it was a more accurately determined measurement.

The statistical model used allowed for a collection of other useful information. Early in the race, those with faster finish times had a greater GT/speed, but with

**Figure 1:** Changes in GT/speed for three categories of running ability.

the greater changes the slower finishers exhibited, they spent more time on the ground after adjusting for speed late in the race. Exponential increases in GT/speed and decreases in SR/speed were observed with a major change in both variables around 18-20 miles into the race. This is the stage of a race marathoners often discuss “hitting the wall”. Various physiological, psychological, or nutritional reasons may exist for hitting the wall. Whatever the reason for this event seems to be reflected by changes in some running mechanics.

Differences in training, physiological capacities, pacing, environmental conditions, and nutrition are among potential reasons for changes in the observed running mechanics.

## CONCLUSIONS

Elite male marathoners here exhibit exponential changes in GT/speed and SR/speed, yet the elite runners with faster average race speeds have smaller degrees of change. This was expected. However, it was interesting to note that slower runners spent less time on the ground after adjusting for speed than faster runner early in the race. During the later stages, the slower runners spent more time on the ground after the speed adjustment. The exponential changes in GT/speed and SR/speed coincided with the timing of when “hitting the wall” is often reported.

## INTRODUCTION

In the Berlin 2014 marathon, Dennis Kimetto established the current world record of 2:02:57 (hr:min:sec), reviving a long-standing controversy as to whether it is possible to break the magical sub-2-hour marathon barrier. Kimetto's overall time translates to an average running velocity of 5.72 m/s, indicating that he needs to increase his velocity to 5.86 m/s, just 2.5% faster to break the sub-2-hour marathon barrier.

Recently, we outlined several biomechanical approaches that could be exploited to improve Kimetto's running economy to a level that would break the 2-hour marathon barrier [1]. The most promising approach would be to reduce the cost of forward propulsion by using a "cooperative drafting" approach, similar to the team trial strategy adopted by cyclists [3], where the runners would take turns in the lead, essentially alternating leading and drafting positions.

Here, we compare improvements in marathon performance time between a "cooperative drafting" and "traditional drafting" approach, where sacrificial runners lead as long as they can while maintaining the target velocity.

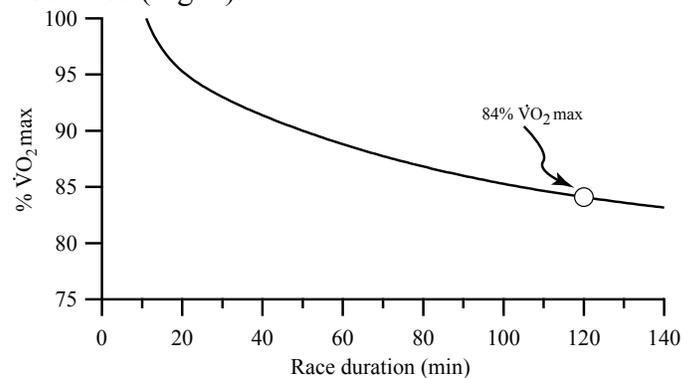

## METHODS

To determine how much metabolic energy an athlete needs to save to run 2.5% faster, we use the empirical relation characterizing gross metabolic cost and running velocity originally reported by [2] and adjust the equation to account for the projected frontal area of elite African runners, as described in [1]. Following Kyle and Caiozzo [3], we introduce a shielding factor,  $n$ , with 1 being complete shielding

and 0 being no shielding which yields the following equation:

$$\dot{V}O_2 \text{ (ml O}_2\text{/kg/min)} = 2.209 + 11.39V + 0.02724(1-n)V^3 \text{ (Eq. 1)}$$

Eq. 1 predicts that without any benefits of drafting, a marathon runner with a typical economy requires 72.46 ml O<sub>2</sub>/kg/min to sustain a velocity of 5.72 m/s. According to Daniels and Gilbert [4], an intensity of 84%  $\dot{V}O_2\text{max}$  can be sustained for a 2-hour race (Fig. 1).

**Figure 1:** Daniels and Gilbert [4] suggest a runner's sustainable % $\dot{V}O_2\text{max}$  exponentially declines as race duration increases.

For both our drafting scenarios, we consider the ideal case that 4 runners work together for a sub-2-hour marathon (e.g., personal best time: Kimetto 2:02:57, Bekele 2:03:03, Kipchoge 2:03:05, and Kipsang 2:03:13). Note that our calculations assume that these 4 runners are all capable of running these times without benefitting from drafting, which is very unlikely.

In the traditional drafting approach, the lead runner maintains a high velocity at a higher %  $\dot{V}O_2\text{max}$  for as long as possible, eventually dropping out when he can no longer sustain the higher %  $\dot{V}O_2\text{max}$ . During this time, the 3 runners behind the lead runner exploit the benefit of drafting and thus can run at the faster velocity while still sustaining 84%  $\dot{V}O_2\text{max}$ . For this "traditional drafting" scenario, we

assume the first runner sustains an intensity of 90%  $\dot{V}O_2\text{max}$  for as long as possible (90% of 84 ml  $O_2/\text{kg}/\text{min}$  [5] = 75.6 ml  $O_2/\text{kg}/\text{min}$ ), then the next runner continues at the same velocity but he can only sustain that for a shorter period of time, since he has already been running at 84%  $\dot{V}O_2\text{max}$ . This process continues until only one runner is left, who then is required to slow down to sustain 84%  $\dot{V}O_2\text{max}$ .

We use the equation by Daniels and Gilbert [4] to predict how long the initial lead runner can sustain 90%  $\dot{V}O_2\text{max}$ ; then use an iterative method (Eq. 2) to solve for how long the next lead runner can sustain that velocity under the constraint that he has been running at 84%  $\dot{V}O_2\text{max}$ .

$$\frac{(T_1 \times 84\%VO_{2max}) + (T_2 \times 90\%VO_{2max})}{(T_1 + T_2)} \leq \frac{DG(T_1 + T_2)}{1} \quad (\text{Eq. 2})$$

In the “cooperative drafting” approach, the only requirement is that on average, the runners consume 72.46 ml  $O_2/\text{kg}/\text{min}$ , the rate needed to run 5.72 m/s without drafting. While leading, a runner would be using metabolic energy faster than this sustainable rate, but while drafting he would be using less metabolic energy, allowing him to recover from the more intense effort. As described in [1], we solve Eq. 1 for the maximum speed, using a shielding factor of 93%.

## RESULTS AND DISCUSSION

As illustrated in Fig. 2, the three lead runners can cover a total distance (before dropping out) of 32.8 km at a velocity of 5.94 m/s. Overall, the 1<sup>st</sup>, 2<sup>nd</sup>,

and 3<sup>rd</sup> runner drop out 50 min, 84 min, and 102 min, respectively. To finish the race, the last runner slows down to 5.72 m/s to sustain 84%  $\dot{V}O_2\text{max}$  as a result of the additional cost of overcoming air resistance. This results in a total marathon time of 1:58:59.

With the cooperative drafting approach, the runners would be able to sustain a velocity of 6.02 m/s throughout the full marathon. This results in a total marathon time of 1:56:49.

## CONCLUSIONS

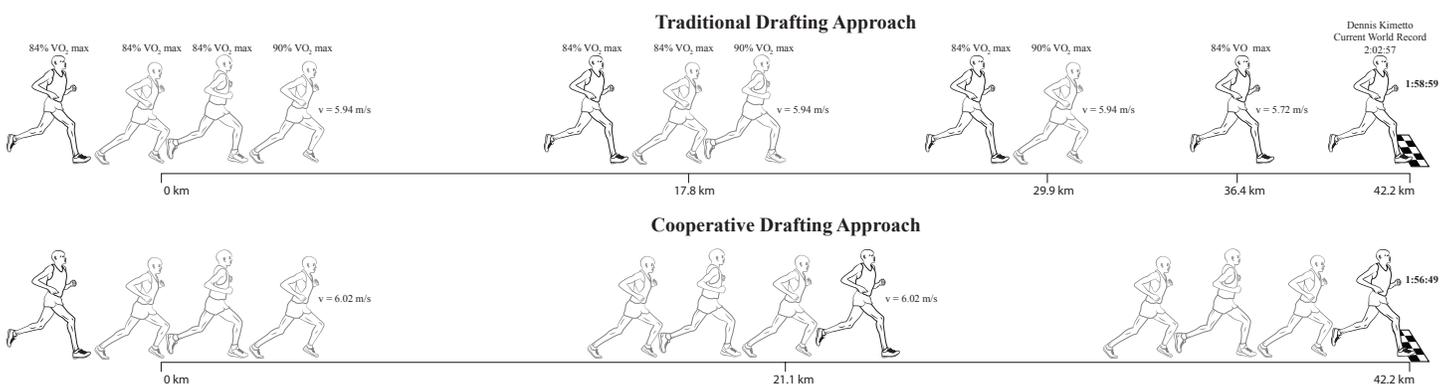

Our calculations show that “cooperative drafting” is substantially faster than a “traditional drafting” approach where sacrificial runners lead as long as they can to maintain the target velocity. In our ideal scenario, a superfast marathon performance time of 1:56:49 is possible.

# GAIT EFFECTS ON JOINT MECHANICS AND CLINICAL OUTCOMES IN HIP DYSPLASIA PATIENTS

Holly D. Thomas, Kevin N. Dibbern, Michael C. Willey, and Jessica E. Goetz  
University of Iowa, Iowa City, IA  
email: holly-thomas@uiowa.edu, web: <https://uiowa.edu/uiobl/>

## INTRODUCTION

Acetabular dysplasia, a hip deformity that alters joint mechanics, results in pain and hip degeneration at an abnormally young age [1]. One common surgical treatment of acetabular dysplasia is the periacetabular osteotomy (PAO), which permits multiplanar rotational correction of the acetabulum to stabilize the hip joint and reduce contact stress [2]. Orthopaedic surgeons currently utilize 2D radiographic measurements to assess pre- and post-operative lateral coverage and acetabular version [3]. However, it is difficult to quantify the effects of 3D acetabular repositioning with a single 2D radiograph. A realistic computational model of joint mechanics in patients with hip dysplasia would assist surgeons with pre-operative PAO planning.

The use of a rapidly-executing discrete element analysis (DEA) technique allows for analysis of large patient populations in order to establish direct relationships between changes in contact stress and patient outcomes [4]. The accuracy of contact mechanics determined with our custom DEA technique has been validated cadaverically, and we have previously shown that there are significant ( $p < 0.001$ ) differences between a gait cycle specific to hip dysplasia patients [5] and the often utilized Bergmann instrumented total hip gait cycle [6] currently implemented by our algorithm [7]. We have implemented the Bergmann gait cycle due to the increased reliability of gait measurements from instrumented total hip replacements. However, Bergmann gait is not necessarily representative of hip dysplasia patients due to the Bergmann patients' advanced ages and lack of need to prevent hip dislocation. The purpose of this study was to evaluate differences in joint mechanics pre- and post-operatively resulting from the use of the Bergmann-derived gait compared to a dysplastic gait. Furthermore, correlations between pre- and post-operative changes in joint mechanics and

common clinical measures for these patients were evaluated.

## METHODS

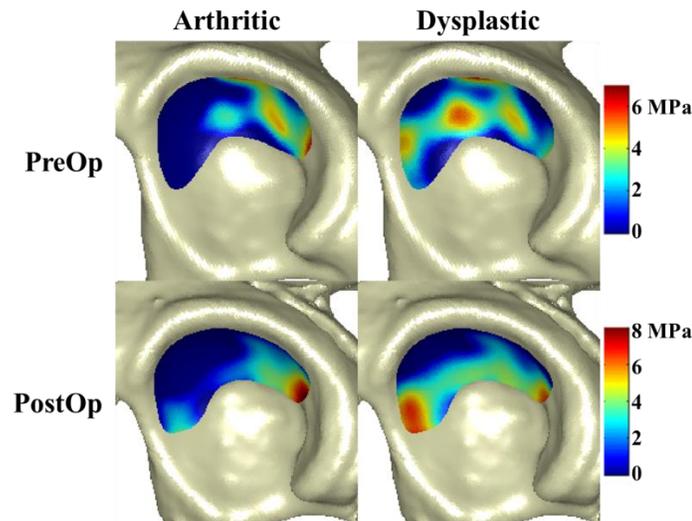

Under IRB approval, femoral and pelvic bone geometry from fifteen PAO patients was segmented from pre- and post-operative CT scans using a semi-automated program developed in MATLAB (Mathworks, Natick, MA). The cartilage surfaces were modeled with 1-mm uniform projections normal to the subchondral bone surfaces that were then smoothed toward sphericity using a custom-written algorithm. Each patient model was aligned to the coordinate system defined by Bergmann *et al.* for application of a walking gait cycle. This walking gait was simulated based on forces and rotations measured from patients that received hip implants to treat osteoarthritis [6]. A dysplastic gait cycle was simulated using joint reaction forces and rotations measured using motion capture from hip dysplasia patients [5]. In both cases, the forces applied to each model were scaled based on the patient's body mass. Maximum contact stress and mean contact area were compared for each loading case in both gait cycles. Changes in pre- and post-operative contact measures were then correlated with changes in clinical outcome measures.

## RESULTS AND DISCUSSION

The implementation of the dysplastic gait cycle tended to decrease contact stress post-operatively, whereas use of the Bergmann gait cycle actually increased contact stress (Figure 1). Average maximum contact stress over the entire gait cycle decreased post-operatively by  $0.71 \pm 0.59$  MPa with the dysplastic gait but increased post-operatively by  $1.99 \pm 0.72$  MPa with the Bergmann gait. This is a significant ( $p < 0.05$ ) difference in the change in maximum contact stress between the two gait cycles. Mean contact area decreased after PAO

surgery by  $35.86 \pm 69.23$  MPa with the dysplastic gait and by  $45.56 \pm 60.35$  MPa with the Bergmann gait. There were significant ( $p < 0.05$ ) differences in the change in maximum contact stress in the toe-off phase of gait (Figure 2, left) and significant ( $p < 0.05$ ) differences in the change in mean contact area for midstance and toe-off (Figure 2, middle). Furthermore, the use of the dysplastic gait cycle improved the correlation between change in maximum contact stress and change in VAS pain score (Figure 2, right, dysplastic  $R^2 = 0.2429$  vs. arthritic  $R^2 = 0.0497$ ).

joint. The strongest finding of this work was the tendency for PAO to decrease maximum contact stress when models used dysplastic gait compared to corresponding increases when models used arthritic gait. Additionally, the correlation between change in maximum contact stress and change in VAS pain score improves with the use of a dysplastic gait. These results indicate that inclusion of a dysplastic gait cycle may be extremely important to provide a realistic representation of contact mechanics in hip dysplasia patients and may be necessary to determine correlations between contact mechanics and clinical outcomes.

**Figure 1:** DEA analysis of pre- and post-operative acetabular contact stress developed from application of the Bergmann (arthritic) or dysplastic gait cycles.

## SIGNIFICANCE

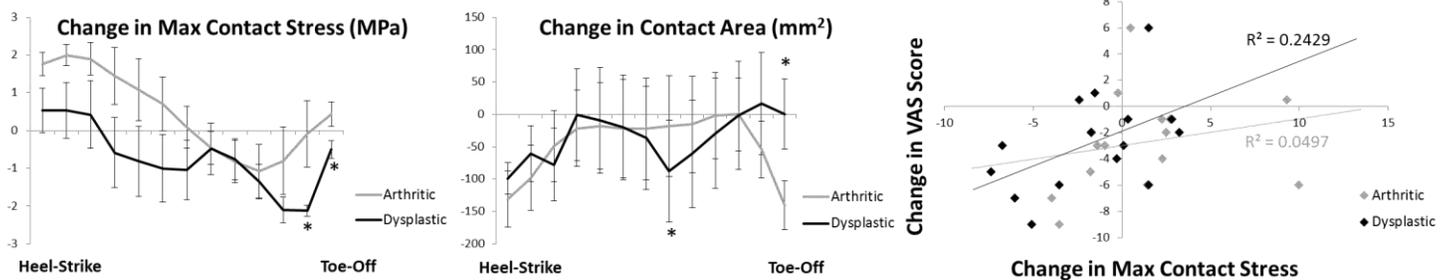

This work will assist in understanding how pre- and post-operative joint contact mechanics relate to clinical outcomes in hip dysplasia patients, which will enable researchers to provide quantitative assistance to surgeons in order to improve these outcomes.

# KINEMATIC VARIABILITY AND LOCAL DYNAMIC STABILITY IN INDIVIDUALS WITH HIP DYSPLASIA

Kari L. Loverro, MS, Anne Khuu, and Cara L. Lewis, PT, PhD

College of Health & Rehabilitation Sciences: Sargent College, Boston University, Boston, MA, USA

email: kloverro@bu.edu, web: <http://sites.bu.edu/movement/>

## INTRODUCTION

We previously reported that individuals with hip dysplasia had increased variability in gait kinematics of the hip and pelvis when constrained to a specific walking speed compared to healthy controls [1]. We speculated that the increased variability may indicate a local (hip joint) adaptation to alleviate pain or a lack of neuromotor control. Recently, the use of nonlinear measures to quantify stability of pathological gait has increased due to the ease with which data can be collected [2]. Local dynamic stability measures use nonlinear time series analysis to examine the (in)stability of a system (i.e. a person walking) as it responds to perturbations. Small or large perturbations are recorded as variations in locomotion patterns and can introduce variability into the system [3]. Pain or lack of neuromotor control may produce small perturbations that decrease the dynamic stability of gait.

The purpose of this study was to investigate kinematic variability and local dynamic stability in individuals with hip dysplasia and in healthy controls, and test for differences with walking speed.

## METHODS

Fifteen individuals with either unilateral or bilateral hip pain and dysplasia diagnosed by a physician (14 Female, 1 Male; age  $25.4 \pm 6.0$  yrs; height  $1.64 \pm 0.05$  m; mass  $63.93 \pm 9.82$  kg; UCLA activity score  $7.9 \pm 2.4$ ) participated in the current study. For comparison, 15 healthy individuals also participated in the current research. Healthy participants were one-to-one matched for sex, age, height, mass, and activity score (14 Female, 1 Male; age  $22.3 \pm 3.3$  yrs; height  $1.64 \pm 0.07$  m; mass  $61.94 \pm 7.14$  kg; UCLA activity score  $7.9 \pm 1.9$ ). All participants provided written informed consent.

Participants completed two minutes of walking at three speeds: 1) their preferred (PRF) speed, 2) a prescribed speed (PRSC: 1.25 m/s), and 3) a speed 1.25 times faster (FAST) than PRF. While walking participants were asked to verbally rate their pain on an 11-point (0: no pain-10: extreme pain) numeric rating scale every 30 sec. All healthy controls reported no pain during walking trials, while all individuals with dysplasia reported pain during at least one walking trial.

Kinematic data were collected using a motion capture system (VICON®) while walking on a split-belt instrumented treadmill (Bertec®) to allow for continuous collection of gait. Visual3D (C-Motion, Inc.) was used to measure kinematics of the ankle, knee, and hip joint angles and pelvic and trunk segment angles for every stride of each trial. For each stride, joint and segment angles were time normalized to the gait cycle and exported for the kinematic variability analysis. Filtered velocity data of a marker placed at C7 were exported for the nonlinear analysis.

A custom MATLAB (The MathWorks, Inc.) program was used to determine the minimum number of strides completed across all participants and speeds (95 strides) and calculate peak (min/max) angles for each joint and segment for all 95 strides in the trial. The within-subject mean standard deviation (meanSD) for each dependent variable (angles), for all speed conditions, was extracted for statistical analysis. An additional MATLAB program was used to resample each participant's filtered marker velocity data to ~100 samples per stride and calculate the maximum Lyapunov exponent ( $\lambda_{\max}$ ) of the marker velocity data in all directions of motion.

Kinematic variability was quantified by meanSD where larger values indicate greater variability and local dynamic stability was quantified by the

maximum Lyapunov exponent where smaller values indicate greater stability.

Separate Generalized Linear Models with Generalized Estimating Equation corrections were used to compare the dysplasia group and control group with speed as a within-subject factor and group-by-speed as an interaction factor (SPSS, IBM Inc.). For individuals with unilateral dysplasia, the dysplastic side was used for analysis. For individuals with bilateral dysplasia, the more painful side was analyzed. For controls, the side corresponding to their match was analyzed. Least significant difference post-hoc tests were performed if the factors were significant.

## RESULTS AND DISCUSSION

The results indicate that individuals with hip dysplasia have significantly greater kinematic variability (meanSD) than controls at the hip, pelvis, and trunk (Table 1,  $p \leq 0.035$ ). However, there was no significant difference in local dynamic stability ( $\lambda_{max}$ ) between groups (Table 2,  $p > 0.05$ ). Speed did affect both kinematic variability ( $p \leq 0.004$ ) and local dynamic stability ( $p \leq 0.002$ ). At the ankle and knee, kinematic variability at the PRF speed was significantly greater than at both the PRSC and the FAST speeds. Local dynamic stability in the anterior-posterior and medial-lateral directions was greatest ( $\lambda_{max}$  is the smallest) when participants were

walking at the FAST speed compared to the PRSC and PRF speeds.

## CONCLUSIONS

Increased kinematic variability was detected in individuals with hip dysplasia compared to healthy controls across all speeds, while differences in local dynamic stability were not detected between groups. Both measures detected speed differences. When walking at their PRF speed, participants were significantly more variable at the ankle and knee and significantly less stable at the system level compared to the FAST walking speed. This study indicates that kinematic variability measures and local dynamic stability measures may quantify different parameters depending on the level of analysis and should not be used interchangeably.

# Hip Strength and Hip Moments during Gait in Women with and without Stress Urinary Incontinence

<sup>1</sup> Erin H Hartigan, <sup>1</sup> Adrienne McAuley, <sup>1</sup> Mike Lawrence, <sup>1</sup> Willis Brucker,  
<sup>1</sup> Adam King, <sup>1</sup> Brooks Tryon, <sup>1</sup> Mary DeSilva

<sup>1</sup> The University of New England, Portland, ME, USA  
email: [ehartigan@une.edu](mailto:ehartigan@une.edu), web: <http://www.une.edu/wchp/mal>

## INTRODUCTION

Women with stress urinary incontinence (SUI) have reduced isometric hip abduction strength [1]. Strengthening deep hip external and internal rotators in sitting and hip external rotators in side-lying and standing reduces frequency of leaking in women with SUI [2, 3]. Hip muscles play an intricate role in controlling the lower extremity during the stance phase of gait [4], yet gait mechanics in women with SUI are not well understood. Profiles of muscle performance and gait at the hip of women with SUI in comparison to healthy, asymptomatic women will inform clinical practice.

We aimed to describe isometric hip strength and hip angles during gait in women with SUI and to compare values to asymptomatic women. We also explored relationships between hip strength and hip angles and moments, but present here are only preliminary results of the strength and kinematic gait analysis data.

## METHODS

The asymptomatic group (n=16) included women who were over 18 years old, had regular menses, no complaints of pain, no known neurological conditions, and no history of back, pelvic, or lower limb surgeries. The group with SUI (n=7) met the above criteria but reported urine leakage when coughing, sneezing, or exercising.

Testing: Over-ground gait data were collected using 3D cameras (Qualisys) and force plates with 6 degrees of freedom (AMTI). Gait speed was controlled at  $1.3 \text{ m/s} \pm 5\%$ . Data were processed using Visual 3D software (C-Motion). Peak hip angles for all three axes of motion were calculated during three phases of stance: weight acceptance [initial contact (IC) to peak knee flexion (PKF),

mid-stance (PKF to peak knee extension[PKE]), and terminal stance (PKE to toe off)]. Five gait trials were averaged for each limb (i.e. dominant and non-dominant). Maximum voluntary isometric contractions (MVIC) were obtained using a dynamometer (Biodex S4). Hip strength testing via MVICs included hip external rotation and internal rotation in sitting and prone and hip abduction in side-lying. Descriptive statistics [mean (standard deviations)] were calculated for each variable of interest. Limb symmetry indexes (LSI) were calculated as  $100 - (\text{Non-dominant/Dominant} \times 100)$  and defined as clinically different if 15% or greater. Mixed model ANOVAs (limb and group) were used to assess differences. (SPSS, IBM) Significance was set at  $p=.05$ .

## RESULTS

Women in the SUI group were significantly older than those asymptomatic women ( $p<.001$ : 36 (5.5) and 26 (4.2) years old, respectively). Number of pregnancies, BMI, and dominant limb did not differ between groups. Hip strength did not differ between groups, yet hip internal rotation strength in sitting was greater in the dominant limb than non-dominant limb for both group (Table 1). LSI were 18% for SUI and 6% for asymptomatic (i.e., 12.5 and 3.6 Nm/kg, respectively). Limb differences in peak hip internal rotation angles during gait were statistically (Table 2) and clinically different (67%; 5.4 degrees) in the SUI group only.

## DISCUSSION

Although women with SUI do not differ in hip strength, they use asymmetrical hip angles during gait compared to asymptomatic women. Others have reported that asymptomatic women with weak hip strength do not alter peak hip angles

during gait, but instead demonstrated different lower limb coordination patterns in the transverse plane during gait [4]. Gait kinematics in our SUI group present novel findings that hip angles during weight acceptance may be related to pelvic floor muscle dysfunction. Although analyses of hip kinetics and correlations have not been reported and the findings reported here bear further investigation in a larger study, it is possible that closed chain kinetic exercises may benefit women with SUI to restore neuromuscular hip control during the weight acceptance phase of gait.

## CONCLUSIONS

Asymmetrical peak hip internal rotation angles during weight acceptance indicate aberrant

neuromuscular control of the deep hip stabilizers among women with SUI.

# HIP LATERAL ROTATOR MUSCLE FORCE DURING VARIATIONS OF THE SINGLE LEG SQUAT

<sup>1</sup> Anne Khuu, <sup>1</sup> Kari L. Loverro, and <sup>1</sup> Cara L. Lewis

<sup>1</sup> College of Health & Rehabilitation Sciences: Sargent College, Boston University, Boston, MA, USA  
email: akhuu@bu.edu, web: <http://sites.bu.edu/movement/>

## INTRODUCTION

The deep lateral rotator muscles of the hip are key stabilizers of the joint [1]. The activity of these rotators, including the quadratus femoris, gemelli, and piriformis, cannot be measured using surface electromyography. Musculoskeletal modeling, however, can give estimations of the force required of these muscle during specific movement tasks.

We have previously demonstrated that the position of the non-stance leg during a single leg squat (SLS) task affects the kinematic and kinetics of the stance leg [2,3]. Variations of the SLS are commonly used in evaluation and treatment for individuals with lower extremity musculoskeletal conditions, but little information is available to direct the selection of the variation.

The purpose of this study was to evaluate hip angles, hip moments, and muscle force of the hip lateral rotators during the SLS with different non-stance leg positions.

## METHODS

Fifteen healthy individuals (8 females, 7 males; age  $22.1 \pm 3.0$  years; height  $1.73 \pm 0.11$  m; mass  $70.4 \pm 11.5$  kg) provided written informed consent and participated in this study. Participants performed 3 SLS tasks, which were differentiated by the position of the non-stance leg. For SLS-Front, the non-stance leg was extended out front during the squat. For SLS-Middle, the non-stance knee was slightly flexed with the non-stance foot adjacent to the stance ankle during the squat. For SLS-Back, the non-stance thigh was vertical and the non-stance knee was flexed  $90^\circ$  during the squat. For each task, participants started standing on both feet with their arms at or out to their sides, positioned their non-stance leg as instructed, squatted as low as possible while maintaining

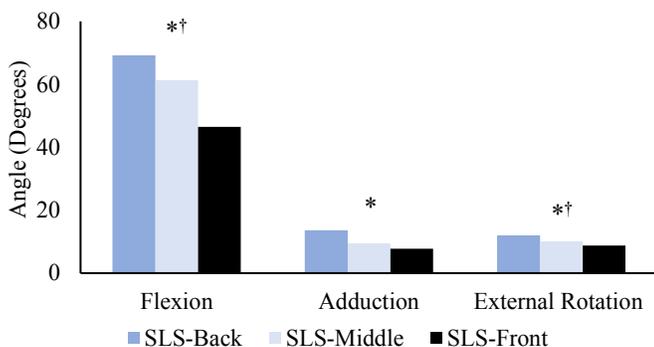

control, and returned to the starting position. Each task was performed 5 times on the right leg. Each performance was recorded as an individual trial. The order of the tasks was randomized. Kinematic data of the trunk, pelvis, and lower extremity were collected using a motion capture system (VICON®). Ground reaction force data were recorded using a split-belt instrumented treadmill (Bertec®). Kinematic and kinetic data were processed in Visual3D (C-Motion) to produce OpenSim compatible motion files. The generic OpenSim gait model (Gait2392) was scaled for each participant according to their height, mass, static calibration data, and segment geometry. In OpenSim, the residual reduction algorithm (RRA) was applied to the simulation. If needed, the RRA was re-run after the model was adjusted to meet the guidelines suggested in the OpenSim software documentation. Next, the computed muscle control algorithm was performed on the simulation to compute the muscle activation levels necessary to track the experimental data. Custom MATLAB code (The MathWorks, Inc.) was used to calculate the average muscle force during the descent phase (start of stance leg flexion to peak knee flexion) and ascent phase (peak knee flexion to returning to standing on both legs) of the gluteus medius (posterior), gluteus minimus (posterior), quadratus femoris, gemelli, and piriformis. In addition, average muscle force was calculated over the 100 ms period surrounding peak knee flexion for each muscle.

The 3D hip angles and moments at peak knee flexion were determined. The muscle force variables of interest were the average muscle force for each of the 5 muscles during the descent phase, the ascent phase, and over the 100 ms period surrounding peak knee flexion. Data were calculated from the first 3 SLS repetitions and averaged per task for analysis. For each variable, a separate one-way repeated measures analysis of variance (ANOVA) was used to test for differences between SLS tasks (SPSS). Least

significant difference post-hoc pairwise comparisons were performed if there was a significant main effect.

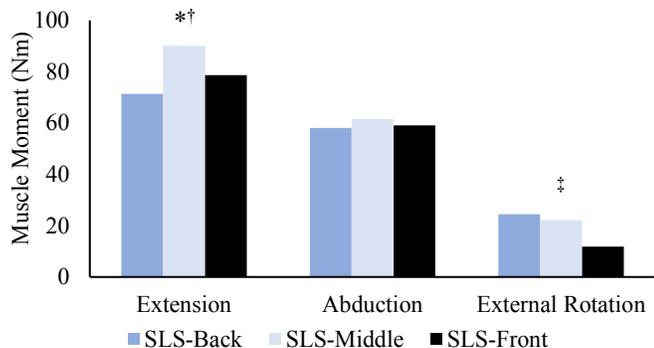

## RESULTS AND DISCUSSION

Performing the SLS with the non-stance leg in different positions affected hip angles and moments, and the force needed from the hip lateral rotator muscles. At peak knee flexion during the SLS-Back, the hip was in more flexion, adduction, and external rotation compared to the other two conditions ( $p \leq 0.04$ ) (Fig. 1). The hip was also in more flexion and external rotation in the SLS-Middle compared to the SLS-Front ( $p < 0.05$ ). In contrast, the hip extension moment at peak knee flexion in the SLS-Middle was larger than in the other two conditions ( $p \leq 0.01$ ), and SLS-Front was larger than SLS-Back ( $p = 0.02$ ) (Fig. 2). The external rotation moment was smaller in the SLS-Front compared to the other two conditions ( $p < 0.01$ ). There were no differences in hip abduction moment between conditions ( $p = 0.45$ ).

\*Significant difference between SLS-Back and other conditions.  
 †Significant difference between SLS-Middle and SLS-Front.

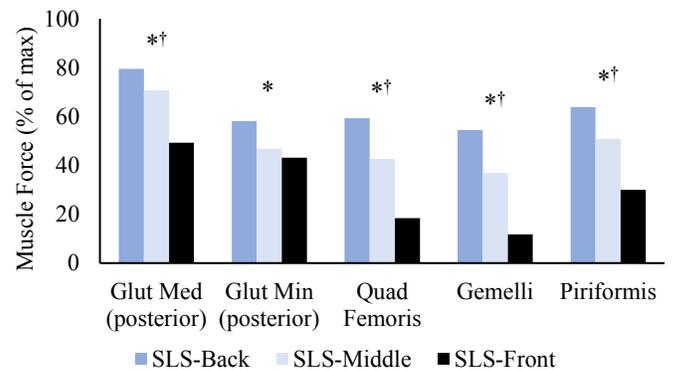

**Figure 1:** Hip angles at peak knee flexion during the single leg squat.

 †Significant difference between SLS-Back and SLS-Front.  
 ‡Significant difference between SLS-Front and other conditions.

**Figure 2:** Internal hip muscle moments at peak knee flexion during the single leg squat.

For all muscle force variables for each muscle assessed, the force in the SLS-Back was higher than in the SLS-Front ( $p \leq 0.02$ ) (Fig. 3). Only for the posterior gluteus minimus during the ascent phase was this difference not significant ( $p = 0.23$ ). The SLS-Middle tended to require higher lateral rotator muscle force than the SLS-Front, but this was not significant for the posterior gluteus minimus at peak knee flexion ( $p = 0.49$ ) or during ascent ( $p = 0.84$ ), and for the gemelli during descent ( $p = 0.05$ ).

\*Significant difference between SLS-Back and other conditions.  
 †Significant difference between SLS-Middle and SLS-Front.

**Figure 3:** Estimated muscle force in the epoch surrounding peak knee flexion.

## CONCLUSIONS

SLS-Front requires the least force from the deep hip lateral rotators. As the deep hip lateral rotators are key muscles for hip stability, we would not recommend this variation of the SLS for hip rehabilitation.

## INTRODUCTION

Femoroacetabular impingement (FAI), a structural abnormality of the hip joint, is a significant cause of hip pain and reduced function in younger active adults [1]. Evidence to support FAI as a principal determinant for the future development of hip osteoarthritis is mounting [2]. Yet, current treatments are suboptimal, likely in part due to the absence of experimental data regarding the physical impairments associated with symptomatic FAI. Hip muscle function in this condition has not been well defined. Initial evidence shows altered coordination of deep hip muscle activity in symptomatic FAI during walking [3], despite the generally pain-free nature of this task in FAI, as the hip joint does not move towards the impingement position (deep hip flexion, combined with hip adduction and internal rotation). Hip muscle activity during squatting, a task towards the impingement position, has not been investigated but may provide further insight into the neuromuscular adaptations of this patient population. This exploratory study aimed to investigate activation patterns of the hip muscles during a deep squat in individuals with and without symptomatic FAI.

## METHODS

Fifteen individuals with symptomatic FAI (clinical examination and imaging (alpha angle  $>55^\circ$  (cam FAI), and lateral centre edge angle  $>39^\circ$  and/or positive crossover sign (combined FAI))) and 14 age- and sex-comparable controls without morphological FAI on magnetic resonance imaging underwent testing. Intramuscular fine-wire and

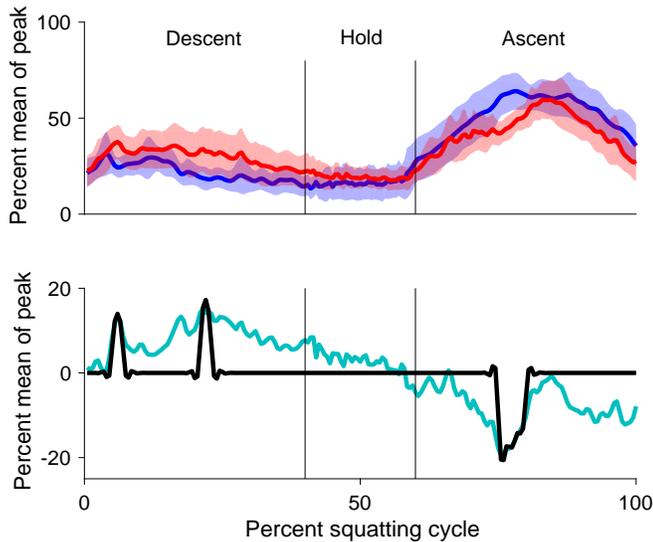

surface electrodes recorded electromyographic (EMG) activity of selected deep and superficial hip muscles during the squatting task. The tri-phase squat included: (i) descent from a standing position to the end of self-chosen available range; (ii) a 3-second hold; and (iii) ascent to the upright standing position. Participants were instructed to use their preferred strategy to squat as deeply as possible at a self-selected controlled pace. Individual muscle EMG patterns were normalized to the mean of the peaks of 5 repetitions, and were statistically compared between groups using a wavelet-based linear mixed effects model based on the technique of wavelet functional ANOVA (wfANOVA) [4]. Demographic and spatiotemporal variables were compared between groups using independent t-tests and Mann-Whitney U tests as required ( $p < 0.05$ ).

## RESULTS AND DISCUSSION

The FAI and control groups were comparable for age, sex, BMI, and dominant leg tested (Table 1). FAI patients reported an average pain score of 2 on an 11-point numerical rating scale after completing the squatting task (range 0-8). There were no between-group differences in leg-length normalized squat depth ( $p=0.12$ ) or ascent speed ( $p=0.11$ ), however, descent speed was significantly slower in the FAI group ( $p=0.05$ ).

During squat descent, FAI patients exhibited greater EMG activity of deep hip external rotator and extensor muscles (gluteus medius (GM), piriformis (PI, Figure 1), obturator internus (OI) and quadratus femoris (QF)) than controls. These muscles have mechanical actions that oppose impingement and

are likely to have an active role in hip joint stabilization. Greater activation may relate to the slower decent speed of FAI patients, and/or be a strategy to stabilize the joint and reduce provocation as the hip approaches deep flexion and impingement.

**Figure 1** Ensemble average ( $\pm 1.96 \cdot \text{SEM}$ ) EMG patterns from piriformis for control (blue) and FAI (red) participants over a squatting cycle (top). Average between-group difference (FAI-control; green), significant contrasts (black) (bottom).

During squat ascent, FAI patients exhibited lower EMG activity of deep hip external rotator and extensor muscles (GM, PI and OI) than controls. Gluteus maximus amplitude was also lower than controls during the initial 14% of ascent as FAI

patients moved out of deep hip flexion. Lower activation of these agonists may relate to pain inhibition.

The different squatting strategies exhibited by FAI patients may relate to enhanced protection for the hip, and be favorable for symptoms and function in the short-term. However, there could be long-term consequences if this leads to increased or abnormal joint loading, given that individuals with symptomatic FAI are at risk for further structural damage and early hip osteoarthritis [2].

## CONCLUSIONS

Deep hip muscle activation is altered during squatting in symptomatic FAI. Future studies should examine patients prospectively and post-operatively to establish whether treatments targeted at these features would be potentially beneficial.

## INTRODUCTION

Femoroacetabular impingement syndrome (FAIS) is a clinical hip disorder that is associated with aberrant hip joint morphology, which results in premature contact between the femur and acetabulum during hip joint motion. FAIS is characterized by anterior hip and groin pain during near end range motion, positive impingement testing, range of motion loss, and imaging findings that point at abnormal structural morphology [1]. FAIS also results in functional limitations while walking, deep squatting, and sitting [2]. Arthroscopic hip surgery for FAIS leads to very good to excellent results in patient reported outcomes; however, information on functional parameters such as gait biomechanics after surgery remains limited [3].

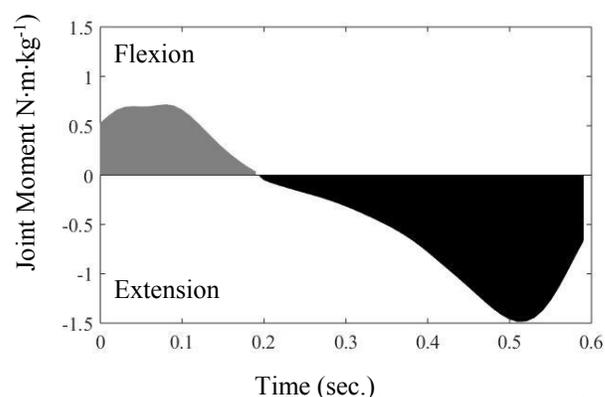

Previous biomechanical studies after hip surgery in people with FAIS show significant improvements in sagittal plane gait kinematics during walking, however, no post-operative improvements in hip joint kinetics were found in these patients [4]. Although arthroscopic hip surgery for FAIS improves patient reported outcomes, it remains unknown if hip joint loading also improves post-operatively. Therefore, the purpose of this study was to determine if sagittal plane joint loading changes after arthroscopic hip surgery for FAIS. It is hypothesized that sagittal plane loading will be greater after hip arthroscopic surgery in persons with FAIS.

## METHODS

Six male and 2 females, who underwent arthroscopic surgical intervention for FAIS, were enrolled in this study. Two patients underwent bilateral surgery for FAIS; therefore, 10 hips were included in the analysis. Hip joint kinetics were measured with 3D

motion analysis and force plates before and greater than one year after arthroscopic hip surgery ( $1.27 \pm .34$  years).

Five gait trials were collected with patients walking at a self-selected speed. Variables of interest were peak sagittal plane hip joint moments and hip joint impulse (Figure 1). Hip joint moments were calculated with inverse dynamics procedures during the stance phase of each walking trial. Joint moments were normalized to body mass ( $\text{N}\cdot\text{m}\cdot\text{kg}^{-1}$ ) and were expressed as external moments. Joint impulse was calculated as the product of the mean external joint moment and change in time during stance phase ( $\text{N}\cdot\text{m}\cdot\text{s}\cdot\text{kg}^{-1}$ ).

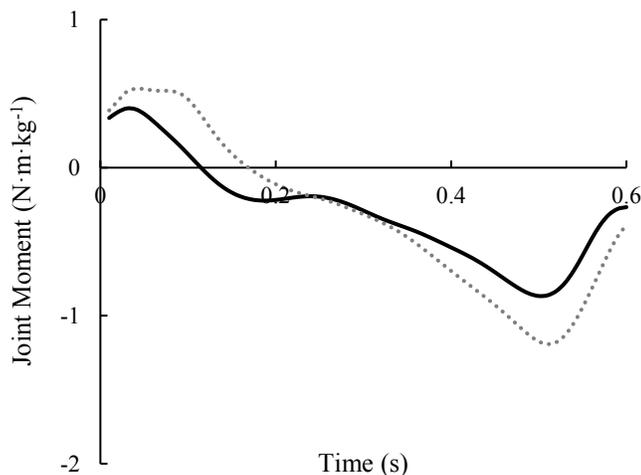

**Figure 1.** Example of hip joint moment during the stance phase of gait. Positive area (grey) indicates hip flexion impulse and negative area (black) indicates hip extension impulse.

An ensemble average of five trials was calculated for each variable of interest and used for analysis. Data are reported as mean  $\pm$  SD. Paired *t*-tests were used to compare pre-operative and post-operative data with an *a priori*  $\alpha$ -level of 0.05.

## RESULTS

The hip flexion and extension impulse during the stance phase of walking were significantly greater after hip arthroscopic surgery (Table 1). Conversely, there were no differences in peak hip flexion and extension moments (Table 1). Moreover, there were no differences in gait speed (Pre:  $1.37 \pm 0.12 \text{ m}\cdot\text{s}^{-1}$ ; Post:  $1.35 \pm 0.06 \text{ m}\cdot\text{s}^{-1}$ ;  $p = 0.641$ ), flexion impulse stance duration (Pre:  $0.18 \pm 0.06 \text{ s}$ ; Post:  $0.17 \pm 0.05 \text{ s}$ ;  $p = 0.585$ ), and extension impulse stance duration (Pre:  $0.49 \pm 0.08 \text{ s}$ ; Post:  $0.50 \pm 0.05 \text{ s}$ ;  $p = 0.389$ ) before and after arthroscopic hip surgery.

**Figure 2.** Exemplary joint moment curves for a single patient before (black solid line) and after (grey dotted line) hip surgery.

## DISCUSSION

The findings of the current study indicate that patients with FAIS demonstrate greater hip flexion and extension impulse after arthroscopic hip surgery. Since the peak joint moment and stance time did not

differ between pre- and post-operative gait testing, it appears that patients exhibit a higher average joint moment across the stance phase of gait. Perhaps reduced pain or improved muscle function may contribute to this greater sagittal plane joint loading during walking. Future research should investigate whether changes in muscle forces and pain could help explain the increase in joint impulse during gait after hip surgery for FAIS.

## CONCLUSION

Patients who underwent arthroscopic surgery for FAIS demonstrated greater peak flexion and extension joint impulse during the stance phase of gait than compared to before surgery. Patients may exhibit a greater average hip joint moment across the stance phase of gait because of a reduction in pain or improvement in muscle function after hip surgery for FAIS. More research is needed to investigate the exact mechanisms associated with the greater joint impulses after hip surgery.

# ENHANCING THE BIOMECHANICS CLASSROOM WITH ENTREPRENEURIAL-MINDSET LEARNING ACTIVITIES

<sup>1</sup> Karen L. Troy, <sup>2</sup> Laurel Kuxhaus

<sup>1</sup> Worcester Polytechnic Institute, Worcester, MA, USA

<sup>2</sup> Clarkson University, Potsdam, NY, USA

email: ktroy@wpi.edu

## INTRODUCTION

It is well-established that project- and problem-based learning engage students in the classroom. Biomechanics classes offer students the opportunity to build technical proficiency by applying mechanics principles to problems involving living organisms. In addition to this technical proficiency, mindset also matters. [1]

“Entrepreneurial Mindset Learning” (EML), as championed by the Kern Entrepreneurial Engineering Network, offers a framework for faculty to consider outcomes beyond technical proficiency, including stimulating curiosity, making connections, and creating value. These outcomes are synergistic with bioengineering education, which by nature must teach students about biocompatibility, ethical decision making, and other issues unique to working with humans and animals. Using the Entrepreneurial Mindset as a framework when developing course projects offers faculty a structure to enrich content and benefit students.

Here we describe the use of EML as a guide to enrich biomechanics class projects dealing with bone fracture. In each project, specific EML principles were identified with the goal of incorporation into a primarily technical project.

## METHODS

The authors systematically enhanced class projects with EML-inspired tasks. The technical nature of the projects was preserved and strengthened. Specific highlights are described.

**Project 1: Vertebral fracture project, “The Elevator Problem”.** (KLT at WPI, Spring 2017)

An earlier version was implemented by KLT at the University of Illinois at Chicago. This enhanced version emphasizes EML principles.

*Overall Summary of the Project:* Students were given an accident scenario in which an elevator malfunction resulted in injury to an occupant (“Mrs. Albert”). A year later, Mrs. Albert filed a lawsuit against the manufacturer, claiming that her recent

vertebral fracture was caused by the accident. The goal of the assignment was to write an expert opinion, supported with data, summarizing how likely it was that Mrs. Albert’s vertebral fracture was caused by the elevator accident. The EML-enhanced version of the project includes the “twist” in which half the students were “hired” by the elevator company’s attorney, while the other half were “hired” by Mrs. Albert’s attorney. All groups were competing for the attorney’s business, giving an incentive to produce coherent, thorough work.

Student groups are prompted in class to discuss mechanisms of injury, and to identify questions they must answer to determine whether Mrs. Albert had a case. Final reports must provide context, rationale, and citations for assumptions, and students are advised to consider upper and lower limits.

The EML-enhanced version includes additional contextual questions designed to encourage exploration of related material, such as: How much should Mrs. Albert sue for? How could this injury be prevented in the future, given that elevators are necessary? Learning will be evaluated through a structured self-assessment that prompts students to identify and reflect on specific aspects of the project that emphasize various EML principles.

*EML synergies and enhancements:* In addition to traditional engineering project goals of *performing analysis* and *validating* results, this project meets EML goals [2] in the following ways:

- Students must *evaluate the technical plausibility, economic and societal impacts* of both the accident and the lawsuit.
- To determine whether Mrs. Albert had a viable case, they *assess policy and regulatory issues*.
- Students understand vertebral structure and function, and the engineering design of elevator braking systems. This allowed them to *analyze their solutions* in a real-world context.
- By writing an expert opinion, students learn to *communicate their engineering analysis in terms of economic and societal benefits*.

## **Project 2: Cervine cancellous bone as an ex-vivo biomechanical model.** (LK at C.U., Fall 2016)

*Overall Summary of the Project:* Students (26) worked in groups of 3 to analyze the microstructural parameters of cervine vertebral cancellous bone, including trabecular thickness, trabecular number, bone volume fraction, and connectivity density. The overall research question posed was whether cervine vertebral cancellous bone was appropriate for use in biomechanical studies; this question remains unanswered in the literature.

Each group was assigned a unique aspect of the research question, such as age- or sex-differences between specimens. MicroCT scans of cervine lumbar vertebrae and rudimentary instructions for using ImageJ [3] and the BoneJ plugin were provided to students. Each group designed their own analysis and delivered a report, structured similar to a journal paper. These reports were peer reviewed in class. Students could revise their reports for additional credit.

To earn an “A” grade, students had to exceed the minimum requirements by completing additional analysis of their own design and compare to literature beyond that provided. Group report scores were scaled by the individual factor from the CATME peer-evaluation survey. [4]

*EML synergies and enhancements:* This particular project meets EML goals in these ways:

- Students considered the value of an ex-vivo model for laboratory research by *investigating the (research) market*, and *evaluating the societal benefits and sustainability* of ex-vivo animal models for biomechanical studies.
- Students developed curiosity about the use of cadaver specimens in research, and learned about relevant *policy and regulatory issues*.
- Students learned about *intellectual property* surrounding ImageJ.
- Students *communicated the societal benefits* of their conclusion in *economic terms* in reports.

## **RESULTS AND DISCUSSION**

Project #1 was originally implemented in a tissue biomechanics course over a four-week period, and received excellent feedback from students, who enjoyed the context, as well as “being forced to research” and think about their answers. The revised

version presented here includes two classroom periods of worktime, plus one classroom period for discussion of the final product.

Project #2 was implemented in an introductory biomechanics class. Informal observations noted a high degree of student engagement in and outside the classroom. While students initially appeared frustrated by the unconstrained nature of the project and by the gaps in their own knowledge, they displayed confidence in their results by the end, as evidenced by dialogue between groups about choice of methods and realism of results. Several indicated that the experience was meritorious of discussion with prospective employers.

Taken together, these biomechanics class projects provide examples of EML incorporation into otherwise straightforward technical analysis projects. These experiences can inspire students to build *connections* between their classroom experience and the real world, look *creatively* at problems, and *create value* through their work.

## **CONCLUSIONS**

The projects described here required relatively minor edits from previous instantiations to incorporate EML. It is important to note that EML is one framework that can be used to enhance student engagement in the classroom. Many elements of EML are synergistic with fundamental principles behind problem-based learning, flipped classrooms, and other contemporary pedagogical techniques. That is, incorporating elements of EML into existing classroom activities, such as projects, can add value and context to students with only a small effort from the instructor.

# ACTIVE LEARNING IN BIOMECHANICS USING WEARABLE SENSORS: A CASE STUDY FROM THE UNIVERSITY OF VERMONT

<sup>1</sup>Ryan S. McGinnis, <sup>1</sup>Ellen W. McGinnis

<sup>1</sup>University of Vermont, Burlington, VT, USA  
email: ryan.mcginis@uvm.edu

## INTRODUCTION

Recent work in engineering education suggests a shift in approach to focus on active engagement of students in the learning process. This approach, so called Active Learning, can include both classroom activities to improve student engagement during lecture, and course-level activities that employ Collaborative (emphasis on student interaction), Cooperative (incentives for student cooperation rather than competition), and/or Problem-Based (student-relevant problems used as motivation) learning approaches. Outcomes have been shown to improve student engagement, academic achievement, and critical thinking, interpersonal, teamwork, and life-long learning skills [1].

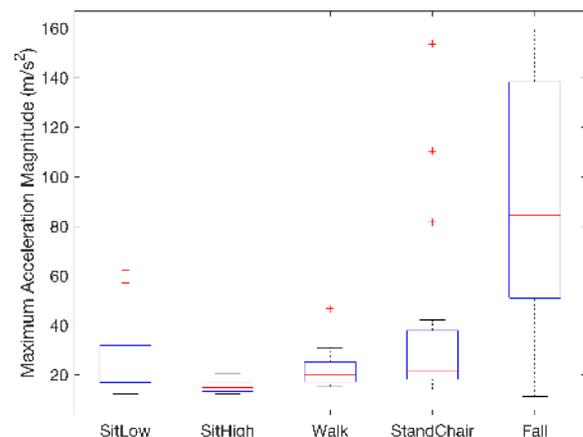

Wearable sensors provide a new, and rapid way to directly measure human motion and physiology outside of typical laboratory environments. Because of the ease with which data can be collected, these new devices provide a unique opportunity for developing research methods courses that employ active learning strategies in biomechanics and biomedical signal processing. In so doing students gain valuable experience designing and conducting experiments that use wearable sensors for measuring human motion and physiology, and communicating their findings through written technical reports and oral presentations. This abstract describes our first effort at creating such a course, BME296 – Wearable Sensing in Biomechanics, at the University of Vermont, and details our experience and preliminary outcomes.

## METHODS

To develop this course, we begin with defining goals for student learning. Specifically, we aimed for students to leave the course with experience:

- Reading and discussing primary articles
- Working in groups on biomedical research
- Conducting research with human subjects
- Processing data from wearable sensors to address specific biomechanical hypotheses
- Presenting scientific findings via written and oral communication

The course begins with four units designed to introduce students to typical uses for wearable sensors in research and commercial settings. These include: postural stability assessment [2], fall detection [3] (see Fig. 1), and two units on gait analysis [4, 5].

**Figure 1:** Student-designed fall detection experiment performed in BME296. Box plot illustrates quantitative difference between typical Activities of Daily Living and falling.

For each unit, a group of four-six students is responsible for leading discussion on a primary source article, designing and conducting an experiment to replicate the results presented in the article, and facilitating a debrief about the replication experiment including discussion of how the experimental or data analysis methods could be improved in the future.

For each unit, each student is responsible for completing a written summary of the primary source article, developing the method for processing the wearable sensor data described in the article, and using the method to answer a series of data analysis questions. After completing the first two units, students are responsible for writing a formal research report describing the findings from one of the experiments.

The course builds to a final group project that uses data collected from wearable sensors during student-designed experiments to address a hypothesis proposed by each group. For example, one group is currently investigating an old Spanish adage that people with larger feet are more stable. Findings from this project are shared with the instructor and class through written and oral reports.

To enable this course structure, we employ a new wearable sensor system, the BioStampRC (MC10, Inc., Lexington, MA USA – Fig. 2). The BioStampRC system is composed of the skin-worn, conformal BioStamp sensors that provide direct measurement of human motion and biopotentials (e.g., sEMG, ECG), a mobile application for enabling sensor data collection and uploading data from the sensors to cloud storage, and a web application for configuring sensors and downloading data.

**Figure 2:** BioStamp wearable sensor is adhered to the skin, and enables direct sensing of human motion and biopotentials (e.g. sEMG, ECG).

## RESULTS AND DISCUSSION

This elective course is part of a new undergraduate program in Biomedical Engineering at the University of Vermont, and is being offered for the first time during the Spring 2017 semester to 24 upper-level engineering students in Electrical, Biomedical, and Mechanical Engineering. The course is well received by students, with one student noting in midterm evaluations that the course is “showing us better than all of my other classes what a career in BME research might be like.” Moreover, it is providing unique opportunities for student achievement where, one experiment has already resulted in a conference abstract describing the results [6].

However, it is important to note that this teaching approach is not without its challenges. Students accustomed to courses that apply more passive learning approaches often find the transition to active learning difficult. This alternative course structure requires more significant engagement during class, and investigation of problems that do not have clear answers during assignments. The self-directed learning required for successful completion of these assignments can initially be anxiety inducing for some students. However, it can be especially helpful to be transparent and explicit with students about the benefits of this Active Learning approach, and the relevance of the skills that they are learning to their future careers in all areas of engineering.

# TEACHING UNDERGRADUATE BIOMECHANICS TO STUDENTS WITH DIVERSE ABILITIES

<sup>1</sup>Melissa Thompson

<sup>1</sup>Fort Lewis College, Durango, CO, USA

email: [mathompson@fortlewis.edu](mailto:mathompson@fortlewis.edu) web: [www.fortlewis.edu/exercise-science](http://www.fortlewis.edu/exercise-science)

## INTRODUCTION

Biomechanics courses are taught at both the graduate and undergraduate level and in a variety of schools and programs, including clinical specialties such as physical and occupational therapy, as well as biomedical engineering, biology, kinesiology, exercise science and other programs. Frequently these academic programs present situations in which students have diverse backgrounds in terms of prerequisite knowledge and abilities. Teaching biomechanics to a mixed-ability classroom creates a challenging environment in which the instructor must engage students while maintaining high standards of learning. The ability of an instructor to adapt instruction to meet students' varied learning needs is essential for fostering a positive learning environment in a classroom of varied abilities [1]. Here I describe teaching techniques utilized in undergraduate biomechanics courses in order to enhance learning for students with diverse abilities.

## METHODS

Data was gathered over the course of four years in which multiple undergraduate courses were taught at a small public liberal-arts college. The majority of students were majors from the Exercise Science Department in the degree options of Exercise Physiology and Exercise Specialist. Additionally, each term there were several students from outside the Exercise Science Department, who were primarily majoring in public health, biology and engineering. While the majority of students were exercise sciences majors, there were considerable differences in abilities of students both within and across degree options. For example, the Exercise Physiology option is described as pre-professional training and requires students to take prerequisite math and physics courses. Most students that pursue this major are seeking careers in health care fields,

such as physical and occupational therapy, and graduate school careers. Alternatively, the Exercise Specialist option has no math or physics prerequisites and is aimed at careers in the fitness industry.

Over the four-year period several different teaching techniques were utilized. Data gathered included quantitative scores on specific assignments and exams, as well as overall course grades. Additionally, qualitative student assessments and student feedback were utilized to address the effectiveness of the different teaching modalities.

The selection of different teaching techniques was based on the following questions:

1. How can student ability levels be identified and accommodated?
2. What did students ultimately need to take away from the course?
3. How could content be adapted to engage students of different abilities?

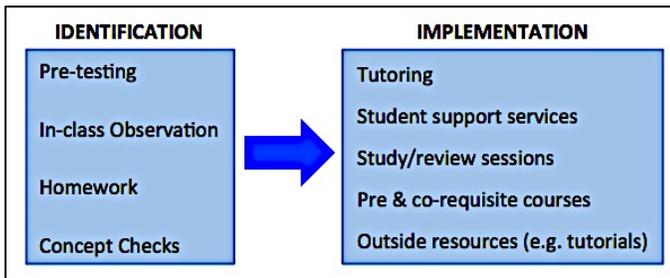

## RESULTS AND DISCUSSION

1. How can student ability levels be identified and accommodated?

An essential first step at being able to teach to a mixed-ability class is to identify student ability levels. Subsequent to this was implementing strategies to address the varied abilities, and in particular offering support for students with deficiencies (Fig 1).

Additionally, the flipped classroom model [2] was utilized as it had a primary benefit of enabling the instructor to identify ability levels and deficiencies in the classroom. Within the flipped classroom model, cooperative learning strategies were employed in which small groups of students with

different ability levels worked together to improve their understanding of specific biomechanics topics or to solve biomechanics problems. These cooperative learning strategies required each member of the team to be responsible for learning all aspects of the topic or problem, as well as being responsible for helping their teammates learn [3].

**Figure 1:** Strategies to identify and address student deficiencies.

2. What did students ultimately need to take away from the course?

In the process of determining what students needed to take away from the course I developed what I termed the “barbell framework” in which the majority of the “weight” or focus of the course was content and application, with calculations being an important, but not wholly essential, bridge between these primary concepts (Fig. 2).

**Figure 2:** The barbell framework for undergraduate biomechanics instruction.

Utilizing this approach allowed students to develop an understanding of biomechanical concepts without the risk of losing students who struggled with the computational aspects of the course. With a solid understanding of biomechanical concepts students were better prepared for, and found considerably more meaning in, calculations. The secondary focus of this framework was application

of course concepts, which was essential for demonstrating relevance and significance of the course content.

3. How could content be adapted to engage students of different abilities?

It was determined that a valuable technique for engaging students with varied abilities when covering a variety of different biomechanical topics, was to have students generate ideas for both application and analysis. In this regard, particular emphasis was made to have students apply course content to their career goals and interests. Further, it was also found to be very effective to get to know students and address their particular interests, and to have students share their backgrounds and experiences in an effort to enhance learning.

## CONCLUSIONS

Each student differs in his or her background knowledge, learning style and interests, thereby, presenting a unique opportunity to teach to. Being able to address individual differences and contribute to a student’s intellectual growth is a gratifying experience. When students are involved, explaining, solving, talking, trying, working, and struggling they not only retain information they learn how to ask thoughtful questions, critique information and sharpen their critical thinking skills.

### **INTRODUCTION**

The American Society of Biomechanics Teaching Repository was first introduced during the 40<sup>th</sup> Annual Meeting of the American Society of Biomechanics.<sup>1</sup> The Teaching Repository is an on-line resource for individuals interested in biomechanics education at all levels to find – and share – lessons, assignments, labs, resources and more. During this session, we will provide a short tutorial of the Teaching Repository, highlighting how to find information and contribute information. Attendees may wish to follow along on their mobile device or computer. Time will also be provided to get your questions answered and to share your suggestions for an improved repository experience (especially for those experienced users).

## INTRODUCTION

*“A paradigm shift is taking hold in American higher education. In its briefest form, the paradigm that has governed our colleges is this: A college is an institution that exists to provide instruction. Subtly but profoundly we are shifting to a new paradigm: A college is an institution that exists to produce learning. This shift changes everything. It is both needed and wanted.”* [1, p. 13]

The scholarship of teaching and learning (SoTL) is a process of applying a scholarly lens to what happens in the classroom [2]. Teaching, learning, and research are synthesized by asking meaningful questions about how students learn and what teaching activities best facilitate their learning [2]. Evidence of thinking and learning is systematically analyzed and the results are used to contribute to a body of knowledge aimed at improving students learning and strengthening teaching practices [2].

In this session, key concepts related to conducting SoTL research will be presented. Topics discussed will include getting started, ethical considerations, design, evidence, best practices, and dissemination of findings. Resources will be made available in the ASB Teaching Repository.

## INTRODUCTION

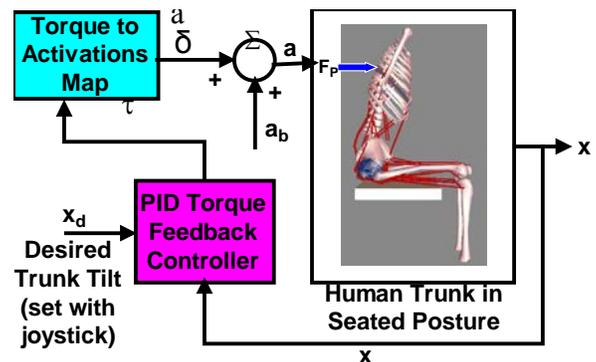

Spinal cord injury (SCI) is a debilitating condition that results in loss of function due to paralysis of muscles of the trunk, legs or upper extremities. Functional Neuromuscular Stimulation (FNS) is a technology that can be used to restore the activity of muscles paralyzed by SCI. This is achieved by applying low-level electric currents to the peripheral motor nerves so as to elicit contractions of the paralyzed muscles and thus restore some or all of the natural movements that were lost. In a survey of individuals with SCI, trunk stability has been ranked third in order of priority by individuals with paraplegia as well as those with quadriplegia [1]. Without trunk control, individuals with SCI have to maintain balance while seated either by holding onto fixed objects with their upper extremities or by using restraints such as belts and straps to keep them constrained to the wheelchair. This greatly limits the workspace that they can explore while seated and reduces their ability to independently perform many activities of daily living (ADLs) and function in typical work environments requiring use of both upper extremities.

The main goal of this study was to use musculoskeletal models to design and test feedback control systems that will stabilize the trunk at erect and non-erect postures so as to expand the seated workspace for individuals with SCI.

## METHODS

A musculoskeletal model of the trunk, pelvis and hips was developed to match the anthropometric characteristics of an individual with SCI (C7 AIS B). The subject had FNS implanted electrodes targeting the core trunk and hip musculature: Erector Spinae, Gluteus Maximus, Hamstrings and Iliopsoas. In simulations with the musculoskeletal model as well as in actual experiments with the subject, it was determined that maximally activating the Erector Spinae muscles

from a forward leaning posture could restore the trunk to an erect posture [2]. To keep the trunk at a forward leaning posture stably for longer periods, a PID feedback controller was designed to modulate the stimulation levels to the hip and back muscles (Figure 1).

**Figure 1:** Feedback control system for maintaining forward-leaning trunk posture.

In the model, the PID controller was designed on the basis of changes in joint moments at the hips and lumbar back. Changes in trunk tilt  $x$  away from the desired value  $x_d$  caused changes in the feedforward (inverse dynamics) torques at the hips and lumbar joints so as to maintain the trunk at the desired value. The changes in torques were fed to a map that had been developed to convert the torques to corresponding changes in muscle activation levels. These were then fed to the FNS neuroprosthesis control unit to apply to the individual muscles.

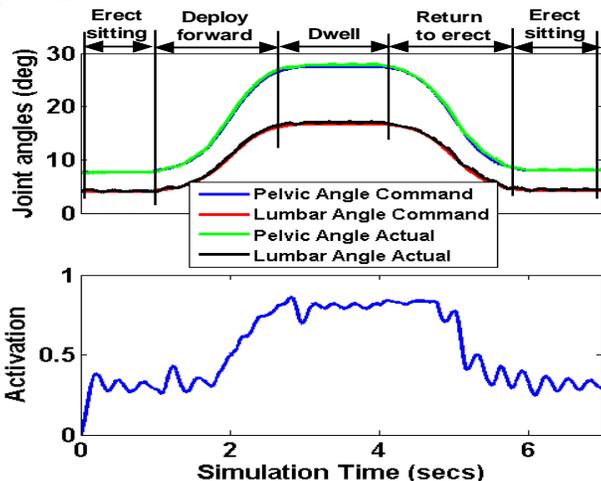

To test the controller with a live subject with SCI, the setup depicted in Figure 3(a) and (b) was used. In this setup a wireless sensor consisting of an accelerometer was taped to the chest close to the clavicle and used to measure trunk tilt.

While sitting quietly in her wheelchair with a chest strap attached to the measurement head of a robotic dynamometer, the subject was instructed to use voluntary upper extremity effort to lean forward to an intermediate trunk position, and then release

her arms so that the forward flexed posture was supported completely by the dynamometer. Activation to the back and hip extensor muscles was then increased until the force exerted on the dynamometer head was reduced to zero. This represented the nominal stimulation required to maintain the trunk in the new, non-erect set-point. After returning to upright sitting with voluntary effort, the rope and chest strap were removed and the subject was again instructed to lean forward to the earlier forward flexed position, at which time the feedback controller was activated. When the subject released her arms, stimulation was modulated about the previously determined set-point values to maintain the new posture.

## RESULTS AND DISCUSSION

Typical responses of the model simulations for a movement of the trunk from erect to a forward posture and return are depicted in Figure 2. Figure 3 shows the plot of the trunk tilt as well as changes in muscle activation to keep the trunk at the desired posture.

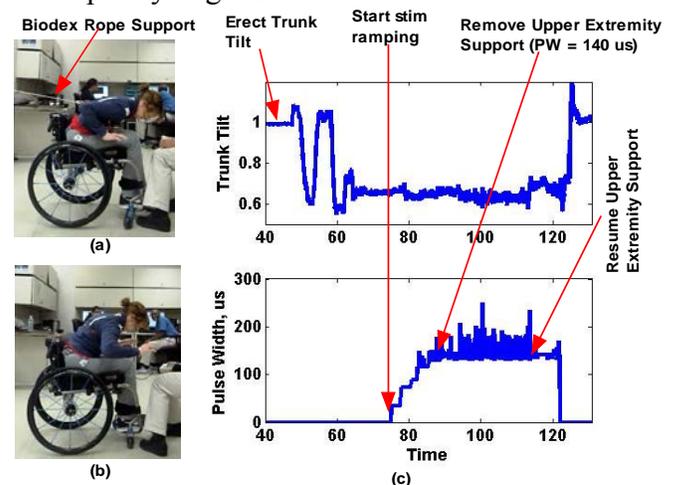

**Figure 2** Simulated Trunk Controller Operation. Top: Pelvic (blue) and lumbar (red) trajectories representing desired trunk movement, and output angles (green, black) achieved by the controller. Bottom: Activation of the *Erector Spinae* specified by the controller.

As shown in Figure 2, muscle activity was primarily required during the dwell phase of the maneuver while the trunk was maintained at the new flexed posture. This confirmed that with suitable choice of stimulus, it is possible to deploy and maintain the trunk at a posture away from erect. From Figure 3(c), as trunk tilt deviated from the

desired value, the controller either increased or decreased stimulation to keep the trunk as close as possible to the original flexed position for upwards of 10 seconds. This would sufficient time for some basic ADLs such as acquiring objects at distances beyond reach while sitting erect.

## CONCLUSIONS

The feasibility of maintaining seated posture in the coronal plane with trunk tilt angles up to  $60^{\circ}$  from erect and for periods up to 10s was established. This exploratory study indicates that the design of FNS systems for maintaining and deploying the trunk at various postures from erect is possible and worth pursuing as an alternative rehabilitation system for individuals with SCI and other paralyzing disorders.

**Figure 3:** Preliminary testing of controller for maintaining trunk at desired forward tilt. (a) SCI subject (C7 AIS B) leaning forward with hands-free while stimulation to the hip and trunk muscles were adjusted to eliminate tension on an instrumented support rope; (b) subject supported at the non-erect set-point by her own stimulated muscles; (c) changes in trunk angle and muscle stimulus for a typical trial.

## INTRODUCTION

Induced Acceleration Analysis (IAA) estimates how muscles facilitate movement by supporting the center of mass (COM) against the force of gravity and contributing to the progression of the COM in the direction of movement [1]. Prior IAA studies provide an important baseline of how healthy adults' muscles facilitate motion during activities of daily living (ADLs) [2, 3]. However, the underlying elements of IAA describing the mechanisms by which muscle forces contribute to movement are complex and not fully understood. While muscle force greatly impacts IAA, kinematics influence these forces, as well as muscle moment arms and contributions to movement. This kinematic component of IAA is important, as it has been suggested that for patients to utilize strength gains from rehabilitation, kinematic retraining may be necessary to reprogram the motor pattern [4]. However, existing methods for estimating muscle contributions to movement require extensive time and experimental resources, making patient specific-IAA impractical in a clinical setting. Thus, the purpose of this study was to develop an efficient method for determining how kinematics impact muscle potentials to contribute to ADLs. We present a case-study comparing the effects of kinematics on muscle support potentials in end-stage knee osteoarthritis (KOA) patients and young adults (YA) during the sit-to-stand transfer (STS).

## METHODS

We created a four link sagittal plane (2D; Fig. 1) model with four revolute joints at the origin (contact point between foot and ground), ankle, knee, and hip. Four generalized coordinates ( $\theta_{0-3}$ ) define the models' degrees of freedom. Link masses ( $m_i$ ), lengths ( $L_i$ ), COM positions ( $r_i$ ), and moments of inertia ( $I_i$ ) came from a generic musculoskeletal (MS) model [5]. From Lagrangian dynamics, the equations of motion of the 2D model are given by,

$$[M]\ddot{\theta} = G(\theta) + V(\theta, \dot{\theta}) + S(\theta, \dot{\theta}) + [R]f \quad (\text{Eq. 1}),$$

where  $M$  is the mass matrix,  $\theta$  are the generalized coordinates,  $G$  is the gravitational force,  $V$  is the force due to Coriolis and centrifugal effects,  $S$  accounts for intersegmental forces, and  $f$  contains the muscle forces transformed to a generalized force by  $R$ , containing muscle moment arms. The acceleration solely due to muscle forces can be calculated as

$$\ddot{q}_m = [M]^{-1}[R]f_m \quad (\text{Eq. 2}).$$

A muscle's *potential* to accelerate the body's COM is a muscle's contribution to acceleration per Newton of force ( $\ddot{q}_m [f_m]^{-1}$ ), calculated as

$$\text{Potential} = [M]^{-1}[R] \quad (\text{Eq. 3}).$$

The mass matrix of the 2D model was derived using the linear and angular contributions to the kinetic energy of each of the links in the system [6]:

$$M = \sum_{i=1}^4 (m_i \times J_{vi}^T \times J_{vi}) + (J_{oi}^T \times I_i \times J_{oi}) \quad (\text{Eq. 4}).$$

To obtain muscle moment arms for a given kinematic state, the 2D model's generalized coordinates were transformed to the coordinate definitions of the ankle, knee, hip, and lumbar flexion in the MS model. Pelvic tilt angle was also included in the coordinate transformation as it alters hip and lumbar flexion angles, affecting moment arms and potentials of muscles crossing those joints.

Support potentials of 23 muscles were calculated for 7,824 kinematic states that could be observed in the STS momentum transfer phase [3], when the task of supporting the body is transferred from the seat to the muscles. The muscle potentials predicted by the presented (new) method were verified by potentials estimated using experimental 3D motion capture, modeling, and simulation (traditional) methods [7].

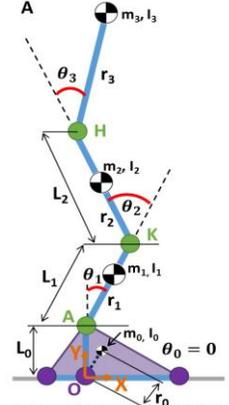

Fig. 1: Four link 2D model. Four revolute joints are at the origin (contact point between foot and ground, O) ankle (A), knee (K), and hip (H). For the STST,  $\theta_0 = 0^\circ$ .

## RESULTS AND DISCUSSION

The new method calculated muscle potentials for a single state in 6-10s using sagittal plane joint angles. The typical frame rate of a video camera commonly used in a clinical setting to capture 2D joint angles is 60 frames (or states) per second and the average STS trial takes 1 second to complete; thus, muscle potentials could be calculated for an entire trial in 10 minutes or less.

Considering a KOA patient with confirmed quadriceps weakness, to maximize the potential of the quadriceps to contribute to support (and decrease the force requirement), the new method predicts that, in a neutral pelvis position, the rectus femoris works with gravity to accelerate the COM downward, but with increasing anterior pelvic tilt the rectus femoris has increasing potential for support (Fig. 2). The new method also predicts the vasti and soleus support potentials would increase slightly with increasing anterior pelvic tilt; however, gluteus maximus potential decreases with increasing anterior pelvic tilt. To maximize the support potential of gluteus maximus, the new method suggests positioning the feet further underneath the COM and increasing lumbar flexion.

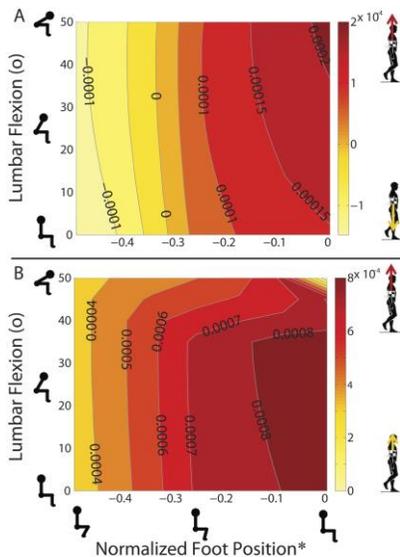

Fig. 2: Rectus femoris support potential at a range of kinematic states for A) 15° and B) 30° anterior pelvic tilt. \*Foot position normalized to leg length.

The new method predicts actual kinematic adaptations used by KOA patients to complete the STS, as confirmed by traditional simulation methods [7], which often require at least 4-6 hours to obtain IAA results for a single trial. During the STS, KOA patients had more rectus femoris support

potential than YA (Fig. 3) with greater anterior pelvic tilt (KOA:  $33.9^\circ \pm 14.0^\circ$  m/Ns<sup>2</sup> YA:  $15.2^\circ \pm 9.5^\circ$  m/Ns<sup>2</sup>) and a slightly more posterior foot position (normalized to leg length; KOA:  $-0.31 \pm 0.15$ ; YA:  $-0.29 \pm 0.11$ ) [7]. However, as

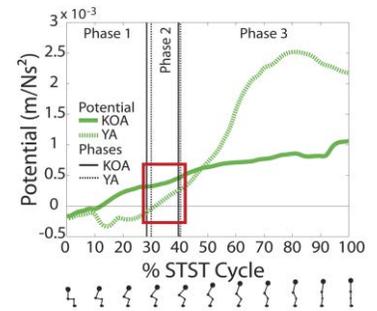

Fig. 3: Rectus femoris support potential produced by KOA patients and YA across one STS cycle [7]. The red box encompasses data from the momentum transfer phase (Phase 2).

predicted by the new method, the increased anterior pelvic tilt angle led to a smaller gluteus maximus support potential in KOA patients ( $0.0006 \pm 0.0003$  m/Ns<sup>2</sup>) than in YA ( $0.0017 \pm 0.0003$  m/Ns<sup>2</sup>). While the new method predicts the compensation strategies observed in the KOA patients, it also suggests additional strategies to further compensate for weakened quadriceps that could be targeted in rehabilitation. The KOA patients could improve overall muscle contributions to support by decreasing their anterior pelvic tilt by 5° and increasing lumbar flexion by 10° to double the gluteus maximus support potential without significantly reducing the rectus femoris potential.

## CONCLUSIONS

This study demonstrates an efficient method to systematically evaluate the effects of kinematic changes on muscle potentials, predict possible sources of pathologic movement, and identify rehabilitation strategies that leverage kinematics and muscle strength to improve mobility.

## INTRODUCTION

An important functional property of muscle is to provide stiffness for the limbs [1]. Joint and limb endpoint stiffnesses are critical to control limb posture, movement and interaction with the environment [1,2]. In general, stiffness produces instantaneous resistance to change in muscle length. Stiffness is known to be modulated muscle length (i.e., by joint angles) and muscle activation levels (i.e.  $\alpha$  drive) [3], but the mechanisms that produce them remain unclear.

Hill-type models are a class of normalized lumped-parameter models of muscle of varying complexities that can be scaled to approximate specific muscles. They estimate muscle force as functions of muscle architecture (physiological cross sectional area and pennation angle), kinematic state of muscle (length, and velocity) and the muscle activation level ( $\alpha$  drive) [4,5]. The goal of this project is to assess the ability of Hill-type models to produce muscle stiffness [6].

## METHODS

In this project, we studied versions of two popular Hill-type muscle models. The first model is a simple linear model consisting of series and parallel springs, a viscous element and a contractile element referred herein as the simple Hill-type model without force-length properties (or the Hill-type w/o fl) [4]. The contractile element converts the  $\alpha$  drive to active muscle force. This model, as presented, did not have force-length properties. Thus, we modified it by adding force-length properties to it (i.e., Hill-type w fl). The two-element Hill-type model incorporates two parallel active contractile elements for slow and fast muscle fibers (i.e., Two-Element model) [5]. Note that the active force-length

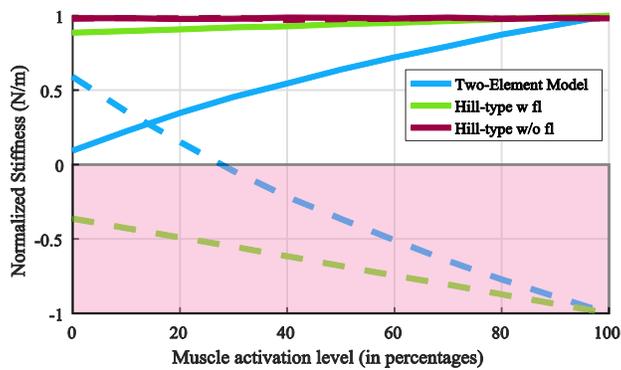

**Figure 1:** Stiffness as a function of muscle length.

properties of muscle (included in the contractile element) are not equivalent to the Hook's law stress-strain relationship. Rather, they represent the active force the muscle can produce at each length for a given activation level [7].

We estimated muscle stiffness in quasi-static condition by applying ten small displacements (of 2.5%  $L_0$ , where  $L_0$  is the optimal muscle length) with the muscle lengths set between 0.5  $L_0$  and 1.8  $L_0$  while the muscle was fully activated. We also calculated values of stiffness at two lengths (0.8 and 1.2  $L_0$ ) for  $\alpha$  drive ranging between 0 to 100 percent in steps of 1%.

## RESULTS AND DISCUSSION

Figure 1 shows stiffness for all models as a function of normalized muscle length. To make figures easier to compare, all figures are normalized to their maximum absolute value. Stiffness for the simple Hill-type model without force-length properties does not depend on muscle length (red). Stiffness varies as a function of muscle length for the other two models (blue and green). However, it becomes negative at some lengths. It is clear that the negative stiffness is not physically possible since it results in instability. Both of the two-Element and modified Hill-type

**Figure 2:** Stiffness as a function of muscle lengths equal to  $0.8 L_0$  (solid lines) and  $1.2 L_0$  (dashed lines).

models, however, show patterns similar to that reported in experiments in their non-negative regions [8]. Figure 2 shows the stiffness for all models as a function of muscle activation level at two representative muscle lengths ( $0.8, 1.2 L_0$ ). Once again, stiffness is *not* a function of muscle activation in the absence of force-length properties (red). Stiffness for the two-Element model *does* vary with the muscle activation level for the other two models in a length-dependent manner (blue and green). Interestingly, this change in the stiffness was consistent with the relative proportions of the derivatives of the active and passive parts of the force-length curve. i.e. the more the activation, the larger the weight of the active part. This result is expected considering that activation applies only to the active part of the force-length curve of muscle. As can be seen on the figures, the stiffness can be negative for both length dependent models (blue and green) when the muscle length is longer than  $L_0$ , which demonstrates that the models fail to replicate realistic muscle stiffness.

## CONCLUSIONS

Our results show the simplest Hill-type model fails to reproduce both muscle length and activation dependence of stiffness. The modified and two-element Hill-type muscle models produced stiffness dependence on muscle length and activation, but invariably produce negative stiffness at some muscle lengths, which is not physically realistic. Although force-length properties are very important in explaining stiffness [1,2], Hill-type models cannot

replicate realistic muscle stiffness even when including presence of force-length properties. Future work will explore if dynamic simulations (as opposed to this quasi-static version) and other extensions, such as the inclusion of force-velocity properties, can produce realistic muscle stiffness. If those efforts are unsuccessful, other models such as population-, fiber- and sarcomere-based—although more computationally complex—would need to be preferred.

# Modeling Stiffening in the Neck in Specified Directions Through Muscle Coactivation

Jonathan Mortensen, Andrew Merryweather

Department of Mechanical Engineering  
University of Utah  
Salt Lake City, UT, USA  
email: Jon.Mortensen@utah.edu

## INTRODUCTION

Neck muscles contract to generate stiffness in preparation for impacts to the head or trunk which alters head kinematics by decreasing maximum accelerations [1, 2]. During unanticipated impacts, or blindsides, the muscle reflex response alone is too slow to develop adequate stiffness. Our current understanding of the role neck stiffness plays in protecting the brain during impacts such as those experienced in popular collision sports is limited. This research aims to develop a musculoskeletal model of the neck to increase our understanding of how muscle contractions initiated with adequate timing prior to an impact affect rotational accelerations of the head.

Previous research modeled coactivation to solve for muscle activations in musculoskeletal models. Three widely used approaches are: maximizing total muscle force, maximizing total muscle activation, and maximizing muscle activation with a constraint of obtaining a certain stiffness level [3-5]. These approaches suggest the need for modeling subject awareness and coactivation. However, the ability to adjust muscle activations based on the direction of an impact is limited. The anatomy of the neck would suggest that it is unlikely that coactivation occurs the same way for all impacts. Our work adds two novel approaches to modeling coactivation that maximizes directional neck stiffness. This exploration of objective functions will allow improved model approximations for experimental data, which will give greater insights to how muscle contraction plays a role in protecting the brain during impacts.

## METHODS

Modifications to an existing model were made to enable the use of dynamic optimization tools in

OpenSim [6]. In order to make the model suitable for dynamic simulations, several modifications were necessary. First, muscles were mirrored across the sagittal plane to produce a more complete muscle set (total number of muscles in the model to 78). Second, values for mass and inertia were added for each solid body represented in the model (i.e. head and vertebrae). Third, joint stiffness caused by ligaments and other passive structures was incorporated. Data from Lee et al. (2006) provided mass and inertia values for each solid body and stiffness properties for each joint.

Muscle properties from the musculoskeletal model were passed into MATLAB, and a function was created to calculate moments generated about various degrees of freedom given muscle activations. Zero net moment was used as a constraint for the optimization problem to calculate muscle coactivation. The MATLAB function is described as:

$$M_k = \sum_{i=1}^{78} a_i f_i r_i$$

where  $M_k$  is the moment about degree of freedom  $k$ ,  $a_i$  is the activation of a single muscle,  $f_i$  is the maximum force a muscle can generate, and  $r_i$  is the moment arm of muscle  $i$  about degree of freedom  $k$ . Coactivation was calculated using objective functions of maximizing activation and maximizing force with the “fmincon” optimizer. This was done to provide a baseline for achieved stiffness with approaches from past research.

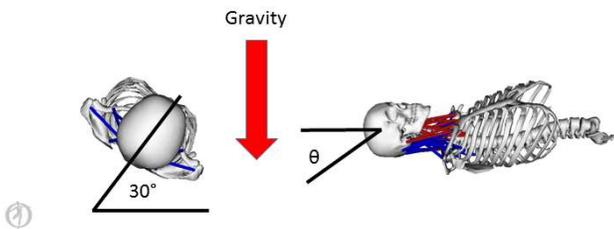

Maximizing Stiffness [MS] was achieved in MATLAB by first computing the stiffness each muscle contributes in a specified direction, and then optimizing for the greatest stiffness in that direction. Stiffness was computed by determining the change in muscle force as the head rotates one degree in a

specified direction. This approach allows for the computation of muscle activations that provide maximum stiffness in any direction.

The Push-Pull [PP] approach was performed using OpenSim's static optimization tool. Activations were computed that resist an applied force in a specified direction. Muscle activations were then computed to resist force in the opposite direction which resulted in stable coactivation.

A valid solution was determined when stability requirements satisfied values published in previous research that limit head rotation to 5 degrees or less in 100ms [3].

The computed muscle activations that produced stability were then tested for stiffness (Figure 1). This was done by rotating the model so that gravity acted in the direction of 30 degrees from the sagittal plane and then applying the muscle activations. Both approaches were performed with the specified direction being 30 and 60 degrees from the sagittal plane. Increased stiffness is manifest by decreased deviation of the head from the neutral position.

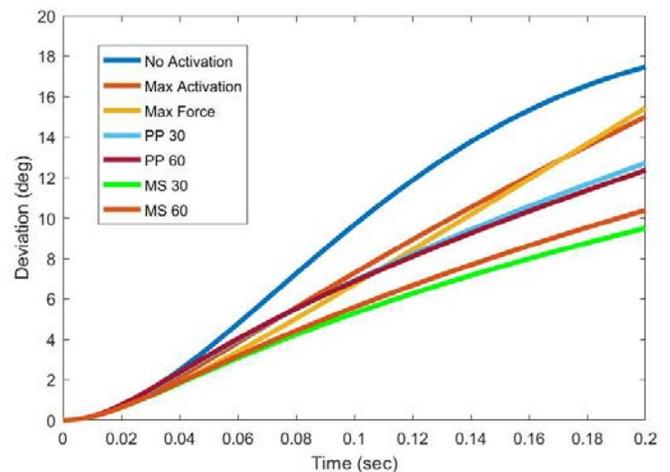

**Figure 1:** Depiction of Stiffness Testing

## RESULTS AND DISCUSSION

The new approaches used in this study were sufficiently stable. Both the MS and PP approaches for 30 and 60 degrees from the sagittal plane obtained higher stiffness levels than maximizing muscle force or muscle activation. The PP approach gave similar results for both the 30 and 60 degree solutions. The MS approaches gave the greatest stiffness of all, with the 30-degree solution being the stiffest.

This work highlights the differences in neck stiffness produced through coactivation to account for forces in off-sagittal-plane directions. This is something that is missing in previous research, but is important to understand the role of muscle contraction during

impacts. This work explored two approaches capable of simulating stiffening response to oblique forces. The MS approach shows particular promise, because it generates the highest stiffness levels achievable through coactivation of muscles alone. Combining this approach with additional constraints on muscle activation levels may be useful to better fit musculoskeletal model parameters to humans preparing for impacts to the head or torso. Future work is needed to confirm the biological significance of this work.

**Figure 2:** Head rotation for each simulation where smaller angles indicate higher stiffness

# A MECHANISTIC DAMAGE MODEL FOR LIGAMENTS

Jeff M. Barrett<sup>1</sup> & Jack P. Callaghan<sup>1</sup>

<sup>1</sup>Department of Kinesiology, University of Waterloo, Waterloo Ontario, Canada

email: jeffery.barrett@uwaterloo.ca

## INTRODUCTION

The cervical spine is vulnerable to acute injury and the development of chronic pain, often attributed to damage of soft tissues from loading [1]. Computational models of this region may be useful to gain insight into the loads placed on tissues in injurious situations; however, accurate models of tissues are required to ensure that they provide realistic force-deformation predictions.

Unfortunately, most models use phenomenological ligament models that neglect behaviour in the failure region [1]. Therefore, the purpose of this investigation was to test whether a mechanistic model of ligamentous tissue portrays behaviour representative of actual ligament failure and cyclic loading tests.

## METHODS

### *Model Description*

The model tracks the time-evolution of a population of collagen fibres ( $n$ ) in a theoretical ligament, distributed by the length they are stretched ( $x$ ), much like the renowned Huxley muscle model [3] (Equation 1). The initial distribution of collagen fibres is assumed to be normal with a mean  $\mu$  and standard deviation  $\sigma$ . Each collagen fibre is treated as a linear cable with stiffness  $k$  for force calculation (Equation 2). A breaking function describes how quickly collagen fibres will break if they are stretched by a given length, and was assumed to be a step-function.

$$\frac{\partial n}{\partial t} - v \frac{\partial n}{\partial x} = -B_0 \Theta(x - x_0) n(x, t) \quad (1)$$

I.C:

$$n(x, 0) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{(x - \mu)^2}{2\sigma^2}\right)$$
$$F(t) = \int_0^{\infty} kx n(x, t) dx \quad (2)$$

Here:  $n(x, t)$  = Collagen fibres stretched by  $x$  at time  $t$ .

$v$  = The shortening velocity

$\Theta(x)$  = The Heaviside step function

$B_0, x_0$  = Parameters which control how quickly fibres break and at which displacement

$\mu, \sigma$  = The mean and standard deviation of the initial collagen distribution

$k$  = The stiffness of each collagen fibre

### *Experimental Data*

The model was fitted to an experimental average force-elongation curve reported in [2] for the Anterior Longitudinal Ligament (ALL) using scipy's minimize function with five free parameters:  $\mu$ ,  $\sigma$ ,  $k$ ,  $B_0$ , and  $x_0$ . These curves were obtained by loading ligaments from young cadavers ( $n = 21$ ) to failure while measuring elongation and force with strain gauges and linear variable displacement transformers (LVDT) (Omegadyne Inc. Model LC412-500), with averaging across all specimens. The curves themselves are presented in [2].

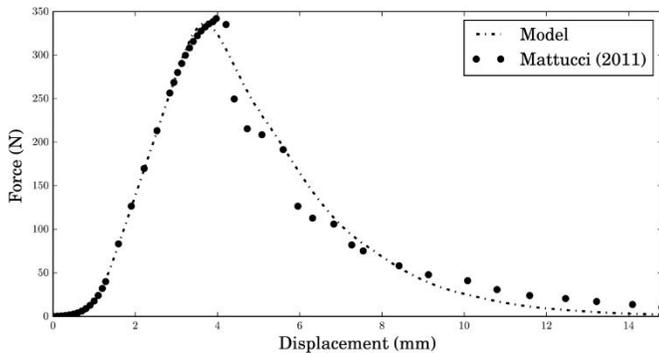

### *Cyclic Loading*

The fitted model was cyclically loaded to a displacement of 3 mm at 0.5 Hz in order to test if micro-traumas in the ligament model manifest as a plastic deformation.

## RESULTS AND DISCUSSION

### Fitted Model

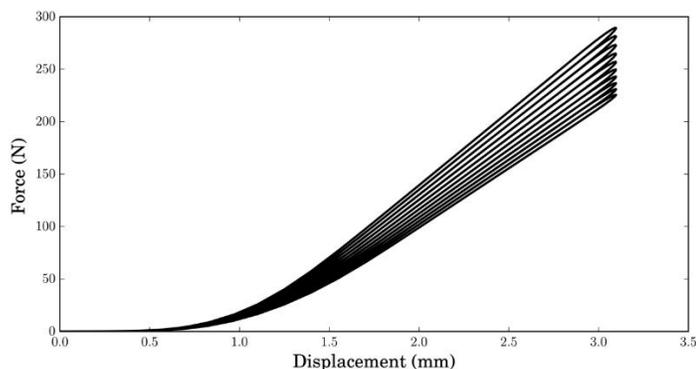

The model agreed very well with experimental data (Figure 1; parameters in Table 1), with a total RMS error of 14.23 N (1.67 N in the toe-region, and 15.697 N in the failure region), and an  $R^2$  of 0.994.

**Figure 1:** The model force-elongation curve versus that obtained from experiment.

### Cyclic Loading

There is a marked decrease in the force production of the ligament with cyclic loading accompanied by a 20% decrease in overall stiffness (Figure 2). Additionally, the ligament returns to a negligible force at a higher degree of strain, indicating plastic deformation of the resting position. With the absence of viscoelastic effects in the model, the observed hysteresis is entirely due to the destruction of collagen fibres.

**Figure 2:** Response of the ligament model to cyclic loading.

**Table 1:** Fitted Parameters derived from experimental data for the Anterior Longitudinal Ligament.

$B_0$ ( $s^{-1}$ )	$x_0$ (mm)	$\mu$ (mm)	$\sigma$ (mm)	$k$ (N/mm)
1.39	2.66	-0.985	0.2941	136.7

The presented model opens the doors for future macroscopic models to predict ligament injury, which may have far-reaching applications from ergonomic assessment, to sport, to the analysis of fringe impact scenarios. More theoretically, it amalgamates the study of ligaments and muscles, as it demonstrates that Huxley's equation can be used to model both tissues.

## CONCLUSIONS

This mechanistic model displayed behaviour reminiscent of true ligaments being strained to failure; featuring toe and failure regions that are consistent with the currently accepted mechanisms which govern their shape. Future work could incorporate viscous effects into the model, and validate it by comparing model predictions to other loading conditions.

In cyclic loading the model plastically deforms, a behaviour which is inherently difficult to model. The plastic deformation in the model is governed by the breaking function, which future investigations should attempt to establish more rigorously across different ligaments.

# DIFFERENCES IN THE ACTIVE STATE OF A SIMULATED ANKLE MUSCLE USING TWO FOOT MODELS

Justin C. Wager and John H. Challis

Biomechanics Laboratory, The Pennsylvania State University, University Park, PA, USA  
e-mail: jcw296@psu.edu

## INTRODUCTION

Muscle-driven simulations of human movement traditionally treat the foot a single rigid segment comprising all the bones proximal to the metatarsophalangeal joint. Recent efforts in kinematic modeling have segmented the foot into three or more links [1, 2] and provided evidence that multisegment and single segment foot models generate different ankle joint kinematics during walking [3]. This difference in ankle joint kinematics could produce a difference in simulated ankle muscle kinematics, thereby leading to changes in the active state required to generate a given joint moment. Though many muscle-driven simulations of human movement utilize a single segment foot, the influence of foot model choices on ankle muscle simulations has not yet been demonstrated. This study aimed to compare the active state of a Hill-type ankle plantarflexor muscle during human running using two different foot models to compute ankle joint kinematics from experimental data.

## METHODS

Marker trajectories and ground reaction forces were collected from seven healthy subjects (3 M, 4 F; age =  $30.7 \pm 10.1$  years; mass =  $66.2 \pm 10.5$  kg) running barefoot at  $3.1 \text{ m}\cdot\text{s}^{-1}$ . The subjects performed three trials using a rearfoot contact pattern. Bony landmarks of the foot and lower leg were tracked using 18 passive retroreflective markers.

Two foot models (single segment and multisegment) were developed within MATLAB 2016a. The single segment foot model was similar to those used in traditional analyses, with one segment to represent the bones between the ankle and metatarsophalangeal joints. In contrast, the multisegment foot model separated the foot into three segments (talus/calcaneus, midfoot, toes) as in [4]. In both models, joint rotation matrices

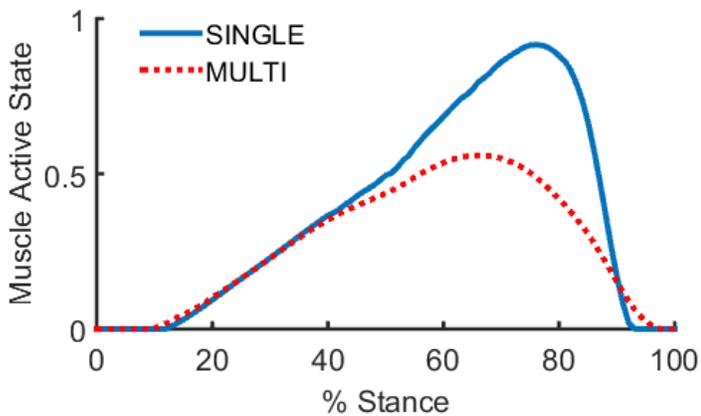

were decomposed into Cardan angles using a ZXY sequence and angles were normalized to a static trial with the ankle at approximately 90 degrees. The ankle joint angle and ankle resultant joint moment were averaged within subjects and then across subjects to obtain group means. These mean values were used as inputs for a uniarticular ankle plantarflexor muscle model to compare the effect of foot model on ankle muscle active state during running.

The uniarticular ankle plantarflexor muscle was represented as a Hill-type model. The muscle tendon unit length change and muscle moment arm over the stance phase were calculated as in [5, 6]. Force-length, force-velocity, and tendon parameters were taken from [7]. Peak isometric force capacity was set to 6000 N, as in [8] for the combined gastrocnemius and soleus of one leg.

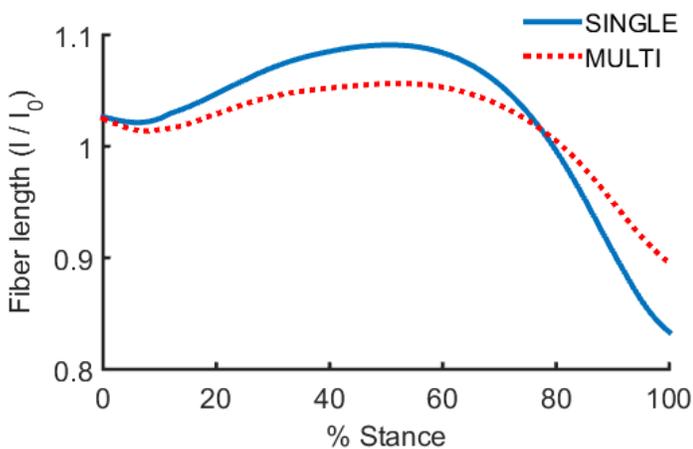

The muscle active state over the stance phase was compared between the two models (single segment foot & multisegment foot) with all parameters held constant except the ankle angles and resultant joint moments computed from the experimental running data.

## RESULTS AND DISCUSSION

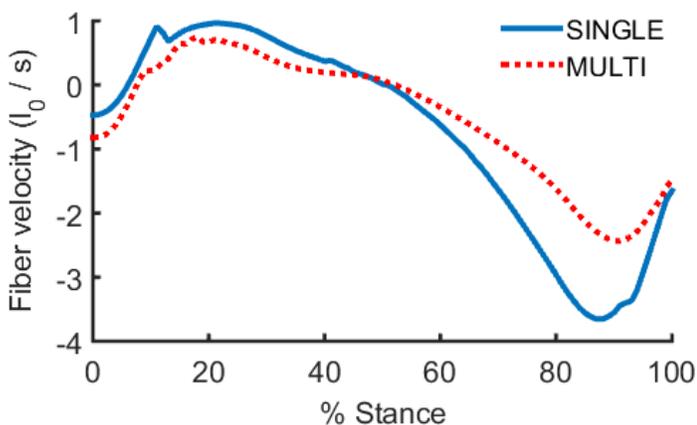

The muscle active state differed between the two models during the second half of stance only (Figure 1). Peak active state using the single segment foot model was double that of the multisegment foot model. As no differences were found in the resultant ankle joint moment or muscle force between the two models, the difference in active state was mainly due to the differences in fiber kinematics. Using the multisegment foot model, the fibers operated closer to their optimal length (Figure 2) and shortened at low velocities during late stance (Figure 3), which agrees with experimental ultrasound data for the soleus muscle during running [9].

**Figure 1:** Active states of the Hill-type muscle models with a single segment foot or multisegment foot model.

**Figure 2:** Simulated fiber lengths (relative to optimum fiber length,  $l_0$ ) of the Hill-type muscle models with a single segment foot or multisegment foot model.

**Figure 3:** Simulated fiber velocities of the Hill-type muscle models with a single segment foot or multisegment foot model. A negative velocity indicates shortening.

## CONCLUSIONS

Muscle-driven simulations of human locomotion have provided significant insights in biomechanics, but most of these simulations have utilized a single segment foot. While this may provide advantages for simulation time and complexity, it may introduce inaccuracies in ankle joint kinematics. These kinematic inaccuracies can propagate to the simulated ankle joint muscles and produce inaccuracies in the active state. Here, a uniarticular plantarflexor muscle driven with ankle kinematics from a multisegment foot model (with the calcaneus tracked separately from the midfoot and forefoot) produced muscle kinematics which were closer to experimental data than an identical muscle model driven with angles from a single segment foot model.

## INTRODUCTION

Muscle fatigue is a decrease in force output capacity of muscles. During motor tasks, people can adapt to muscle fatigue by modifying their movement patterns and control strategies. However, this process is cognitively demanding [1]. In complex environments, competing stimuli may affect the way that people are able to adapt during muscle fatigue.

Like muscle fatigue, painful stimuli can cause people to modify their movements [2]. When people experience pain, they direct their attention to the painful area. This can impair motor-cognitive performance [3] and affect the way that people learn motor tasks [4]. In some settings, the cognitive processes related to pain and muscle fatigue may compete for limited mental resources.

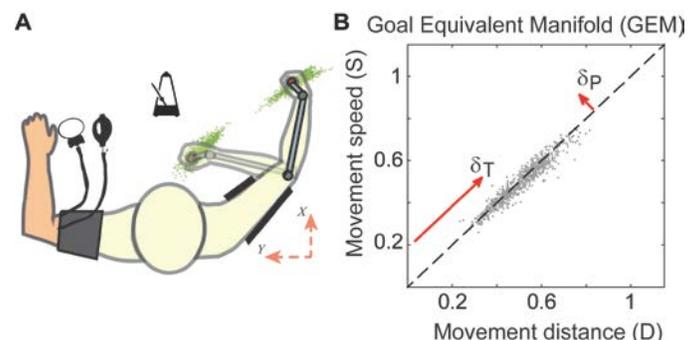

This study examined how pain in a remote area of the body affects muscle fatigue during repetitive movements. We hypothesized that pain would reduce the ability to develop successful movement strategies during fatigue, leading to larger errors and faster rate of fatigue.

## METHODS

22 right-handed subjects (11 male) completed the same repetitive task to voluntary exhaustion on two separate days (pain and no pain sessions). They were harnessed to a chair with the right upper arm strapped to a solid brace at  $\sim 90^\circ$  of humeral elevation (Fig. 1A). They grasped a handle attached to a weighted sled (15 % max. elbow flexion strength) and slid the weight back and forth on a low-friction surface in time to a metronome ( $\sim 2.6$  Hz) until they felt they could not continue. In the pain session, ischemic pain was induced in the left arm by applying a blood pressure cuff to the arm (220 mmHg) until subjects

could no longer tolerate the pain or reached a 20 min. safety limit [5]. The fatigue task began when subjects reached a pain threshold ( $\geq 3/10$ ) and continued until voluntary exhaustion. Every 30 seconds, subjective ratings of perceived exertion (RPE) and pain were obtained verbally using numeric scales. Elbow and wrist maximum voluntary contraction strength (MVC) was measured before and after the fatigue task to quantify muscle fatigue. The position of a marker on the handle was tracked at 120 Hz.

Subjects were instructed to maintain movement time so the end of each flexion or extension movement coincided with a metronome beat. Non-dimensional movement distance ( $D$ ) and speed ( $S$ ) were obtained by dividing the length of each movement by forearm length and average speed by forearm length and metronome frequency. A goal equivalent manifold (GEM) was defined as any combination [ $D$ ,  $S$ ] which achieves the correct movement duration (Fig. 1B). Timing errors, and  $D$ , and  $S$  were obtained for all push and pull movements of each fatigue trial. Five equally spaced data bins (160 movements:  $\sim 1$  min.) from each trial were examined, where the first and

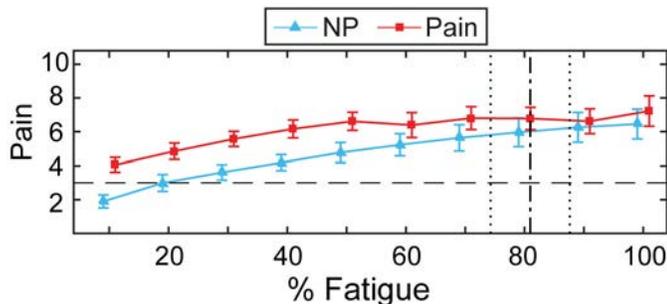

**Figure 1.** Subject setup (A). The task goal was to complete each movement in one metronome beat ( $T$ ). The goal equivalent manifold is shown (B; dashed line). Data points (grey) lying on the dashed line satisfy the timing goal of the task, wherein  $D/S = T$ . Deviations away from the GEM ( $\delta_p$ ) affect performance. Deviations along the GEM ( $\delta_T$ ) do not.

last minutes of fatigue were bins one and five, respectively. Detrended fluctuation analysis was applied to all data series to obtain temporal correlations,  $\alpha$ . The value  $\alpha$  indicates how quickly deviations are corrected in a data series. Lower values indicate that deviations are corrected more rapidly. Dependent measures were analyzed using two-factor within subjects ANOVAs to test for differences due to fatigue state (bin 1-5) and session (pain vs. no pain). Session order was included as a covariate to control for effects of order (pain first vs. no pain first).

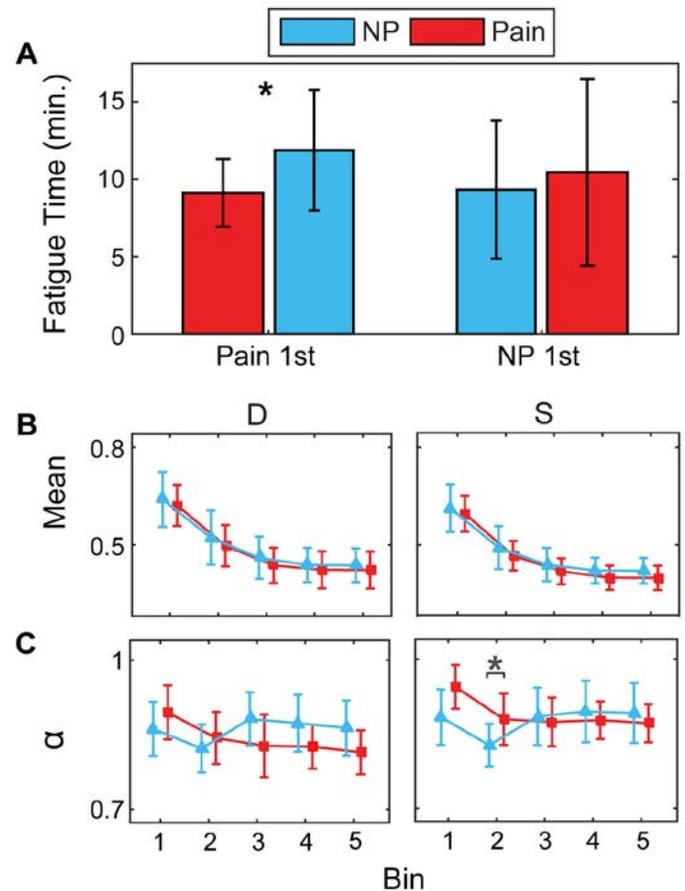

## RESULTS AND DISCUSSION

Subjects reported higher pain ratings during the pain session than the no pain session ( $p < 0.001$ ; Fig. 2). They reached an RPE of 8 or greater during all fatigue trials, and MVC strength declined after fatigue in all muscle groups measured ( $p < 0.004$ ).

**Figure 2.** Subjective pain ratings during fatigue. Error bars show 95% confidence intervals. Black lines show the pain threshold of 3 (horizontal dashed) and mean cuff deflation time (vertical dash-dot) with 95% confidence interval (dot) during the pain session.

Endurance time increased on the second test day for the subjects who completed the pain session on day one ( $p = 0.014$ ; Fig 3A). Timing errors did not change with pain or fatigue ( $p > 0.13$ ). Deviations perpendicular to the GEM ( $\delta_P$ ) decreased on the second test day, suggesting that subjects improved their ability to maintain the timing goal regardless of session order. Movement distance,  $D$ , speed,  $S$ , and  $\delta_T$  declined during the fatigue task in both sessions ( $p < 0.001$ ; Fig. 3B). Session  $\times$  fatigue interaction effects ( $p < 0.04$ ) indicated that subjects exerted less control (higher  $\alpha$ ) over  $D$ ,  $S$ , and  $\delta_T$  during the first part of the pain session. However, this effect disappeared by the end of the pain session (Fig. 3C).

**Figure 3.** Fatigue task duration (A). Mean (B) and temporal correlation,  $\alpha$  (C), of movement distance,  $D$ , and speed,  $S$ . Error bars show 95% confidence intervals. \* indicates a significant difference between sessions.

## CONCLUSIONS

Remote ischemic pain initially caused subjects to reduce movement control, but this effect was reduced quickly as subjects acclimated to the painful stimulus. Previous exposure to the fatigue task and the painful stimulation affected the execution of the task during subsequent sessions. Future work should examine changes in movement control and muscle fatigue in people with chronic pain conditions.

# STIFFNESS PERCEPTION AT THE HUMAN ANKLE AND KNEE

Alejandro F. Azocar and Elliott J. Rouse

Northwestern University, Evanston, IL, USA; Rehabilitation Institute of Chicago, Chicago, IL, USA  
email: erouse@northwestern.edu; web: <http://neurobionics.smpp.northwestern.edu/>

## INTRODUCTION

Regulation of neuromuscular activation during walking causes changes in joint kinetics, kinematics, and mechanical impedance. Joint impedance—the relationship between position and torque—is often parametrized by stiffness, damping, and inertia, and governs energy storage and exchange between joints. Recently, perturbation studies have quantified human joint impedance during gait, providing new insight beyond the traditional biomechanical descriptions of kinetics and kinematics [1]. However, the role of joint impedance in control of locomotion and, consequently, in the development of wearable robotic systems, is not fully understood; in particular, the human ability to sense changes in mechanical impedance properties is unknown.

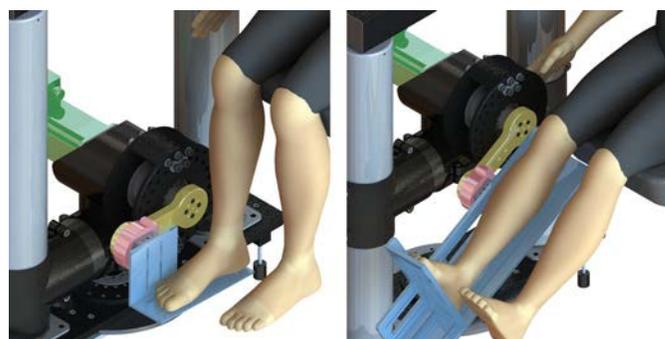

The purpose of this psychophysical study is to quantify the minimum detectable change in the stiffness component of impedance with the ankle or knee. We sought to determine the just noticeable difference (JND) and corresponding Weber fraction (WF) for stiffness. The JND is the smallest stimulus increment that a subject can detect, and normalizing it results in the WF [2]. We found that subjects can sense a stiffness change of 12% or higher.

## METHODS

Ten healthy, able-bodied subjects (4 female, 6 male; age  $24.9 \pm 3.7$  years; mass  $71.2 \pm 12.4$  kg; mean  $\pm$  s.d.) gave written informed consent to take part in the ankle study, which was approved by the Northwestern University Institutional Review Board; ten healthy, able-bodied subjects (6 female, 4 male; age  $22.2 \pm 2.0$  years; mass  $64.5 \pm 11.0$  kg) gave written informed consent to take part in the knee study. Subjects had neither neurological impairment nor ankle/knee injury.

The Neurobionics Lab Rotary Dynamometer, a frame-mounted motor (Fig. 1, green) with a six-axis

load cell (Fig. 1, pink) used an admittance controller to render the dynamics of a virtual rotational spring-damper system in parallel with the ankle or knee joint. Subjects sat in a Biodex chair and placed their right leg on a plate (Fig. 1, blue) connected to the motor output shaft via a linkage (Fig. 1, yellow); the load cell was attached between the leg plate and the linkage. The ankle or knee joint was aligned with the motor axis and was free to rotate. Subjects were blindfolded and wore noise-reducing headphones to prevent use of visual and auditory cues and to reduce environmental distractions.

**Figure 1:** Experimental setup for the (left) ankle and (right) knee experiments.

The experiment implemented a two-interval forced-choice (2IFC) paradigm; during each trial, the subjects interacted with the motor while it rendered the spring-damper dynamics. Two sets of dynamics were presented per trial; one with a reference stiffness and the other with a comparison stiffness. Subjects were instructed to interact with the motor by voluntarily extending and flexing the ankle or knee joint. Subjects were exposed to each set of dynamics for eight seconds, then were asked to report which set had a higher stiffness, or resistance to movement. A response of “equal stiffness” was prohibited. Additionally, subjects were not told if their responses were correct or incorrect.

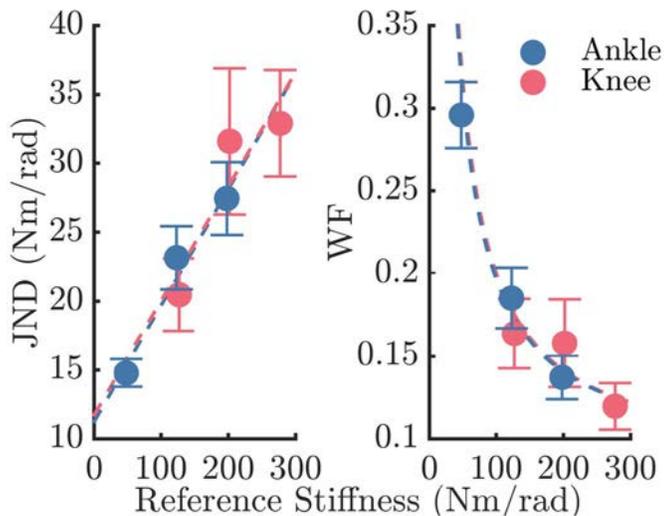

For the ankle experiment, we tested reference stiffness values of 50, 125, and 200 N·m/rad, and for the knee experiment we tested at 125, 200, and

275 N·m/rad. Higher reference stiffness values were too difficult to interact with. The inertia and damping values were 0.3 kg·m<sup>2</sup> and 1 N·m·s/rad, respectively, for all trials.

We implemented Kaernbach's weighted up-down staircase method; this method converges to the JND at the 75% performance point, halfway between guessing (50%) and perfect performance (100%). A base step size,  $\Delta$ , of 5 N·m/rad was used [3]. The better a subject performed, the more challenging the experiment became, and vice versa.

## RESULTS AND DISCUSSION

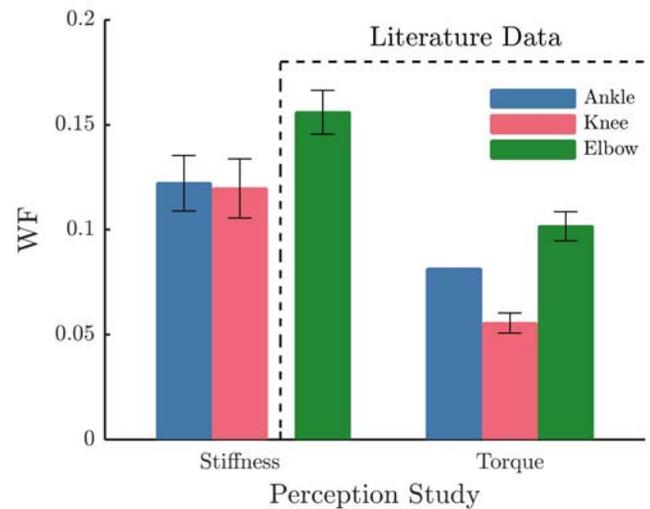

Stiffness JND increased linearly whereas WF decreased reciprocally for both joints (Fig. 2).

**Figure 2:** JND and WF change with reference stiffness. Error bars denote standard error of the mean. Data are offset for clarity.

At a stiffness level of 275 Nm/rad, the WFs for the ankle and knee were  $0.122 \pm 0.013$  and  $0.120 \pm 0.014$ , respectively (Fig. 3). In other words, stiffness must change by at least 12% at both the ankle and knee for consistent discrimination at a 75% success rate.

Torque perception at the ankle, knee, and elbow, as well as stiffness perception at the elbow, has been studied by other groups [4]–[6]. As Fig. 3 shows, subjects have better stiffness perception at the lower limb than at the elbow; the difference between ankle and elbow perception was significant ( $p = 0.016$ ), in addition to the difference between knee and elbow

**Figure 3:** Stiffness and torque perception at various joints. Error bars denote standard error of the mean.

perception ( $p = 0.014$ ). Additionally, stiffness perception is worse than torque perception ( $p \leq 0.007$ ). The ability to detect stiffness supports the importance of this impedance parameter in the context of neural control and motor performance, in particular at the ankle and knee joints.

Stiffness perception was also studied to understand the accuracy required by impedance-controlled wearable robotics systems, including exoskeletons. We found that stiffness errors below 12% are permissible; however, it is unclear how errors near the threshold may affect gait dynamics, even if a subject cannot detect the changes. Future research on powered wearable robotic systems will address how continuously-variable impedance affects gait dynamics, and how this relates to perception.

# MECHANICAL & VISUAL PERTURBATION OF HUMAN WALKING TO FIND GENERAL PRINCIPLES OF GAIT CONTROL

<sup>1</sup> Shakiba Rafiee, <sup>1</sup> Tim Kiemel,

<sup>1</sup> Department of Kinesiology, University of Maryland, College Park, USA

Email: [shrafiee@umd.edu](mailto:shrafiee@umd.edu)

## INTRODUCTION

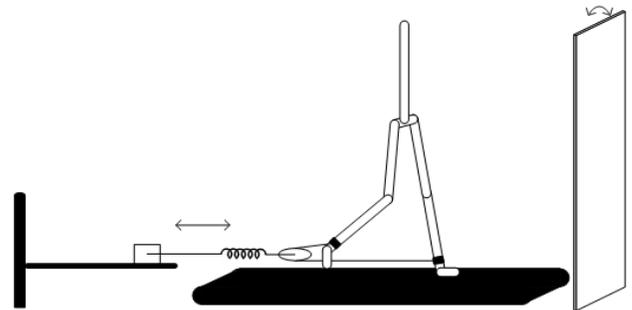

Our research goal is to understand how the nervous system controls locomotion. More specifically, we are interested in identifying general control strategies that the nervous system uses to insure stability in face of different classes of perturbations (both physical and sensory) that naturally occur throughout the gait cycle. To this end, in this study we seek to systematically characterize the properties of neural feedback by examining responses of human walking to small deviations from the desired gait pattern, and to compare the response of the system to different classes of perturbations. Logan et al. [1] previously used simultaneous visual perturbations and upper-body (trunk) mechanical perturbations to investigate the subtasks of controlling orientation relative to vertical (balance) and walking speed. In this study, we take an important next step by studying responses to lower-body perturbations that can potentially affect foot placement.

Foot placement is one of the important strategies that the nervous system can use to stabilize walking. Experimental studies have found that the timing and placement of the foot at heel strike contributes to walking stability (e.g., [2]). Similarly, in simulation studies, controlling the angle of the leg at heel strike ensures stability in simple models of human locomotion (e.g., [3]). In this study we used mechanical and visual perturbations to investigate control strategies that either ensure desired foot-placement or compensate for deviations from it.

## METHODS

We mechanically perturbed walking by applying small continuously-changing forces at the ankles using a spring attached to a motor (Figure 1). We simultaneously applied small continuous sensory perturbations, movement of a virtual visual scene, in order to compare how neural feedback responds to

actual and illusory deviations. The kinematic and muscular responses to the continuous sensory and mechanical perturbations were used to compute phase-dependent impulse response functions ( $\phi$ IRFs) that describe the system responses to small brief perturbations (impulses) applied at any phase of the gait cycle. [4, 1]

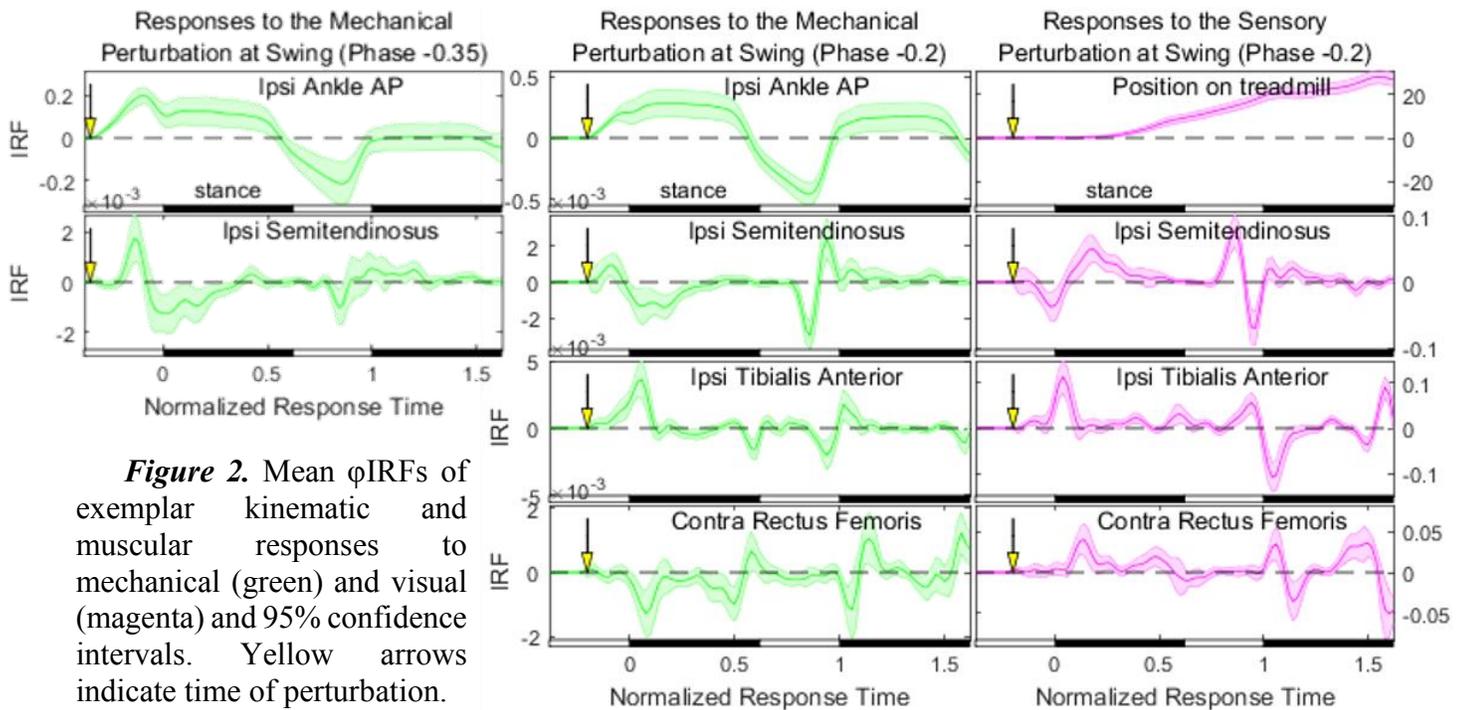

**Figure 1.** Schematic figure of the mechanical and visual perturbation

We collected data from twenty subjects walking on a treadmill for 12 trials each of length 250 seconds. Filtered white noise signals were used to specify the position of the motor (mechanical perturbation) and the velocity of the visual scene (visual perturbation). The kinematic data were collected from right and left sides of the body at external landmarks. The muscular activities were recorded from the right leg and the trunk using surface electromyography (EMG).

## RESULTS AND DISCUSSION

The mechanical perturbation caused zero-latency passive kinematic responses. After some delay, these kinematic deviations were corrected by neural feedback modulating EMG activations at specific phases of gait cycle during which muscles are normally active. We observed similar responses to both forward motion of the visual scene during swing and the mechanical perturbation during swing that caused a forward deviation in foot placement. Both perturbations resulted in increased activation of the

**Figure 2.** Mean  $\phi$ IRFs of exemplar kinematic and muscular responses to mechanical (green) and visual (magenta) and 95% confidence intervals. Yellow arrows indicate time of perturbation.

ipsilateral tibialis anterior (Figure 2) and quadriceps muscles (not shown) in early stance, followed by forward acceleration of the pelvis. These results suggest a general mechanism of early-stance neural control of walking that is used to accelerate the pelvis relative to the foot to correct various kinematic deviations. In the case of the mechanical perturbation, the pelvis is accelerated forward to catch up with foot. In the case of the sensory perturbation, the pelvis is accelerated forward to correct an illusory slowing in walking speed caused by forward visual-scene motion. In contrast to the similar early-stance responses, contralateral rectus femoris activity during the stance-to-swing transition increased in response to the sensory perturbation and decreased in response to the mechanical perturbation (Figure 2). These results are consistent with the presumed role of rectus femoris in controlling cadence, since the sensory perturbation produced a phase advance in the gait cycle, whereas the mechanical perturbation produced a phase delay (not shown). Finally, the ipsilateral hamstring muscle group showed increased activity during swing in response to mechanical perturbations and decreased activity in response to visual perturbations (Figure 2). This discrepancy in behavior is caused by a difference in the strategy used by the nervous system.

In response to mechanical perturbations, a “reactive strategy” partially corrects for the forward displacement of the foot (for perturbations applied in early swing); whereas, in response to visual perturbations, a “compensatory strategy” increases step length to correct for the illusory slowing in speed.

## CONCLUSIONS

In this study, we looked for strategies that the nervous system uses to stabilize walking. We found general control strategies used in the face of both physical and sensory perturbations, e.g., early-stance neural control used to accelerate pelvis through activation of tibialis and other anterior muscles. We also found some characteristic differences in the used control strategies; reactive strategies were used during swing to control foot placement, and compensatory strategies were used during stance to correct for errors in foot placement.

# EFFECT OF MIRROR VISUAL FEEDBACK ON MOTOR ADAPTATION AND LEARNING

Amanda E. Stone, Matthew J. Terza, Devan R. Ludden, Tiphonie L. Raffegeau, Lisa M. Krehbiel, and Chris J. Hass

University of Florida, Gainesville, FL, USA  
email: stonaman@ufl.edu

## INTRODUCTION

The ability to adapt gait is an important aspect of negotiating a complex and dynamic world. Further, successful rehabilitation is often reliant on an ability to adapt current motor patterns or learn completely new patterns based on task demands. In recent decades asymmetric walking has received attention in gait rehabilitation, particularly post-stroke. In this population, acute split-belt treadmill training has been successfully used to correct asymmetries during both treadmill [1] and overground walking [2] by exaggerating the participants' natural asymmetry. However, it is common that individuals with different injuries or diseases, such as those with cerebellar damage [3], Parkinson's disease [4], or ACL injury [5], may demonstrate difficulty or complete inability to adapt gait on a split-belt treadmill. This highlights the need to develop methods which facilitate adaptation to broaden the split-belt treadmill's utility in clinical use.

Providing visual feedback (FB) has improved rehabilitative outcomes in previous studies. For example, providing task-relevant visual FB accelerated adaptation to a novel task [6,7] while visual distractions impeded it [6]. Many of these FB methods require expensive technical equipment which may not be accessible to all and are often delayed temporally which may impact its effect. One common method for guiding individuals in physical therapy is the use of mirror FB. Frontal plane mirror FB has already been shown to facilitate proper running mechanics and improve motor learning in runners with patellofemoral pain [8]. It is unknown, however, what effect mirror FB may have on individuals' ability to adapt to the split-belt treadmill. The purpose of this study was to evaluate the effects of frontal view mirror FB on adaptation and learning during split-belt treadmill walking.

## METHODS

Thirty-four healthy young adults naïve to the split-belt treadmill volunteered to participate and provided

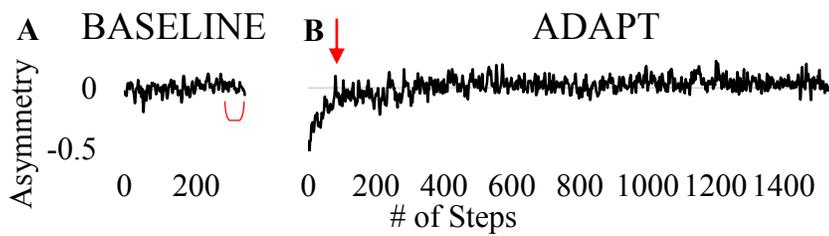

informed consent. Individuals were divided into a mirror FB group (10 females, 7 males, mean  $\pm$  SD: 21  $\pm$  3 yr, 1.7  $\pm$  0.1 m, 67.2  $\pm$  8.6 kg, 5.0  $\pm$  2.4 hrs/week exercise) or a control group with no FB (10 females, 7 males, 21  $\pm$  3 hr, 1.7  $\pm$  0.1 m, 66.4  $\pm$  15.2 kg, 5.1  $\pm$  1.7 hrs/week exercise).

Three dimensional kinematics were collected while participants walked on the split-belt treadmill. After a five-minute accommodation period, participants walked for five minutes at 0.5 m/s (BASELINE). Gait parameters were averaged over the last five strides of the BASELINE condition. All participants were instructed to look at an X on the wall in front of them. The belts then decoupled and participants walked for 15 minutes at a 3:1 split (1.5 m/s, 0.5 m/s) with their non-dominant leg on the fast belt (ADAPT). Individuals in the visual FB group had a mirror placed two meters in front of them that reflected their lower extremity from the pelvis to the feet. These individuals were instructed to look at their legs in the mirror while walking in the split condition, but no other instruction were given. Gait parameters were analyzed at three different time points during ADAPT: the first five strides (EARLY), the first five strides at the seven-and-a-half-minute mark (MID), and the last five strides (LATE). Following the split condition, participants walked with both belts moving at 0.5 m/s for 10 minutes to washout the effects of the split condition. They then returned to the same 3:1 split condition for 5 minutes (RE-ADAPT) and the first five strides were used to calculate gait parameters.

Asymmetry was defined for step length and double limb support time using the following asymmetry index:

$$\text{Asymmetry} = \frac{(\text{fast leg parameter} - \text{slow leg parameter})}{(\text{fast leg parameter} + \text{slow leg parameter})}$$

Rates of adaptation were quantified as previously described by Malone et al. [2010] with the exception that baseline symmetry was defined as the mean  $\pm$

**Figure 1:** Gait parameter asymmetry scores plotted across BASELINE (A) and ADAPT (B). A. Baseline symmetry conditions were determined using the last 30 strides (red bracket). B. Individuals were considered adapted when they had five consecutive strides within the baseline range (red arrow). For example, this participant adapted by stride 109.

SD of the last 30 strides of the baseline trial (not the split condition) (Figure 1).

A  $2 \times 5$  (Group  $\times$  Condition) repeated measures ANOVA was performed to analyze differences in gait parameters. Additionally, a one-way ANOVA was performed to analyze differences in adaptation rate between groups (SPSS,  $p \leq 0.05$ ).

## RESULTS AND DISCUSSION

The mirror FB group showed smaller step length asymmetry ( $p=0.013$ ) and larger double support asymmetry ( $p=0.017$ ) in EARLY compared to the no FB group (Figure 2). The mirror FB group adapted their double limb support time at a significantly slower rate than the no FB group (Mirror FB:  $269 \pm 168$  steps, No FB:  $114 \pm 175$  steps,  $p=0.013$ ). Both groups adapted step length similarly.

Based on previous findings, we initially hypothesized mirror FB would result in motor improvements similar to those present with video camera visual FB [6]. Alternatively, mirror FB could act as a distraction rather than an aid. Individuals who used the mirror for visual FB were initially more perturbed in terms of double support time and able to return to symmetry by LATE adaptation but at a significantly slower rate than those without visual FB. When presented with a mirror, individuals must interpret the viewed image as a mirror interpretation

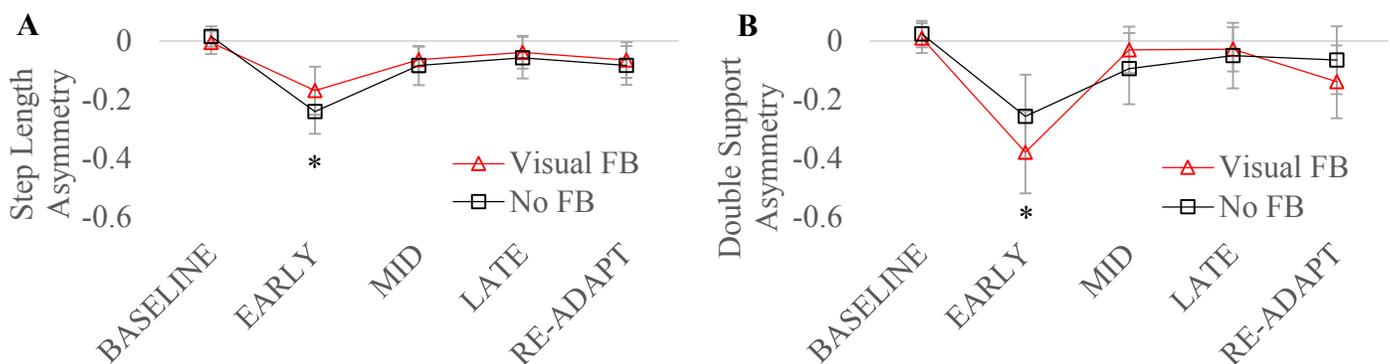

of themselves, then chose the appropriate course of action, thus leading to a slower rate of adaptation. Additionally, a view of the frontal plane provides little information regarding step length and double support time and therefore individuals in the mirror FB group may have spent more time and resources trying to get useful information out of a potentially useless tool, slowing down the rate of adaptation. Conversely, providing frontal plane mirror FB may distract individuals from the sagittal plane, facilitating a quicker reaction to step length perturbation. This may be beneficial to individuals with step length asymmetries, such as persons who have suffered a stroke.

## CONCLUSIONS

Visual FB via a frontal plane mirror reflection appears to impede double support adaptation, but may improve initial reaction to step length perturbation.

## INTRODUCTION

The ability to turn safely while walking is crucial for functional mobility. Even early in the disease, people with idiopathic Parkinson's disease (PD) experience difficulties turning. It has been suggested that the segmental coordination of rotation is impaired in people with PD and that they tend to turn 'en-bloc' instead of leading with the head [1].

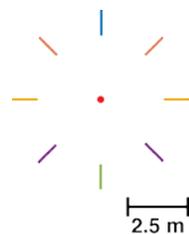

The goal of this study is to determine the effect of speed, turning angle and antiparkinsonian medication on segmental coordination during turning in people with PD. We hypothesize antiparkinsonian medication will increase turning velocity, but not to alter the segmental coordination.

## METHODS

Seventeen people with idiopathic PD (10 male, 7 female) with a mean age of 71.5 (5.8 SD) years, and a disease severity of Hoehn & Yahr stage 2.

Participants were tested in the practical OFF medication state, after withholding their antiparkinsonian medication for at least 12 hours. Subsequently, they were retested in their ON medication state, 1 hour after taking a supra-threshold dose of levodopa (*i.e.*, 1.25 times of their regular dose).

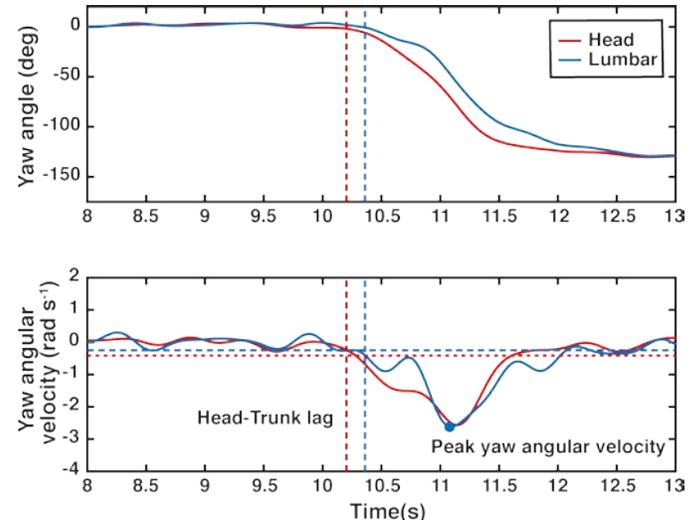

Participants performed preplanned turns to the left and right, at different turn angles (45, 90, 135, and 180 degrees) while walking at normal and fast speeds. Floor markings similar to a clock face consisting of a turning point in the center and turn

**Figure 1:**  
Experimental setup.

angle marks in the periphery were used as guidance to indicate turn angle (Fig. 1).

Wireless inertial sensors (Opals, APDM Inc.) attached to the lumbar and head were used to capture the sequence and timing of reorientation of body segments at a sampling frequency of 128 Hz (Fig. 2). Outcome measures were peak turn velocity [2] and the lag between head-trunk reorientation when initiating a turn. The onset of segmental reorientation was defined as the time at which the yaw angular velocity exceeded 150% of the range of yaw angular velocity during straight ahead gait.

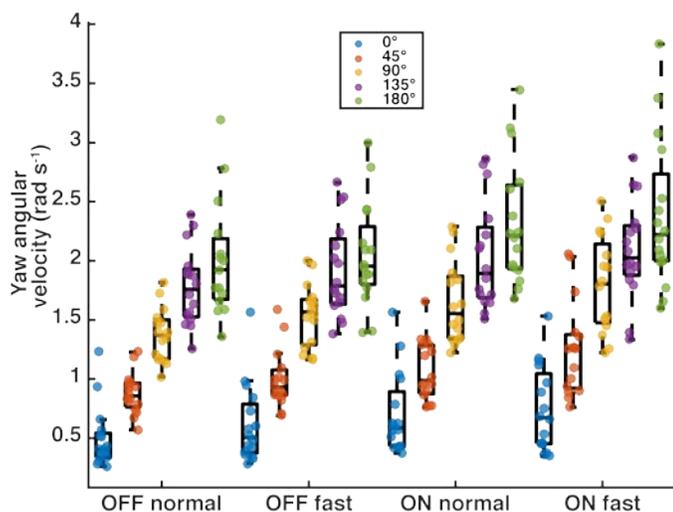

**Figure 2:** Example of a 135-degree turn with cranial to caudal sequence. The head is reorienting into the turn first, followed by the trunk. The onset of segment reorientation (vertical dashed line) the threshold (horizontal dashed line), and the peak yaw angular velocity (circle) are highlighted.

To determine the effect of speed, angle, and medication on turning behavior, linear mixed-effects models were fit for each outcome with random intercepts for each subject to account for within-subject correlations in the data.

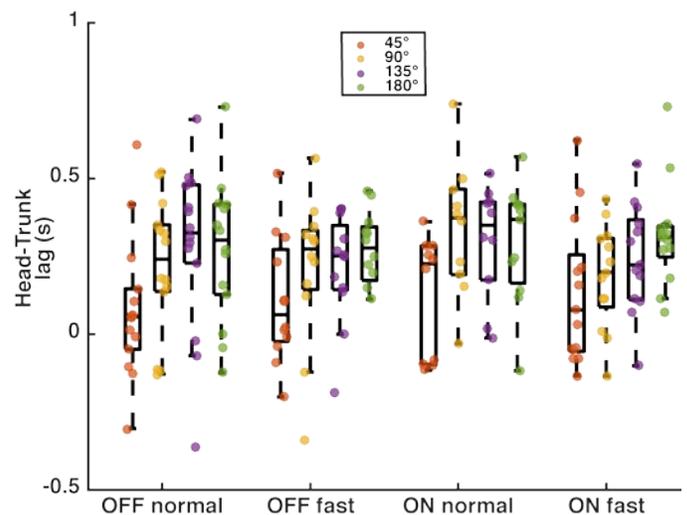

## RESULTS AND DISCUSSION

Participants exhibited faster yaw angular velocities at larger turn angles ( $p < 0.001$ , Fig. 3) and when walking faster ( $p = 0.001$ ). Medication state had a significant effect on peak angular velocities; people with PD exhibited significantly lower peak angular velocities during turning in the OFF state compared with the ON medication state ( $p < 0.001$ ).

**Figure 3:** Peak yaw angular velocity.

The angle of a turn significantly influenced the delay in initiation of reorientation of the trunk ( $p < 0.001$ ; Fig. 4). At low turning angles, people with PD exhibited a more en-bloc turning strategy, while at larger turning angles, they lead with the head more consistently. Walking at faster speeds reduced the amount of intersegmental reorientation lag between the head and trunk ( $p = 0.03$ ). Medication state did not have a significant effect on the reorientation lag time ( $p = 0.12$ ).

**Figure 4:** Lag of Head-Trunk reorientation.

## CONCLUSIONS

People with PD did not change intersegmental coordination when in ON versus OFF medication state, despite faster turn peak velocities when in the ON medication state. People with PD reoriented their head, with respect to their trunk, later during smaller angle turns compare with large angle turns.

# Specific Manual Tasks Transform EMG into a Probe for Neural Dysfunction in Parkinson's Disease

<sup>1</sup>Christopher Laine and <sup>1</sup>Francisco J. Valero-Cuevas

<sup>1</sup> University of Southern California, Los Angeles, CA, USA  
email: [claine@usc.edu](mailto:claine@usc.edu), web: <http://bbdl.usc.edu/>

## INTRODUCTION

Parkinson's disease is the second most common neurodegenerative disease. Without methods for screening and detecting the disease early, diagnosis often occurs only after the nervous system has sustained substantial and irreversible damage [1].

*It may be possible to detect the subtle fingerprints of early disease within patterns of EMG*

Specifically, many of the neural circuits involved in muscle coordination operate at distinct frequencies, and may function to 'bind' multiple muscles together into flexible, task-specific synergies [2]. The oscillatory action of these circuits causes muscles that have been 'bound' together to become synchronized with each other. This can be quantified in the frequency-domain using EMG coherence analysis [2,3].

*Tasks based on muscle coordination could be used to 'probe' the integrity of coordination-related neural circuits*

In this study, we measured EMG-EMG coherence between finger muscles while participants engaged in either a pinch-force modulation task, or a pinch-and-rotate task. One group consisted of healthy adults and a second group consisted of patients with mild-moderate severity Parkinson's disease.

During the rotation task, it was expected that a distinct ~40 Hz drive called the 'Piper Rhythm' would emerge due to the requirement of digit movement [4], but would be notably weak in the patient group, as this drive is reduced by dopamine depletion [5]. The pinch-force modulation task was expected to elicit some 30-50 Hz coherence, but very little at ~20 Hz [6]. Patients were expected to show increased 20 Hz drive, as this may be related to the symptom of bradykinesia [7]. Of course, any

tremor would tend to cause coherence at lower frequencies (<10 Hz).

Our overall hypothesis was that the patient group would show a reduced overall proportion of high (30-50 Hz) frequency coherence in both manual tasks. We also speculate that this reduction could serve as a diagnostic aid if the effects are sufficiently strong.

## METHODS

EMG-EMG coherence was measured between the *abductor pollicis brevis* (APB) of the thumb and *first dorsal interosseous* (FDI) of the index finger of participants as they performed 3-minute manual task trials. The patient group consisted of 11 individuals (ages 42-69, 6 male), all on medication, and our preliminary control group consisted of 10 individuals (ages 24-36, 6 male).

In the first task, participants pinched a small dial as shown in Figure 1 A. They used visual feedback to generate a pinch force that was scaled slowly between 1 and 3 Newtons. The modulation rate was 0.1 Hz for patients and 0.25 Hz for our preliminary control group. In the second task, participants rotated the dial to the left and right  $\pm 22.5^\circ$  at the same frequency. The color of the cursor indicated when forces fell outside of the 1-3 Newton range, to ensure that pinch forces remained similar to the force scaling task.

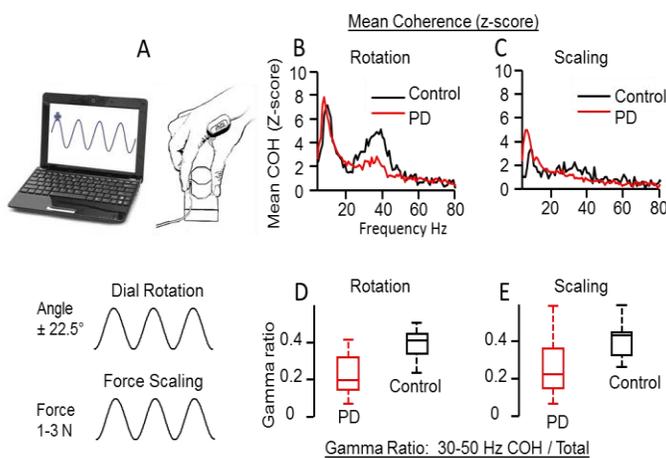

To evaluate coherence within each task, we calculated a 'gamma ratio' per participant, representing the proportion of total coherence within the 30-50 Hz frequency range. To evaluate differences across groups, we used an unequal variance t-test on ranked data. To evaluate effect size, we calculated Cohen's D. Finally, we evaluated the ability of the 'gamma ratio' to

discriminate patients from controls by determining the area under a Receiver Operating Characteristic curve (ROC\_AUC).

## RESULTS AND DISCUSSION

Figure 1 B and C display the average APB-FDI coherence across all participants in each group, and for each task. The coherence values have been transformed to standard Z-scores prior to averaging. The boxplots in Figure 1 D and E depict the results of calculating the proportion of total coherence in the 30-50 Hz band for each participant, in each group, and for each task. In both the rotation and scaling task, the proportion of coherence in the 30-50 Hz band was low in the patient group relative to the controls.

In fact, during scaling, this ‘gamma ratio’ differed significantly between groups ( $p = 0.0012$ ), showed a large effect size (Cohen’s  $D = 1.08$ ), and good discriminability between patients and controls (ROC\_AUC = 0.81). For dial rotation, this gamma ratio statistically differed across groups ( $p = 8.33e-5$ ), had a very large effect size (Cohen’s  $D = 1.58$ ), and showed excellent discrimination potential (ROC\_AUC = 0.9).

**Figure 1:** EMG-EMG coherence calculated during manual tasks (A) differs between healthy adults and those with Parkinson’s disease (B-E).

It is relevant to note that neural drive to muscles has been studied in Parkinson’s disease before, but the results have not shown diagnostic potential [5]. A major difference between our study and previous work is that we quantify muscle synchronization rather than neural drive to individual muscles. This takes advantage of the interpretation of high frequency EMG coherence as an index of neural ‘binding’ (i.e., an inherently coordination-related phenomenon). Our strategy is also unique in that physical tasks are designed specifically to evoke different frequencies of muscle-synchronizing drive, whose origins are thought to lie within relevant (in this case, disease-affected) neural circuits.

## CONCLUSIONS

Our work demonstrates that simple measures of EMG activity in distinct neuromechanical contexts can be used to probe disrupted neural mechanisms in Parkinson’s disease. This work shows a clear, if preliminary, example of how the specific study of neural drive as subordinate to basic mechanical task demands can be of great benefit in the clinical domain.

## INTRODUCTION

The study of human motor control has long been driven by a desire to understand the principles that underlie the selection of motor behaviors. In attempts to identify these principles, a broad class of research has converged on ideas which suggest that motor behaviors may be selected through the optimization of cost functions that include variables such as movement error, reward, and/or effort. Among the broad class of potential cost functions explored in motor control, minimization of energy has often been invoked to explain how we select motor behaviors. However, not all studies provide support for this hypothesis.

In this symposium, we will address the strengths and limitations of the energetic optimization hypothesis in light of current findings from healthy and pathological behavior. We will also ask the more general questions of whether the identification of optimization principles underlying human movement is a worthy quest or whether our efforts should be focused elsewhere. Through an interactive dialogue between the speakers and the audience, we hope to spur a discussion about the evidence for and against the role of energetic optimization in human motor control and highlight potential directions for future research.

## PRESENTATION SCHEDULE

The symposium will proceed according to the following schedule:

Introduction – James Finley – 5 min

Energy Optimality in Unconventional Tasks –

Manoj Srinivasan – 15 min

Energy Optimization and Walking – Max Donelan  
– 15 min

Energetic Consequences of Asymmetry - James  
Finley – 15 min

Kinematic Costs Explain Reaching Movements -  
Dinant Kistemaker – 15 min

Representation of Effort in Decision Making - Alaa  
Ahmed – 15 min

Discussion – 10 min

## ENERGY OPTIMALITY IN UNCONVENTIONAL TASKS IN HUMAN LOCOMOTION AND ITS TRADE-OFF WITH ROBUSTNESS - Manoj Srinivasan

We will begin by explaining how reduced order biomechanical models can be used to predict energetically optimal locomotor behaviors, and will then present evidence from a range of tasks that support the hypothesis that humans optimize energetic cost during walking. In particular, we will present evidence for approximate energy optimality in not just steady straight-line walking, but also in other unconventional situations: unsteady walking

with changing speeds, walking sideways, walking with turns (walking in circles and other complex curves), and recovering from external perturbations during walking. Finally, we will present simple mathematical models of posture (equilibrium) and walking (periodic motion) to examine the trade-offs between energetics on the one hand and stability/robustness on the other. We use numerical optimization to obtain the nominal body motion or state along with feedback controllers that minimize a combination of energy and susceptibility to uncertainty. We find that there is a non-trivial trade-off between these quantities, such that an increase in some kinds of uncertainty also increases the energy cost and also changes the nominal optimal state/motion, for instance, increasing stance width in standing.

### **ENERGY OPTIMIZATION AND THE CONTROL OF WALKING – Max Donelan**

People prefer to move in ways that minimize their energetic cost. Although aspects of this preference may be established over both evolutionary and developmental timescales, we have been interested in the possibility that our nervous systems can optimize energetic cost in real-time. To study this, we use robotic exoskeletons and other mechatronic devices to shift people's energetically optimal gaits to gaits that they don't normally prefer. We find that when subjects are given experience with this new cost landscape, subjects adapt their gaits to converge on the new energetic minimum within minutes and in response to relatively small costs savings. Interestingly, some subjects do not require experience with the cost landscape to initiate energy optimization. This population has naturally high gait variability, suggesting that they are constantly exploring to seek lower cost gaits. However, most subjects do not spontaneously initiate optimization and instead persevere at their originally preferred and now suboptimal gait in the new cost landscape. The experience required to initiate optimization is

experience with a lower cost gait, at which point subjects begin adapting their gait to converge on the new energetic minimum. This behaviour is consistent with a simple reinforcement learning algorithm that selects energetically optimal gaits from a learned prediction of the cost landscape. Our collective findings indicate that energetic cost is not just an outcome of movement, but also plays a central role in continuously shaping it, which is reflected in the algorithms that our nervous system uses to learn new ways of moving through our world.

### **ENERGETIC CONSEQUENCES OF ASYMMETRY IN HEALTHY AND HEMIPARETIC GAIT – James Finley**

Our work focuses on understanding the extent to which asymmetry is actively adjusted during locomotion to reduce energetic cost. We will first present results from studies on healthy individuals adapting to walking on a split-belt treadmill, which can be used to impose a left-right asymmetry in step lengths. In response to this imposed asymmetry, participants gradually adjust their foot placement to adopt steps of equal length. Although this adaptation process is associated with a reduction in metabolic cost, we will show that taking steps of unequal length is often the energetically optimal solution for this task. We will also share recent work exploring the role of energetic optimization in the selection of walking patterns in people post-stroke. Here, we are interested in understanding whether damage to the brain modifies the value placed on different features of walking by, for example, increasing the value placed on stability and being more willing to adopt asymmetric strategies that are energetically costly. We found that spatiotemporal asymmetries were indeed associated with a heightened metabolic cost, and, interestingly, we also observed that people post-stroke do not choose walking speeds that are most economical. The results from these studies highlight the limitations of the energy optimization

hypothesis by demonstrating that both short-term adaptations to imposed asymmetries, and long-term adaptations to brain lesions result in locomotor patterns that are energetically sub-optimal.

### **KINEMATIC COSTS EXPLAIN THE CONTROL OF REACHING MOVEMENTS – Dinant Kistemaker**

It has been widely suggested that central nervous system solves motor behavior redundancy by minimizing a combination of cost variables at the level of kinematics, mechanics and muscle input. To test which variables may underlie the control of arm movements, we had subjects make point-to-point movements while grasping a robotic manipulandum, and we visually perturbed their seen hand position. The robot created a force field (FF) designed to have distinct optimal movements for muscle-input and dynamic costs, yet leaving kinematic cost unchanged. We also used visual perturbations to change kinematic cost, while leaving the dynamical and muscle-input costs unchanged. An optimal control model of the arm, actuated by 6 Hill-type muscle-tendon units, was used to predict movements minimizing various cost variables. The experiments show that after extended exposure to the FF, subjects moved exactly as they did in the absence of the FF, yet were strongly influenced by the small visual perturbations. Experimental results were clearly not consistent with minimization of control and dynamic costs, including mechanical energy. All experimental conditions were adequately predicted by a kinematic cost function comprised of both visually and somatosensory perceived jerk. This study provides evidence that the CNS solves kinematic and mechanical redundancy in separate steps.

### **A REPRESENTATION OF EFFORT IN DECISION MAKING AND MOVEMENT CONTROL - Alaa Ahmed**

Decisions depend on the reward at stake and the effort required. However, these same variables

influence the vigor of the ensuing movement, suggesting that factors that affect evaluation of action also influence performance of the selected action. We describe a mathematical framework that links decision-making with optimality principles in motor control. Each action has a utility, i.e. cost function, which combines the reward at stake with its effort requirements, both discounted as a hyperbolic function of time. The critical assumption of this model is to represent effort via the metabolic energy expended to produce the movement. This energetic representation describes a parameterization of effort as a function of movement duration, mass of the limb, distance, and force, which we confirmed experimentally in reaching movements. Our main result is to show that a single mathematical formulation of action, a utility describing the goodness of the movement via effort, reward, and time, predicts both the decisions that animals make as well as the vigor of the movements that follow. This framework accounts for choices that birds make in walking vs. flying, and the choices that people make in reaching and force production. We suggest that decision-making and movement control share a common utility in which the expected rewards and the energetic costs are discounted as a function of time.

### **AUDIENCE ENGAGEMENT**

Audience participation will be encouraged through real-time feedback using the text message-based audience response system, SMS Poll (<http://www.smspoll.net/>). Specifically, we will administer a pre/post survey to determine the audience's baseline opinions about optimization, and ultimately see if these opinions change in response to evidence presented by the panel. Participants can also pose questions or comment on the topic through the use of the Twitter hashtag #ASB\_Energy. After the conference, the comments, questions, and poll responses will be curated for online storage through Twitter's Moments feature.

# ANKLE-FOOT ORTHOSIS ALIGNMENT AFFECTS CENTER OF PRESSURE VELOCITY

E-mail: mitchell.d.ruble.ctr@mail.mil

## INTRODUCTION

Ankle foot orthoses (AFOs) are commonly prescribed to restore function after severe lower extremity injury. Although AFOs can improve pain and the ability to perform daily tasks, they inherently affect gait. For example, a semi-rigid footplate alters how the foot rolls over the ground during gait impacting center of pressure trajectory. The velocity of the center of pressure (vCOP) is a specific measure that has been utilized to help determine different variables such as the dead spot phenomenon in prosthetic gait [1], overall gait efficiency in healthy and injured populations [2], and postural control [3]. Prior research has shown that the vCOP in barefoot walking is characterized by a triple peak pattern at 1) loading response, 2) early-mid stance, and 3) late stance) [2]. The semi-rigid design of AFOs may not allow for biomimetic motion across the three rockers, which may alter both the magnitude and the timing of the vCOP. The specific AFO used in this study was the Intrepid Dynamic Exoskeletal Orthosis (IDEO), a custom, passive-dynamic AFO that has been shown to improve function to a greater extent than other types of AFOs [4]. The purpose of this study was to analyze the effect of IDEO alignment on the peak magnitude and timing of the vCOP.

## METHODS

A total of 12 subjects (11 M, 1 F) with unilateral limb injuries (age  $30 \pm 6$  yrs, height  $1.78 \pm 0.09$  m, mass  $87.3 \pm 9.7$  kg) underwent gait analysis in a motion laboratory (Marker data: 120 Hz, Motion Analysis Corp; Analog data: 1200 Hz, AMTI, Inc.). Three IDEO alignments were tested using a  $3^\circ$  wedge between the footplate and posterior strut (Fig 1): Neutral (Neu) (clinically determined by orthotist),  $3^\circ$  more Dorsiflexed (DF), and  $3^\circ$  more Plantarflexed (PF).

**Figure 1:** The IDEO aligned in dorsiflexion (left) and plantarflexion (right) using a  $3^\circ$  wedge.

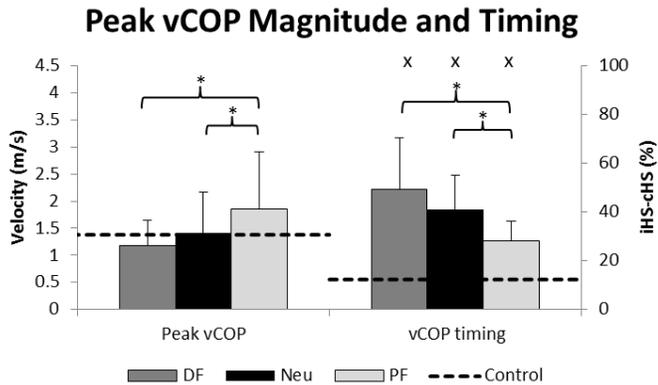

Each subject walked at a standardized speed, determined by leg length, until their affected and unaffected limbs made full contact with a force plate 5 times. COP was calculated during a truncated portion of stance phase from ipsilateral heel strike (iHS) to contralateral heel strike (cHS) in Visual 3D. vCOP was calculated as the first derivative of the COP position, and the magnitude and timing of the peak was identified. These dependent measures were compared to data from able-bodied subjects who were group matched for age, height, weight, and leg length.

Data were first tested for normality, and non-normally distributed data were normalized with a logarithmic transformation. A 2-way repeated measures ANOVA (limb x alignment) identified significant main effects and paired t-tests with Bonferroni-Holm corrections identified significant differences between alignments and limbs ( $p < 0.05$ ).

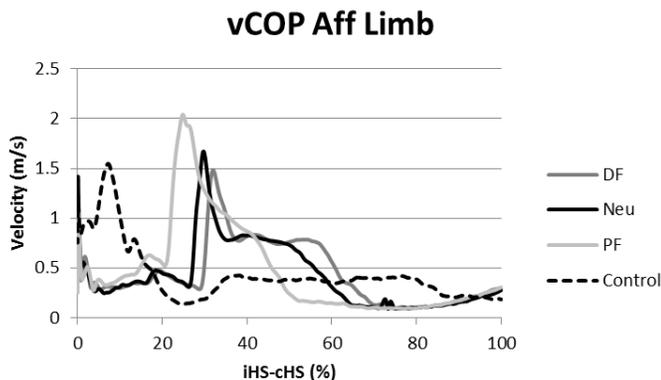

## RESULTS AND DISCUSSION

The  $3^\circ$  modifications in sagittal plane IDEO alignment significantly affected the magnitude and timing of the peak vCOP (Fig 2-3). Significant interaction effects were recorded between limb and alignment for both the magnitude ( $p = 0.002$ ) and timing ( $p = 0.001$ ) of the peak vCOP. The PF alignment of the affected limb had significantly

greater vCOP magnitudes than both the DF ( $p=0.002$ ) and Neu ( $p=0.004$ ) alignments. Additionally, the timings of these peaks were significantly earlier in the PF alignment than the DF ( $p=0.001$ ) and Neu ( $p<0.001$ ) alignments. Patients generally preferred the PF alignment (8/12).

**Figure 2:** Affected limb peak vCOP magnitude and timing with SD bars. \* indicates difference between alignments, X indicates difference from controls.

**Figure 3:** Mean vCOP of the affected limb and control data from ipsilateral heel strike (iHS) to contralateral heel strike (cHS) for a representative subject.

Between limb effects were observed for the vCOP magnitudes and timing. The timing of the peak vCOP occurred significantly earlier in the unaffected limb for the DF ( $p<0.001$ ), Neu ( $p<0.001$ ), and PF ( $p<0.001$ ) alignments. However, no significant differences between limbs were found for the vCOP peak magnitudes (DF:  $p=0.115$ , Neu:  $p=0.876$ , PF:  $p=0.193$ ).

Differences between the subject data and the control data were also observed. Peak vCOP timing occurred 25-39% later in the patient data than the control data for the DF ( $p<0.001$ ), Neu ( $p<0.001$ ), and PF ( $p=0.002$ ) alignments. No differences were found between the patient and control data for the peak vCOP magnitudes.

With the earlier and greater peak vCOP magnitudes in the PF alignment, the foot would be expected to transition from heel loading to foot flat faster than the other alignments. However this may not be beneficial for some patients as it may increase the risk of stalling after this rapid peak (Fig 3).

One limitation of this study was that the neutral alignment for each subject was determined by the orthotist's clinical assessment, largely influenced by the subject's pain-free range of motion, and may have differed among subjects.

## CONCLUSIONS

A 6-degree range of changes in the sagittal plane alignment of an AFO significantly influenced the vCOP peak magnitudes and timings. With an increasingly plantarflexed alignment, the peak vCOP magnitudes increased and occurred earlier.

## INTRODUCTION

Gross anatomical misalignments, such as flatfoot (pes planus) or high-arch foot (pes cavus), affect normal hindfoot and midfoot joint function, increasing risk of injury or degeneration, and reducing overall quality of life. Further, the factors differentiating symptomatic and asymptomatic pes planus subjects are still unclear. Quantification of kinematic variations between foot types is essential to elucidating the complex joint interactions specific to these conditions and aiding surgeons designing procedures and hardware to correct such deformities. Determination of finite helical axes (FHA) of joints in response to passive loading may reveal the “true” joint axes orientations resulting from the guiding articular surfaces and ligaments.

The primary purpose of this study was to quantify hindfoot and midfoot finite helical axes of rotation in four clinical foot type classifications: 1) pes cavus (PC), 2) neutrally aligned (NA), 3) asymptomatic pes planus (APP), and 4) symptomatic pes planus (SPP). The secondary aim was to explore differences between symptomatic and asymptomatic planus feet. We hypothesized that the rotation about, and the orientation of the joint axes in cavus and planus subjects will differ from neutrally aligned feet. Specifically, planus feet would exhibit greater rotation at the midfoot with dorsiflexed, everted, and externally rotated axis orientations, indicative of a flexible foot. SPP differences relative to NA would be exaggerated compared to APP. Additionally, PC subjects would exhibit restricted midtarsal joint motions, and plantarflexed, inverted, and internally rotated axes.

## METHODS

Subjects (17 female/22 male, body mass index (BMI):  $29.1 \pm 6.1$ , age:  $52.4 \pm 8.9$  years) were recruited from the University of Washington and VA Puget Sound Medical Centers with institutional review board approval. Subjects were self-ambulating and classified by an orthopaedic surgeon as: NA: 10, PC: 9, APP: 10, SPP: 10.

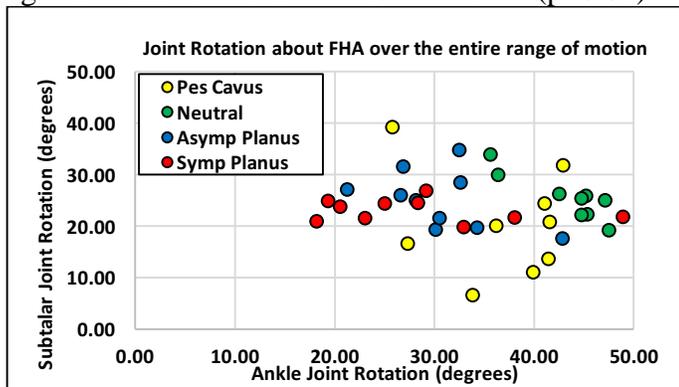

Feet were positioned using a custom loading device [1] in eight, equally-spaced, predefined poses inside a magnetic resonance imaging machine (1.5T Phillips Intera Gyroscan, voxel size:  $0.57 \times 0.57 \times 0.70$  mm, SENSE-Flex-M coil). A static imaging volume was acquired at each of the eight poses ranging from maximum plantarflexion, hindfoot inversion, and internal rotation through the neutral position (Path 1), and then from the neutral position to maximum dorsiflexion, hindfoot eversion, and external rotation (Path 2) [1].

Foot and ankle bony anatomy was segmented within subjects, across poses using custom software (Multi-Rigid) [2] that calculates the relative transformation matrices between bone poses. Finite helical axes were calculated directly from the relative homogeneous transforms as outlined by Spoor [3]. The rotation amount and orientation of the FHAs were calculated over Path 1, Path 2, and the overall motion path (Path 1+Path 2) for each subject. FHA orientations were expressed with respect to anatomical coordinate systems based on the inter-malleolar axes [4] and the normal vectors of the loading device platform for each subject.

Differences between foot types were tested using a general linear model (age, sex and BMI included as covariates), and post-hoc comparisons of PC, APP and SPP subjects to the NA group were performed. Linear regressions correlated the rotational contributions of synergistic joint pairs to overall motion (**Figure 1**). Statistical analyses were performed in SPSS (v23, IBM) and significance level was set at  $p < 0.05$ .

## RESULTS AND DISCUSSION

No differences in FHA orientation between both planus and neutral feet were detected. Both planus feet groups had less ankle rotation compared to NA (APP:  $-9.1 \pm 3.5^\circ$ ,  $p = 0.014$ , SPP:  $-12.3 \pm 3.3^\circ$ ,  $p = 0.001$ ) (**Figure 1**). Calcaneal-cuboid joints in SPP subjects had  $4.9 \pm 1.8^\circ$  less rotation than NA ( $p = 0.01$ ). Moderate interactions between BMI and cuboid-fifth metatarsal rotation ( $p = 0.054$ ), medial cuneiform-navicular rotation ( $p < 0.001$ ), and calcaneal-cuboid sagittal plane FHA orientation ( $p = 0.062$ ) were observed. Significant interaction of age and ankle rotation was also observed ( $p = 0.02$ ).

**Figure 1:** Subtalar vs ankle joint rotation for each subject by foot type. SPP exhibited narrow subtalar and wide ankle rotation range. The slope of APP subjects falls between the flat SPP response and negatively correlated NA response ( $R^2 = 0.87$ ).

PC subjects had significantly less rotation through Path 1 at the subtalar ( $7.0 \pm 2.1^\circ$ ,  $p = 0.002$ ), calcaneal-cuboid ( $3.2 \pm 1.3^\circ$ ,  $p = 0.018$ ), and talonavicular ( $10.9 \pm 3.3^\circ$ ,  $p = 0.003$ ) joints compared to NA, suggesting increased midfoot rigidity.

Compared to APP subjects, SPP FHAs were more inverted in the coronal plane for the cuboid-fifth

metatarsal and medial cuneiform-navicular joints. SPP FHAs were more dorsiflexed in the sagittal plane for the calcaneal-cuboid, talonavicular, tibio-calcaneal, and talus-first metatarsal axes, relative to APP.

## CONCLUSIONS

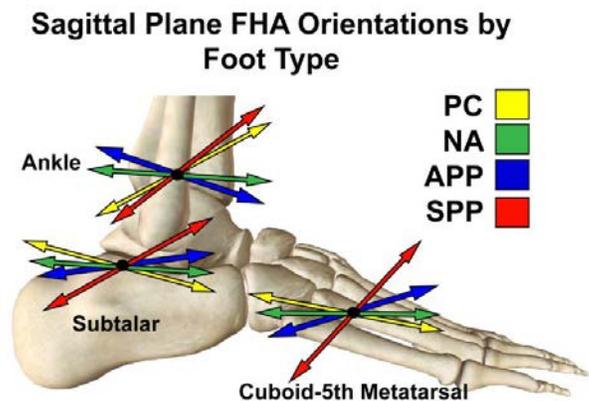

Foot shape deformities disrupt the normal interplay of ankle and subtalar joint axis behavior. Overall, FHA orientations were highly variable for non-neutral groups. The relationships between adult-acquired flatfoot and obesity are highly debated, but increased daily loading may contribute to arch collapse. Future work will investigate relationships between bony morphology, articular surface congruity, and kinematic contributions of foot/ankle motion segments to overall motion.

## INTRODUCTION

The use of foot pressure distribution analysis in the evaluation of foot deformities has been established [1]. Certain parameters of this analysis, such as the line of progression of the center of force (COF) has been shown to accurately describe lever arm deficiencies that result from foot deformities [2, 3, 4, 5, 6].

One foot deformity, often demonstrated by children with cerebral palsy, which requires careful evaluation and treatment, is the valgus foot. Treatments that have been implemented to address the valgus foot include the triple arthrodesis and the increasingly popular calcaneal-cuboid-cuneiform osteotomy procedure, or triple C (3C) [7]. The 3C procedure combines calcaneal sliding with cuboid and cuneiform wedge osteotomies. Advantages of this procedure include correction of the foot deformity while avoiding long-term complications associated with increased stress on the adjacent joints, which has been found to be related to the triple arthrodesis procedure [7, 8, 9].

However, although to determine the need for the 3C procedure, children often have pre-operative foot pressure distribution analysis, to-date, to the best of our knowledge, there have been no studies that have used pedobarographic analysis to quantify the effects of the 3C procedure. We have assumed that the foot pressure distribution parameters of the COF and peak pressure (PP) would be able to describe the post-operative changes as a function of the procedure. A foot corrected for a valgus deformity should display a more lateral COF trajectory pre-operatively accompanied by a complementary

lateral shift of the PP and, potentially, with a reduction of that pressure in the surgical region. If we can establish foot pressure analysis parameters as a means for assessing planovalgus foot deformity functionally, then we can potentially use it to assess the efficacy of clinical procedures such as the 3C procedure, used to address the deformity. Foot pressure analysis parameters may allow objective assessment of the outcomes of this procedure, which, in turn, will contribute to the effectiveness of the decision making process in addressing valgus foot deformities, as well as monitor progress.

Consequently, the purpose of this study was to determine if selected foot pressure distribution analysis parameters can be used to describe functional changes as a result of the 3C procedure by comparing differences in pre- and post-operative COF trajectory and PP in the surgical region.

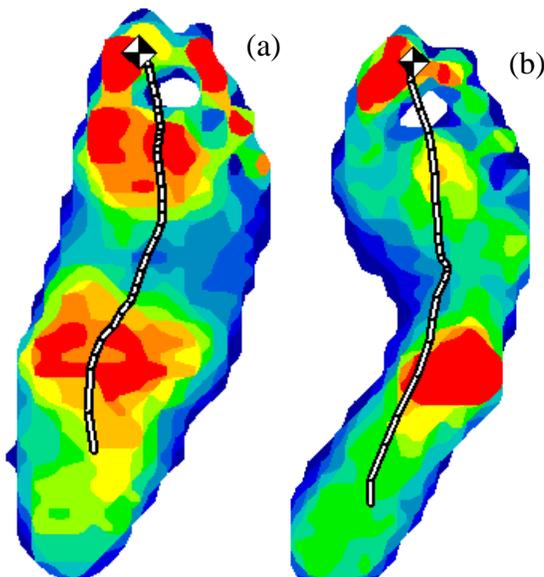

## METHODS

This study included twelve subjects (8 males, 4 females, 18 feet) ranging from 6 to 18 years of age. All subjects had a diagnosis of cerebral palsy with valgus foot deformity and had the 3C procedure. Original foot pressure data was collected using the Tekscan HR Mat and related software before and 1 year after surgery. Approximately, three foot pressure distribution trials were selected for each foot for analysis for each pre- and post-operative tests based on the consistency of the COF trajectory and the foot pressure distribution. First, the longitudinal excursion of the COF trajectory was determined and expressed relative to the functional length (the length of the foot in contact with the ground) and estimated actual foot length. Then, we

determined the surgical region and the maximum medial and lateral excursion of the COF trajectory within this region. The excursion was expressed relative to the functional surgical width (the width of the foot in the surgical region in contact with the ground) and estimated actual foot width. The PP within this region was also determined and the distance between the PP location and the functional lateral border of the foot was measured. Pre- and post-operative differences were compared within and across subjects.

## RESULTS

Figure 1 demonstrates the changes in the foot pressure distribution analysis parameters for one of the participants. Sixty nine percent of the feet evaluated demonstrated a longer COF trajectory following surgery. The average percent lengthening relative to the estimated actual foot length was 20% (SD 41). Seventy nine percent of the feet demonstrated a medial to lateral shift of the COF trajectory.

**Figure 1:** Functional changes in foot pressure parameters between pre- (a) and post- (b) surgery using the 3C procedure.

The average percent shift relative to the estimated actual foot width was 7% (SD 11). The PP location demonstrated a medial to lateral shift for eleven of the twelve subjects or 94% of the feet. The average lateral shift of the PP location within the functional surgical width was 22% (SD 22) from the lateral border of the foot. The PP magnitude was reduced for eight of the twelve subjects or 67% of the feet.

## DISCUSSION AND CONCLUSIONS

Following the 3C procedure, most subjects demonstrated a longer COF trajectory, suggesting a greater amount of foot contact with the ground in the longitudinal direction. Furthermore, most subjects showed a lateral shift in the PP location, suggesting that the valgus deformity was reduced. This was complemented by a corresponding lateral shift of the COF trajectory within the functional surgical width.

Consequently, our results suggest that foot pressure distribution analysis is an effective means for assessing the efficacy of the 3C procedure. Pedobarographic analysis can provide information about functional pre- and post-operative differences that can document change.

## INTRODUCTION

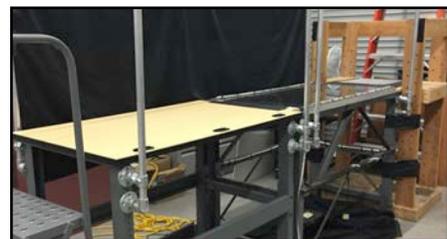

Measuring dynamic footprints during gait can help identify foot deformities and pathology [1] and aid in managing conditions such as diabetic foot pathology [2]. Dynamic footprints are typically produced using electronic pedography [3]. This technique is somewhat limited by the poor resolution of sensor arrays. Also, there exist limited data relative to its reliability and validity. Digital image processing techniques may overcome this limitation through generating high-resolution footprints with adequate frame rates to capture specific events during gait. Image processing has been used to generate static footprints using algorithms that segmented the foot and generated a binary image footprint [3, 4, 5]. This approach requires the foot to be placed on an acrylic sheet and imaged using a digital camera. Previously published techniques used a podoscope in which fluorescent bulbs illuminated the contact area of the foot simplifying image processing [4]. A primary limitation of commercially available podoscopes is their relatively small surface area, which constrains the performance of dynamic movements.

The purpose of this exploratory investigation was to examine the concurrent validity of an automatic digital imaging processing technique to measure plantar contact area during the mid-stance phase of gait with respect to a manual processing method.

## METHODS

*Experimental set-up:* In this institutionally approved study, an elevated acrylic (Plexiglas) walkway (2.54 cm thick, 0.6 m wide, and 1.21 m long) was designed and built to characterize unobstructed gait (Figure 1).

The walkway was extended on both ends of the Plexiglas window (total dimensions: 0.9 m high, 0.6 m wide, 3.6 m long) allowing for unobstructed natural gait. Stairs and guardrails were added for safety and comfort of the participants. LED strips were fitted along the perimeter of the walkway to illuminate the plantar contact area. The light intensity in the testing area was standardized for all data collection sessions, with ambient light also controlled. A high definition camera (Nikon 1 J4, 60 fps, Tokyo, Japan) was placed in a 3D printed camera box directly underneath the center of the walkway to ensure a consistent camera placement for all experiments. The starting position of each participant was marked with tape to help ensure that the right foot of each participant landed near the center of the Plexiglas portion of the walkway without participant targeting.

**Figure 1:** Experimental Setup.

All participants (N=42, age=24.3±3.2 years, mass=67.2±16.9 kg, height=1.63±0.08 m) were free from lower extremity injuries and foot deformities. Participants were fitted with tight-fitting black clothing and gloves to reduce noise during image processing.

*Calibration:* A checkerboard (size=20x30 cm, square dimensions=2x2 cm) was placed on the acrylic plate and used to calibrate the images resulting in, 1 pixel-length=0.0016 cm, which was used for calculating contact areas.

*Automated Identification of Plantar Area:* All of the image-processing algorithms were developed in MATLAB, incorporating Image Processing Toolbox functions. A total of 11,564 images were generated from 420 walking trials (N = 42, 10 trials each). The identification process started by cropping each full contact image to a rectangle closely surrounding the foot to simplify image processing. Background noise was filtered. A contour was drawn manually to enclose contact area on a test image during the full contact phase. Red-Green-Blue (RGB) values of pixels within this contour were identified. Average and standard deviation (SD) of the RGB values of all pixels within the contour were calculated. Contact area for all other frames during the full contact phase were identified as those pixels whose RGB values were within the average RGB  $\pm$  twice the SD of the test image. To improve the quality of the identification process, borders were smoothed and gaps were filled.

*Manual Calculation of the Plantar Area:* One hundred frames during the full contact phase of all trials were randomly selected and contact areas were traced by 3 trained researchers using drawing tablets (Wacom, Intuos Pro, Portland, OR). Inter-rater reliability for the manual tracing method was conducted.

*Statistical Analysis:* Statistical tests were performed using SPSS (IBM SPSS Statistics for Windows, Version 23.0, IBM Corp, Armonk, NY). Two analyses were conducted. First, the intra-class correlation coefficient (ICC) was employed to examine the degree of agreement between area measurements of the same image taken by the three researchers. Second, concurrent validity between automated and manual methods were evaluated.

## RESULTS AND DISCUSSION

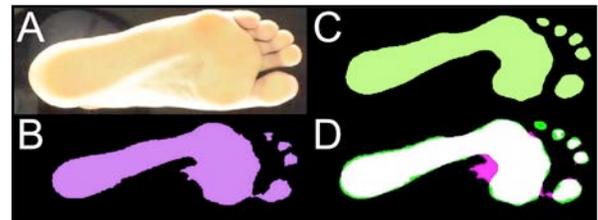

*Inter-Rater Reliability Results:* The results showed that there existed strong agreement among the 3 researchers (ICC=0.99, 95% CI=0.98-0.99).

*Concurrent Validity Results:* Concurrent validity between the automated and manual methods was acceptable for calculating plantar contact area (ICC = 0.92, 95% CI=0.81-0.96). The average plantar

contact area error between the methods was  $-5.8 \pm 13.1\%$ . This error shows the automatic method underestimated plantar contact area.

*Qualitative Analysis:* An example of images processed using the automatic imaging-processing algorithm and manual tracing method are demonstrated in Figure 2. A common source of error observed in the automatic imaging-processing algorithm was shadow in the mid-arch region. Future studies should aim to reduce these sources of error.

The results from the current study demonstrate a valid approach to produce dynamic footprints for the mid-stance of gait. Future research should examine additional phases during the support phase.

**Figure 2:** Unprocessed image (A), automatic method (B), manual method (C), white shows overlap between the images (D).

## INTRODUCTION

A forefoot strike pattern (FFS) has received considerable attention in running literature due to its theorized benefit in attenuating loading rates, shifting loads distally, and storing/ returning more energy in the foot (compared to rearfoot strike, RFS). While the effects of strike pattern on sagittal plane knee and ankle mechanics have received considerable attention in the literature, less is known about the mechanics of the joints distal to the ankle. Differences in the manner in which the foot is loaded when changing strike pattern [1] may provide an interesting model to test the validity of two traditional clinical models of the foot: midtarsal locking and the windlass mechanism. Research using a multi-segment foot model [2] shows that a FFS is accompanied by a more inverted hindfoot. This could affect midtarsal mechanics via the midtarsal locking mechanism, where hindfoot inversion is purported to reduce flexibility across the joints of the midfoot [3]. In addition, a more anterior center of pressure throughout stance in FFS [1] has the potential to increase the role of the windlass mechanism during push-off, wherein toe extension results in concomitant arch rise [4].

Both the midtarsal locking theory and the windlass mechanism have the potential to alter kinetics across the foot joints. The purpose of this study, therefore, was to explore the effects of running strike pattern on foot kinetics within the context of these clinical theories. We hypothesized that midtarsal locking would result in a less compliant midfoot during loading in FFS, while the windlass mechanism would increase power absorption at the metatarsophalangeal joints and concurrent power generation at the midtarsal joint during push off in FFS.

## METHODS

Eighteen female runners (25±4 yrs., 1.65±0.06 m, 61±7 kg) ran overground at 3.7 m/s using both RFS and FFS patterns. Subjects wore minimalist shoes with cut-outs and reflective markers were placed directly on the skin according to a modified kinetic multi-segment foot model [5]. Marker trajectories and force plate data were collected at 150 and 1,500 Hz respectively.

Midtarsal (MT) and metatarsophalangeal (MP) joints were modeled in Visual 3D software [5]. Joint angles were extracted using a typical Euler sequence. Joint moments and powers were calculated by first partitioning the ground reaction force to each segment sequentially using the center of pressure [6]. Stance was divided into two phases: 1- loading, from initial contact until peak midfoot dorsiflexion, and 2- propulsion, constituting the rest of stance. Metrics differed slightly between the two phases, targeted towards the most dominant foot theory (midtarsal locking in loading and windlass mechanism in propulsion). Range of motion (RoM) and MT joint work (integral of power) were calculated for both phases. MT angular impulse and rotational stiffness (slope of the linear portion of the sagittal plane moment / angle graph) were added to loading, while MP and combined MT/MP joint work were added to propulsion. Strike pattern was compared using paired t-tests ( $\alpha = 0.05$ ).

## RESULTS AND DISCUSSION

LOADING (Table 1): FFS resulted in greater MT dorsiflexion RoM ( $p=0.005$ ), but reduced abduction RoM ( $p=0.003$ ). No differences were observed in frontal plane RoM ( $p=0.122$ ), but the motion

directions were reversed (see [2]), with FFS inverting and RFS everting. MT angular impulse was also greater in FFS ( $p < 0.001$ ), as was MT stiffness ( $p = 0.024$ ). No differences were seen in MT negative work ( $p = 0.912$ ). These results suggest, first, that total MT motion, or deformation, is likely similar between strike patterns, but that MT axes of rotation differ due to changes in postural configuration. The similar deformation occurs despite much greater loading in FFS, suggesting that the altered rotation axes are causing a greater stiffness across the MT joint (i.e. “locking”). This perspective helps explain why energetics conclusions based solely on sagittal plane kinematics [7] differ from tri-planar modeling studies [8, 9] and provides further evidence against any FFS energy storage advantage within the MT joint [8, 9].

**Table 1:** MT joint metrics during loading.

	RFS	FFS	<i>p</i>
ROM (°)			
Dorsiflexion	5.4 ± 1.5	6.4 ± 2.2	0.005
Inversion	(-)3.0 ± 1.3	2.2 ± 1.6	0.122
Abduction	4.5 ± 1.2	3.7 ± 1.2	0.003
Impulse (Nm·s/kg)	.11 ± .02	.16 ± .02	0.000
Stiffness (Nm/°kg)	2.4 ± 0.7	2.8 ± 1.0	0.024
Work (J/kg)	-.11 ± .03	-.11 ± .05	0.912

**PROPULSION (Table 2):** During propulsion, there was greater MT plantarflexion RoM in FFS ( $p < 0.001$ ), but no differences in the other planes ( $p = 0.313, 0.118$ ). By toe off, MT kinematics curves had converged so that there were no distinguishable differences between strike patterns (see [2]). This convergence in MT kinematics suggests that midtarsal locking would affect both strike patterns similarly. However, MP extension RoM was greater in FFS ( $p < 0.001$ ), which appears to engage the windlass mechanism earlier and to a greater extent. This mechanism is evident in the joint work values and illustrated by the power profiles (Figure 1). Although there is greater MT positive work done in FFS ( $p < 0.001$ ), there is also greater concurrent MP negative work ( $p < 0.001$ ), as power is transferred from the MP joint to the MT joint. The integrated manner in which these joints act needs to be considered when evaluating midfoot mechanics (see also [8, 9]). Furthermore, the combined MP and MT work across stance shows no difference between strike patterns ( $p = 0.244$ ), and is a net negative,

suggesting that the foot’s contribution to active propulsion may be limited.

**Table 2:** MT and MP joint metrics during propulsion.

	RFS	FFS	<i>p</i>
MT RoM (°)			
Plantarflexion	7.1 ± 1.7	8.5 ± 2.2	0.000
Inversion	(-) 2.1 ± 1.4	2.5 ± 1.8	0.313
Adduction	4.8 ± 1.5	5.2 ± 1.9	0.118
MP Extension (°)	30.0 ± 3.2	34.8 ± 2.9	0.000
MT Work (J/kg)	.09 ± .04	.15 ± .04	0.000
MP Work (J/kg)	-.16 ± .04	-.23 ± .05	0.000
Combined Work	-.15 ± .04	-.17 ± .06	0.244

**Figure 1:** MT and MP joint powers across stance

## CONCLUSIONS

The midtarsal locking theory explains why the greater MT joint loading that occurs in a FFS pattern does not result in more negative MT joint work, as altered MT axes stiffen the joint. During propulsion, the windlass mechanism similarly explains why greater MT plantarflexion and positive work do not result in differences in total work done by the integrated MT and MP joints.

## INTRODUCTION

During stance, the plantar flexors eccentrically control the rate and timing of dorsiflexion [1]. This function controls the shank's rotation and influences the kinetics, energetics, propulsion, support and forward progression of gait [1,2]. Insufficient resistance to dorsiflexion due to plantar flexor weakness results in shorter or asymmetrical step lengths and decreased walking speeds common in patients, such as individuals post-stroke [3].

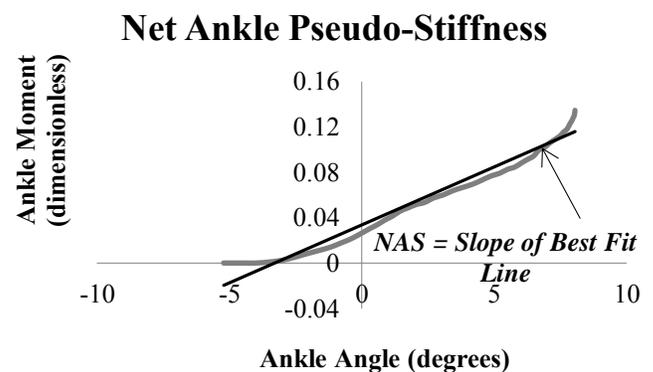

Resistance to dorsiflexion can be quantified via net ankle pseudo-stiffness (NAS), defined as the slope of the ankle joint moment-angle curve during the second and third rockers [4] of the stance phase of gait. Individuals with plantar flexor weakness are often prescribed Passive-Dynamic ankle-foot orthoses (PD-AFOs) with the intent of using the spring-like bending stiffness of the orthosis to replace a patient's lost dorsiflexion resistance [4]. However, current methods of orthosis fabrication rely on trial-and-error. Beginning with a model-predicted baseline has many benefits, including increased efficiency and rapid, objective fabrication methods. As a first step to developing this baseline model, the purpose of this study was to understand the influence of age and walking speed on NAS beyond the age of 65 years. We hypothesized that NAS would decrease with slower gait and older age.

## METHODS

A total of 113 community-dwelling, ambulatory women between the ages of 65 and 91 (age: 76.3 ± 7.4 yrs; BMI: 27.3 ± 5.0) participated in this IRB-approved study at the Mayo Clinic. Kinematic data

from a 10-camera system (Motion Analysis Corp, Santa Rosa, CA; 120 Hz) and kinetic data from forceplates (2 AMTI, Watertown, MA and 3 Kistler, Amherst, NY 600Hz) embedded in the walkway were processed in Visual3D (C-Motion, Inc, Germantown, MD).

Ankle moments were scaled by body mass, leg length and gravitational constant to create a dimensionless moment [5]. Four to six gait trials were analyzed for each participant. The second and third rockers of stance were defined from the first instance of the plantar flexion moment to the maximum dorsiflexion angle [4]. A Froude-scaled walking speed was also calculated.

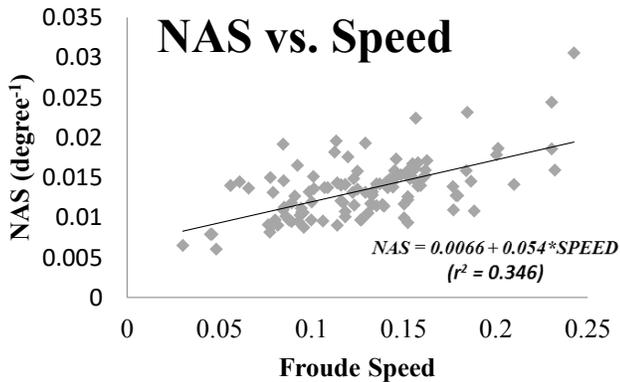

**Figure 1:** The observed ankle angle and moment relationship (gray) for one representative trial. The net ankle pseudo-stiffness (NAS) is calculated from the slope of a best-fit linear regression line (black).

Using custom MATLAB (MathWorks, Inc. Natick, MA) script, NAS was calculated as the slope of a linear regression between sagittal-plane ankle angle and moment for each stance phase (Figure 1). The NAS values were averaged across limbs for each participant. Then, a multivariate linear regression model was used to evaluate the influence of age,

Froude-scaled walking speed, and limb (if necessary) on NAS. Finally, to understand how the components of NAS (change in ankle angle and moment) were influenced by age and walking speed, Pearson correlation analyses were conducted. All statistical analyses were conducted in SPSS (IBM, Armonk, NY).

## RESULTS AND DISCUSSION

Approximately 36% of the variance in NAS was explained by walking speed and age ( $p < 0.001$ ,  $R^2 = 0.355$ ). The NAS increased with walking speed ( $\beta = 0.057 \pm 0.007$ ,  $p < 0.001$ ,  $r = 0.59$ ; Figure 2), but was not influenced by age ( $\beta = 5.0 \times 10^{-5} \pm 4.2 \times 10^{-5}$ ,  $p = 0.23$ ,  $r = -0.11$ ). Further analysis revealed that the change in dorsiflexion angle was negatively correlated with speed, with less dorsiflexion as speed increased ( $r = -0.42$ ,  $p < 0.001$ ). A larger change in the plantar flexion moment was associated with faster walking speeds ( $r = 0.54$ ,  $p < 0.001$ ).

**Figure 2:** The observed relationship between net ankle pseudo-stiffness (NAS) and Froude-scaled walking speed. A linear best-fit line and associated regression equation quantify the positive relationship between NAS and walking speed.

Changes in NAS with speed were influenced by both ankle kinematics and kinetics. With reduced walking speed, the plantar flexion moment decreased and the dorsiflexion angle increased, both of which decreased NAS.

By including a large sample of mobile, elderly women with ages evenly distributed between 65 and 91 years, we were able to treat age as a continuous parameter in the regression analysis. With a patient's weight, leg length and targeted walking speed, a prescribed NAS can be calculated using the regression equation generated in this study (Figure 2). This objectively-determined NAS value could prove critical for effectively personalizing PD-AFO bending stiffness.

## CONCLUSIONS

This study establishes a relationship between gait speed and NAS. PD-AFOs rely on the customized spring-like bending stiffness to replace a patient's lost NAS [4]. Thus, we are providing a foundation for objectively prescribing PD-AFO bending stiffness to achieve a targeted gait speed for older adults with plantar flexor weakness.

### INTRODUCTION

According to NIH/NSF reports fewer than half of STEM related PhDs pursue a career in academia, either in research or in teaching, and only 23% of those are in tenure track positions. Importantly, many biomedical-trained scholars enter research roles in industry (18%) and government (6%). Concurrently, the number and diversity of research and development positions for biomechanists in industry has increased. Employers now range from consulting roles (safety/injury), clinical research, health and wellness tracking and preventative care, sports equipment, sports injury and performance consultation, video game and movie animation, and virtual reality development, among others. There are many reasons why individuals with Master's and PhD degrees may pursue opportunities outside of academia; including changing research interests or the appeal of non-academic work, settings, access to more diverse resources for conducting research, job benefits (Sauermaann & Roach, 2012), and the potential to have research outcomes more quickly impact the wider community. Career development training and exposure to opportunities outside of academia is required, but the support and training for this by many institutions is lacking. In this symposium, we will get a glimpse of why several outstanding scientists moved from academia to industry and how their doctoral and postdoctoral training influenced their careers and lives. Panelists will cover "a day in the life," "work life balance," "what skills from your graduate training or research experiences directly translate to a nonacademic position" and "what skills do you wish you would have developed as part of your graduate training that apply to your job today," and will compare and

contrast research endeavors within these two communities. Further, the audience will be able to contrast the career paths and skill sets needed and developed across the variety of companies associated with the panelists. We will also discuss best practices regarding graduate training programs for workforce readiness. Importantly, the panel will discuss the ability to move back and forth between industrial and academic research settings and will highlight the symbiotic nature of this relationship rather than the "either/or" approach that many institutions still promote.

The symposium will follow the proposed schedule:

Introduction- Chris Hass- 2 minutes

Maria Pasquale -12 minutes

Alison Sheets-Singer 12 minutes

Kate Pate-12 minutes

Michael Zabala-12 minutes

Inge Wefes-12 minutes

Panel Discussion / Audience Questions- 28 minutes.

**Maria Pasquale, M.S.**, Director of Application Development for Novel Electronics Inc. For over a decade she has worked building meaningful partners and relationships for novel and maintaining the important relationship between industry and research. Maria studied bioengineering at the University of Pittsburgh where she obtained both her Undergraduate and Master's degree. Maria works closely with the software and hardware development team at Novel to bring new products and customers' wishes to fruition. She continues to

be involved in research projects (design, management, logistics, collection and analysis) with universities, clinical sites, and the military and enjoys this link “back to her research roots.” Maria will discuss important questions to answer before looking for industry positions and the roles that industry sponsors play in the field of biomechanics

**Alison Sheets-Singer, Ph.D.**, Dr. Sheets-Singer is a Senior Researcher in the Nike Sport Research Lab in Portland, OR. The goal of the lab and her research is to enhance athlete performance by creating innovative products and services. Prior to joining Nike, Inc. in 2012, Dr. Sheets-Singer was an Assistant Professor in the Mechanical and Aeronautical Engineering Department at The Ohio State University. Dr. Sheets-Singer will discuss her experiences leading research programs in industry and working with multi-disciplinary teams to create new products, and will compare compare industry and academic research settings.

**Kathryn (Kate) Pate, Ph.D.**, Dr. Pate is currently a Principal Scientist at Roccor (Longmont, Colorado), leading company research efforts in Combat Casualty Care. Dr. Pate has effectively transitioned back and forth between research intensive, teaching, and industry positions. She will describe the skills / experiences from her graduate and postdoctoral training that are similarly valuable among her careers and the skills she wish she would have focused on during her graduate training to prepare her for each of her career roles.

**Michael Zabala, Ph.D.**, Dr. Zabala is an Assistant Professor in the Department of Mechanical Engineering in the Samuel Ginn College of Engineering at Auburn University. Prior to joining the faculty at Auburn in the fall of 2016, Dr. Zabala was a professional consultant at Exponent, Inc. in Atlanta, Georgia, specializing in Injury Biomechanics. He will discuss his academic pathway and will compare and contrast consulting and academic positions. Further, he will provide insights into the process of transitioning back to academia following his consulting career.

**Inge Wefes, Ph.D.**, Dr. Wefes is the Director of the Biomedical Sciences and Biotechnology Program

and Associate Dean of the Graduate School at the University of Colorado Denver|Anschutz Medical Campus. Further, she is the Principal Investigator of a prestigious NIH Best award given to create and implement development opportunities in biomedical science training that will increase the preparedness and employability in the non-academic workforce. Dr. Wefes will discuss best practices and effective programing for career development training for workforce readiness.

# VALIDATION OF A MODEL BASED TRACKING TECHNIQUE TO MEASURE *IN VIVO* PATELLOFEMORAL KINEMATICS

## INTRODUCTION

The patellofemoral (PF) joint is a common site for non-specific anterior knee pain that occurs in physically active individuals. The pathophysiology of anterior knee pain is not well understood. It is believed that changes in patellar tracking (*i.e.* the changes in anterior-posterior and medial-lateral position, in addition to rotation) may be an underlying cause for PF pain [1].

The movement of the patella within the femoral trochlea is difficult to measure precisely, especially *in vivo*, during dynamic functional activities. Cadaveric studies can provide some insight to PF kinematics, however these studies are unlikely to duplicate the forces or muscle firing patterns of live humans [2]. *In vivo* techniques to measure patella kinematics include intracortical bone pins, externally affixed targets/markers, static and dynamic MRI, and quasi-static radiographs [2-7]. These methodologies provide valuable insight into patella kinematics, however, they are limited by the speed, applied loads, and range of motion that can be analyzed. The aim of the current study was to evaluate the performance of a model-based tracking (MBT) technique for assessing PF motion *in vivo* during dynamic, functional motion.

## METHODS

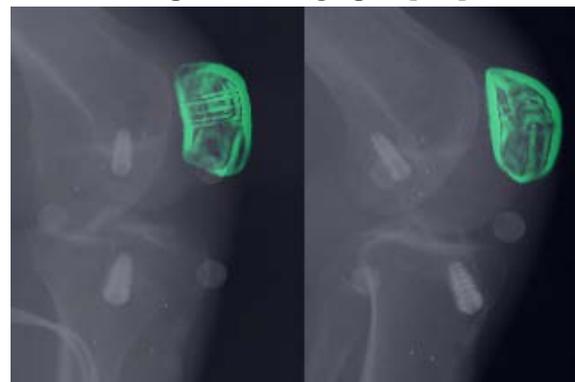

After obtaining informed consent to participate in this IRB-approved study, nine tantalum beads (1.0 mm dia.; 3 beads per bone) were inserted into the femur, patella, and tibia of two patients undergoing ACL-reconstruction (1 M, 1 F; age 22yrs. and 21yrs, respectively). Both participants completed a standard rehabilitation protocol, and were tested 6 months after surgery. Participants performed three

trials each of over ground walking and stair ascent movements at a self-selected pace within a biplane radiography system (Figure 1).

**Figure 1.** Laboratory setup during stair ascent.

Biplane radiographs were collected at 100 images/s for 1 second during each trial. A high-resolution computed tomography (CT) scan (0.5 x 0.5 x 0.625 mm)(GE LightSpeed Pro 16) was collected after movement testing. The femur, tibia and patella bone tissue was segmented from the CT images (Simpleware software, Exeter, UK). The center of each bead was identified within the CT scans. Voxels containing beads were replaced with voxels containing bone tissue, and the CT slices were reconstructed to create three-dimensional (3D) bone models. Patella motion was tracked using RSA bead tracking as a “gold-standard” and a volumetric MBT process that matches digitally reconstructed radiographs created from the subject-specific bone models to the biplane radiographs [8,9].

**Figure 2.** Patella bone model (green) tracked onto biplane radiographs.

**Table 1:** Model-based tracking (MBT) patellofemoral joint kinematics. Differences between model-based and bead-based tracking were calculated for each data frame. These differences were used to calculate mean differences (bias) and the standard deviation (precision). Data from level walk and stair ascent trials were averaged separately for each subject and then averaged together to get the values in this table. Standard deviations for each value reflect the inter-trial difference.

	Bias		Precision		RMS error	
	Level Walk	Stair Ascent	Level Walk	Stair Ascent	Level Walk	Stair Ascent
Medial-lateral translation	0.16 mm ± 0.48 mm	0.09 mm ± 0.22 mm	0.45 mm ± 0.22 mm	0.28 mm ± 0.15 mm	0.61 mm ± 0.22 mm	0.39 mm ± 0.16 mm
Anterior-posterior translation	0.28 mm ± 0.02 mm	0.01 mm ± 0.13 mm	0.18 mm ± 0.03 mm	0.08 mm ± 0.05 mm	0.34 mm ± 0.01 mm	0.15 mm ± 0.03 mm
Superior-inferior translation	-0.48 mm ± 0.12 mm	-0.02 mm ± 0.04 mm	0.24 mm ± 0.04 mm	0.14 mm ± 0.03 mm	0.54 mm ± 0.13 mm	0.15 mm ± 0.04 mm
Flexion-extension	0.33° ± 0.82°	0.26° ± 0.57°	1.30° ± 0.19	0.57° ± 0.19°	1.46° ± 0.32°	0.91° ± 0.39°
Tilt	1.19° ± 1.84°	1.36° ± 1.15°	1.17° ± 0.71°	0.87° ± 0.44°	2.25° ± 0.61°	1.85° ± 1.05°
Rotation	3.71° ± 3.80°	-0.23° ± 0.64°	2.38° ± 1.17°	0.79° ± 0.24°	4.56° ± 3.66°	1.09° ± 0.45°

The accuracy of the MBT technique was quantified in terms of bias (the average difference), precision (the standard deviation of the difference) and RMS error. The bead-based and MBT techniques were used to determine the centroid of the three beads implanted in the patella. Six degrees-of-freedom PF joint kinematics were also calculated for each frame of movement (medial-lateral, anterior-posterior and superior-inferior translations relative to the femur, and flexion (*i.e.* rotation about a medial-lateral axis of the femur), tilt (*i.e.* rotation about the patella's long axis), and rotation (*i.e.* rotation about the patella's anterior-posterior axis)) [10].

## RESULTS AND DISCUSSION

Average bead tracking precision (based on the 3D intermarker distances in the patella) was 0.13 mm. Using the bead-based tracking as a gold standard, the precision of the MBT in locating the centroid position of the implanted tantalum beads was  $0.90 \pm 0.2$  mm. In general, kinematic accuracy of the MBT was better in the stair ascent than in over ground walking (Table 1). These kinematic precision values are in line with our previous reports for similar *in vivo* validations for tracking cervical vertebrae (0.33 mm and 1° or less) and tibiofemoral kinematics (0.5 mm and 0.6°) [8,9]. The kinematic RMS error during knee flexion (stair ascent) is similar for translational and slightly higher in rotational measures than previously reported biplane cadaveric knee flexion values (0.395 mm and 0.877°) and cine-MRI knee flexion (0.33 mm and .97°) [2,7]. The ability of this technique to study PF motion during normal weight bearing exercise will help clinicians to better understand the pathology of PF knee pain and the effect of surgical and nonsurgical interventions to treat PF pain. Using cadaver specimens to validate bone tracking does

not provide a realistic representation of all challenges encountered when testing *in vivo*, such as occlusion from the contralateral limb. The patella presents unique challenges when imaging and tracking due to its symmetric shape and small size. These challenges can be overcome through proper placement of the imaging equipment during data collection.

## CONCLUSION

Given appropriate imaging configurations, the volumetric MBT process can track PF kinematics during dynamic functional movements with a precision of 0.45 mm and 2.4° or better.

## INTRODUCTION

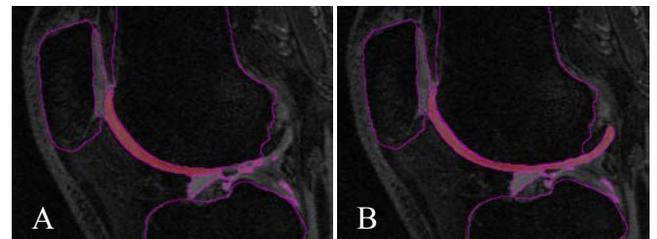

Reliable measurement of knee articular cartilage is important for many reasons. Magnetic resonance imaging (MRI) is a direct and noninvasive measurement modality that can be used to detect the morphological (e.g., cartilage thickness and volume) changes in knee articular cartilage. Previously, researchers have used MRI to measure effects of physical exercise on knee articular cartilage morphology, using manual methods of measurement (i.e., each region of interest was manually contoured) [1]. The purpose of this study was to describe our efforts to use a semi-automated approach to reliably measure knee articular cartilage thickness and volume. We hope to establish our ability to do so, so that we can later measure the influence of mechanical load, during physical activity, on knee articular cartilage thickness and volume.

## METHODS

Three recreational runners (1 male and 2 females; Ages: 22, 24, and 26 yrs; Masses: 52, 54, and 72 kg; Heights: 1.75, 1.58, and 1.85 m) received two MRI scans of the right knee, before and after a 60-min run (45 minutes of treadmill running and 15 minutes of overground running). Running speeds ranged from 3.0 to 4.0 m/s. Scans were acquired via a dedicated unilateral knee coil on the 3 Tesla Siemens Trio MRI system (Siemens Healthcare, Erlangen, Germany), using the sagittal 3D double-echo steady-state protocol.

A single rater (one of the coauthors—MM), quantified femoral cartilage thickness and volume for five of the six aforementioned scans, on two occasions that were separated by approximately four weeks. A first pass segmentation for femoral

cartilage thickness and volume was obtained using COLIPE software (Qmetrics, Pittsford, NY, USA) [2]. Next, the aforementioned rater manually adjusted the segmented femoral cartilage that was inaccurately segmented by the software's first pass, for each slice (e.g., see Figure 1). Then, using the COLIPE software and refined segmentations, mean cartilage thickness and volume were recalculated for seven cartilage regions: femur (F), central medial femur (cMF), central lateral femur (cLF), medial trochlear (MFT), lateral trochlear (LFT), posterior medial Femur (pMF) and posterior lateral femur (pLF).

**Figure 1:** Semi-automated segmentation of femoral articular cartilage in the sagittal plane (1 of 160 slices). (A) Initial segmentation via the software; (B) Refined segmentation via the rater.

Intraclass correlation coefficients (ICC) and standard errors of measurement (SEM) were used to assess the intra-rater reliability of the single rater, between the measures of articular cartilage thickness and volume that were quantified four weeks apart. ICC and SEM were calculated using the equations shown at the bottom of Table 1 [3]. The mean square variances for ICC calculation were computed using SPSS (IBM, Armonk, NY, USA).

## RESULTS AND DISCUSSION

Results of the intra-rater reliability analysis are summarized in Table 1. ICC values for all measures of volume were greater than 0.99. ICC values for all measures of thickness, except for one (LFC = 0.76), were greater than 0.91. These high ICC values reflect a high degree of intra-rater reliability between measurement trials, for this specific rater. Differences between the first and second measurements of thickness and volume, for the same rater, are described in more detail in Table 2. Like the ICC values, the data presented in Table 2 also show that our trained examiner was able to consistently (1) adjust the segmentations that were initially established by the software, and (2) derive characteristics of articular cartilage morphology (thickness and volume) via the segmentations.

**Table 2:** Differences between measurements of articular cartilage morphology that were derived from the same MRI scan, four weeks apart.

Region	Thickness (mm)		Volume (mm <sup>3</sup> )	
	Mean Diff (±)	% Diff	Mean Diff (±)	% Diff
F	0.05 (0.03)	2.6	94.9 (67.1)	1.0
cMF	0.08 (0.06)	4.6	19.2 (16.2)	1.2

$$*ICC_{(2,1)} = \frac{BMS - EMS}{BMS + (k-1)EMS + k \left[ \frac{TMS - EMS}{N} \right]}, \text{ where } k=2 \text{ (trials), } N=5 \text{ (number of scans)}$$

$$*SEM = s\sqrt{1 - r}, \text{ where } s = \text{standard deviation of the measurements, } r = ICC_{(2,1)}$$

\*Mean: the mean of the measured values (i.e., cartilage thickness and volume) in 10 scans (5 scans × 2 trials)

[2], which are millimeter (mm) in this case. Note that mean differences shown in Table 2, for both thickness and volume are within SEM range (Table 1). This indicates that the mean differences reported in Table 2 are within an acceptable error range. Although there was generally good intra-rater reliability, the results showed that the rater did have lower reliability for some regions (e.g., pLF thickness). Although we are unsure what the cause of these differences in reliability is, across different femoral regions, we speculate that generally thinner thicknesses may influence segmentation reliability [2]. Finally, it will obviously be important to assess the accuracy of our method. Our values fit well with similar values, from previous literature, describing femoral thickness and volume; however, we still plan to evaluate the accuracy of our measures by comparing our results with results, from the same MRI scans, analyzed by an experienced radiologist.

## CONCLUSIONS

In conclusion, our results show that our trained rater can reliably derive measures of femoral cartilage thickness and volume, from MRI scans, using this semi-automated quantitative analysis method.

# FEASIBILITY OF BIPLANE FLUOROSCOPY FOR QUANTIFICATION OF SHOULDER KINEMATICS DURING MANUAL WHEELCHAIR USE

Joseph D. Mazingo, Mohsen Akbari-Shandiz,  
Cynthia H. McCollough, and Kristin D. Zhao

Mayo Clinic, Rochester, MN, USA  
Email: zhao.kristin@mayo.edu

## INTRODUCTION

The majority of individuals with a spinal cord injury that use a manual wheelchair (MWC) report shoulder pain. Shoulder mechanical impingement, caused by narrowing of the subacromial space during MWC use, is considered a primary extrinsic mechanism associated with shoulder pain and rotator cuff pathology [1]. It has been suggested that a change as small as 1-2 mm in the subacromial space may constitute an overall 10-70% reduction [2]. Thus, marker-based kinematic approaches, which are prone to skin motion artifact, are insufficient for elucidating the biomechanical basis of this problem. 3D-2D model-image registration, using biplane fluoroscopy and computed tomography (CT), has become the gold standard for noninvasive in vivo quantification of bony motion, providing sub-millimeter and sub-degree kinematic accuracy. Investigators have demonstrated the utility of this technique for quantification of shoulder kinematics and changes in the subacromial space, but previous work has mainly been limited to arm elevation tasks in able-bodied individuals. *Thus, the goal of this work was to develop, validate, and demonstrate the feasibility of an approach to quantify shoulder kinematics during MWC use using a clinical biplane fluoroscope.*

## METHODS

A cadaveric validation study was first performed in order to determine the accuracy of this technique. One male fresh frozen cadaver (age 82 yrs.) with the thorax and arms intact was obtained from the Mayo Clinic anatomical bequest program after the protocol was approved by the Mayo Clinic biospecimens subcommittee. 4-6 radiopaque beads were implanted directly into discrete regions of the humerus and scapula of both shoulders in order to conduct radiostereometric analysis (gold standard).

The specimen was CT imaged (Definition Flash, Siemens Healthcare) at 120 kVp, 250 quality reference mAs, 200x200 mm FOV. In order to create 3D models, the scapula and humerus were manually segmented from the image volume by defining regions of voxels that corresponded to each bone (AnalyzePro; Mayo Clinic).

Next, the specimen was secured upright in a custom device that allowed for unconstrained motion of the upper limb, and the glenohumeral joint was centered in the imaging volume of a clinical flat-panel biplane fluoroscope (Artis Zee; Siemens Healthcare). Fluoroscopic images were acquired at 15 frames/second per plane (pulse width= 3.2 ms for each source) during 3 simulated motions, including elevation in the scapular and sagittal planes, and external rotation of the shoulder.

Bone models were registered to fluoroscopic images using freely available model-image registration software (Autoscooper; Brown University). The pose of each model was adjusted such that its DRR was aligned with its fluoroscopic projection in each image plane. RSA was performed using freely available software (XMA Lab; Brown University) in order to track the 3D position of each bead. These positions were used to calculate frame-to-frame motion of bead-based coordinate systems and, therefore, the respective bones to which the beads were rigidly fixed. Global orientation and position data of the bone models and bead clusters were transformed to anatomical coordinate systems for direct comparison using landmarks established by the International Society of Biomechanics [3].

Following IRB approval and informed consent, 1 healthy able-bodied male subject (age 24 yrs.) was enrolled in this pilot study to determine the feasibility of this approach. The subject sat in a rigid low-back manual wheelchair atop a set of stationary manual wheelchair rollers (McLain

Wheelchair Roller; Riverfront Cycle) and the dominant shoulder was centered in the imaging volume of the biplane fluoroscope. Each source and image receptor was positioned to allow unconstrained movement and to provide an imaging volume that captured the shoulder anatomy across its range of motion. After practicing the activity, fluoroscopic images were acquired at 15 frames/second per plane during three cycles of propulsion (Fig. 1). A CT scan of the subject's dominant shoulder will be obtained in order to generate 3D models of the humerus and scapula, conduct 3D-2D registration, and quantify glenohumeral motion.

## RESULTS AND DISCUSSION

We evaluated the accuracy of our approach by computing the absolute difference between 3D-2D model-image registration and RSA for each rotational and translational kinematic parameter (results included in Table 1). For scapula kinematics, the mean absolute difference did not exceed 0.49 mm and 0.27° across all degrees of freedom, with maximum errors of 1.07 mm and 0.77°. For humerus kinematics, the mean absolute difference did not exceed 0.34 mm and 0.44° across all degrees of freedom, with maximum errors of 0.92 mm and 1.09°.

This work defined the accuracy of 3D-2D model-image registration for the quantification of dynamic shoulder motion using a clinical biplane fluoroscope, CT, and open-source DRR-based registration software. Importantly, the observed mean kinematic errors of 0.30 mm and 0.31° were comparable to previous studies (mean kinematic

errors ranging from 0.2 – 0.4 mm, 0.1 – 0.5°). These results supported our decision to proceed with the pilot study on an able-bodied individual, for which preliminary images have been provided (Fig. 1).

Axis	Translation (mm)		Rotation (°)	
	Scapula	Humerus	Scapula	Humerus
<b>X</b>	.36 ± .23	.25 ± .17	.19 ± .13	.42 ± .26

## CONCLUSIONS

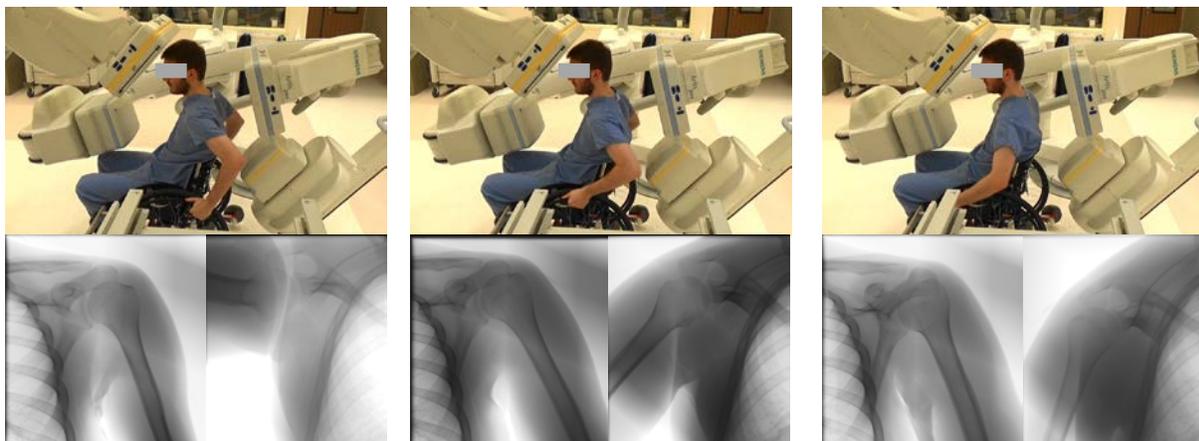

Sub-millimeter and sub-degree kinematic accuracy was obtained using an off-the-shelf clinical biplane fluoroscope, enabling quantification of small changes in subacromial space. Furthermore, our pilot subject study demonstrates the ability to use this approach to obtain biplane fluoroscopy images during manual wheelchair propulsion. Future work will involve application of this technique in individuals with a spinal cord injury in order to determine which MWC-based activities and conditions impose an increased risk of rotator cuff damage.

## INTRODUCTION

Wrist instability is a major cause of pain, disability, and premature osteoarthritis [1]. In early stages, instability may be difficult to diagnose and pain may only be manifest during joint motion [1]. Clinically, wrist MRI is performed only in the static, neutral position. Therefore, there is no opportunity for assessing early stages of joint instability. Our goal was to implement a quick (<5 min) MRI scan “sequence” as part of our standard clinical wrist MRI exam to assess continuous, active, uninterrupted motion, and extract biomechanical information of relevance to wrist instability.

Two candidate real-time MRI (RT-MRI) pulse sequences were implemented and compared *in vivo*: (1) spoiled gradient echo (fast low angle shot, FLASH) and (2) steady-state free precession (true fast imaging with steady-state free precession, TrueFISP) [2]. We asked (1) can these two RT-MRI sequences provide a direct visualization of the actively moving wrist joints, and (2) which of the two sequences had superior performance with respect to image quality, artifacts and temporal resolution?

## METHODS

Data Acquisition: All protocols were approved by the UC Davis Institutional Review Board. A Skyra 3T System (Siemens Healthcare, Erlangen, Germany) using a 32-channel head radiofrequency coil was used. Preliminary experiments involved phantom scanning and multiple scans of two human participants to optimize scan parameters. The default sum-of-squares based image reconstruction was adopted for all the sequences. RT-MRI datasets were then acquired from three healthy volunteers (age 27±3 years; 2 males). Each sequence acquired 10

different positions of radial ulnar (RU) deviation and clenched fist maneuvers for every subject. Further, each maneuver was repeated thrice to evaluate reproducibility. Finally, the underlying contrast associated with the FLASH sequence was optimized to further improve the visualization of joint spaces by adopting a fat-suppression scheme. The inclusion of fat-suppression marginally increased the temporal resolution by 4%.

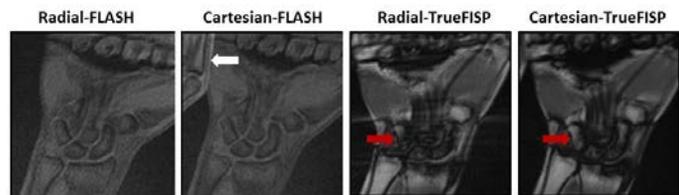

Data Analysis: In the first part, the performance of the two sequences was evaluated visually in terms of spatial resolution and degree of artifacts in images. Further, a comparison of the radial and Cartesian (rectilinear) k-space sampling was performed for real-time imaging with the afore mentioned wrist maneuvers. Secondly, fat-suppressed radial-FLASH was evaluated for both spatial and temporal resolution to demonstrate its viability to visualize the moving wrist joints. The scan re-scan reproducibility was quantified by placing regions of interest on the carpal bones and computing the signal-to-noise-ratio (SNR) across all the slices.

## RESULTS AND DISCUSSION

The achievable temporal resolution with the optimized parameters for each sequence is given in Table 1. Note that spatial resolution (determined by the number of radial spokes/Cartesian lines) and temporal resolution are inversely related, therefore there is a trade-off. Radial-FLASH had promising results in terms of spatial and imaging artifacts compared to other sequences (Fig. 1). Although TrueFISP resulted in an appreciably higher image contrast, images were affected by banding artifacts/signal loss (red arrows in Fig. 1) caused by field inhomogeneity that arises due to wrist motion. On the other hand, FLASH provided images

relatively free of banding artifacts, making it a viable scheme for tracking the wrist motion.

The advantage of using radial rather than Cartesian sampling is illustrated in Fig. 1. Radial sampling eliminated wrap around effect (white arrow) since it relied only on frequency-encoding gradients that cover both low- and high-frequency components in every single spoke [2].

**Figure 1:** Representative coronal slices using radial-FLASH, Cartesian-FLASH, radial-TrueFISP, and Cartesian-TrueFISP from a healthy subject during RU deviation. Red and white arrow(s) point at the banding artifacts and wrap around effect respectively.

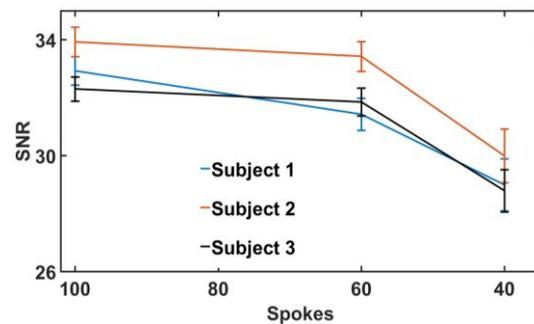

The efficacy of the fat-suppressed FLASH in terms of image quality and contrast is illustrated in Fig. 2. The contrast provided by fat-suppressed FLASH was reasonable to distinguish carpal bones and joint spaces of the wrist. Further, Fig. 2 and Table 1 suggests that higher frame rates are possible (up to 7 frames/sec) to assess the wrist kinematics, while maintaining acceptable image quality. Finally, radial-FLASH was also consistent in intersubject and intrasubject reproducibility (Fig. 3).

From our preliminary results, the RT-MRI radial-FLASH sequence demonstrated superiority in its ability to assess the motion of the actively moving wrist. The present study will be extended by increasing the sample size and deriving quantitative measures such as distal radioulnar joint congruity

and changes in the scapholunate interval during wrist motion from the radial-FLASH images.

**Figure 2:** Representative coronal slices (during RU deviation) using fat-suppressed radial-FLASH at 100, 60 and 40 spokes corresponding to 3, 5, and 7 frames/sec.

**Figure 3:** SNR versus number of radial spokes (with error bars) for three different subjects (RU deviation) to demonstrate the reproducibility of radial-FLASH.

## CONCLUSIONS

This study designed a feasible RT-MRI protocol and suggests the use of radial-FLASH to achieve adequate spatial and temporal resolution for monitoring active wrist motion.

## INTRODUCTION

Fascicle length is an important parameter in defining a muscle's force-generating capacity. Currently, ultrasound is the most common method of measuring fascicle length *in vivo* [1]. However, 24 of 26 forearm muscles have fascicles longer than the field-of-view of common traditional ultrasound (T-US) probes. As such, little work has been done to quantify *in vivo* forearm muscle architecture. The extended field-of-view ultrasound (EFOV-US) algorithm fits together a sequence of T-US images obtained via a continuous ultrasound scan [2], facilitating direct measurement of longer, curved fascicles. Misalignment of the ultrasound probe from the plane of the fascicles has been shown to result in fascicle length error using T-US. Because EFOV-US requires long, dynamic scans, there is concern such misalignment error could aggregate, reducing accuracy and reliability. The objective of this study was to determine the validity and reliability of the EFOV-US method for obtaining fascicle lengths in the extensor carpi ulnaris (ECU).

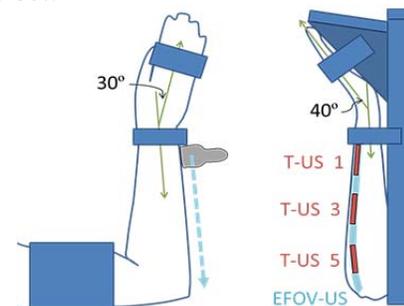

## METHODS

T-US and EFOV-US images of the ECU were obtained from 8 subjects (4F/4M, ages 23-29, height range 59-73") with no history of musculoskeletal disease or injuries of the upper limb. All subjects provided informed consent; Northwestern University's Institutional Review Board approved this study's procedures.

To evaluate the validity of our measurement protocol, an ultrasound phantom was imaged using EFOV-US. The phantom was constructed to mimic the sonic properties of muscle tissue. Wooden blocks and guitar strings (20-75mm) were measured with a caliper precise to 0.01mm before placement

inside the phantom. Image collection occurred with the ultrasound machine set to EFOV-US mode. Images were exported in DICOM format and object lengths were measured using the segmented line tool in ImageJ (NIH, Bethesda, MD). A Bland-Altman test of agreement was implemented to compare phantom object dimensions measured using the caliper and EFOV-US.

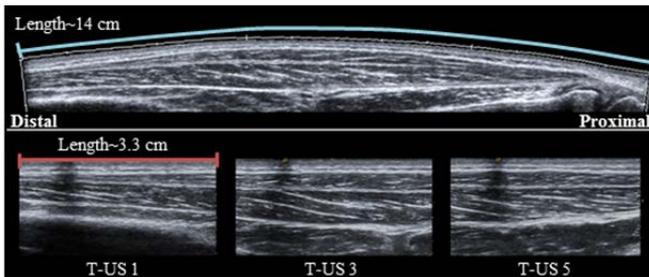

To determine if EFOV-US's long scan yields greater fascicle measurement error than T-US, the right arms of 8 healthy subjects were imaged using both methods. Subjects were seated with their arm rigidly secured in a joint posture that shortened the ECU to the extent that entire fascicle lengths could be captured within a single T-US image (Fig. 1). To enable comparisons between the two methods, the sonographer first obtained an EFOV-US image of the ECU then collected 6 corresponding T-US images that spanned the length of the ECU (Fig. 2). Three corresponding "image sets" (1 EFOV-US and 6 T-US images) were collected per subject. An average of 8 fascicles were measured per method per image set.

**Figure 1:** Subject's arm position during imaging. Light blue lines indicate the transducer path for a single EFOV-US scan; superimposed red lines illustrate 3 of the 6 corresponding T-US images collected within a given "image set".

A matched-pairs t-test was implemented to compare the average fascicle lengths obtained from the first "image set" collected. A pre-hoc power analysis,

based on uncertainty calculated via the phantom study, indicated that a power greater than 0.80 would be achieved with 6 subjects and an effect size of 1.69. A Bland-Altman plot tested agreement between fascicle measurements obtained using EFOV-US and T-US. The intraclass correlation coefficient (ICC) was calculated from repeated “image sets” to test between trial reliability of EFOV-US.

**Figure 2:** EFOV-US image and three example T-US images of the ECU from the same “image set”.

## RESULTS AND DISCUSSION

The measurements from the ultrasound phantom indicate that the EFOV-US imaging and analysis methods produced valid results. We observed an average error of  $2.2 \pm 1.3\text{mm}$  (4.6% average phantom object length). A Bland-Altman plot demonstrated agreement between direct caliper and EFOV-US measurements of the phantom objects (bias =  $-0.67\text{mm}$ , 95% CI:  $-5.57$  to  $4.23\text{mm}$ ).

EFOV-US fascicle measurements are comparable to those obtained from T-US, a well-established method. Average EFOV-US fascicle lengths over the full length of the muscle ( $27.9 \pm 3.7\text{mm}$ ) were not significantly different ( $p = 0.18$ ) than T-US fascicle lengths ( $28.2 \pm 4.0\text{mm}$ ). Bland-Altman analysis also indicates that the two methods agree (bias =  $-0.35\text{mm}$ , 95% CI:  $-1.47$  to  $0.77\text{mm}$ ). Fascicle lengths at the end of the EFOV-US image, where misalignment error associated with the continuous scan would presumably aggregate, were not significantly different ( $p = 0.42$ ) from T-US lengths in the same location within the muscle. Between trial reliability (ICC=0.99 95% CI:0.95-1.00) was excellent [3].

The EFOV-US method is more accurate than an approximation method commonly used when fascicles are longer than the field-of-view of T-US.

Trigonometric estimation was shown to yield an absolute error of  $7.7 \pm 6.2\text{mm}$  in the vastus lateralis, which was approximately 9% of total fascicle length [3]. Our error, determined by the analysis of our phantom images, was 4.6% of object length ( $2.2 \pm 1.3\text{mm}$ ). Notably, differences in fascicle length between the paretic and non-paretic arm of individuals post-stroke are larger than the error observed in our phantom study. For example, a study implementing T-US on the brachialis muscle found fascicles of the paretic arm to be 9-15% shorter (8-21mm) than fascicles of the non-paretic arm [4]. Thus, EFOV-US may be the best available ultrasound imaging approach to study clinically relevant changes in forearm fascicle length.

## CONCLUSIONS

Only one previous study has quantified *in vivo* fascicle lengths in a forearm muscle, despite the ubiquity of ultrasound studies in other muscle groups and the importance of architecture in understanding muscle force generation. The EFOV-US method has the capacity to capture the entire length of the fascicle in one image; this is advantageous in the forearm where over 90% of muscles have optimal fiber lengths longer than the field-of-view of T-US. Utilizing this method in patient populations, such as individuals post-stroke or post-surgery, may enable subject-specific muscle models and improve rehabilitation strategies.

# INTRA-OP BIOMECHANICAL GUIDANCE IMPROVES ARTICULAR FRACTURE REDUCTION

Andrew M. Kern, Michael C. Willey, J. Lawrence Marsh, Donald D. Anderson  
Department of Orthopedics and Rehabilitation, The University of Iowa, Iowa City, IA  
email: andrew-kern@uiowa.edu, web: <http://www.uiowa.edu/uiobl/>

## INTRODUCTION

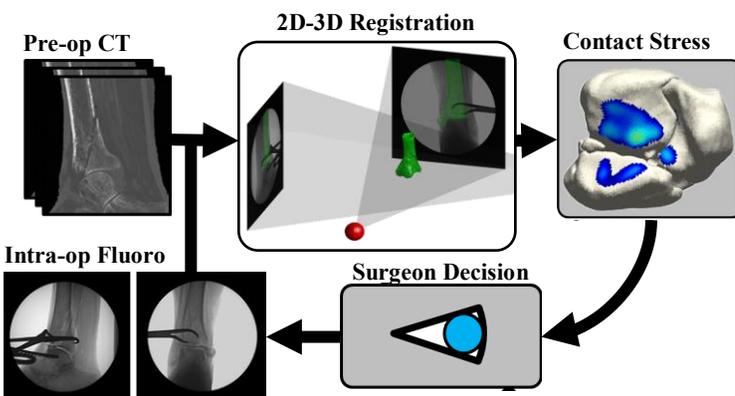

Intra-articular fractures (IAFs) often lead to poor outcomes, despite surgeons' best efforts at reconstructing the fractured articular surface. The objective of articular fracture reduction is to lower contact stress within the joint, thereby minimizing risk of post-traumatic osteoarthritis (PTOA). Surgical fracture reductions performed using less invasive approaches (i.e., percutaneously) rely heavily upon C-arm fluoroscopy to judge articular surface congruity. The use of 2D imaging alone for this purpose may prove inadequate<sup>1</sup>.

We explored the value of a biomechanical guidance system for aiding in articular fracture reduction. In five fractured cadaveric ankles, contact stresses, and contact areas were compared in surgeries performed with or without biomechanical guidance.

## METHODS

The biomechanical guidance system uses C-arm fluoroscopic imaging, along with pre-op CT data, to intra-operatively determine fracture fragment poses, (**Fig. 1**). This is done using established 2D-3D registration methods. Optional contact stress analysis provides complementary biomechanical data<sup>2</sup> to inform surgeon decision making.

Five cadaveric ankles obtained from the University

**Figure 1.** Overview of intra-op biomechanical guidance system.

of Iowa Deeded Bodies Program were fractured into clinically relevant patterns using an osteotome and a mallet. Following fracture, the proximal end of the tibia and fibula were potted in bone cement, and a baseline CT image was acquired.

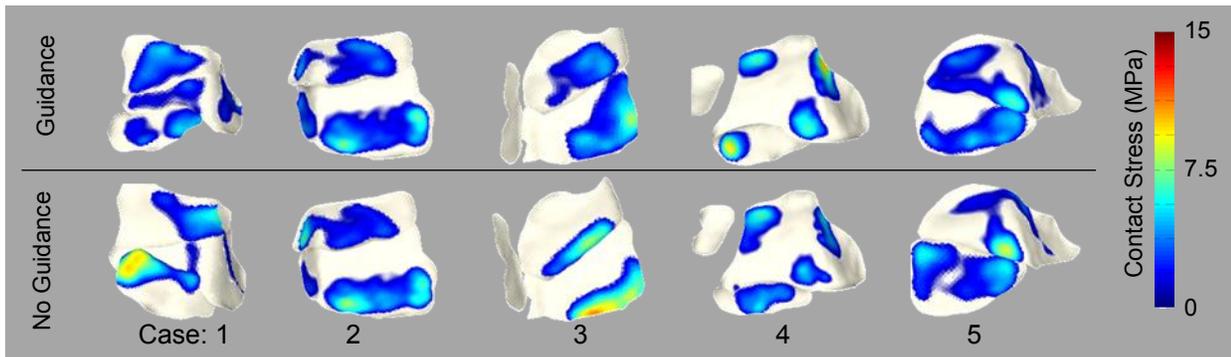

Each fractured ankle was surgically reduced and fixed using percutaneous methods. Surgery was performed twice on each ankle (i.e., 10 surgeries), once in which biomechanical guidance information was shown to the surgeon, and once in which the information was withheld. To mitigate training effects, the order in which surgeries were performed was randomized, three of the ankles were reduced with guidance on their first operation. Repeat surgeries on the same ankle were separated by at least 48 hours, with all fixation hardware removed and incision sites sutured between surgeries.

During surgeries assisted by the biomechanical guidance system, the surgeon was instructed to use the system whenever there was doubt about the state of the reduction. Upon completion of the surgery, the biomechanical guidance system was used once again to determine the final fragment pose and contact stress distribution. A post-op CT scan was obtained to provide gold-standard data.

Following surgical fixation, the post-op result was compared between cases with vs. without information displayed to the surgeon. Contact stress metrics and contact area were compared.

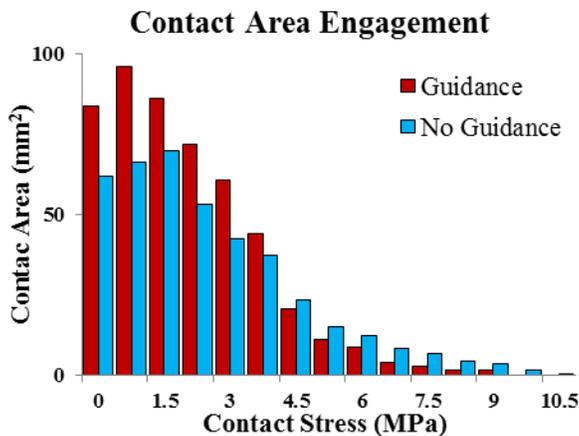

## RESULTS AND DISCUSSION

All surgical reductions were satisfactorily completed. Visual comparisons of contact stress distributions between guided and unguided cases suggest value to using the guidance system (**Fig. 2**). Mean and maximum contact stresses were lower using guidance in four of five cases tested. The average reduction was 0.71 and 1.51 MPa for mean

**Figure 2.** Contact stress distributions following definitive reduction with and without biomechanical guidance. Notable improvement (reduction) in contact stress shown in all cases except for case 4.

and maximum contact stress, respectively. Contact area engagement histograms show that unguided cases had greater areas at higher levels of contact stress than did the guidance cases. (Fig. 3)

**Figure 3.** Contact stress area engagement histogram. Area reported is mean area across all bins. Note that cases with guidance had less contact area engaged >4.5 MPa.

The single case that did not show a reduction in contact stress with guidance (**Case 4 in Fig. 2**) was unique in that it was the only case with four fracture fragments, and the articular surface was completely separated from the diaphysis of the tibia. The increased complexity of this fracture or the specific fracture pattern may explain the worse outcome using biomechanical guidance.

Due to the prototype nature of this system, it is expected that additional experience with this system will further improve results, as the clinician is able

to better integrate this information. The contact area engagement histogram shows a trend consistent with prior work linking contact stress to PTOA risk, where contact area engaged at contact stresses >4.5 MPa was shown to be particularly deleterious<sup>3</sup>.

## CONCLUSIONS

A biomechanical guidance system was used to aid in the reduction of 5 fractured cadaver ankles. Metrics of contact stress and contact area were improved in four of the five cases tested when the guidance was used. These encouraging results suggest that the provision of intra-op biomechanical information to surgeons has potential to improve long-term outcomes of these difficult fractures. Future work will involve improvement to the core algorithms of the system, additional cadaveric experimentation, and if suitable, eventual translation to the OR.

# EXPLICIT MODIFICATION OF STEP LENGTH ASYMMETRY TRANSFERS TO OVER-GROUND WALKING POST-STROKE

<sup>1</sup> Natalia Sanchez and <sup>1</sup> James M. Finley

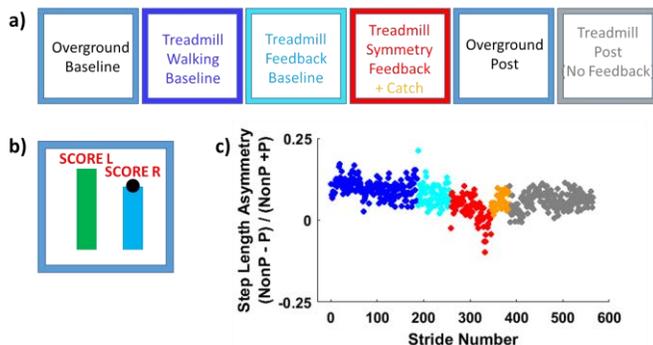

<sup>1</sup> University of Southern California, Los Angeles, CA, USA  
email: sanc232@usc.edu

## INTRODUCTION

After a stroke, changes in the control of the lower extremities lead to asymmetric step lengths during walking [1,2]. Asymmetries can occur in both directions, with some individuals taking short steps with their paretic leg (and long steps with their non-paretic extremity) or vice versa. However, the degree to which differences in the direction of asymmetry impact the potential for modification of step lengths has not been investigated systematically.

Here, we use visual feedback of foot placement to modify step length asymmetry during treadmill walking in individuals with chronic hemiparetic stroke. We hypothesized that online, visual feedback of actual and desired step lengths could help people post-stroke to improve symmetry. Furthermore, we predicted that this improvement in symmetry would transfer to over-ground walking.

## METHODS

**Figure 1:** a) Experimental protocol b) Visual feedback c) Data from a single participant color-coded to match the corresponding task in (a).

Twelve chronic, hemiparetic stroke survivors participated in this study. Initial walking function was evaluated using the 6-minute walk test. The average speed obtained from this test (or at least 75% of this speed [3]) was used as the target speed for the

treadmill. Motor impairment was quantified using the lower extremity portion of the Fugl-Meyer Assessment.

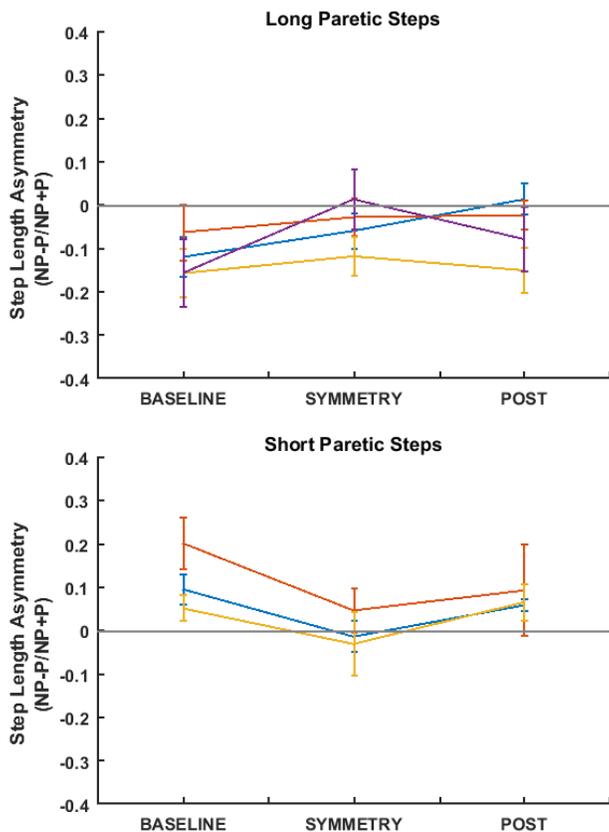

All participants were tested under the following conditions (sitting breaks of at least five minutes were given between trials): an overground walking trial (OG BASE), a treadmill familiarization trial (FAMILIARIZATION), and a 5-minute treadmill BASELINE trial where we measured their natural step length asymmetry. The visual feedback consisted of two vertical bars corresponding to desired right and left step lengths, and real-time location of their feet was projected onto the bars using markers placed on their ankles (Figure 1b). The length of the bar corresponding to the short step was lengthened to match their long step and generate a symmetric walking pattern (SYMMETRY). Participants then walked across a 4m walkway to determine whether the symmetric walking pattern that was enforced on the treadmill transferred to over-ground walking (OG POST). Finally, participants walked on the treadmill for an additional five minutes to test for retention of the symmetric walking pattern (POST).

Kinematic data for markers placed bilaterally were collected using a ten camera Qualisys Oqus camera system (QTM, Sweden). The fore-aft distance between markers on the lateral malleoli was used to measure step lengths and step length asymmetry (Equation 1).

$$\text{Step Length Asymmetry} = \frac{SL_{NonParetic} - SL_{Paretic}}{SL_{NonParetic} + SL_{Paretic}} \quad (1)$$

Participants were classified as symmetric if the magnitude of their asymmetry was below 0.035. This value corresponds to the mean  $\pm$  two standard deviations of the step length asymmetry measured in healthy participants from a previous study.

## RESULTS AND DISCUSSION

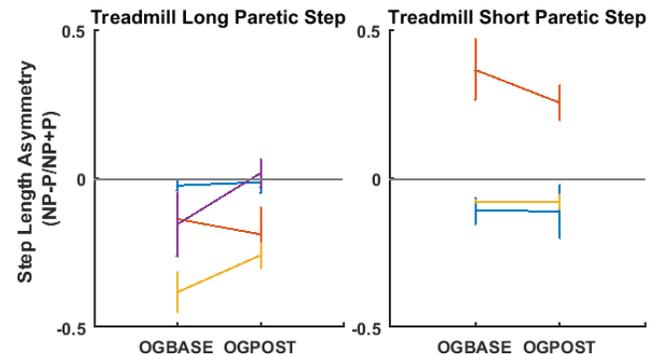

**Figure 2:** Step length asymmetry during treadmill walking for BASELINE, SYMMETRY and POST conditions for each type of asymmetry. Error bars indicate standard deviations.

Of the 12 participants tested, 7 participants were classified as asymmetric. Of these individuals, 3 took short steps with their paretic leg and had step length asymmetries of  $12 \pm 7\%$ , and 4 participants took long steps with their paretic leg and had asymmetries of  $-12 \pm 4\%$ . Aided by visual feedback, participants in the long paretic group reduced their asymmetry by  $60 \pm 35\%$  whereas participants in the short paretic group reduced their asymmetry by  $108 \pm 30\%$  (Figure 2). These preliminary results suggest that participants with short paretic steps may be more capable of using an explicit strategy to improve their symmetry on the treadmill.

After walking on the treadmill, 4/7 participants transferred improvements in symmetry to over-ground walking (Figure 3). The three participants in the long paretic group reduced their over-ground

asymmetry by  $33 \pm 53\%$ , whereas participants in the short paretic group reduced their asymmetry by  $9 \pm 18\%$ . Lastly, some of the improvements in symmetry were retained upon return to the treadmill during the POST trial (Figure 2). Here, we observed a  $58 \pm 44\%$  reduction for the long paretic group relative to BASELINE and a  $25 \pm 37\%$  reduction for the short paretic group.

**Figure 3:** Mean (+/-SD) overground step length asymmetry before and after treadmill training.

## CONCLUSIONS

Our results demonstrate that real-time feedback of step length can help to reduce step length asymmetry in chronic post-stroke individuals. Although the observed reductions in asymmetry were acquired on a treadmill using an explicit strategy, practice with a more symmetric pattern generalized to over-ground walking. This result demonstrates that improvements in symmetry were not simply tied to the online, visual feedback, but instead led to a recalibration of participants' walking pattern. Our findings also demonstrate that despite decreased performance of participants with longer paretic steps during on-line feedback, they tended to show greater transfer to over-ground walking and better retention of improvements in symmetry when they returned to the treadmill. These results are preliminary, and it remains to be seen if these patterns hold for a larger sample of participants.

## INTRODUCTION

Stroke is a leading cause of disability. Resulting hemiparesis limits hip, knee, and ankle movement. Gait impairments increase the likelihood of falls and decrease independence and community involvement. Ankle Foot Orthoses (AFO) and peroneal nerve stimulation assist dorsiflexion to improve toe clearance, reducing fall risk. However, many patients would also benefit from hip and knee assistance. Multi-joint Functional Electrical Stimulation (FES) has been studied as a therapeutic tool; a recent case study demonstrated an implanted multi-joint FES system targeting hip, knee, and ankle muscles improves poststroke gait [1]. Stimulation assistance doubled walking speed. There is further room for improvement as the stimulation pattern did not stimulate plantar flexors, which musculoskeletal models suggest significantly contribute to gait speed [2]. Surface plantar flexion stimulation has modestly improved kinematics [3].

Incorporating plantar flexion stimulation into a gait pattern has been challenging. It requires accurate timing as initiating plantar flexion too early could deter forward progression while stopping stimulation too late could result in toe catching resulting in trips and falls. This study evaluated adding implanted plantar flexion stimulation to a multi-joint FES system and the response to coordinating stimulation with different aspects of gait.

## METHODS

We evaluated plantar flexion stimulation in a single individual. The participant had left sided hemiparesis resulting from a hemorrhagic stroke.

Gait was slow and asymmetric due to lower extremity weakness and hypertonia. He was implanted with a neuroprosthesis 2 years after his stroke [1]. The neuroprosthesis consisted of an 8-channel implanted pulse generator, 8 intramuscular electrodes, and an external control unit. A stimulation pattern was developed to coordinate stimulation with his volitional gait. Stimulating electrodes in the pattern targeted the following muscles: sartorius, tensor fasciae latae, gluteus maximus, quadriceps, and tibialis anterior. A heel switch triggered stimulation transitions between swing and stance phase stimulation.

We compared three walking patterns during a single session. Conditions included 1) no plantar flexor stimulation, 2) gastrocnemius stimulation triggered by -7 degrees stance phase ankle dorsiflexion, and 3) gastrocnemius stimulation triggered by contralateral heel strike. These conditions compare introducing stimulation during the stance phase in anticipation of push off and at the weight transition at the onset of push off. Stimulation parameters were consistently applied to other muscles across trial conditions.

An encoder instrumented on an AFO measured ankle dorsiflexion to trigger stimulation during stance. Stimulation remained on for at least 300ms in this condition and turned off at heel off. A heel switch in the contralateral shoe detected heel strike to trigger stimulation at weight transition. The minimum stimulation duration was 100ms in this condition. Gastrocnemius stimulation durations were chosen to prevent toe catches during early swing.

The participant walked along an 8m walkway while wearing reflective markers on the lower extremities measured by a Vicon motion tracking system. Hip, knee, and ankle angles were calculated using the Vicon software. At least 15 strides per condition were used for analyses.

The primary outcome was joint kinematics. Lower extremity flexion and extension joint angles were time normalized between strides from heel strike to heel strike. Strides were ensemble averaged. Compared kinematic parameters include peak ankle dorsiflexion during push-off, peak ankle dorsiflexion during swing, and peak knee flexion during early swing. Analysis of Variance and post-hoc t-tests evaluated statistical significance.

## RESULTS AND DISCUSSION

Fig. 1 shows the effect of plantar flexor stimulation on stride normalized sagittal plane gait kinematics. Table 1 presents joint angles and statistical comparisons for ankle dorsiflexion during push off and swing as well as knee flexion during early swing. Plantar flexion stimulation reduced dorsiflexion during stance and increased plantar flexion in push-off. Although peak dorsiflexion decreased during swing with plantar flexor stimulation, dorsiflexion stimulation still generated adequate dorsiflexion for toe clearance. Introducing plantar flexor stimulation earlier in the gait cycle was associated with earlier hip flexion.

**Table 1:** Peak joint angles during gait phases.

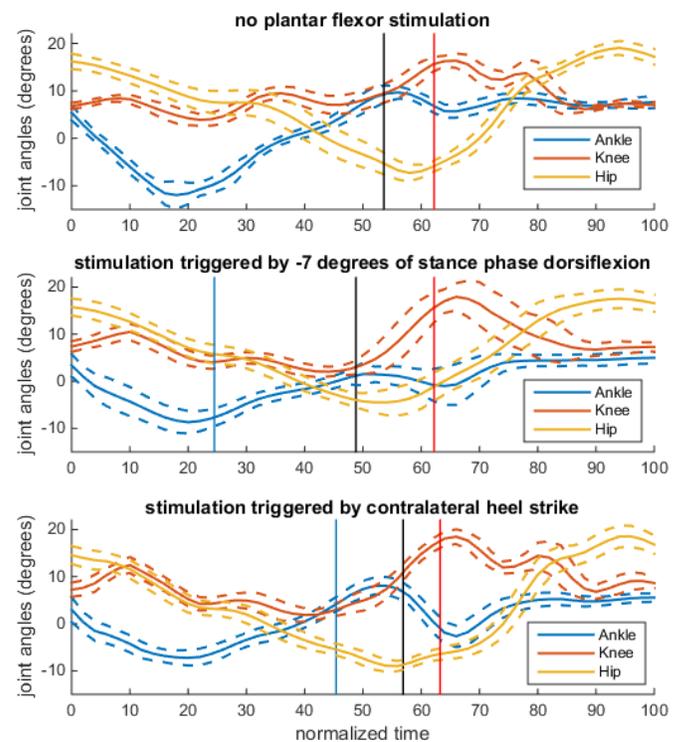

Peak Angle	Plantar flexion trigger		
	None	Ankle	C. Heel Strike
Push off DF	5.0 (1.6)	-2.1 (3.5)*	-3.7 (2.5)~
Swing DF	10.5 (1.3)	5.6 (1.5)*	8.0 (2.3)†
Knee Flexion	16.9 (1.5)	20.8 (1.8)*	18.9 (1.6)†

\* statistical significance between None and Ankle ( $p < 0.05$ )

~ statistical significance between None and C. Heel Strike ( $p < 0.05$ )

† statistical significance between Ankle and C. Heel Strike ( $p < 0.05$ )

These results suggest the addition of plantar flexion makes plantar flexion push off and swing knee flexion more similar to normal gait. Improved knee flexion contributes to toe clearance as well. Initiating plantar flexor stimulation during mid stance increases the effect on knee flexion. The participant did not have extensive time to practice

**Figure 1:** Time normalized ensemble averaged strides during stimulation assisted walking with additional plantar flexion stimulation. Red vertical line represents average toe off timing. Blue vertical lines represent the transition to push off while black vertical lines represent the stimulation transition to swing phase.

walking with plantar flexion stimulation incorporated into the stimulation pattern. Further practice walking with plantar flexion stimulation may improve confidence while loading the impaired limb. After additional training, further study should evaluate the effect of plantar flexor stimulation on joint torques, gait speed, and metabolic efficiency. Although this study compared introducing plantar flexor stimulation at two points in the gait cycle, additional optimization of timing would ensure plantar flexor stimulation generates the optimal benefit.

## INTRODUCTION

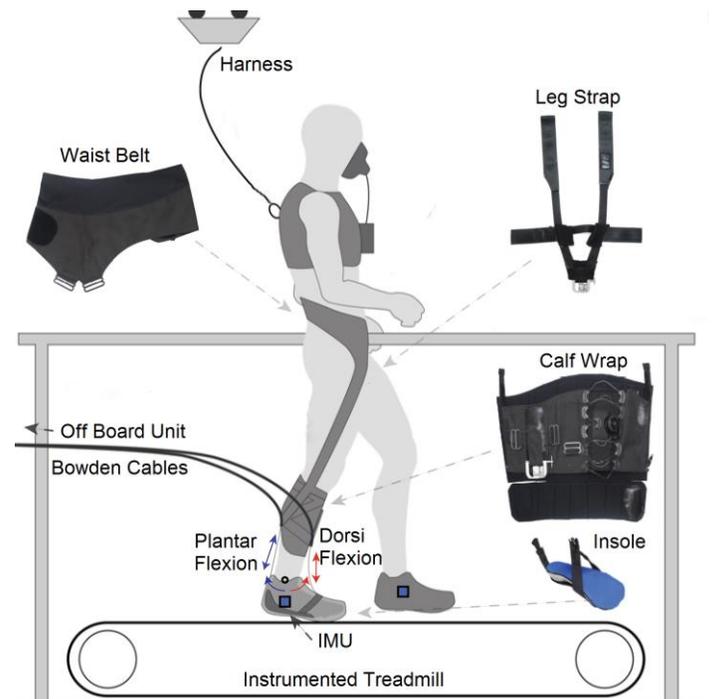

Our group has been developing soft wearable robots (exosuits) made from garment-like, functional textiles to augment healthy individuals carrying heavy loads [1] and to assist individuals who have gait impairments due to hemiparesis following a stroke [2]. We have demonstrated that an ankle-joint assisting robot can reduce the metabolic cost of walking in healthy individuals [3]. In patients post-stroke, we have shown that by providing uni-lateral force assistance to the paretic ankle joint during ambulation, we can assist and improve key gait metrics such as foot clearance and paretic propulsion [4].

The goal of this study was to investigate the effects of exosuit provided ankle assistance on common post stroke gait impairments such as reduced step length and compensatory walking strategies resulting from a hemiparetic gait. With this in mind, we sought to evaluate changes in hip hiking, circumduction, and spatiotemporal gait parameters of individuals in the chronic phase of stroke recovery. We hypothesized that walking with the ankle assistance provided while wearing the exosuit will lead to reductions in hip compensations as well as in improvements in spatiotemporal parameters (e.g. longer step length) compared to walking with the exosuit in its unpowered state.

## METHODS

Nine participants with hemiparesis (4F, 49±4y, time since stroke 4.4±1.4y) completed two walking trials on an instrumented treadmill (Bertec Corp., Columbus, OH; 2160Hz) in a motion capture lab (VICON, Oxford Metrics, UK; 120Hz). Each

walking trial was 8 minutes in length with the last two minutes used for analysis. Participants walked on the treadmill at a predetermined overground comfortable walking speed [4]. Patients first walked with the suit unpowered (no assistance) followed by a powered condition. During the exosuit powered condition, assistive forces (approximately 25% body-weight for plantarflexion assistance) from an off-board actuation system were transmitted to the exosuit textile (Fig. 1). The tethered exosuit assisted ankle plantar flexion during the end of stance phase and ankle dorsiflexion during swing phase. Foot mounted IMUs were used to detect the specific gait events with which onset and offset times for the assistive forces were determined [2].

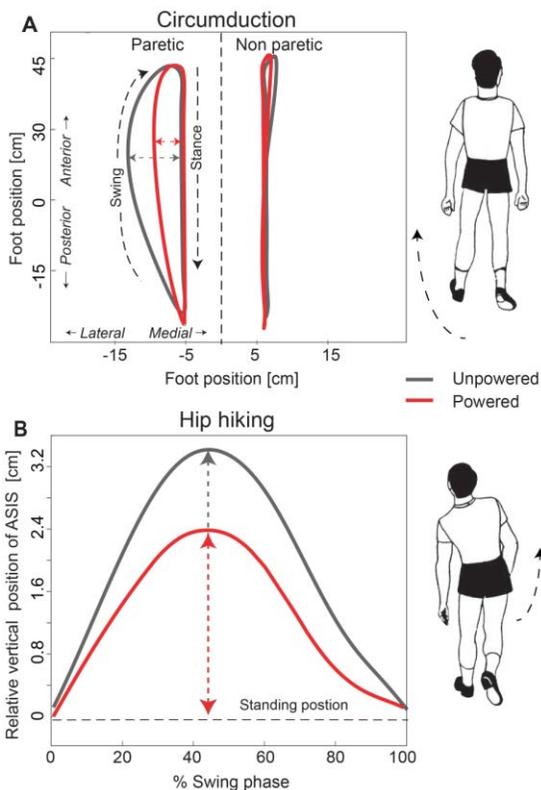

**Figure 1:** Experimental setup and exosuit components

To calculate circumduction, the center of gravity (CoG) of the foot taken from the link-segment model in Visual 3D (C-Motion, Rockville, MD, USA) was used. The difference between the position of the CoG during stance phase and its maximum lateral displacement during swing phase defined the amount of circumduction (Fig.2A) [5]. To calculate the amount of hip hiking, the vertical position of the anterior superior iliac spine (ASIS) markers calculated during quiet standing (static calibration pose taken for kinematic analysis prior to each walking trial) was compared to the maximum vertical position during swing phase (Fig.2B). Lastly, spatiotemporal measures were calculated using heel marker data. Conditions were compared on a group and individual level using a paired t-test ( $p < 0.05$ ).

## RESULTS AND DISCUSSION

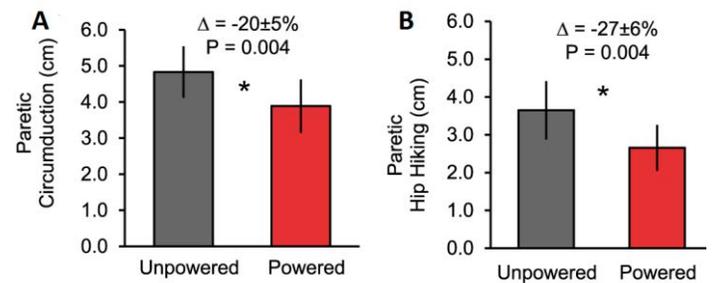

Compared to unpowered, walking with the exosuit powered reduced hip hiking by an average of  $27 \pm 6\%$  ( $p = 0.004$ , Fig. 3A) and circumduction by an average of  $20 \pm 5\%$  ( $p = 0.004$ , Fig. 3B) on the paretic side.

**Figure 2:** Compensatory gait pattern of representative subject showing **A.** Circumduction and **B.** Hip Hiking during exosuit unpowered and powered conditions

At the individual level, each participant presented with a significant decrease in paretic hip hiking and/or circumduction. Step length during the exosuit powered versus unpowered condition increased by  $3 \pm 1\%$  ( $p = 0.002$ ) on the non-paretic side. No significant changes in other spatiotemporal parameters were observed.

These preliminary results suggest that compensatory measures are at least in part secondary deviations resulting from deficits in ankle function. With the known heterogeneity of poststroke walkers, the exosuit provides a platform suitable for subject specific interventions during gait retraining.

**Figure 3:** Group results showing **A.** Circumduction and **B.** Hip Hiking for the paretic limb comparing exosuit unpowered and powered conditions (mean  $\pm$  SE).

## CONCLUSIONS

This study demonstrated that gait compensations in patients poststroke can be reduced by targeting the paretic ankle with a lightweight, soft wearable robot. This is an important step in evaluating and developing a soft exosuit targeting paretic ankle deficits. Further work will focus on translating these findings to overground studies using a body-worn actuator system. With the ability to control applied forces and timing, such technology can potentially extend to gait impairments related to other neurological conditions.

## INTRODUCTION

Individuals with post-stroke hemiparesis often have reduced mobility and decreased gait symmetry [1]. Since walking is typically a bilaterally symmetric movement, a common goal of stroke rehabilitation is to reduce gait asymmetry caused by stroke-induced hemiparesis. Current rehabilitation strategies often seek to improve gait symmetry by using weight supported treadmill walking or physical therapist directed over-ground walking [2]. Most of these therapies have focused on sagittal plane asymmetry, although frontal plane asymmetry has also been reported [3]. As frontal plane balance is dependent on active stabilization [4], the observed frontal plane asymmetry may be partially attributable to deficits in ensuring balance with the paretic leg.

Whole body angular momentum ( $H$ ) is a promising measure of frontal plane balance, as decreased control of frontal plane  $H$  correlates with lower clinical balance scores in post-stroke individuals [5]. A common response to perceived deficits in frontal plane balance is to use a compensatory gait pattern with increased step widths (as well as reduced cadence and decreased step lengths) [6]. However, while wider steps increase the base of support, they can also increase the peak-to-peak  $H$  in the frontal plane [5]. It is currently not known if removing the need for active control of frontal plane balance would allow stroke patients to reduce their gait asymmetry and range of frontal plane  $H$ .

The purpose of this study was to investigate if external mediolateral stabilization is effective at reducing walking asymmetry in hemiparetic gait. We hypothesized that subjects who were capable of adapting their gait with the addition of mediolateral stabilization (Responders) through a reduction in step width would show improved gait symmetry and decreased range of  $H$  in the frontal plane.

## METHODS

Kinematic data were collected at 120 Hz using a 16-camera motion capture system (PhaseSpace Inc.) from nine hemiparetic post-stroke individuals (4 right hemiparesis, 3 male, age:  $49 \pm 17$  years) during steady state walking on a dual-belt, instrumented treadmill (Bertec Corp.).

Subjects were analyzed during two walking conditions: normal and stabilized. For the normal condition, subjects walked at their self-selected speed on the treadmill for three 30-second trials. The subjects were then fitted with the lateral stabilization apparatus, which applied mediolateral stabilization at the pelvis. Subjects adapted to the added stabilization over a 6-minute period, and once comfortable, completed three 30-second trials at their normal condition self-selected speed. Subjects were classified as a Responder if their step width significantly decreased ( $p < 0.05$ ) between the normal and stabilized conditions as determined by a two-tailed t-test. Step width was defined as the mediolateral distance between heel markers at consecutive heel strikes.

$H$  was calculated using a 13-segment inverse dynamics model, which summed the angular momentum of each segment about the whole-body center of mass ( $CoM$ ).  $H$  was normalized by subject mass, walking speed and height. The range of  $H$  was defined as the peak-to-peak difference in  $H$  over consecutive heel strikes of the paretic leg. Walking symmetry was quantified using a foot placement ratio (the lateral distance between the paretic leg and the center of mass upon heel-strike divided by the sum of the lateral distance of the paretic and non-paretic leg from the  $CoM$ ). A value of 0.5 indicates perfect symmetry while a value larger than 0.5 indicates that the subject placed the paretic leg farther from the  $CoM$  than the non-paretic leg.

A paired t-test was used to test for significant differences between normal and stabilized conditions for the range of  $H$  and symmetry ratio. A change was considered significant if  $p < 0.05$ .

## RESULTS AND DISCUSSION

Of the nine subjects, five were classified as Responders. Despite the decrease in step width, foot placement ratios were not significantly different between conditions ( $0.55 \pm 0.05$  normal vs.  $0.59 \pm 0.06$  stabilized). This result was contrary to our hypothesis and suggests that lateral stabilization does not improve walking symmetry. A study with more subjects and statistical power would be necessary to confirm this finding. It is interesting to note that even though there were no significant differences between the ratios, subjects consistently placed their paretic leg further away from the  $CoM$  even though their overall step width decreased. The strategy of placing the non-paretic leg closer to the  $CoM$  could be the result of no longer needing a non-paretic leg compensatory mechanism to provide balance control.

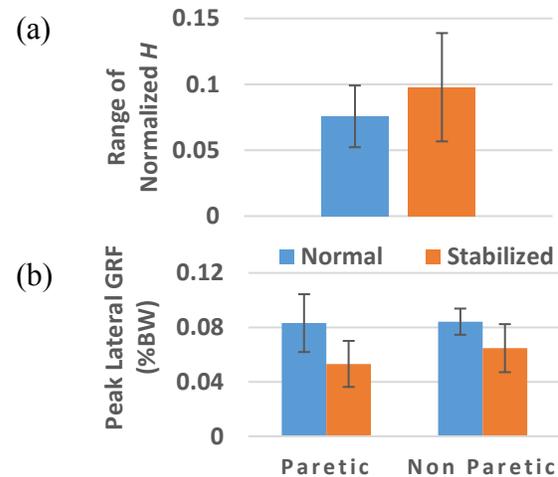

Also contrary to our hypothesis, the Responders' range of frontal plane  $H$  increased during the stabilized condition ( $p < 0.05$ ) compared to the normal condition (Fig. 1a). This result is surprising, given the observed decrease in step width, and the presumed relationship between narrower steps and lower  $H$ . A possible explanation is that the change in  $H$  was more related to a change in ground reaction force (GRF) rather than foot placement. The time rate of change in frontal plane  $H$  is defined as:

$$\dot{H} = r_{lateral} \times F_{vertical} - r_{vertical} \times F_{lateral}$$

where  $r$  is the moment arm and  $F$  is the GRF acting in the specified direction. A post-hoc analysis showed that the peak vertical GRF only increased  $1\% \pm 0.8$  and  $3\% \pm 1$  for the paretic and non-paretic legs, respectively, thus the increase in  $\dot{H}$  was due to a change in the lateral moment arm or lateral GRF since the vertical moment arm remains largely unchanged. When the step width decreased, the lateral moment arm and lateral GRF also decreased. We assumed that the lateral moment arm decrease would be large enough to reduce  $\dot{H}$ , but that was not the case. The peak lateral GRF decreased by  $34\% \pm 14$  and  $24\% \pm 7$  from the normal to stabilized

condition for the paretic and non-paretic legs, respectively (Fig. 1b), while step width only decreased by  $14\% \pm 10$  between the two conditions, thus resulting in an increase in  $\dot{H}$ .

An alternative explanation for the increased  $H$  range is that the lateral stabilization removed the need for participants to tightly control their frontal plane  $H$ , thus giving participants the freedom to walk with larger ranges of  $H$  without the fear of falling. This possibility requires further investigation.

**Figure 1:** a) Peak-to-peak range of  $H$  ( $\pm$ SD) in the frontal plane for normal and stabilized walking, and b) Peak value of lateral GRF ( $\pm$ SD) for normal and stabilized walking.

## CONCLUSIONS

The results suggest that lateral stabilization may not improve walking performance in stroke subjects by decreasing peak-to-peak  $H$  or increasing symmetry. Future studies should examine additional subjects and determine whether increased training with the stabilization influences these results.

## INTRODUCTION

Impaired balance control has a dramatic impact on the lives of individuals post-stroke, with over 70% experiencing one or more falls within 6 months of discharge from the hospital [1]. Falls can lead to injuries with long-term consequences. An increased range of frontal plane whole-body angular momentum ( $H$ ) is often indicative of poor dynamic balance control [e.g., 2]. In healthy walkers, muscle force generation is used to regulate  $H$  during gait [e.g., 3]. Thus, individuals post stroke with impaired muscle coordination patterns may be unable to regulate their  $H$  as effectively.

Prior studies have shown that well-coordinated walking in healthy subjects can be produced by five co-activation modules: 1) hip and knee extensors in early stance, 2) ankle plantarflexors (PFs) in late stance, 3) tibialis anterior and rectus femoris in swing, 4) hamstrings in late swing and early stance, and 5) hip flexors in pre- and early swing [4], and that merged modules in individuals post stroke predict impaired walking performance [5]. Previous research has shown that the PFs are critical to controlling balance in both the frontal and sagittal planes [4, 6]. However, the influence of a merged PF module on balance control is unclear.

The purpose of this study was to determine the influence of a merged PF module on balance control during walking in individuals post stroke by examining the range of  $H$ . Since the PFs are primary contributors to the regulation of frontal and sagittal plane  $H$  [6], we hypothesized that stroke subjects without an independent PF module would have a higher range of  $H$  in both planes than those with an independent PF module.

## METHODS

Kinematic and electromyography (EMG) data were collected from 23 hemiparetic stroke patients (11 left hemiparesis, 10 female; age:  $61 \pm 12$  years) and 15 healthy controls (8 female, age  $55 \pm 8$  years) during 30-second treadmill walking trials at a self-selected speed.

EMG data were processed and analyzed using nonnegative matrix factorization (NNMF) similar to previous work [5]. NNMF determined the minimum number of muscle modules required to account for >90% of the EMG variability and the weighted contribution of each muscle to the module. Subjects were classified as having an independent PF module if NNMF produced a PF module where gastrocnemius and soleus were weighted at 0.4 or greater and all other muscles were weighted at 0.4 or less for at least half of the trials.

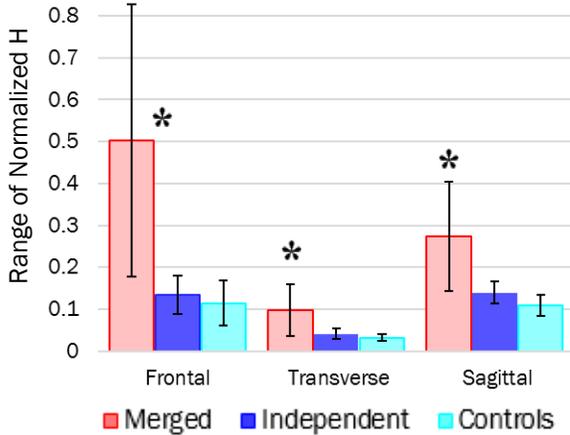

A 13-segment inverse dynamics model was used to calculate  $H$  by summing the angular momentum of each segment about the whole-body center of mass in the frontal, transverse and sagittal planes.  $H$  was normalized by subject mass, walking speed and leg length. The range of  $H$  was defined as the peak-to-peak difference in  $H$  in each plane over each stride.

For the range of  $H$  in each plane, an ANOVA with three levels (independent and merged PF module, control PF module) and three two-sample t-tests were used to test for significant differences between each group ( $p < 0.05$ ).

## RESULTS AND DISCUSSION

Seven subjects had an independent PF module (Group A) and 16 did not (Group B). Group B had a

significantly higher frontal, transverse and sagittal range of  $H$  than both Group A and the control group ( $p < 0.05$ ). Group A and the control group were not significantly different from each other in any plane (Fig. 1).

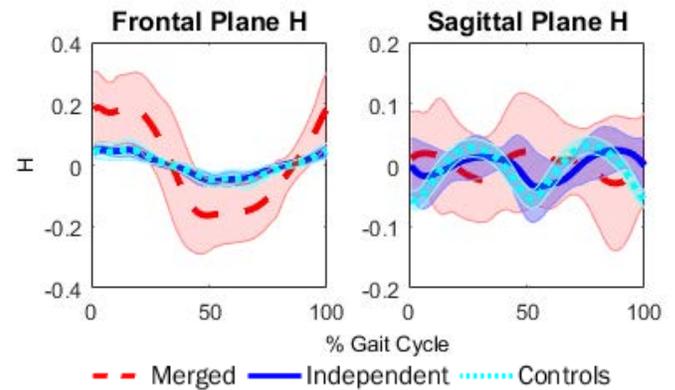

**Figure 1:** Mean ( $\pm$  SD) range of  $H$  in stroke subjects with (Group A) and without (Group B) an independent PF module and in healthy control subjects (\* denotes a significant difference between both of the other groups).

In addition to having a higher range of  $H$ , Group B had more variation in  $H$  between subjects than Group A or the control group (Fig. 2). Thus, having an independent PF module was indicative of a low range of  $H$ , but having a merged PF module yielded a variety of  $H$  patterns.

The higher range of  $H$  in Group B may be the result of the inability to actively regulate  $H$  with the PFs. In the control group, the PFs regulate frontal plane  $H$  by generating vertical and mediolateral ground reaction forces that act to rotate the body towards the contralateral leg [6]. When the PFs are merged with other muscle groups, individuals may not be able to perform this critical biomechanical function. The higher range of  $H$  in Group B may also result from intentional compensation to correct for low paretic propulsion. A number of Group B subjects use a circumduction strategy where they generate angular momentum with the upper body in the frontal and transverse planes to swing the paretic leg forwards. Future work will aim to quantify the contributions of individual body segments to  $H$  to assess which segments contribute to the increased range of  $H$  and

identify rehabilitation strategies for gaining an independent PF module.

**Figure 2:** Mean ( $\pm$  SD) of frontal and sagittal plane  $H$  during self-selected walking in Group A, Group B and control subjects.

## CONCLUSIONS

These results suggest that an independent PF module is critical for successful balance control. Previous research has shown that stroke subjects can gain independent modules through rehabilitation [7], and thus obtaining an independent PF module should be a crucial aim in stroke rehabilitation.

# TASK-SPECIFIC PERTURBATION TRAINING PROVIDES A VIABLE REHABILITATION STRATEGY TO REDUCE FALLS IN STROKE SURVIVORS: PRELIMINARY RESULTS

<sup>1</sup> Claire F. Honeycutt, <sup>1</sup> Masood Nevisipour, <sup>2</sup> Mark D. Grabiner

<sup>1</sup> Arizona State University, Tempe, AZ, USA

<sup>2</sup> University of Illinois at Chicago, Chicago, IL, USA

email: claire.honeycutt@asu.edu

## INTRODUCTION

Half of the 6.5 million stroke survivors in the United States will fall, making falls the most common and expensive medical complication in stroke survivors. Task-specific training, whose targeted approach allows faster improvements, has become an increasingly credible alternative. Task-specific training is designed to expose subjects to falls in a controlled setting, where injury is not possible, in order to improve their response. Recent results using trip-specific training have revealed a 50% reduction in prospectively measured trip-related falls by middle age and older women [1]. Still, there is very limited information about the effectiveness of task-specific perturbation-based training in stroke survivors. Stroke survivors are afflicted with spasticity, abnormal synergistic patterns of muscle activation, and weakness; therefore it is unclear if the same task-specific training programs that have been implemented in healthy older adults will be effective.

The primary objective of the present study was to determine the impact of a single session of task-specific training on enhancing the compensatory stepping response in stroke survivors. We have previously shown that laboratory induced falls in older adults and stroke survivors are characterized by larger trunk flexion angle, larger trunk flexion velocity, and shorter recovery step length at the first recovery step completion [2,3]. Task-specific perturbation-based training enhances these metrics associated with compensatory stepping as well as reducing number of falls in older adults [2]. Therefore, we hypothesized that trunk kinematics would be significantly modified after training similar to the previously reported results in older women.

## METHODS

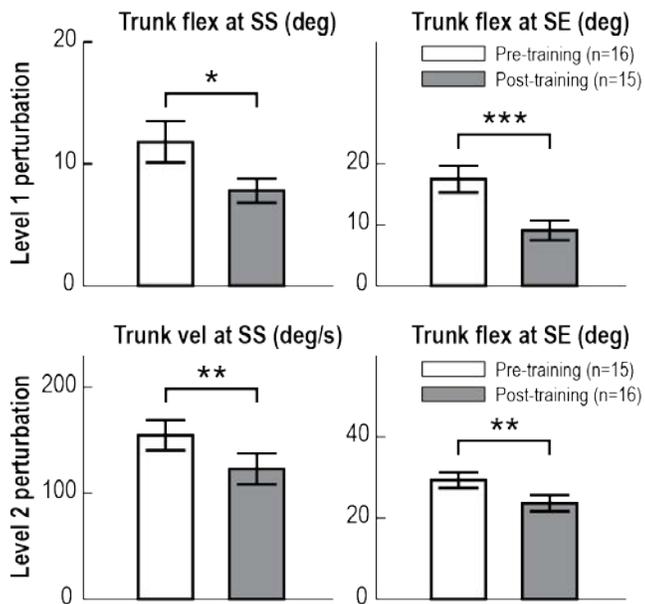

Seventeen subjects with unilateral stroke participated in this study. The study was carried out at the University of Illinois at Chicago (UIC) and was approved by Rehabilitation Institute of Chicago, Northwestern and UIC's Institutional Review Boards. Subjects stood on a dual-belt, stepper motor driven and computer controlled treadmill (ActiveStep™, Simbex, Lebanon, NH). Subjects wore a safety harness attached to the ceiling to protect them from falling in the event of an unsuccessful stepping response.

A total number of 27 perturbations were divided into three groups of pre-training test, training, and post-training test. Pre-training and post-training tests consisted of the same 6 perturbations in which 3 posteriorly-directed and 3 anteriorly-directed perturbations were delivered in a randomized fashion. Posteriorly-directed perturbations were designed in three different levels of magnitude (1: small, 2: medium, 3: large). The direction of the perturbation was randomized, but the magnitude was sequenced from small to large for safety. Training consisted of 15 posteriorly-directed perturbations of medium magnitude (displacement: 0.22 m, constant velocity: 0.56 m/s, acceleration/deceleration: 13.89 m/s<sup>2</sup> and -13.89 m/s<sup>2</sup>).

Trials were classified as either a "fall" or "recovery". If the subject became unambiguously supported by the safety harness following a perturbation, that trial was considered as a fall. Twenty-two passive-reflective markers were attached to upper and lower extremities and trunk using a modified Helen Hayes marker set. Dependent variables, including trunk kinematics, step kinematics and center of mass (COM) stability, were calculated for the first recovery step following the perturbation.

## RESULTS AND DISCUSSION

Nine subjects were classified as Fallers (i.e. they fell at least once). Seven of the 9 Fallers fell during both pre- and post-training. Only two Fallers who fell in pre-training could avoid falling in post-training. Still, when all subjects were considered, training led to improvements in the compensatory stepping response. Specifically, Trunk flexion angle and velocity on level 1 and level 2 perturbations (Fig. 1) were diminished indicating enhanced trunk stability. At level 1, Trunk flexion at Step\_Start(SS) and Step\_End(SE) were significantly reduced in post-training trials ( $P=0.016$  and  $P<0.0001$  respectively). At level 2, Trunk flexion velocity at SS and Trunk flexion at SE significantly decreased in post-training trials ( $P=0.006$  and  $P=0.003$  respectively). No significant differences were found in Trunk flexion velocity at SE, Reaction time, Step duration, Step length, Dx and MOS (all  $P>0.05$ ).

**Figure 1: Pre-training vs. post-training trials comparisons for all subjects.** Figure represents significant differences between pre-training and post-training trials on different levels of perturbation. \* =  $P$ -value  $< 0.05$ , \*\* =  $P$ -value  $< 0.01$ , \*\*\* =  $P$ -value  $< 0.001$ .

Fallers demonstrated changes in a larger number of kinematic and stability variables (8) after training compared to Non-faller group (2) indicating that they were more responsive to training. In addition,

Fallers showed numerous differences from Non-fallers during pre-training but showed enhancements in Trunk movement post-training that made them resemble Non-Fallers. Trunk flexion at SE was significantly different between Fallers and Non-fallers prior to training (at level 1 and 2,  $P=0.028$  and  $P=0.023$  respectively). Further, Trunk flexion velocity at SE was significantly larger for Fallers compared to Non-fallers prior to training (at level 2 and 3,  $P=0.014$  and  $P=0.002$ ). However, Trunk flexion at SE reduced for Fallers after training and was not statistically different from Non-fallers Trunk flexion in pre-training trials (at level 1 and 2,  $P=0.48$  and  $P=0.52$  respectively). Trunk flexion velocity at SE was reduced in Fallers after training and was not statistically different from Non-fallers Trunk flexion velocity before training at level 2 perturbation ( $P=0.22$ ). Training did not adequately decrease these measures at level 3 as Trunk flexion velocity remained significantly different between Fallers and Non-fallers at level 3 ( $P=0.016$ ).

## CONCLUSIONS

These results indicate that despite the unique challenges faced by stroke survivors (e.g. spasticity, abnormal muscle synergies), they are still amenable to task-specific perturbation training. We have previously shown that stroke survivors fall for remarkably similar reasons as other adult populations – most specifically a poor compensatory stepping response including diminished trunk stability and shorter step lengths [3]. While our results here are preliminary in nature and a larger study is needed, the results presented here indicate that task-specific training is a viable rehabilitation strategy to decrease falls in stroke survivors and that it should be pursued as such.

# RESIDUAL LIMB SKIN STRAIN WITHIN A SOCKET PROSTHESIS IN TRANSFEMORAL AMPUTEES DURING WALKING

<sup>1,2</sup> Tom Gale, <sup>1</sup> Richard McGough, <sup>1</sup> Mark Goodman, <sup>1,2</sup> William Anderst

<sup>1</sup> Department of Orthopedic Surgery, University of Pittsburgh, Pittsburgh, PA, USA

<sup>2</sup> Biodynamics Laboratory, University of Pittsburgh, Pittsburgh, PA, USA

email: thg17@pitt.edu, web: <http://bdl.pitt.edu/>

## INTRODUCTION

For transfemoral amputees, the typical solution to regain mobility is a socket type prosthetic. Due to the various liners and non-anatomical loading the residual limb is subjected to by the socket type prosthetic, discomfort and skin problems are a common occurrence that often lead to reduced activity and quality of life [1]. Although relative motion of the bone to the socket and residual limb motion relative to the socket have been reported [2–4], skin strain occurring within the socket during dynamic functional movement is not well studied. The purpose of this study was to develop a novel method for measuring skin strain within a socket type prosthetic using dynamic biplane radiography.

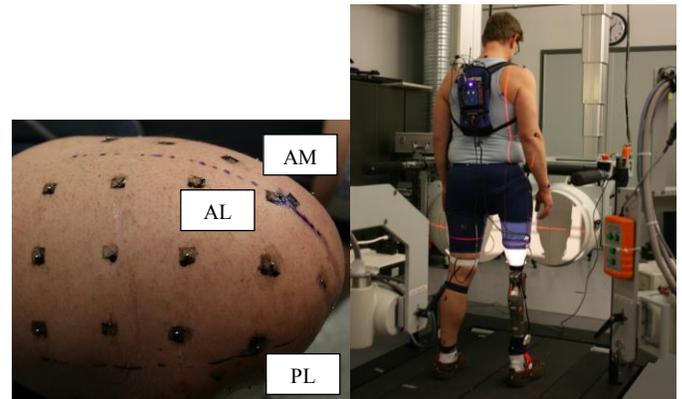

## METHODS

Two subjects with transfemoral amputations were enrolled in the study. Both participants used a socket type prosthetic with a locking pin liner for anchoring the limb to the prosthetic.

Forty-five to fifty 1.0 mm diameter stainless steel beads were glued on to the residual limb using a grid pattern, with an average distance between beads of 25mm (Figure 1). Based upon bead locations, the residual limb was separated into anterior medial (AM), anterior lateral (AL), posterior medial (PM), and posterior lateral (PL) regions (Figure 1). After the beads were secured to the skin, the participants then put the liner, sock, and prosthetic over the residual limb as they normally would for everyday use.

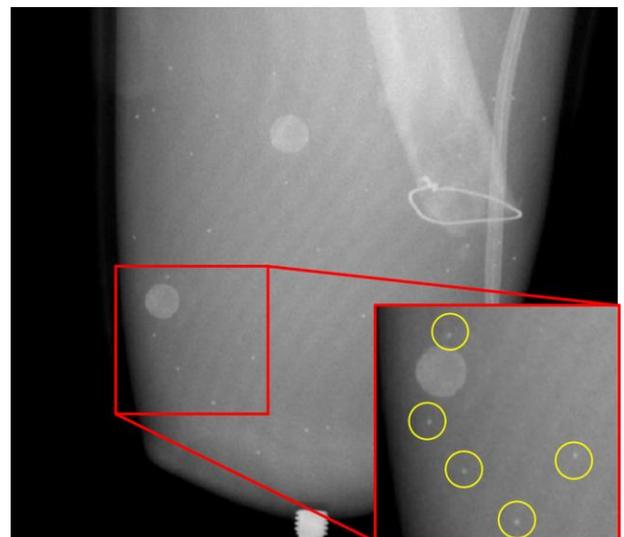

Participants were imaged standing upright and during walking on an instrumented treadmill (Bertec, OH, USA) at a self-selected speed while

biplane radiographs were collected at 100 images/s (Figure 1). A total of 3 walking trials were collected per subject.

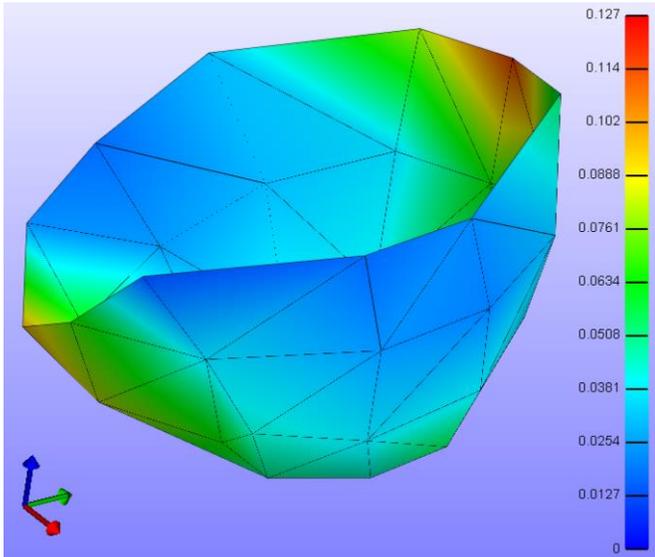

**Figure 1:** Bead grid glued on subject's residual limb with AL, AM, and PL sections visible (left). Subject in upright position within DSX system with prosthetic on over the beads (right).

Dynamic RSA was used to determine bead locations in 3D space during each static and dynamic trial (Figure 2).

**Figure 2:** A typical frame from one of the biplane radiographic image sequences. Yellow circles highlight the beads glued to the skin.

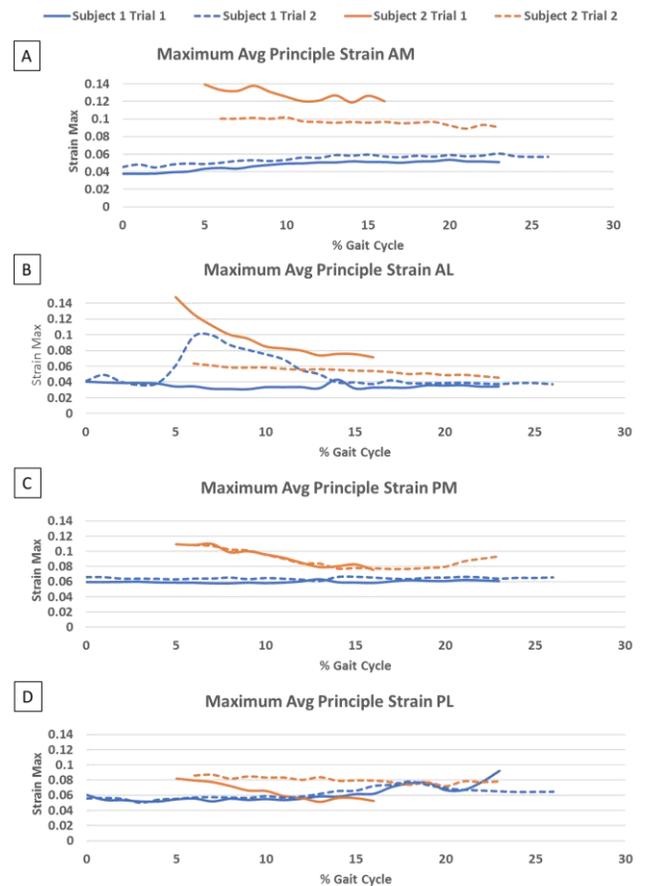

**Figure 3:** The skin surface of the residual limb modeled as shell elements in FEBio. The colormap represents skin strain at one instant of walking.

Bead coordinates in the static standing images were exported as a point cloud and meshed using Geomagic (3D systems, SC, USA). The meshed file was then used in a custom MATLAB (The Mathworks Inc, MA, USA) program in conjunction with the bead coordinates during the dynamic trials to generate a 3D displacement map, formatted for finite element analysis using FEBio (University of Utah, UT, USA). FEBio was used to estimate skin surface strain during walking. Average principal strain  $\left(\frac{\sigma_1 + \sigma_2}{2}\right)$  and maximum shear strains ( $\tau_{max}$ ) were analyzed (Figure 3).

## RESULTS AND DISCUSSION

Dynamic principal strains and shear strains ranged from 4% to 20% depending on participant and anatomic region (Figure 4). The results suggest that skin strain patterns differ greatly from patient to patient and, to a smaller extent, within regions of the residual limb for each individual. This could be due to the location of amputation and the compensatory adjustments to the gait cycle.

**Figure 4:** Maximum average principal strain over the gait cycle for each anatomic region. Foot strike occurred at 0% gait cycle and mid-stance at approximately 25% of gait cycle.

## CONCLUSIONS

This study demonstrated a novel method for measuring dynamic skin strain in transfemoral amputees wearing a socket type prosthetic. This technique can be used to investigate relationships between skin strain, patient-reported pain and function, and the development of skin-related pathology.

# Shoulder Posture, Torque Magnitude, and Torque Direction Highlight the Heterogeneous Elasticity of the Pectoralis Major Fiber Regions

<sup>1</sup>Joshua Leonardis, <sup>1</sup>David Desmet, and <sup>1,2</sup>David Lipps

<sup>1</sup> School of Kinesiology, University of Michigan, Ann Arbor, MI, USA

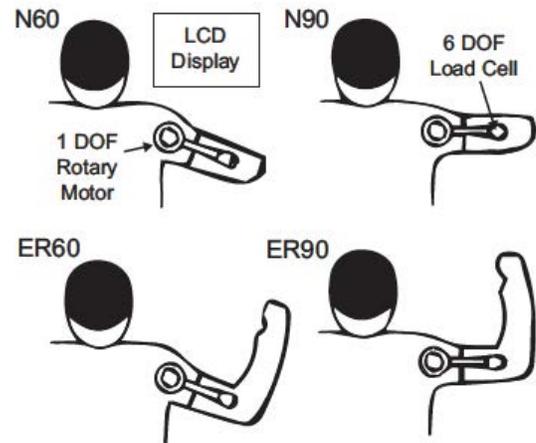

<sup>2</sup> Department of Biomedical Engineering, University of Michigan, Ann Arbor, MI, USA  
email: jleo@umich.edu, web: <http://www.kines.umich.edu/research/mbil>

## INTRODUCTION

The pectoralis major is a wide, flat muscle that consists of two fiber regions with distinctly different architecture. The sternocostal region originates on the sternum and costal cartilage and constitutes roughly two-thirds of the muscles volume. The remaining muscle volume originates on the clavicle and is referred to as the clavicular region. Either region may be harvested individually to provide structural support to the glenohumeral joint when treating irreparable rotator cuff repairs [1]. During clinical decision making, physicians often assume that any function lost due to the disinsertion of either fiber region will be compensated for by the remaining shoulder musculature, giving little consideration to the biomechanical consequences of choosing one region over the other [2]. This lack of consideration is due, in large part, to the limited knowledge regarding each regions elastic properties, characteristics that depict its potential to produce force, and to contribute to shoulder joint function [3]. By characterizing the passive and active elastic properties of each fiber region, one may be better suited to determine the effect their removal has on shoulder function. The present project utilized shear wave elastography to characterize the *in vivo* elastic properties of the individual pectoralis major fiber regions as a function of shoulder position and torques.

## METHODS

The right shoulder of ten male subjects (mean (SD) age: 24 (5) yrs., weight: 81 (14) kg, height: 177 (8) cm) with no history of shoulder injury was placed in a removable plastic cast that was attached to a computer-controlled rotary motor instrumented with a six-degree of freedom load cell. Subjects were positioned in a combination of two shoulder

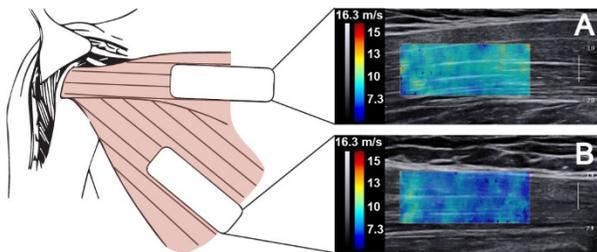

**Figure 1:** Experimental shoulder postures. Subjects were attached to a rotary motor while their shoulder was externally rotated in a neutral (N) or 90° position (ER) and abducted 60° (60) and 90° (90).

abduction angles (60° and 90°) and two external rotation angles (0° and 90°) for a total of four experimental shoulder positions (Figure 1). At each experimental position participants were asked to produce and maintain isometric shoulder torques for approximately five seconds, with the help of visual feedback. These torques were equivalent to 0, 15, and 30% of their maximal voluntary contraction (MVC) in the vertical and horizontal adduction directions. Visual feedback was provided to assist with force accuracy. Surface electromyography data were collected from the pectoralis major, deltoids, trapezius, and latissimus dorsi muscles to further validate task performance.

During each isometric task, a Supersonic Imagine Aixplorer ultrasound elastography machine connected to an SL-15 linear transducer array was used to measure the shear wave velocity (SWV) (Figure 2) of the clavicular and sternocostal regions of the pectoralis major. A greater SWV is associated with a greater shear elastic modulus. Two images were collected from each region for each isometric

force task, resulting in approximately 80 images per subject.

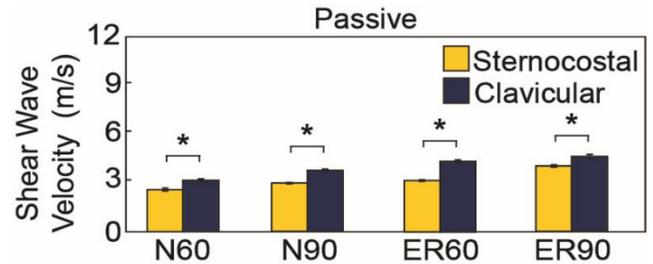

**Figure 2:** Probe locations (left) and representative ultrasound shear wave elastography images of the clavicular (A) and sternocostal (B) fiber regions during 30% MVC horizontal adduction.

One-way ANOVAs were used to assess differences in SWV between fiber regions (clavicular, sternocostal), shoulder positions (N60, N90, ER60, ER90), force directions (horizontal, vertical adduction), and force levels (0, 15, 30% MVC). All significances are reported at  $\alpha = 0.05$ .

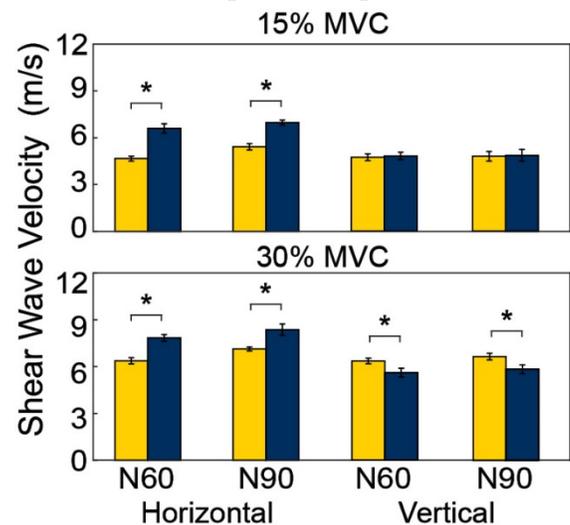

## RESULTS AND DISCUSSION

Consistent with the literature, SWVs generally increased with increasing activation for each fiber region in each experimental shoulder position (all  $p < 0.001$ ) [4]. In the clavicular region, SWVs were higher at every experimental shoulder position and force level when force was produced in the horizontal direction (all  $p < 0.001$ ). In the sternocostal region, horizontal adduction torques resulted in higher SWVs at every experimental position except N60 (all  $p < 0.05$ ).

Resting SWVs were higher in the clavicular region for all four experimental shoulder positions (Figure 3) (all  $p < 0.001$ ). For the ER60 and ER90 conditions, there was no difference between the clavicular and sternocostal regions for either force direction at any force level greater than passive. For the N60 and N90 conditions, the clavicular region exhibited significantly higher SWVs at 15% and 30% MVC when force was produced in the horizontal adduction direction (Figure 4). When force was produced in the vertical adduction direction, SWVs were greater in the sternocostal region, but only at 30% MVC (Figure 4).

**Figure 3:** Between region passive shear wave velocities for each experimental position.

**Figure 4:** Between region 15% (top), and 30% (bottom) shear wave velocities for the N60 and N90 shoulder positions.

Altering shoulder joint position and torque direction underscores the heterogeneous elastic properties of the pectoralis major. The results of this study suggest the clavicular fiber region may contribute more to passive stability and horizontal adduction torques, while the sternocostal fiber region may assist more in vertical adduction torques of greater magnitudes. Additional work is needed to identify the contributions of each fiber region to dynamic movements.

## CONCLUSIONS

The elasticity of the sternocostal and clavicular fiber regions of the pectoralis major are heterogeneous across various postures and contraction levels.

## INTRODUCTION

Volumetric muscle loss (VML) refers to a traumatic loss of muscle that has an adverse resultant effect upon function. [1] Currently, there exists no effective clinical treatment for VML that results in a full recovery of muscle function.

Experimental data and computational models show a marked decrease in active force production in muscles with VML injury and a partial recovery of force when repaired. [2] A greater percentage of force recovery is seen when the muscles are repaired with a tissue engineered muscle repair (TEMR) compared to a bladder acellular matrix (BAM) suggesting an advantage to the cell seeding and bioreactor protocols over the use of acellular matrices alone. [2]

In order to fully understand where current methods fall short in regenerating muscle as well as differences between methods, we must first understand the passive properties of both native tissue as well as the regenerated tissue. Once we accomplish this, we can begin to understand how to further improve current methods to bring injured muscle closer to the behavior of native muscle. The goal of this study was to develop a method to use a biaxial testing machine to examine the passive properties of native muscle and then apply this method to measuring the properties of regenerated tissue.

## METHODS

BAM scaffolds were prepared from porcine urinary bladder as previously described. [3] TEMR constructs were then generated from these scaffolds using previously described cell culture, seeding, and bioreactor protocols. [3]

VML injuries were surgically created in 12 week old male Lewis rats as previously described [3]. Briefly, a longitudinal incision was made along the midline of the back, the trapezius muscle was lifted to expose the latissimus dorsi (LD), and an 11x15 mm defect was excised from the medial half. The injured muscle was then treated by either suturing an unseeded BAM scaffold or a TEMR construct to the site of injury.

To obtain the samples for testing, animals were sacrificed at 2 months post-surgery and the LD muscles were isolated from the rats. Samples were excised from within the injured area with care to not include any of the surrounding native muscle tissue. Native samples were taken from the same region in the contralateral LD.

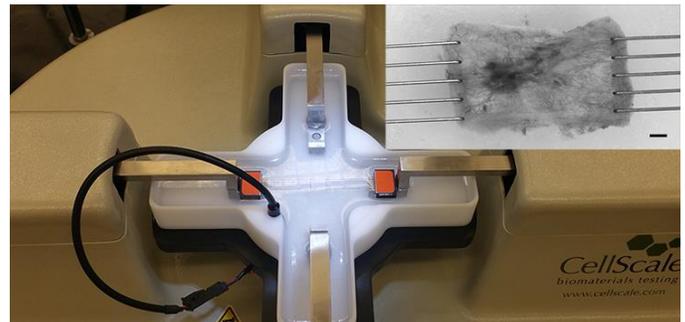

Figure 1: CellScale biotester biaxial testing machine and mounted specimen. Scale bar = 1mm

Immediately after explantation, the samples' unloaded length, width, and thickness measurements were taken. Samples were then mounted on a CellScale BioTester (Fig. 1) and submerged in a room temperature Krebs bath. Samples were stretched at 1% of original mounting length per second until passive resistance began at which point images were taken to be used to measure the mounted length and width in imageJ.

The length at which passive resistance began was defined as optimum fiber length and the new initial length for the tensile testing. Each sample underwent 10 cycles of preconditioning to 10% strain using the

new initial length measurement at 1% strain per second ( $1\%s^{-1}$ ) similar to previous methods. [4] Following preconditioning, the samples were stretched to 10% strain at  $1\% s^{-1}$  for 10 cycles, and finally pulled to failure or a load of 2N at  $1\% s^{-1}$ .

Following testing, the initial size measurements were used to calculate the thickness of the mounted muscle assuming isochoric properties. Using the initial volume and the known displacement rate of the muscle, the cross-sectional area was calculated and subsequently used to calculate stress for each sample. Stress was then normalized using peak isometric stress data obtained from in vitro experiments. [3]

Force, stress and strain data for each sample were resampled and average curves for each treatment group were found. Stress-strain curves were then fit to a previously described model of passive muscle properties. [5]

## RESULTS AND DISCUSSION

The testing protocol was developed in order to obtain repeatable results and we further verified it by comparing native rat LD tissue samples to expected passive muscle behavior in the literature (Fig. 2A). As expected, literature values have a large variance as a result of the differing types of muscles tested as well as the animals tested. Our values fall within this expected range and have a relatively small sample-to-sample variance.

There is not a significant difference in the passive mechanical behavior between tissue regenerated with BAM and tissue regenerated with TEMR (Fig. 2B). Combining this finding with the previous findings of a better active force recovery with the TEMR points toward a recovery of active muscle fibers using this novel treatment given no difference in passive properties but a significant difference in active force production.

## CONCLUSIONS

We have shown here a method that is able to reliably produce stress-strain data from both native tissue as well as regenerated tissue. This method can now be

utilized to investigate the effects of different VML treatments on the passive properties of injured muscle, as well as in other neuromuscular diseases that are known to affect passive muscle properties.

## INTRODUCTION

Historically considered less important than the more specialized organs and muscles it envelopes [1], thoracolumbar fascia (TLF) is now gaining recognition for its potential role in key functions such as stabilizing the lumbar spine, providing attachment for spinal and abdominal musculature, and even sensing body position and pain [1,2]. Thus, its inclusion in pathological models of low back pain (LBP) warrants investigation.

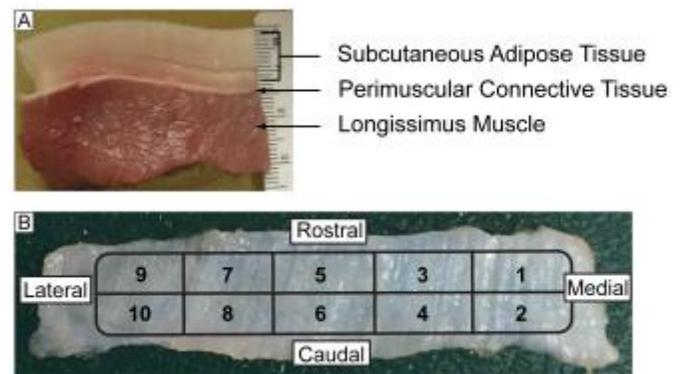

Ultrasound recordings have shown that humans with chronic LBP exhibit increased thickness and decreased mobility in the TLF [2]. Recent work demonstrated similar changes to the TLF in a porcine model subjected to surgical injury combined with movement restriction [3]. To better understand why these functional and morphological changes occur, we sought to investigate if there were associated changes to the porcine TLF stiffness after surgical injury and movement restriction.

## METHODS

Twenty castrated male domestic swine, between 4-6 weeks old, weighing approximately 4-7 kg were acquired from E.M. Parson's Hadley, MA. A stabilization period of 7 days was allowed before subsequent randomization into one of four cohorts: Control (n = 5), Injury (n = 5), Hobble (n = 5), and Injury + Hobble (n = 5) for eight weeks. The injury condition involved a 4x4 cm incision at the L3-4 vertebral level, 2 cm lateral to the midline, between the subcutaneous membranous layer and the perimuscular connective tissue. Hobbled animals were fitted with a harness that constrained the distance between the fore and hind limbs to two-thirds that of unrestrained animals. After 8 weeks,

animals were euthanized and 1x5x3 cm tissue samples were excised. For injured animals, this tissue was extracted contralateral to the injury site. Tissue samples were then immediately frozen in liquid nitrogen.

The TLF samples were transported to the University of Waterloo (Waterloo, ON, Canada) and thawed for dissection. The TLF (perimuscular fascia) was carefully dissected from the underlying muscle and overlying adipose tissue, and cut into 5x5 mm test specimens (Fig. 1).

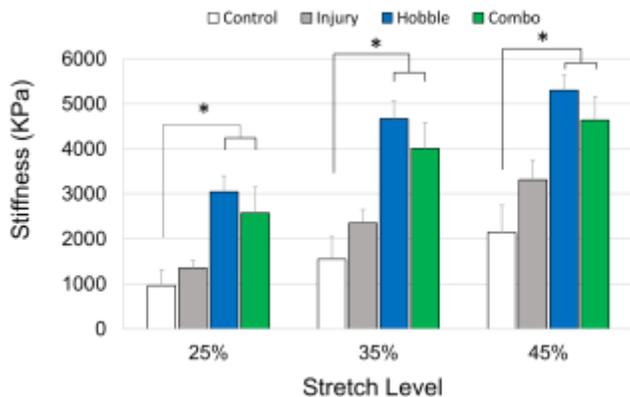

**Figure 1** Perimuscular connective tissue (A) extracted from sample blocks and (B) cut into 5x5 mm specimens.

These 5x5 mm specimens were then mounted onto a displacement-controlled tensile testing apparatus (CellScale, Waterloo, ON). Each specimen was loaded either uniaxially – in the longitudinal or transverse direction, or biaxially – both directions simultaneously. Only the uniaxial longitudinal condition is considered in this submission. The loading protocol was identical for all specimens: preconditioning with 5 cycles of loading/unloading to 10% of initial stretch, followed by 5 cyclic loads to 25%, 35%, and 45% of initial stretch. Initial stretch was defined as the distance between the rakes (which applied the tensile loads) at a preload of 10

mN. All loading and unloading was performed at a 6%/sec stretch rate. Stiffness was calculated from the slope of the linear region of the last two loading curves at each stretch level. A two-factor mixed model analysis of variance was performed to compare stiffness among the four cohorts and three stretch levels. Separate two-factor ANOVAs were then computed at each stretch level with test samples nested within each cohort. An alpha level of 0.05 was used for all tests, with a Bonferroni adjustment for multiple comparisons (SPSS Inc., Chicago, IL).

## RESULTS AND DISCUSSION

Fascia from hobbled animals—whether only hobbled or combined with injury—were significantly stiffer than control fascia, at all three stretch levels ( $F = 9.17$ ,  $p < 0.001$ ; Fig. 2). Specifically, the combo (injury + hobble) and hobble TLF were, on average, 2.4 ( $p < 0.01$ ) and 2.8 ( $p < 0.001$ ) times stiffer than control. Hobble TLF were also stiffer than injured tissue at each stretch level.

**Figure 2:** Thoracolumbar fascia stiffness at 25%, 35%, and 45% stretch. Significant ( $p < 0.05$ ) differences are denoted by asterisks (\*).

Stretch level significantly affected stiffness ( $F = 105.6$ ,  $p < 0.001$ ) across all cohorts, with tissues becoming progressively stiffer at higher stretch levels.

Individuals with LBP are frequently found to have limited spinal mobility, both gross and segmental. It is unknown if this limited mobility is directly caused by pain, predisposing mechanical factors, or mild trauma such as a muscle strain. Our findings suggest that limiting movement increases local TLF stiffness.

It is well known clinically that restricting joint movement causes adhesions in periarticular connective tissue [4]. Similar pathological processes may have occurred in the dorsal trunk fascia of the hobbled swine in this study, whereby adhesion formation contributed to increased stiffness.

The finding that movement restriction so profoundly increased TLF stiffness beyond that resulting from injury is somewhat surprising. It is possible, however, that the injury was not severe enough to either (1) induce a pathological response on its own or (2) cause animals to voluntarily reduce their mobility. The latter hypothesis is supported by the observation that, before euthanasia, injured animals exhibited no difference in gait speed compared to control animals; only those subjected to mobility restriction walked slower than control animals, even after restraints were removed [3].

## CONCLUSIONS

This study suggests that movement restriction plays a particularly important role in increasing thoracolumbar fascia stiffness. This is a substantial finding highlighting the mechanical contribution of the TLF to the reduced mobility observed in persons with LBP. Future work investigating potential changes to the biochemical composition of the TLF is needed to explain these changes to tissue stiffness. Further, therapeutic interventions aimed at breaking adhesions and reducing tissue stiffness may warrant exploration to determine if mechanical changes associated with LBP can be reversed.

# PATH-SPECIFIC VON-MISES STRESSES INFLICTING THE PRE- AND POST-THR FEMUR DURING WALKING

<sup>1</sup> Mohamed Z. Bendjaballah and <sup>1</sup> Wissal Mesfar

<sup>1</sup> Biomedical Technology Department, College of Applied Medical Sciences, King Saud University  
Riyadh, Saudi Arabia

email: [bendja@ksu.edu.sa](mailto:bendja@ksu.edu.sa), web <http://www.ksu.edu.sa>

## INTRODUCTION

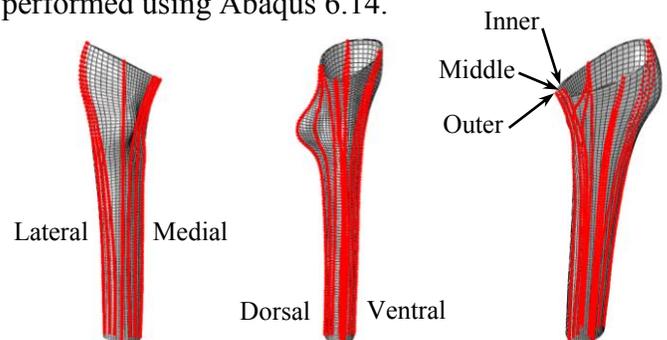

Numerous numerical studies aimed to explore the femoral regions prone to develop stress shielding after a THR. Some researchers adopted the use of a dimensionless factor known as stress shielding rate (SSR). This factor relates the change in the von Mises stress between prosthetic and intact states prorated to that of the intact state [1, 2]. Despite its wide usage in literature, this rate does not capture only the regional stress variation regardless of the stress gradients and intensities. As a consequence, similar rates can occur for two locations with completely different stress gradients rising between the pre- and post-THR cases. Depending on its sign, this rate should be thus used as a dualistic rate that indicates if a site is likely to develop stress shielding or not and must not be used whatsoever in evaluating the stress shielding severity.

The aim of this study is thus to explore the severity of stress shielding by direct investigation of the changes occurring in the von Mises stresses generated under walking activity at specific locations. To achieve this goal, twelve paths were selected in pertinent locations of the intact model and meticulously reproduced in the prosthetic one.

## METHODS

A three-dimensional CAD model of an intact proximal left femur was developed based on series of CT-scan images acquired from a healthy female donor. The prosthetic CAD model was generated by sectioning the femoral head and superimposing the prosthesis' CAD model, which geometry was inspired from a cementless commercial design. Orthotropic and isotropic material properties were

assigned to the cortical and cancellous bone tissues, respectively while 'Ti-6Al-4V' Titanium alloy was chosen for the stem material [3]. A bonded contact was adopted between all interacting components while a fixed boundary condition was set to the bottom surface of the shaft. Loading conditions characteristic of walking activity reported in Ref [4] were implemented in the FE analyses considering our subject's body weight of 700N. The bone tissues and prosthesis were meshed using hexahedral solid elements. Special attention was focused on the meshing operation to reproduce an identical mesh for the bone common to intact and prosthetic models. This procedure helps generate identical paths where the nodal von Mises stresses are explored. Four cardinal locations around the shaft were considered; the lateral, medial, ventral and dorsal. For each of these locations, three distinct paths were further demarcated and represented by sets of nodes located at the inner, middle and outer locations over the cortex thickness (Fig. 1). Direct comparison of the pre- and post-THR von Mises stresses computed along these twelve (12) paths was performed aiming to discern the bony regions prone to develop stress shielding. The static nonlinear FE analyses were performed using Abaqus 6.14.

**Figure 1:** Different views of the cortical bone mesh showing node sets composing 12 paths identically demarcated in intact and prosthetic models.

## RESULTS AND DISCUSSION

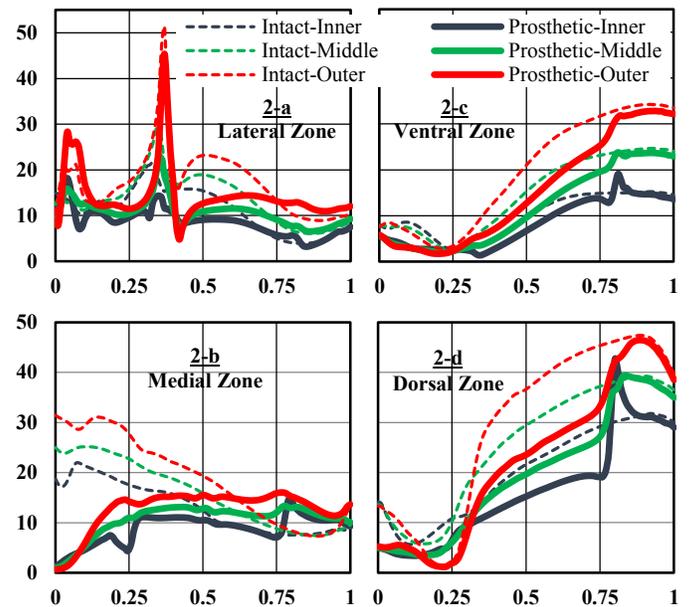

The von Mises stresses plotted along the normalized distance of the selected paths were found to be in general higher on the outer cortex regardless of the model cases. The highest peak stresses of around 50MPa were computed on the lateral location close to the Vastus Lateralis attachment site (see fig. 2-a) and the dorsal location distally near the model's bottom surface (see fig. 2-d). In the medial region, the stress patterns developed in the intact bone showed that the stresses started at their highest values (~30MPa) proximally to gradually diminish reaching around 12MPa distally. Once the implant is inserted, the stresses dropped drastically to almost vanish at the most proximal region of the shaft. The highest drop (~30MPa) was recorded on the outer cortex of the calcar region (most proximal site of the medial zone, Figure 2-b). Moreover, for this zone, the peri-prosthetic stresses slightly increased in the first quarter of the shaft length and remained almost constant for the rest of the bony shaft (Figure 2-b).

The rest of the bony tissue underwent lesser stress reductions following THR, not exceeding 14MPa computed on the outer cortex of the dorsal region, distal to the lesser trochanter (see Figure 2-d). Along the dorsal and ventral regions, and irrespective of the model condition, pre- or post-THR, the von Mises stress values mainly increased when moving towards the distal direction (see figures 2-c and 2-d).

The highest stress fluctuations were noted in the peri-prosthetic bone close to the implant's tip as well as in bone laying at the muscles' attachments sites. These findings are more tangible at the inner layer for the former case and outer layer for the latter case, respectively. Distal to the implant's tip, the effect of the prosthesis generally disappears, that is, the von Mises stress values computed post-THR literally converged to those obtained in the pre-THR condition.

The use of series of paths generated from node sets identically located in pre- and post-operative models enabled us to make a precise site estimation of the stress change occurring following THR. Our numerical findings were in good agreement with experimental studies nominating the proximal calcar

area, also known as Gruen zone 7, for extensive stress shielding and peri-prosthetic remodeling [5, 6].

**Figure 2:** von Mises stress distribution in the intact and prosthetic cortical bone computed along the normalized shaft length at the inner (blue), middle (green) and outer (red) paths among the lateral (2-a), medial (2-b), ventral (2-c) and dorsal (2-d) zones.

## CONCLUSIONS

The current study used subject-specific finite element models to accurately predict the sites prone to develop stress shielding and estimate its severity as well. Unlike the SSR which estimates the zonal stress shielding occurrence in a dualistic manner, this study uses the stress decay precisely occurring in a typical site to estimate the severity of stress shielding and the subsequent bone loss expected to occur. Finite element models generated from human cadaveric or patient femora could thus find an extensive use in the pre-planning of THRs through clinical evaluation of new prostheses and/or novel surgical procedures.

# EVIDENCE OF LOW BACK INJURY IN THE ABSENCE OF RADIOGRAPHIC DETECTION

Nicole C. Gale, Stacey L. Zeigler, Christopher Towler, Kathleen A. Issen, Arthur J. Michalek, and Laurel Kuxhaus

Clarkson University, Potsdam, NY, USA

email: corbienc@clarkson.edu, web: <http://people.clarkson.edu/~lkuxhaus/>

## INTRODUCTION

Low back injuries of varying etiology can occur in bone or soft tissue. Vertebral fractures and soft tissue injuries can occur during the repetitive loading of activities of daily living (ADLs). For example, ring apophysis fractures (RAFs) occur without memorable trauma in healthy young athletes [1-2], and osteoporotic fractures occur without memorable trauma in older adults. We hypothesized that application of high cycle non-traumatic motion to an *ex-vivo* model (absent of bone remodeling) would result in biomechanical symptoms of injury resulting from the combined effects of increased spinal laxity (soft tissue damage) and vertebral fractures. This hypothesis was tested by applying low-load, low-angle cyclic flexion to cervine and cadaver 5-vertebra motion segments. Cervine (white tailed deer, *O. virginianus*) specimens had a similar degree of skeletal maturity and have a similar range of motion [3] to adolescent humans. The cadaver specimens were older with osteoporotic degeneration.

## METHODS

Seven cervine (2 male, 5 female;  $2.4 \pm 0.2$  years) and five human cadaver (1 male, 4 female;  $64.2 \pm 4.8$  years) 5-vertebra motion segments (L1-L5) were prepared [4] and cyclically loaded. X-ray images were obtained before and after cyclic loading on all specimens. Load-displacement, kinematic, and deformation data were collected.

Specimens were loaded (Instron 1331, Norwood, MA) in pin-ended cyclic eccentric axial compression to 20,000 cycles at 0.5Hz, between  $0^\circ$  and  $15^\circ$  of flexion to simulate a low-angle ADL movement. Periodically (after cycles 0, 1,000, 3,000, 6,000, 10,000, 15,000 and 19,995), three-dimensional digital image correlation (3D-DIC) and motion capture imaging occurred during five slower

witness cycles (0.01Hz), the fifth of which were analyzed. Load-displacement data were post-processed (4<sup>th</sup> order Butterworth filter,  $\omega_c=0.01\text{Hz}$ ) using a custom MATLAB code (The MathWorks Inc., Natick, MA). The area, neutral zone length, and slope of each hysteresis loop were computed.

A motion capture system (4 Oqus 500 cameras, Qualisys AB, Sweden) tracked the regional centroid angle ( $\alpha$ ) and the intervertebral angles (IVAs) during the witness cycles. The relative IVAs were computed in QTM (Qualisys Track Manager Version 2.10, Qualisys AB, Sweden). Kinematic data from the analyzed cycles were aligned and then filtered (4<sup>th</sup> order Butterworth filter,  $\omega_c=0.0075\text{Hz}$ , MATLAB). Images for 3D-DIC were captured at 4Hz from two-cameras (Scorpion IEEE-1394, Point Grey Research Inc., Richmond, BC, Canada). During the witness cycles, regions of high localized cortical surface strain were identified using VIC3D 7 (Correlated Solutions Inc., Columbia, SC).

## RESULTS AND DISCUSSION

All tests were completed without obvious evidence of catastrophic fracture and without radiographic evidence of fracture on plain x-rays. The hysteresis loop area trends are similar between the cervine and cadaver specimens (Figure 1), and agree with our previous work [5].

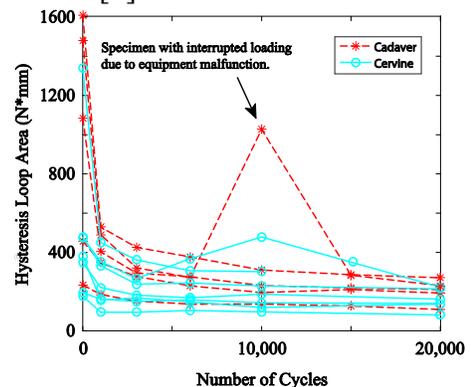

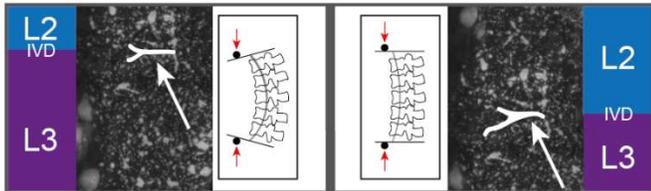

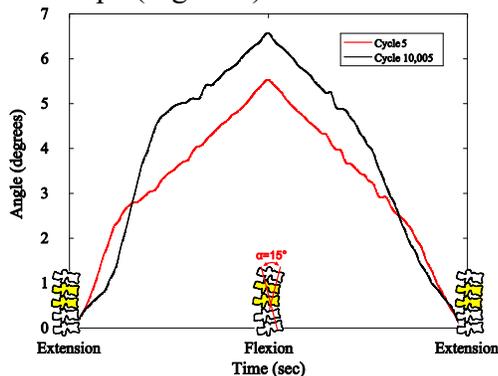

Figure 1: Hysteresis loop area for all specimens.

There is evidence of injury from the surface strain during the witness cycles, despite the absence of radiographic findings. 3D-DIC provides visible evidence of cortical shell cracks opening and closing as early as 6,005 cycles. Comparing images from these specimens (Figure 2) to our previous research [5] that created RAFs under a different loading protocol suggests that the current cervine specimens also have fractures and/or bony injuries.

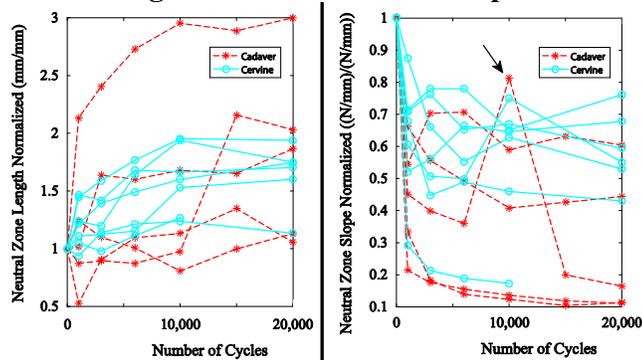

**Figure 2: Surface strain evidence of fracture in a cervine specimen.**

This evidence is echoed in the observed kinematic changes. The shape of the L2/L3 IVA changes from the beginning of the test to the time of observable crack opening (cycle 10,005), due to the combined effect of injury and disc relaxation (Figure 3). The increase in apparent compliance (increase in angle) near extension from cycle 5 to 10,005 indicates damage and/or disc relaxation, which is consistent with increases in neutral zone length and slope (Figure 4).

**Figure 3: L2/L3 IVA example.**

**Figure 4: Neutral zone lengths and slopes.**

The IVAs during each witness cycle show observable change in kinematics throughout the test. When comparing the 5<sup>th</sup> and 10,005<sup>th</sup> cycles there is a clear change in IVA. The angle increases, and the behavior throughout the application of the same displacement condition is markedly different. This change is expected given the increase in neutral zone length, and represents the combined effects of fluid re-distribution in the intervertebral discs and any soft- or hard-tissue damage that occurred during the loading.

## CONCLUSIONS

Both an increase in instability and vertebral injury can occur during low-load, low-angle cyclic loading. An increase in laxity, as evidenced by the increase in neutral zone length and decrease in neutral zone slope, may result in a clinically-significant increase in the risk of hyperflexion injury following prolonged cyclic flexion activities. The bony injuries would likely be symptomatic, but would most likely not be diagnosed as fractures. Our work demonstrates that vertebral injuries can occur in the absence of radiographical findings.

Future clinical work will identify optimal radiographic imaging to detect these injuries. Efforts to prevent and rehabilitate injury in both healthy, physically active adolescents and older adults should consider the role that small movement ADLs may play in injury risk.

## INTRODUCTION

Military recruits commonly sustain stress fractures, an injury common to distance runners, during Basic Combat Training (BCT). Interestingly, the recruits at lowest risk of musculoskeletal injury are those with the fastest 2 mile run time at the start of BCT [1]. It is possible that they participated in more running prior to BCT, which may be protective against injury for the large increase in training volume that occurs during BCT. Studies have shown that bone can adapt its structure to best resist habitual loading, potentially reducing fracture risk. While we have shown that high strain regions in bone experience greater bone apposition than low strain regions [2], the degree to which loading experienced during endurance running changes skeletal microstructure is still not well understood.

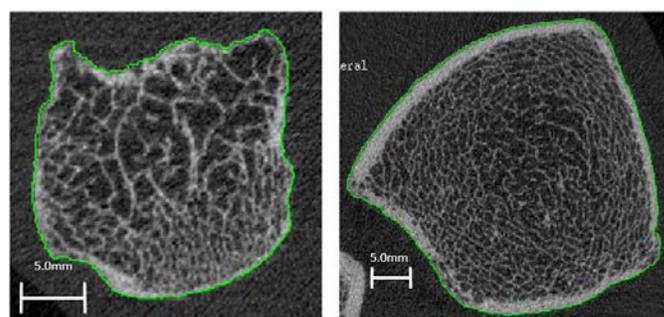

Our objective was to quantify changes in running mechanics and bone microstructure in novice marathoners participating in a structured training program. We hypothesized that (1) peak ankle and toe moments would be positively correlated with cortical and trabecular bone microstructure at the distal tibia and first metatarsal, respectively, and (2) change in bone post-marathon training would be positively related to ankle and toe moments.

## METHODS

Fifteen healthy adults training for a first marathon (7 males, age: 36.5±12.9 years, height: 171.4.9±11.9 cm, mass: 77.0±12.9 kg) were recruited. These subjects had never run more than 13.5 miles in a single bout, and had fewer than four weeks of >20 miles/week training over the last five years. Thirteen age and sex-matched physically-active non-runners (6 males, 36.6±12.7 years, 174.2±11.2 cm, 72.8±16.1 kg) were recruited as controls. All subjects provided written informed consent for this ongoing institutionally approved study.

Subjects received high resolution computed tomography (HRpQCT) scans of a 9.02 mm portion

of the right distal tibia (TIB) and first metatarsal (1MT) (Figure 1). Scans were acquired prior to beginning a marathon training regimen for runners and again 5-7 months later, within a month of completing their marathon. Non-runners received scans at a similar time interval.

**Figure 1** HRpQCT (XtremeCT, Scanco, Switzerland) image of distal-1M (left) and TIB (right) of a runner. Green line shows segmentation of bone from soft tissue.

Scans were analyzed for a battery of microarchitectural measures including: cortical bone thickness (Ct.Th; mm) and area (Ct.Ar; mm<sup>2</sup>), trabecular number (Tb.N, 1/mm), trabecular spacing (Tb.Sp; mm), volumetric density (BV/TV; mm<sup>3</sup>/mm<sup>3</sup>), trabecular area (Tb.Ar, mm<sup>2</sup>), cortical bone mineral density (Ct.BMD, mg/cm<sup>3</sup>), total area (Tt.Ar, cm<sup>2</sup>), mean slice area (MSA, mm<sup>2</sup>), total bone mineral density (Tt.BMD, mg/cm<sup>3</sup>) and bone mineral content (BMC; g).

Running biomechanics were collected on runners at the beginning of their training and again after their marathon. Three dimensional kinematic and kinetic data were collected while participants jogged around a 50-meter track at their average training speed. Trials were considered valid when the right leg fully hit one of the force plates. For the purpose of this analysis, a simplified two-linkage inverse dynamics model of the right foot and lower leg was used to calculate the forces and moments acting at the ankle and metatarsal joints in the sagittal plane.

Currently, pre- and post- data are available for 7 runners, and complete pre-data are available for 13 runners and 13 non-runners. Baseline bone microstructural data were compared in runners versus non-runners using a t-test. To test whether joint moments were related to bone microstructure, Pearson correlations were calculated for these parameters versus runner pre-data. To examine the dependence of bone adaptation on running biomechanics, percent change in bone microstructure was correlated with baseline running biomechanics parameters.

## RESULTS AND DISCUSSION

At baseline, runners exhibited enhanced cortical and trabecular parameters, indicating increased bone strength compared to nonrunners (Table 1). Although this group was marathon-naïve, these differences suggest that low-volume running in adulthood is beneficial to bone. Self-selection into a marathon training program is likely associated with a life-long commitment to physical activity that may not be as present in the non-runner group. A larger prospective cohort should clarify this point.

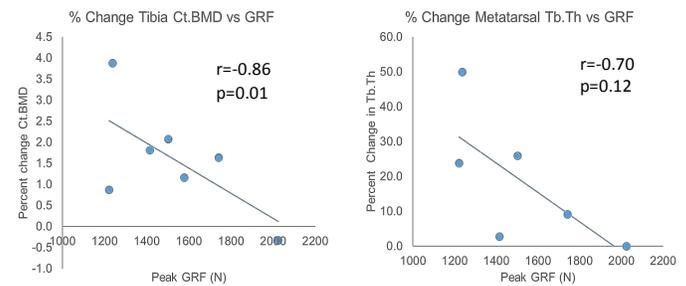

**Table 1** Baseline CT measures for TIB in controls vs runners. P-values test for between-group differences. 1MT data were similar.

Measure	Control Mean(SD)	Runner Mean(SD)	P-val
Tb.BMD	172.4(28.1)	211.6(33.7)	0.014
BV/TV	0.144(0.023)	0.176(0.028)	0.013
Tb.Th	0.071(0.011)	0.080(0.010)	0.030
D100	291.8(44.3)	315.0(47.6)	0.012
Ct.Ar	117.5(23.6)	143.3(30.7)	0.035
Ct.Th	1.07(0.24)	1.31(0.26)	0.014

Units: Tb.BMD, mg/cm<sup>3</sup>; BV/TV, mm<sup>3</sup>/mm<sup>3</sup>; Tb.Th, mm; D100 (total bone mineral density), mg/cm<sup>3</sup>; Ct.Ar, mm<sup>2</sup>; Ct.Th, mm.

In runners, bone parameters were closely related to ground reaction forces (GRF) and ankle/toe moments. After normalizing for body mass, several TIB parameters remained correlated with kinetics measures (e.g. Ct.Ar vs. ankle moment  $r=0.58$ ,  $p=0.048$ ; BMC vs. moment  $r=0.64$ ,  $p=0.025$ ). In general, bone mass scales with body mass, but our data suggest that running biomechanics provide an additional important input for bone mass and structure. It is unclear whether this relationship is present in non-runners and whether it is also a reflection of walking moments – a more common daily activity.

Preliminary analysis indicates a trend towards negative relationships between peak GRF and

**Figure 2** Change in microstructure was consistently negatively correlated with GRF magnitude. This correlation was weakened by normalizing to body mass. 1MT data were incomplete for one subject.

percent change in both TIB and 1MT bone (Figure 2). Heavier individuals generally generate larger peak GRF and have stronger bone, so it is possible that those with initially weaker bone experience the greatest changes to bone structure. On average TIB bone parameters indicated increased strength (e.g. BMC increased by  $1.2\pm 2.4\%$  from pre to post), and 1MT indicated decreased strength and mineral (BMC decreased by  $2.4\pm 4.5\%$ ), although our sample was small.

The 1MT is loaded primarily in bending in the simplified two-linkage running model. In contrast, the distal tibia is loaded primarily in compression. Whether loading mode, strain rate, or other factors are responsible for the differential effects is yet to be determined. In the future, models will include muscle forces that also contribute to bone loading.

## CONCLUSIONS

Preliminarily, marathon trainees had enhanced bone structure compared to non-runner controls, which may be related to running biomechanics. Improved tibia parameters may indicate a positive effect of marathon training on strength. In the future, an inclusion of musculoskeletal modeling and imaging techniques may better inform stress fracture risk assessment. We expect these trends to be reinforced in the forthcoming full study population.

## INTRODUCTION

Neonatal brachial plexus injury (NBPI) occurs in 1.5 per 1000 live births [1]. Children affected with this injury undergo permanent osseous and postural deformities. NBPI presents as either postganglionic injury – resulting in restricted longitudinal growth of paralyzed muscles – or preganglionic injury which causes paralysis without substantial muscle shortening [1]. It is believed that compressive and posterior joint loading subsequent to NBPI increases with shortened muscles, and severe morphological changes are observed in rats with shortened muscles after postganglionic NBPI [3]. Further, the injury imposes a restricted range of motion and reduced limb use, leading to an increase in static loading [2]. Static compressive joint loads are known to significantly inhibit the synthesis of cartilage matrix proteins, while dynamic compression stimulates matrix production in developing bone [2]. It is unknown whether, for NBPI, altered loading due to growth restriction or static loading is the primary driver of joint deformity, and whether the extent of deformity can be predicted. The goal of the study was to evaluate the effect of static vs dynamic joint loading and muscle shortening on the morphology of the developing glenohumeral joint after NBPI.

## METHODS

An iterative finite element modeling approach was used to predict osseous morphological growth in response to biological and mechanical stimuli (Abaqus 6.13.3, Dassault Systemes). We used a thermal expansion analog to capture the biological and mechanical contributions to growth [2]. Biological growth was modeled using a cubic equation which was a function of distance from the growth plate [2]. The mechanical growth was proportional to compressive hydrostatic stress at every node. Stress due to static loads restricted the growth while dynamic hydrostatic stress stimulated growth [2], according to the following equations:

$$\dot{\epsilon}_m = C_d \left( \frac{\sum_{i=1}^N \sigma_{hi}}{N} \right), \text{ for static loads}$$

$$\dot{\epsilon}_m = -C_d \left( \frac{\sum_{i=1}^N \sigma_{hi}}{N} \right), \text{ for dynamic loads}$$

$\dot{\epsilon}_m$  is the mechanical growth rate,  $\sigma_{hi}$  is the compressive hydrostatic stress,  $N$  is the number of movements per step and  $C_d$  is the chondrocyte density. The resultant geometry was the summation of biological and mechanical growth.

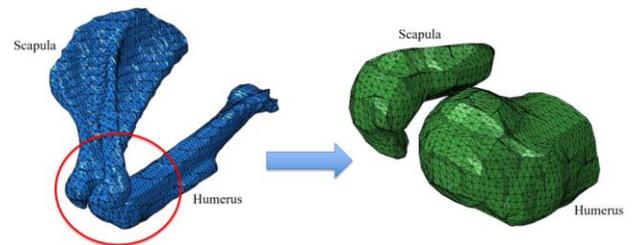

Fig 1: Reduced glenohumeral joint geometry

We created 3 simulations to address our study goals: 1) Dynamic, 2) Static: Preganglionic and 3) Static: Postganglionic. Initial geometry of the glenohumeral joint was the same for all simulations and was derived from micro-CT scans of unimpaired neonatal rats. The geometry was subsequently reduced to the regions near the articulating surfaces to minimize computational time (Fig. 1). For the dynamic simulation, a compressive joint load of 0.1 N was applied under a cyclic motion from 0° to 30° abduction. In the static preganglionic (no muscle restriction) and postganglionic (muscle growth restriction) simulations, the static joint loads were computed with the shoulder in 30° abduction using an upper extremity musculoskeletal model [2] in OpenSim by denervating the NBPI affected muscles and all other unaffected muscles at 30% activation [5]. To evaluate the effect of impaired muscle growth, we performed both simulations with the base musculoskeletal model, and with the affected muscles shortened by 40% relative to the skeletal geometry to represent 8 weeks of the growth period

[3]. The joint loads from OpenSim were incorporated as a displacement boundary condition in Abaqus by considering a joint stiffness of 2kN/mm [6]. The glenoid surfaces for each simulation were measured to assess glenoid inclination angle (GIA), and the glenoid radius of curvature (GRC). GIA is the angle complementary to the angle between the centerline of the spine of the scapula (red) and the tangent line to the rim of the glenoid cavity (Fig. 3).

## RESULTS AND DISCUSSION

Both static conditions (i.e. preganglionic and postganglionic) showed a substantial increase in the GIA and the GRC from the baseline model (Fig. 3, Table 1), confirming that absence or reduction of dynamic loads on the joint following NBPI increases glenoid flatness and declination. In contrast, both GIA and GRC were found to decrease from baseline in the dynamic analysis, retaining the glenoid curvature essential for effective functioning of the glenohumeral joint. Postganglionic simulations exhibited more severe deformity than preganglionic, but changes were less marked than between static and dynamic conditions.

The simulated results compare well with experimental data from a rat study of NBPI in which a postganglionic neurectomy was performed postnatally [3]. An increase in both GIA and GRC in the case of affected rats at 8 weeks postnatal corroborated our simulation predictions that static loads and muscle shortening drive joint deformation due to NBPI. In addition, the magnitude of inclination for postganglionic injury in both experiment and simulation were in close agreement ( $56.1^\circ$  vs  $59^\circ$ , respectively) (Table 1). Limitations in the current simulation should be considered. We modeled a single biological center for the scapula, but there are three growth centers at this stage of development, and each may have different biological growth rates. Differing rates along the glenoid may

contribute to the differences in predicted and experimental GRC.

The computational methodology described here, integrating musculoskeletal joint loading with finite element growth models, provides an important platform to capture the effect of altered musculoskeletal loading following NBPI on the time progression of joint deformation. With this foundation, surgical strategies and effect of intervention timing can be explored.

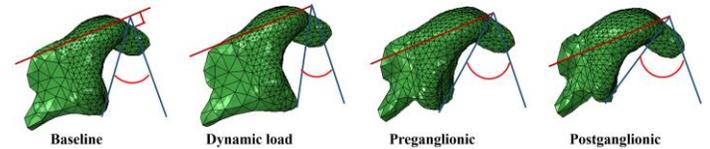

Fig 3: Glenoid deformations in each simulation

## CONCLUSIONS

The study successfully developed a computational framework that captured developmental changes to bone following NBPI, and validated predictions against experimental data. The finite element model predicted that static loading of the joint was primarily responsible for joint deformation due to the neurological injury. The model also captured the effects of altered muscle forces due to preganglionic and postganglionic injuries on a musculoskeletal structure and predicted that postganglionic injuries were responsible for more severe joint deformations, which is consistent with the existing literature [3].

## INTRODUCTION

Total knee arthroplasty (TKA) is a common surgical procedure that attempts to restore the functional mechanics of the normal knee [1]. Recent modifications in design have resulted in substantial decrease in complications such as instability and component loosening. However, complications involving the patellofemoral (PF) joint are the cause of as many as 50% of all total knee revisions [2]. While in-vitro experiments provide an improved understanding of the passive structures of the PF joint, knowledge of in-vivo PF joint stresses during daily activities are limited.

Computational models of the musculoskeletal system provide access to the internal loads at the tibiofemoral (TF) and PF joints based on external measurements. In the past, multibody (MB) dynamics has focused on whole-body dynamic musculoskeletal models while finite element (FE) methods have been used for joint level models. These methods were either isolated or applied at different stages during a simulation. This study introduces a framework for co-simulating MB dynamics and linear FE methods to estimate von Mises stress in the patellar button during smooth, normal and bouncy gait. In this study we also validated the musculoskeletal model by comparing model predictions of TF contact forces to subject specific in-vivo measurements obtained from an instrumented TKA.

## METHODS

The data for this study was collected from an 83-year-old male subject (mass=70 kg and height=172 cm) with an instrumented right TKA that measures the six loading components acting on the tibial tray. The experimental data were provided by the sixth

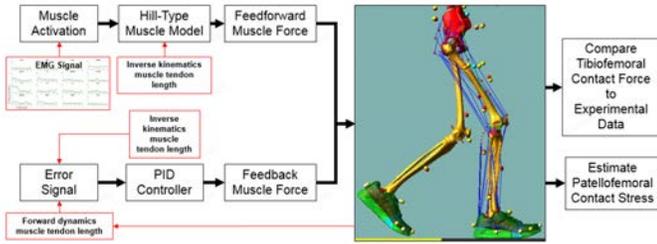

edition of the Grand Challenge Competition to Predict In-vivo Knee Loads [3].

The subject model (Fig. 2b) was developed in the commercially available multibody dynamic analysis program MSC ADAMS, NASTRAN, and PATRAN (MSC Software Corporation, Santa Ana, CA). The generic musculoskeletal model was comprised of 21 rigid body segments, 53 revolute joints, and 44 right leg muscles [4]. The knee joint (Fig. 2c) consisted of a 12 degrees-of-freedom anatomical right knee that included both the TF and PF joints. The tibial insert was divided into medial and lateral geometries with separate contacts created for each part. The ligaments were modeled as bundles, attached to the bones according to the origin and insertion site footprints based on anatomical studies. Deformable contacts between force plate geometries and shoe geometries were used to model the shoe-ground interface.

This study captures the von Mises stress on the patellar button using rigid-flexible multibody dynamics theory [5]. The patellar button is made flexible using MSC NASTRAN. A FE mesh of the button is generated using MSC PATRAN with tetrahedral elements. The button material is assumed to be linear and isotropic. The material properties were Young's modulus  $5.72E+008$  N/m<sup>2</sup>, Poisson's ratio 0.45, and density 945 kg/m<sup>3</sup>. One attachment node with 6 DOFs is generated at the center of the patella bone. Rigid body spider web elements (RBE2) are used to connect the attachment node to the adjacent surface nodes on the patella button. Thirty fixed boundary mode shapes are exported from MSC NASTRAN.

The experimental motion capture data for smooth, normal and bouncy walking trials provided input to an inverse kinematics step for each model. A feedforward with feedback trim control scheme

(Fig. 1) is used to produce muscle force for muscles with EMG signal. The feedforward muscle scheme incorporates experimental EMG when available with a Hill-type muscle model to produce feedforward muscle force. A feedback scheme is used for remaining muscles.

**Figure 1:** Feedforward with feedback control scheme to calculate muscle force and predicting joint contact forces.

## RESULTS AND DISCUSSION

Comparisons of model predictions with measured contact forces showed (Fig. 2a) that the EMG-driven musculoskeletal model using patient-specific input data can estimate tibiofemoral contact forces with root mean square errors (RMSEs) of 0.18-0.29 times body weight (BW) for smooth, 0.15-0.21 BW for normal, and 0.21-0.33 BW for bouncy gait trials. The maximum von Mises stress (Fig. 2b) was computed at the mid-stance (20%, 17%, 22% gait cycle for smooth, normal, and bouncy) when the

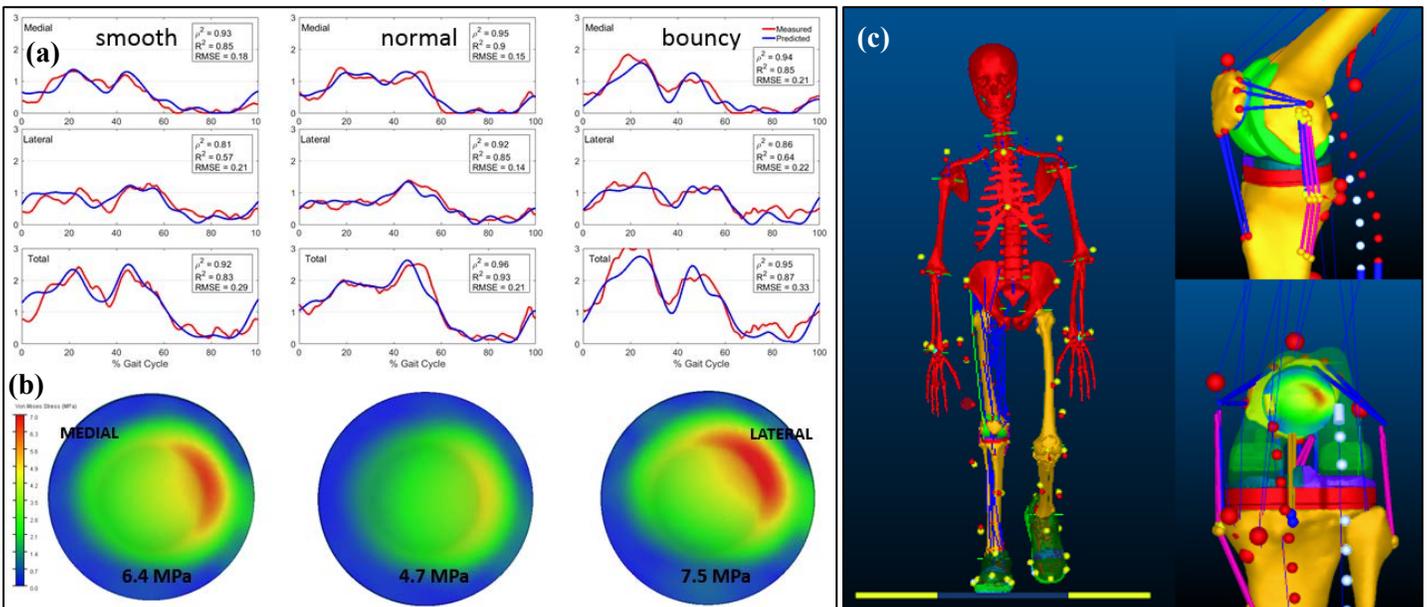

average quadriceps muscle force is maximum. The von Mises stresses were 6.4 MPa, 4.7 MPa, and 7.5 MPa for smooth, normal and bouncy gait trials respectively.

## CONCLUSIONS

This study involved co-simulation of a prosthetic patellar button FE model embedded in a validated MB musculoskeletal model of gait. TF contact force RMSEs between model predicted and measured ranged from 0.15-0.33 BW for the three gait types. The von Mises stress in the patellar button increased in smooth and was the greatest in bouncy gait when compared to normal gait due to the increase in flexion angle and quadriceps force.

## INTRODUCTION

Osteoarthritis (OA) of the knee is common disease that impacts functional mobility and quality of life for many individuals [1]. Total Knee Arthroplasty (TKA) is the most common surgical treatment for end-stage OA. While the cause of OA is multifactorial, loading patterns have been correlated with OA progression [2]. Most of the existing data on movement patterns before and after TKA has been assessed using optical motion capture systems and ground reaction forces. However, these measurements are limited to constrained laboratory settings, which may not reflect real-world movement patterns.

Due to the advancement in wearable technologies, wearable sensors have become a viable alternative to assess the initial loading pattern during walking [3]. They are advantageous since they require minimal equipment and can capture kinetic attributes outside of the laboratory setting. Monitoring multiple and sequential kinetic parameters in real-world conditions may lead to a more accurate understanding of the relationship between movement patterns and recovery from TKA. Therefore, the purpose of this study was to estimate kinematic and kinetic gait metrics using two ankle-worn wearable sensors in individuals after unilateral TKA.

## METHODS

15 subjects (1.70±0.1m, 84.5±17.1kg, 67.1±7.5yr, speed=1.13±0.20m/s) after unilateral TKA participated in this study. Data were acquired in the Neuromuscular Biomechanics Laboratory at the University of Delaware. An instrumented split-belt treadmill and an 8 camera motion capture system were used to collect kinetic and kinematic gait variables. Acceleration data were collected using two angle-worn accelerometers. Accelerometers were attached above the lateral malleoli. Each subject

walked at self-selected comfortable walking speed, as determined by a 6 meter walk test, for one minute.

Eleven gait variables were extracted to estimate magnitude, impulse, and angles of initial loading from 3D-acceleration data (Table 1). Then, the wearable sensor-based gait variables were compared to three kinetic and kinematic gait variables averaged across the one-minute trial: maximum knee flexion moment (KFM), maximum knee adduction moment (KAM), and first peak of vertical ground reaction force (vGRF).

**Table 1:** Eleven inertial gait features based on one all-step inclusive and three directional gait feature categories.

Category	Description
Inclusive	Step time
	Step vector magnitude
	Initial loading vector mag.
Lateral	Lateral heel-strike magnitude
	Lateral heel-strike impulse
	Lateral stance phase angle
Vertical	Vertical heel-strike magnitude
	Vertical heel-strike impulse
Anterior	Anterior heel strike magnitude
	Anterior heel-strike impulse
	Anterior stance phase angle

Hierarchical linear regressions were applied to determine contribution of directional gait variables from wearables for each biomechanical gait feature. To analyze directional effect of inertial gait variables, inclusive-, lateral-, vertical-, and anterior-gait inertial variables were sequentially appended as additional dependent variables of regression models.

## RESULTS AND DISCUSSION

Outcomes of the hierarchical linear regression indicated that inertial gait features significantly

estimated all three biomechanical gait features (Table 2). KFM was significantly and solely explained by vertical heel-strike magnitude. The addition of anterior heel-strike magnitude slightly improved the model, but the rest of the nine inertial gait features did not improve prediction of KFM. Lateral heel-strike magnitude and stance phase angle deviation were significant predictors of KAM outcomes after accounting for step time and vector magnitude. For the vGRF prediction model, both lateral and anterior inertial gait features equally contributed to explain 75.4 % of the variance in vGRF measure.

Hierarchical regression models provided evidence that accelerometer-based metrics can be used to predict biomechanical gait variables. With all inertial gait variables, 48.7%, 69.0%, and 75.4% of the variance in KFM, KAM, and vGRF measures were explained, respectively.

Knee flexion moment was primarily explained by vertical inertial gait variables. It is likely that vertical inertial variables are related to limb impact during heel strike. Impact may be partially controlled by knee flexion with an increase in knee flexion during weight acceptance serving to soften impact but subsequently increase peak knee flexion moment. On the other hand, knee adduction moment was primarily explained by lateral inertial gait variables. Gait modifications including increased step width, increased trunk sway and toe-in gait have been shown to be effective at reducing knee adduction moment in healthy population [4]. It is likely that

individuals post-TKA may adapt similar strategies to reduce knee adduction moment as a result of pain or functional compensations. It is reasonable to believe that such gait adaptations may be evidenced through lateral inertial gait variables, given the changes in side to side movement (i.e. swaying, wide steps).

## CONCLUSION

Although generalization to the TKA population as a whole is limited due to the small sample size of this study, the current results provide evidence that inertial measurements can be used to reasonably estimate conventional biomechanical metrics. Future work will examine the relationship between additional kinematic and kinetic variables and inertial variables.

## INTRODUCTION

Abnormal knee joint biomechanics during walking have been associated with increased prosthetic wear of a total knee arthroplasty (TKA). Concurrent osteoarthritis of the contralateral knee (CKOA) often requires inter-limb compensation and may have the potential to affect the post-arthroplasty knee biomechanics. While TKA is an effective surgical intervention for knee arthritic pain, CKOA is common among post-TKA patients. When it comes to the management of CKOA, the effect of CKOA on post-arthroplasty knee is often ignored. This study tried to determine if and how CKOA altered knee biomechanics with a mobile-bearing implant.

## METHODS

Patients were selected after a unilateral TKA with mobile-bearing implant (DePuy). The average time past surgery was  $13 \pm 8$  months with a range from 3 to 39 months. At the time of testing, they all could walk without aid, and had no symptoms other than CKOA or any previous injury that would affect gait. A total of 22 patients were recruited. There were 10 CKOA patients (2M/8F, 4L/6R,  $69 \pm 7$  years) and 12 patients (2M/10F, 8L/4R,  $68.8 \pm 5$  years) with asymptomatic contralateral knee. The operated knee of all patients had no or very mild pain at the time of testing.

All subjects signed consent forms after an IRB approved testing protocol was introduced. Each subject walked five times at a self-selected speed in a lab equipped with ten-camera motion capture system (100Hz, MX-F40, VICON, Oxford, UK) and two force plates (1000Hz, AMTI, MA, USA). Marker data was smoothed using a zero-lag 4<sup>th</sup>-order Butterworth filter at a cut-off frequency of 6Hz. A redundant marker set was used to determine the tibiofemoral joint motion which follows our

previously reported study [1]. Intersegment joint loading was obtained through inverse dynamics method. Spatiotemporal parameters, tibiofemoral joint motion and knee joint kinetics were compared between CKOA group and CKNON group using a one-way ANOVA (significance level 0.05). A bivariate correlation analysis was also conducted to investigate the interaction between kinematics and loading.

## RESULTS AND DISCUSSION

**Spatiotemporal:** CKOA group had a bigger stance percentage than CKNON group by 4% gait cycle (GC). CKOA group walked with a 20.5% longer stance phase by 0.17s and 17.5% slower stride speed (Table 1).

**Kinematics:** As knee extended (85%-95% GC), the operated knees in CKOA group were  $5.7^\circ$  less extended than those in CKNON group ( $p < .05$ , Table 1 and Fig. 1). In the transverse plane, a  $3.9^\circ$  more tibia external rotation was observed around heel strike (HS), 95%-20% GC in CKOA group ( $p < .01$ ). Anteroposterior translation was also altered, with about 2mm posterior offset at HS, around mid-stance (25%-35% GC) and around toe-off (60~65% GC).

For range of motion during stance, CKOA group was similar in flexion-extension and anteroposterior translation, but had  $2.5^\circ$  bigger axial rotation range than CKNON group (CKOA,  $9.91^\circ \pm 2.54^\circ$ ; CKNON,  $7.48^\circ \pm 2.55^\circ$ ,  $p < .05$ ).

**Kinetics:** Peak knee axial (vertical) joint force was significantly reduced by 5%BW in CKOA group (Fig. 1 and Table 2,  $p < .01$ ). The peak knee extension moment of CKOA group was also smaller than CKNON group. No difference was found in peak/mean knee adduction/flexion/rotation moment.

**Correlation:** The knee flexion angle at HS was positively correlated with the magnitude of mean

knee flexion moment ( $p < .01$ ,  $r = .77$ ). The tibia external rotation angle at HS was negatively correlated with the magnitude of mean knee adduction moment ( $p < .01$ ,  $r = -0.61$ ) and peak knee rotation moment ( $p < .01$ ,  $r = -0.54$ ). Knee axial rotation range was correlated with rotation angle at HS ( $p < .01$ ,  $r = .63$ ) but not correlated with loading.

**Discussion:** CKOA altered kinematics at HS and increased knee axial rotation range, which might increase the wear rate of the implant [2]. Muscle firing pattern (i.e. a quadriceps overuse pattern) were linked with the extension loss. The internal rotation loss is linked with a reduced mean knee adduction moment which might be a result of front plane

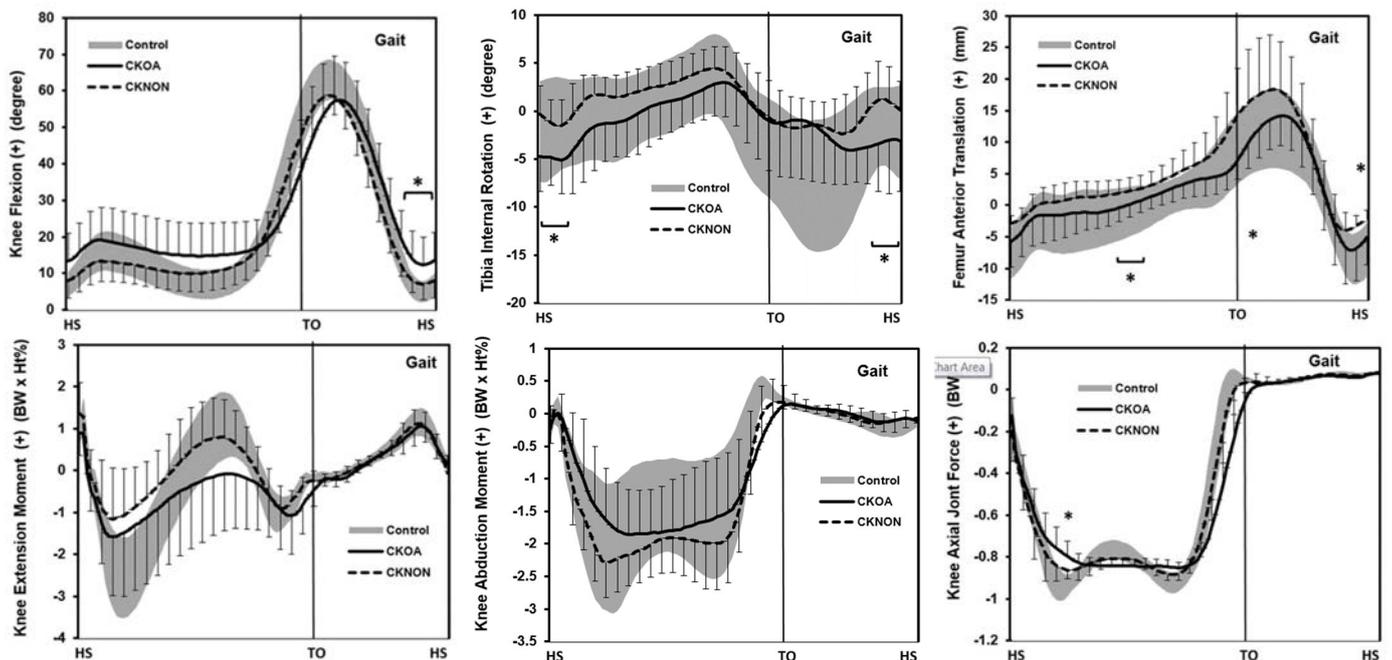

compensation such as trunk leaning in CKOA patients.

## CONCLUSIONS

Concurrent osteoarthritis of the contralateral knee alters the mechanical environment of the knee implant and may affect its function in long-term.

## INTRODUCTION

Total knee arthroplasty (TKA) is a common surgical procedure for treating end-stage knee osteoarthritis (OA). Patients with TKA and knee OA often have difficulty in daily movement tasks such as stair ambulation [2]. Although a majority of TKA patients is satisfied with their surgeries, some TKA patients reported dissatisfaction with decreased capacity of daily living activities [1, 4]. However, it is not entirely clear why the TKA patients are not happy with their TKA procedures.

Previous research on TKA level and stair gait biomechanics has been focused on differences from healthy individuals and between replaced and non-replaced limbs [3, 5]. Research on gait biomechanics of the dissatisfied TKA patients is scarce.

Therefore, the purpose of this study was to compare knee biomechanical characteristics of stair ascent for dissatisfied TKA patients to satisfied TKA patients and healthy controls. It was hypothesized that dissatisfied TKA patients would exhibit decreased knee extension moments and increased knee abduction moments in their replaced limb compared to their non-replaced limb during stair ascent.

## METHODS

Participants were recruited from a local orthopaedic clinic: nine dissatisfied TKA patients (68.0±4.2 years, BMI: 28.4± kg/m<sup>2</sup>, 34.6±14.3 months from surgery) and fifteen satisfied TKA patients (66.6±6.3 years, BMI: 29.1± kg/m<sup>2</sup>, 29.3±12.8 months since surgery). Fifteen healthy controls (60.7±9.2 years, BMI: 25.4± kg/m<sup>2</sup>) were recruited with the same exclusion criteria as the TKA groups. The inclusion criteria for TKA patients were having a unilateral total knee replacement (conducted by a single surgeon) at least 12 months but less than 60 months prior to testing and between the ages of 50 and 75 at the time of testing. Potential participants were

excluded if they had any additional lower extremity joint replacements, any additional diagnosed osteoarthritis of the hip, knee, or ankle, BMI greater than 38, or neurological diseases. TKA patients were then asked, “How satisfied are you with your total knee replacement?” and patients answering “Neutral” were excluded from the study. Any participant who responded “very dissatisfied” or “dissatisfied” was placed into the dissatisfied group and participants who answered “satisfied” or “very satisfied” were placed into the satisfied group.

A 12-camera motion capture system (240Hz, Vicon, UK) and an instrumented staircase (FP-stairs, AMTI, USA) in conjunction with two force platforms (1200Hz, AMTI, USA) were used to collect three-dimensional kinematic and ground reaction force (GRF) data, respectively. Anatomical markers and tracking markers were placed bilaterally on the trunk, pelvis, thighs, shanks, and lab shoes (Noveto, Adidas). Each participant performed five successful stair ascent trials at ±5% of the preferred stair ascent speed. Participants were provided practice trials to become familiar with test settings.

Kinematic and force data were filtered using a low pass fourth-order zero-lag Butterworth filter (8Hz), and processed using Visual3D (5.0, C-Motion, Inc.). Joint moments were computed as internal moments and normalized to mass (Nm/kg).

A 2×3 (limb × group) mixed model analysis of variance (ANOVA,  $p < 0.05$ ) was performed to detect differences between limbs and groups for kinematic and kinetic variables (9.4, SAS). In the presence of a significant interaction or a main effect, *post hoc* comparisons were conducted using paired-sample *t*-tests with Bonferroni adjustments.

## RESULTS AND DISCUSSION

The preferred walking speed for the dissatisfied group (0.53±0.16 m/s) was slower than the satisfied

(0.74±0.10 m/s) and healthy (0.69±0.12 m/s, p<0.0099 for both) group.

Significant interactions were present during stair ascent trials for 2<sup>nd</sup> peak vertical GRF, peak loading-response knee extension moment, knee abduction ROM, and peak loading-response internal rotation moment (Table 1). Post-hoc analysis revealed that the dissatisfied group had lower 2<sup>nd</sup> peak vertical GRFs compared to their non-replaced limb and both the satisfied and healthy groups. The peak loading-response extension moment was lower in the replaced-limb of the dissatisfied group compared to their non-replaced limb and both the satisfied and healthy groups.

For all four variables with significant interactions, the satisfied group was different in their replaced limb compared to their non-replaced limb, experiencing reduced peak vertical GRF, peak loading-response extension moment, and peak loading-response internal rotation moments along with an increased knee abduction ROM. In addition, significant limb main effects were present in the 1<sup>st</sup> peak vertical GRF, peak loading-response abduction moment, and peak push-off abduction moment, with the replaced limbs showing reduced values compared to the non-replaced limbs.

These results showed that the replaced limb of TKR patients had reduced peak vertical GRFs, peak knee extension moment, peak knee abduction moments and peak knee internal rotation moment compared to their non-replaced limbs. More importantly, the dissatisfied TKA patients had slower stair ascent speed, and reduced peak loading-response knee extension moment and peak push-off vertical GRF in their replaced limb compared to their non-replaced limb and satisfied TKA patients and healthy counterparts. Our study has demonstrated that the dissatisfied TKA patients have deficits in not only the speed, but also during loading- response and push-off in stair ascent. Furthermore, it is important to understand associations of other aspects with TKA patient dissatisfactions.

## INTRODUCTION

Although only a relatively small amount of muscular activity is required to maintain an erect standing posture, the control of it, is complex and involves motor control and neuromuscular systems. When motor or sensory components are altered or defective, body's postural sway generally increases, indicating decreased postural stability. Concurrently, there is an increased demand on the central mechanisms and peripheral muscles to maintain postural equilibrium [1]. An intrinsic human factor, such as a physiological workload leading to muscular fatigue and an extrinsic factor such as, inappropriate footwear that alter lower extremity muscle activity have been shown to contribute to decrements in postural stability and subsequently an increased incidence for falls. Biomechanical analysis of military load carriage has suggested a decrease in postural stability and a greater incidence for injuries [2]. Such physical demands in the military along with inappropriate military footwear might predispose the wearer to inefficient muscular exertion to maintain erect stance and result in postural instability. Therefore the purpose of this study was to analyze the impact of two types of military footwear and a military type workload on muscle activity during postural stability tasks.

## METHODS

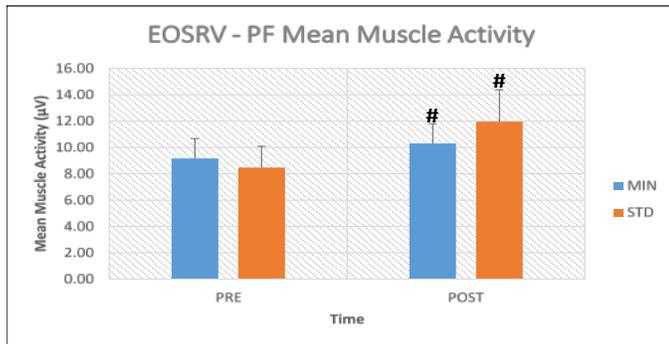

The study followed a pre-test-post-test repeated measures design, with a total of sixteen male participants [age:  $26.63 \pm 3.93$  years; height:  $178.04 \pm 6.2$  cm; mass:  $87 \pm 12.4$  kg] tested for muscle activity during postural stability tasks, prior to (PRE) and after a simulated military type 16 kg rucksack carrying workload (POST) [3], in two AR670-1 complaint military footwear on separate days using a counterbalanced footwear assignment. [Boot #1: Belleville TR101 MiniMil ultra-light minimalist tactical military boot (MIN) (mass:  $500.13 \pm 24.1$

gm; sole surface area:  $235.4 \pm 8.2$  cm<sup>2</sup>; flexible boot shaft height: 20 cm; heel-midfoot drop: 2 mm); Boot #2: Belleville 310ST hot weather standard tactical boot (STD) (mass:  $801.13 \pm 40.4$  gm; sole surface area:  $288.6 \pm 24.1$  cm<sup>2</sup>; stiff boot shaft height: 20 cm; heel-midfoot drop: 18 mm)]. Electromyography (EMG) muscle activity from ankle plantar-flexor (PF): medial gastrocnemius and dorsi-flexor (DF): tibialis anterior were assessed using a Noraxon™ TeleMyo EMG system, during sensory organization test (SOT) [eyes open (EO), eyes closed (EC), EO sway referenced vision (EOSRV), EO sway referenced support (EOSRS), EC sway referenced support (ECSRS), EO sway referenced vision and support (EOSRVS)] and motor control test (MCT) [small, medium, large backward (BWS, BWM, BWL) & forward (FWS, FWM, FWL) support translations] on the Neurocom Equitest™ synced with triggered start-stop using a transistor-transistor logic (TTL) pulse. Mean muscle activity during SOT and MCT were calculated after filtering and rectifying the raw data and analyzed using a 2×2 footwear (MIN-STD) × time (PRE-POST) repeated measures ANOVA at an alpha level of 0.05 using SPSS.

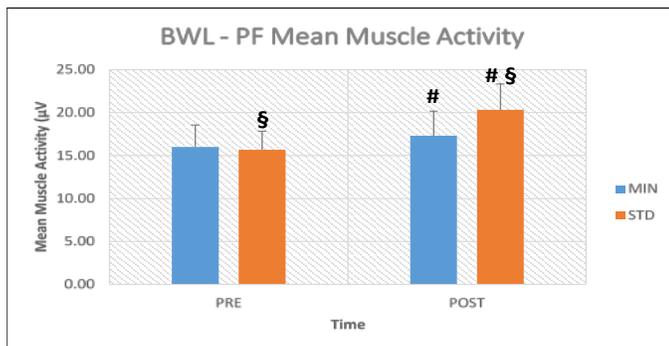

## RESULTS AND DISCUSSION

On average, significantly greater muscle activity was required to maintain postural stability in the post workload condition and in STD. Results revealed significant time effect for PF during EO ( $p = 0.006$ ), EC ( $p = 0.016$ ) & EOSRV ( $p = 0.035$ ) conditions. Significant time effect was evident during BWM for DF ( $p = 0.026$ ) and during BWL for PF ( $p = 0.026$ ). Pairwise comparisons revealed significantly greater muscle activity from PF & DF in POST workload compared to PRE workload. Significant footwear × time interaction ( $p = 0.028$ ) was found during BWL for PF with simple effects revealing significantly greater muscle activity in POST workload in STD. The results from the study suggest that a simulated

physiological military type workload with a 16 kg rucksack and wearing the STD boot required greater muscular exertion to maintain postural stability with absent and/or conflicting sensory information in the SOT and during external perturbations in the MCT. Balance results from the SOT and MCT are reported elsewhere, with decreased postural stability in the post-workload condition and superior balance performance in the MIN compared to STD.

**Figure 1:** Plantar flexor (PF) during eyes open sway referenced vision (EOSRV) condition. # represents significant time difference & § represents significant footwear difference.

**Figure 2:** Plantar flexor (PF) during backward large perturbations (BWL) condition. # represents significant time difference & § represents significant footwear difference.

Muscular fatigue may impair the proprioceptive and kinesthetic properties of joints by increasing the threshold of muscle spindle discharge, disrupting afferent feedback and ultimately altering conscious joint awareness [4], thereby requiring a greater magnitude of muscle activation to maintain postural control. Results from this study support previous literature, as greater muscle activity was seen in during both SOT and MCT during the post workload conditions, suggesting the need for greater muscular exertion to maintain stability after the workload. Significant differences in EC and EOSRV can be attributed to the reduced activity of the proprioceptive system and the inability of the

postural muscles to produce and sustain a required muscular output [2,4] especially when the postural control system is relying more on proprioceptive system with absent or inaccurate afferent feedback.

Earlier studies have shown that footwear with heavier mass, increases energy expenditure [5] as well an increase in muscular fatigue [6]. The rate of oxygen uptake ( $VO_2$ ) increases by approximately 1% for every 100 gm of mass added to the footwear [5]. Moreover, a lower heel-to-toe drop or minimalist type of foot orientation with an absence of significant heel height, increases postural orientation by minimizing an anterior shift in the body's center of mass and a less severe tipping angle [7], thereby requiring less muscular activity to maintain erect stance. Wearing the STD boot, demonstrated greater muscle activity to maintain postural stability especially in the post workload condition during BWL perturbations. Muscle activity differences between the two military footwear can be attributed to the MIN boot being 300 gm less heavier than STD boot, and incorporating a minimalist sole design with a heel-to-toe drop of 2 mm, with a low heel height compared to the STD's 18 mm, thereby requiring less muscle activation and aiding in a superior performance in the MIN.

## CONCLUSION

Results from the study report a greater requirement of muscular exertion to maintain postural stability after a physiological workload especially in STD military boot. Findings will help offer footwear design suggestions to improve postural stability with minimal muscular exertion and also on work-rest intervals in the military to prevent overexertion induced postural instability.

### INTRODUCTION

The term “military personnel” is a large umbrella term for all United States service members regardless of assigned duties. Military personnel jobs vary from infantry, medical personnel, mechanics, flight controllers, pilots and other personnel. Many of the military occupations consist of environments that are further inclusive in extrinsic factors such as diverse terrains, lack of light, increased decibel range, unstable ground surfaces and intrinsic factors such as fatiguing workloads including load carriage. Proper postural control and slip responses are essential in military settings in order to prevent falls. The US Army Annual Injury Epidemiology Report in 2008 found 18.4% of all causes of injuries were attributed to falls/near falls [1]. Slips, trips and falls (STFs) are a consequence of failure of normal locomotion and equilibrium recovery following an induced imbalance [2]. During a slip, there are correctional responses, such as increased knee flexion, and ankle plantar flexion. Footwear characteristics such as the boot shaft height, mass, mid-sole hardness and thickness, elevated heels and type of material of the footwear influence balance and gait and ultimately the slip propensity. Intrinsic factors such as decrements of the postural control systems can contribute to falls. Dysfunction in the visual, vestibular, somatosensory or the musculoskeletal system and any undue muscular fatigue due to excessive workload in the military environment can potentially lead to falls. Thus, the purpose of this study was to examine kinematics of the lower extremity during slip events while wearing military footwear before and after a simulated military workload.

### METHODS

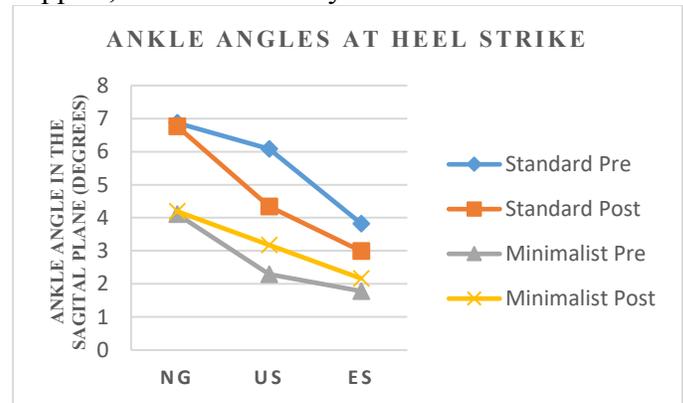

A total of eighteen healthy male adults (Height:  $178.04 \pm 6.2$  cm, Mass:  $87 \pm 12.4$  kg; Age range: 18-35 years) with no history of any musculoskeletal, neurological, cardiovascular or vestibular disorders were recruited for the study. An 8 camera Vicon Nexus (Oxford, UK) 3D motion capture system was used to collect and analyze kinematic gait data. A lower body plug-in gait model from the Helen-Hayes marker system was used for the participant configuration and the kinematic data was sampled at 100 Hz and collected using the Vicon Nexus software. A back-pack type fall arrest system with a movable trolley was used to prevent any undesired falls. Glycerol mixed with water in the ratio of 75% glycerol and 25% water was used as the slippery agent [3]. During the slip trials, glycerol was applied and evenly distributed on a force plate for contact of the leading left leg. Participants were tested using a repeated measures design on two days separated by a minimum of a 72 hours. The footwear used in the study were the Belleville TR101 MiniMil Ultra-Light Minimalist Tactical Military Boot (MIN) and the Belleville 310ST Hot Weather Standard Tactical Boot (STD). Both of these boots comply with the US Army standards for footwear design under regulation AR670-1. Each testing session began with an initial warm up protocol of 10 minutes consisting of body weight squats, high-knees, jogs, gait swings and exaggerated lunges. Participants were strapped to a harness and performed multiple gait trials until normal self-selected pace walking with appropriate foot positioning onto the force plate was achieved. Participants turned away and listened to music on noise cancellation head phones for about 1 minute between each of these normal gait trials. One trial was then chosen to be the unexpected slip (US) and

the contaminant was applied. With the completion of the US and cleaning the floor and footwear, participants performed a similar protocol for the expected slip (ES) with instructions of “will be slippery”. The simulated physiological workload consisting of walking on the treadmill donning the boots and a 16kg weighted back pack. The walking protocol [4] consisted of 3 minute increment periods starting at 3mph at 0% grade, and increasing to 3.5mph and 4mph at 0% grade until minute 9, following which the grade was increased by 5% every three minutes until minute 18. After the load carrying protocol, participants then completed the same set of slip assessments consisting of another set of US and ES as a post-workload measure. A 2 x 2 x 3 (footwear x time x gait trial) repeated measures ANOVA was conducted for ankle, knee, and hip angles at heel strike and 120 ms post heel strike. If main effect significance was observed, post hoc testing was performed using a Bonferroni correction factor. Analyses were performed in SPSS version 24, with an a priori alpha level of 0.05.

## RESULTS AND DISCUSSION

The results revealed footwear main effect significance for the ankle angle at heel strike ( $F(1,17) = 6.546, p = 0.020$ ). Post hoc comparisons suggest an increased dorsiflexion angle at heel strike for the standard boot. A gait main effect was also observed for the ankle angle at heel strike ( $F(2,34) = 19.514, p < 0.0005$ ). For the gait effects, an increased plantarflexion angle was observed between the US, the ES, and the NG trials. For the ankle angle at 120 ms post heel strike, there was a significant gait effect ( $F(2,34) = 3.362, p = 0.047$ ). Comparisons revealed an increased plantarflexion angle in the NG condition compared to the US condition. For the knee angle at heel strike, significant footwear effects ( $F(1,17) = 5.661, p = 0.029$ ) and gait effects ( $F(2,34) = 9.750, p < 0.0005$ ). Footwear comparisons showed increased knee flexion for the standard boot compared to the minimalist. While the gait effect showed greater knee extension angles in the NG condition compared to both the US and ES trials. Slip parameters are reported elsewhere, and revealed increased slip responses in the standard boot compared to the minimalist. The current findings

corroborate those results, and further suggest altered kinematics at the ankle and knee in response to a slip. Specifically, the increased knee flexion in the standard boot could represent a reactionary response to the slip that attempts to lower the base of support, and thus, recover balance [5]. In addition, different gait kinematics could lead to this increased slip propensity, explained by the increased dorsiflexion at heel strike, which may provide a smaller base of support, and decreased dynamic balance.

**Figure 1:** Ankle angles at heel strike for the standard and minimalist boot, before and after workload.

## CONCLUSIONS

We observed potential slip response kinematics in the lower extremities dependent on footwear and knowledge of slip. These findings suggest that the minimalist boot may be more appropriate when military personnel could experience unexpected slippery conditions.

## INTRODUCTION

Athletes often select equipment, such as running shoes, that is designed to maximize energy storage and return. However, athletic footwear is typically characterized by poor energy storage and return (~1-2%) as a result of current technological limitations in the design of and material properties used in shoe midsole construction [1, 2]. As a result, most of the energy that is stored in a shoe midsole when the foot contacts the ground is lost through heat, friction, and vibrations and, thus, decreases the efficiency of the athlete.

There is limited research to date that has addressed the role of orthotics/shoe insoles on performance improvement. Increasing the stiffness of shoes (via the use of carbon fiber plates inserted into the shoe midsole or under the shoe sock liner) has resulted in a 1.7 cm increase in vertical jump height [3], a 0.7% improvement in sprint performance [4], and a 1% improvement in running economy [5]. While all three of these studies demonstrated improvements in performance when using footwear enhanced with carbon fiber plates, these studies used a flat carbon fiber plate design with a uniform stiffness distribution and limited optimization for the athletes.

The purpose of this study was to examine the effects of a carbon fiber shoe insert on athletic performance. The specific parameters related to athletic performance that were assessed in this study were speed and power. It was hypothesized that the use of a carbon fiber shoe insert will result in improved linear speed (assessed by a 40-yd sprint) and lower-body muscular power (assessed by a vertical jump) through increases in peak ground reaction force (GRF), rate of force development (RFD), and peak power (P).

## METHODS

Twenty-eight male collegiate athletes (NCAA Division II American football skill-position players; age:  $19.4 \pm 1.1$  yr, height:  $178.7 \pm 4.5$  cm, mass  $85.9 \pm 6.9$  kg) participated in this study. Participants provided informed consent according to the policies and procedures of the Institutional Review Board at Southern Connecticut State University.

The participants performed vertical jump and 40-yard sprint tests while using a control shoe insert and carbon fiber shoe inserts (VK Performance Insoles; VKTRY Gear; Milford, CT). The vertical jump was performed on the first day and the 40-yd sprint took place seven days later. Participants used three different stiffness (medium, stiff, and extra stiff) and two different stiffness (medium and extra stiff) carbon fiber shoe inserts during the vertical jump and 40-yd sprint tests, respectively. The shoe insert conditions were presented in random order for both tests; all vertical jump trials (three for each shoe insert) and sprint trials (two for each shoe insert) were separated by a period of 2 min and 5 min, respectively, to minimize the effects of fatigue.

Vertical jump height was determined from takeoff velocity using a force platform (QuattroJump; Kistler Instrument Corp.; Winterthur, SUI), while sprint times (0-10 yd split time and 40-yd total time) were determined using a laser timing system (Power Dash 3x; Zybek Sports; Broomfield, CO). Peak GRF, RFD, and peak P were measured during the vertical jump takeoff via the use of a single force platform and during the sprint start via the use of two force platforms (Type 9260AA; Kistler Instrument Corp.; Winterthur, SUI). A repeated-measures MANOVA was used to compare changes in performance across the shoe insert conditions; the level of significance was set at  $p < 0.10$ .

## RESULTS AND DISCUSSION

The use of a carbon fiber shoe insert resulted in increased vertical jump height. There was no difference in vertical jump height across the four different shoe insert conditions. However, when comparing the control shoe insert versus the optimal stiffness carbon fiber shoe insert for each individual participant, there was a significant ( $p < 0.0005$ ) increase in vertical jump height from  $62.8 \pm 9.4$  cm to  $65.4 \pm 13.0$  cm (a 4.1% increase).

The use of a carbon fiber shoe insert also resulted in improved 0-10 yd split time during a 40-yd sprint. There was no difference in 0-10 yd split time across the three different shoe insert conditions. However, when comparing the control shoe insert versus the optimal stiffness carbon fiber shoe insert for each individual participant, there was a significant ( $p < 0.05$ ) improvement in 0-10 yd split time from  $1.72 \pm 0.07$  s to  $1.69 \pm 0.06$  s (a 1.6% decrease). Even though there was an improvement in 40-yd total time from  $5.06 \pm 0.12$  s to  $5.05 \pm 0.12$  s when comparing the control shoe insert versus the optimal stiffness carbon fiber shoe insert for each individual participant, this difference was not statistically significant ( $p = 0.26$ ).

The increases in performance in both the vertical jump and 40-yd sprint tests were associated with improvements in the movement kinetics of both tasks. The use of the optimal stiffness carbon fiber shoe insert resulted in significant increases in propulsive (vertical) peak GRF ( $p < 0.05$ ), RFD ( $p < 0.005$ ), and peak P ( $p < 0.005$ ) during the vertical jump takeoff (see Table 1). The use of the optimal stiffness carbon fiber shoe insert resulted in significant increases in propulsive (horizontal) peak

GRF for the rear foot ( $p < 0.05$ ), RFD for both the front foot and the rear foot ( $p < 0.05$  and  $p < 0.10$ , respectively), and peak P ( $p < 0.10$ ) during the start of the 40-yd sprint (see Table 1).

The use of a carbon fiber shoe insert did not appear to increase the amount of energy stored and returned during the propulsive phase of the vertical jump takeoff and sprint start. Instead, a carbon fiber shoe insert reduced the amount of energy lost at the metatarsophalangeal joint and resulted in a corresponding improvement in performance in both the vertical jump height and 10-yd sprint time.

## CONCLUSIONS

Increasing footwear bending stiffness through the use of a carbon fiber shoe insert improved both vertical jump and sprint performance. The optimal stiffness was subject-specific. To experience benefits in performance improvement, an athlete must choose the correct stiffness carbon fiber shoe insert that matches his/her body weight and movement biomechanics.

## INTRODUCTION

The effect of footwear on running mechanics has been a major topic of investigation over the last forty years as changing footwear may impact running performance or alter risk of sustaining a running related injury. Within the last ten years in particular, there has been a substantial amount of research on possible merits and risks associated with using minimalist shoes [1, 2]. At the opposite end of the spectrum, the last five years have seen rising popularity in ultra-cushioning shoes. However, to date there have only been a handful of studies examining these shoes. These studies have reported basic kinematic and kinetic comparisons between minimalist and ultra-cushioning shoes [3], as well as differences in internal loading between the shoe types [4].

One area which has not yet been examined is whether lower extremity stiffness differs when running in minimalist or ultra-cushioning shoes. Stiffness plays a role in both injury and performance, and provides insight into how the neuromuscular system controls movement [5]. As such, understanding how stiffness changes with footwear would provide additional insight into the biomechanical effects of different types of running shoes. Therefore, the purpose of this study was to evaluate changes in lower extremity stiffness when running in minimalist (MIN), traditional (NEUT), and ultra-cushioning (ULTRA) shoes.

## METHODS

Fifteen recreational runners (age:  $23.5 \pm 2.2$  years; height:  $1.68 \pm 0.19$  m.; body mass:  $76.5 \pm 4.5$  kg) participated in this study. All participants were running at least 20 miles per week and were injury

free in the 6 months preceding testing. Participants were provided 3 pairs of laboratory shoes in their self-reported size (MIN shoe: New Balance 1400v3, NEUT shoe: Nike Air Zoom Pegasus 32, ULTRA shoe: Hoka One One Bondi 4, Figure 1).

**Figure 1.** Examples of the three shoes used in the study. Left to right: MIN, NEUT, and ULTRA.

Running kinematics were recorded using a 12-camera motion capture system (Qualisys, Inc., Gothenburg, Sweden) while participants ran on an instrumented treadmill (Bertec Corp, Columbus, OH) at 3.0 m/s. Kinematics and ground reaction forces were sampled at 200 and 1000 Hz, respectively. Participants ran for 10 minutes in each shoe, with data being collected during the last minute. Ten consecutive strides were then extracted for analysis. The order in which participants wore the shoes was randomized.

Raw marker trajectories and ground reaction forces were exported to a custom Matlab (Mathworks, Natick, MA) program where they were filtered using 4<sup>th</sup> order, zero lag, low pass Butterworth filters with cutoff frequencies of 8 Hz and 50 Hz, respectively. Sagittal plane joint angles and moments at the ankle, knee, and hip were then calculated using Cardan angle rotations and standard inverse dynamics techniques. Leg stiffness was calculated using a spring mass model and the methods of McMahon and Cheng [6]. Joint stiffness was calculated by dividing the change in joint moment by the change in joint angle over the absorption portion of stance phase, operationally defined as the time from initial contact until the

ankle reached peak dorsiflexion [5]. To assess whether participants changed their foot strike pattern when changing shoes the strike index was calculated for each step.

One-way repeated measure ANOVAs were used to evaluate differences in strike indices, legs stiffness, and joint stiffness between shoe conditions. When a significant main effect was observed, post hoc comparisons were performed using a Bonferroni correction. A  $p < .05$  was used for all comparisons.

## RESULTS AND DISCUSSION

Strike indices were not different between the MIN ( $24.1 \pm 15.8$ ) and NEUT ( $20.9 \pm 13.6$ ,  $p = .565$ ) shoes. However they were smaller in the ULTRA shoe ( $12.1 \pm 7.5$ ) than in either the MIN or NEUT shoes ( $p = .017$ ,  $p = .033$ , respectively). Though not indicative of a different foot strike pattern, this means that there was a more pronounced heel strike in the ULTRA shoes and that the initial contact point in this condition was closer to the ankle joint center thereby reducing the ankles' ability to absorb energy during the loading phase.

There were no differences in leg stiffness between the three shoe conditions (MIN:  $12.0 \pm 2.0$  kN/m, NEUT:  $12.3 \pm 1.9$  kN/m, ULTRA:  $12.2 \pm 2.3$  kN/m,  $p = .586$ ). Compared to the MIN shoe, the ULTRA shoe resulted in lower joint stiffness at the hip ( $p = .006$ ) and knee ( $p = .047$ ) and higher joint stiffness at the ankle ( $p = .026$ ). There were no differences between the MIN and NEUT shoe at any of the joints (Table 1).

**Table 1.** Mean and standard deviations for hip, knee, and ankle stiffness (N\*m/°) in the minimalist, neutral, and ultra-cushioning shoes. \* indicates significantly different than MIN condition.

	Hip	Knee	Ankle
MIN	$5.1 \pm 2.7$	$6.0 \pm 2.2$	$12.3 \pm 1.2$
NEUT	$4.3 \pm 0.9$	$5.9 \pm 1.7$	$13.0 \pm 1.8$
ULTRA	$3.7 \pm 0.9^*$	$5.3 \pm 1.4^*$	$14.8 \pm 2.4^*$

Our results suggest that while overall leg stiffness remains the same when changing shoe types, the

strategies used by the neuromuscular system to achieve that stiffness varies. The more pronounced heel strike and higher ankle joint stiffness observed in the MIN condition means the ankle is not being used to absorb energy in MIN shoes. This may be one reason why previous studies have reported greater tibial shock [7] and reduced shock attenuation [8] in ULTRA shoes compared to MIN shoes. If the ankle is not helping absorb energy then the other joints must become more compliant, hence the lower joint stiffness in the knee and hip in the ULTRA shoe. However, a more compliant joint will absorb more energy. Whether this is good or bad from an injury perspective remains unknown. But one of the few other studies on maximalist footwear reported higher patellofemoral forces and pressures in ULTRA shoes compared to MIN shoes [4]. Given that the knee is the most common injury site in runners this suggests further studies on injuries associated with ULTRA shoes are needed.

## CONCLUSIONS

These results suggest that compared to MIN and NEUT shoes, running in ULTRA shoes results in re-organization of how the neuromuscular system controls lower extremity stiffness. Implications for this re-organization for injury and performance require further investigation.

# PLANTAR PRESSURE CHANGES WITH USE OF A CUSTOM DYNAMIC ANKLE-FOOT ORTHOSIS

Julianne Stewart, Tatiana Djafar, Richard Miltenberger, and Marilyn Wyatt  
Naval Medical Center San Diego, San Diego, CA, USA  
E-mail: julianne.m.stewart.ctr@mail.mil

## INTRODUCTION

Of the combat injuries sustained in the current and recent U.S. military conflicts, injuries involving the extremities comprise the largest category. Limb preservation procedures have become a much more common alternative to amputation after critical limb trauma, but high levels of disability have been reported with both lower limb amputation and lower limb (LL) preservation [1, 2].

The Intrepid Dynamic Exoskeletal Orthosis (IDEO®) is a custom dynamic ankle-foot orthosis developed for use in military service members with critical LL injuries [3]. The IDEO was designed as a high-level functional brace that is thought to transfer loading from the foot to the anterior proximal tibia via deformation of the carbon fiber struts and custom molded tibial cuff that occurs during mid to terminal stance [4]. A proposed mechanism for pain reduction seen with the IDEO is decreased loading or pressure experienced during weight bearing. However, until this study, no actual plantar pressure data had confirmed this unloading during walking gait and this proposed mechanism has not been examined. Additionally, the effects of the brace itself prior to training in use are unknown.

The aim of this study was to evaluate the effect of an IDEO on peak plantar pressure in the total foot as well as in each of eight areas of the foot in a sample with foot and/or ankle injury.

## METHODS

Forty-two participants (40 males) were identified via retrospective review of a clinical registry of patients at Naval Medical Center San Diego. Patients were  $29.7 \pm 8.1$  years old, had unilateral LL injury causing significant deficits to gait and function, were prescribed an IDEO by an orthopedic physician, and were able to walk on level surfaces for at least 15 minutes in each shod and IDEO

conditions. Patients were excluded if they had bilateral LL injury, spine or pelvis injury, or central neurological disorder. For each patient, data collection was performed prior to initiating training in use of the IDEO.

After consenting, each patient was fit with an appropriately-sized pair of novel pedar-x® (novel, Inc., Munich, Germany) pressure-sensitive insoles. For the shod condition, the insoles were placed in the patient's shoes directly underneath his or her feet. For the IDEO condition, the insole on the affected side was placed between the patient's foot and the IDEO footplate. For each condition, the patient walked for two 35-meter trials at a self-selected velocity while plantar pressure data were collected at 50 Hz and transmitted wirelessly to the data collection computer. These trials were performed in a flat, linear hallway without turns or obstacles.

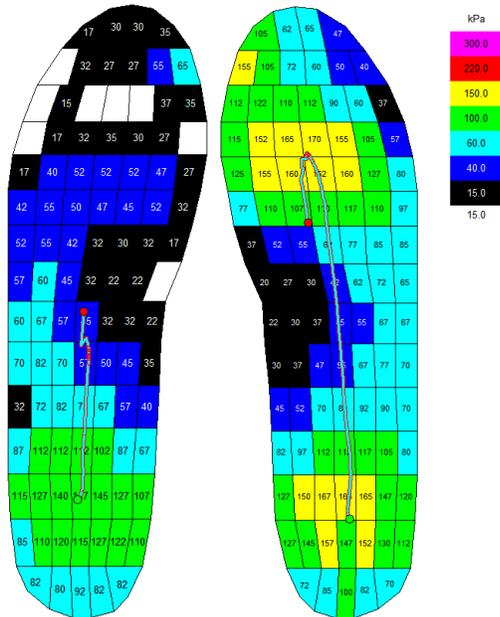

The foot was divided into eight sections for analysis: medial and lateral sections of the hindfoot, midfoot, and forefoot, and greater and lesser toes. A two-way ANOVA with foot (affected and unaffected) and condition (shod and IDEO) as factors was performed for the total foot and for each section. A significance value of  $p < 0.05$  was chosen. Post-hoc t-tests were performed and a Bonferroni correction was applied.

## RESULTS AND DISCUSSION

Peak pressures were significantly decreased in the affected foot with use of the IDEO with up to 64% decreases seen at the forefoot and toes (Fig. 1). Increases in peak pressure of up to 19% were seen in some regions of the unaffected foot as well as the total foot (Table 1).

An interaction effect between foot and condition was found for the total foot and for each of the eight sections of the foot with exception of the medial

midfoot. Additionally, an effect of foot was found for the total foot and all sections of the foot except the lateral midfoot. These findings help provide insight into the mechanism behind the improvement in function and decrease in pain that has been seen with use of the IDEO [5].

**Figure 1:** Group averaged peak plantar pressures with IDEO affected foot on left and shod unaffected on right.

The slight increases in plantar pressure seen in the unaffected foot with use of the IDEO may be due to increased gait velocity. Velocity during testing was self-selected and was not measured. However, velocity in this patient group during an instrumented gait study performed on the same day was significantly higher ( $p < 0.001$ ) with the IDEO ( $1.19 \pm 0.17$  m/s shod vs.  $1.26 \pm 0.14$  m/s IDEO). Alternately, overloading of the sound limb may be occurring due to unfamiliarity with the IDEO.

## CONCLUSIONS

**Table 1:** Peak pressure mean values  $\pm$  standard deviations in kPa in the total foot and selected foot masks in the affected foot (AF) and unaffected foot (UF) for each shod and IDEO conditions. Cell shading indicates statistically significant difference between shod and IDEO conditions ( $p < 0.0028$ ).

	Total Foot		Med. Hindfoot		Lat. Hindfoot		Med. Forefoot		Lat. Forefoot		Great Toe		Lesser Toes	
	AF	UF	AF	UF	AF	UF	AF	UF	AF	UF	AF	UF	AF	UF
Shod	230.0	258.3	179.2	195.9	175.9	190.0	185.6	226.1	187.1	210.5	165.8	223.0	160.9	202.6
	$\pm$ 47.5	$\pm$ 45.1	$\pm$ 46.6	$\pm$ 40.7	$\pm$ 45.9	$\pm$ 39.7	$\pm$ 58.1	$\pm$ 53.2	$\pm$ 59.2	$\pm$ 51.5	$\pm$ 70.7	$\pm$ 55.5	$\pm$ 69.0	$\pm$ 57.7
	169.3	294.2	157.6	233.5	157.4	235.1	71.1	254.2	67.8	219.4	89.2	245.6	59.3	204.3
IDEO	$\pm$ 36.4	$\pm$ 3.3	$\pm$ 37.9	$\pm$ 60.2	$\pm$ 37.2	$\pm$ 58.4	$\pm$ 40.5	$\pm$ 63.0	$\pm$ 28.5	$\pm$ 50.7	$\pm$ 43.0	$\pm$ 54.8	$\pm$ 21.9	$\pm$ 59.4

Despite a growing body of evidence for functional improvements with use of the IDEO, this is the first study to confirm that this brace can decrease peak plantar pressure, particularly in the forefoot and toes of the affected foot, during walking. This outcome provides insight to clinicians seeking a device to improve painful gait, particularly for conditions of the foot or ankle that produce pain in weight-bearing. Additionally, though the IDEO was designed to enable performance of high-level activities in population with critical limb injury, this study provides support for using the IDEO for walking by those with a diverse collection of injuries.

## INTRODUCTION

Abnormal standing balance and straight gait have been widely documented in individuals following mild traumatic brain injury (mTBI) [1]. Yet, daily activities require complex movements that involve change of direction and coordinated head and trunk reorientation [2]. Sport-related concussion has been associated with increased intersegmental coordination variability during unplanned turns [2] and decreased center-of-mass speed and curvature when walking around an obstacle [3], but planned turning tasks have not been well explored in populations with mTBI. In particular, it is unclear whether turning performance is associated with self-reported symptoms in individuals with mTBI. As rapid head movements can exacerbate symptoms, individuals reporting mTBI symptoms may limit the velocity of reorientation based on their symptoms. We hypothesized that individuals with mTBI would reduce their reorientation velocity and increase the variability of head-to-trunk coordination during planned turns compared with controls. Further, we hypothesized that the reduction in the velocity and increase in variability would be associated with their self-reported symptom score.

## METHODS

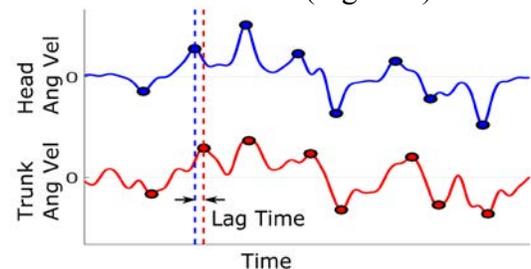

Ten individuals with mTBI {mean (SD) age = 34 (6.7) years, height = 171.8 (8.4) cm, mass = 90.7 (19.9) kg} and 25 healthy controls {age = 28 (8.4) years, height = 169.3 (8.46) cm, mass = 70.3 (13.9) kg} provided informed written consent to participate. All mTBI participants had self-reported complaints of imbalance and a diagnosed mTBI >3 months before the testing session. At the beginning of each session, participants completed the Neurobehavioral Symptom Inventory (NSI). Participants then walked at their comfortable pace around a marked course containing four 45° turns, four 90° turns, and two

135° turns (Figure 1). Each participant completed 12 continuous laps of the course. The first and last laps were excluded from the analysis. Walking speed was determined from the average time to complete each lap. Inertial sensors affixed over the forehead and lumbar region of the spine collected angular velocities of the head and trunk, respectively.

**Figure 1:** Turning course marked with arrows. Eight turns were analyzed, 2 turns (red x) were excluded.

Angular velocities were low-pass filtered at 1.5 Hz. For each turn, the magnitude and time of each peak axial angular velocity was extracted for the head and trunk. Two 45° turns were excluded from the analysis because a clearly defined peak velocity was lacking across all participants. Head-to-trunk coordination was defined as the lag time, calculated as the difference in time between peak velocities of head and trunk for each turn (Figure 2).

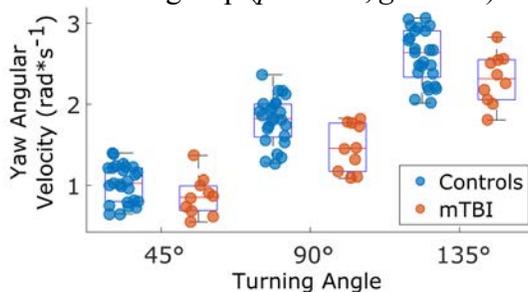

**Figure 2:** Example angular velocity traces showing the peak for each turn (markers) and lag time.

For each participant, the peak angular velocities were averaged across turns of the same angle. Lag time and lag time variability were determined from the mean and standard deviation, respectively, across all turns. Linear mixed models compared the average peak angular velocities between groups after adjusting for covariates of age, height, mass, walking

speed, and turning angle. Independent sample t-tests compared lag time and lag time variability between groups. Pearson correlation coefficients compared the relationship between each outcome and NSI symptom scores within the mTBI group.

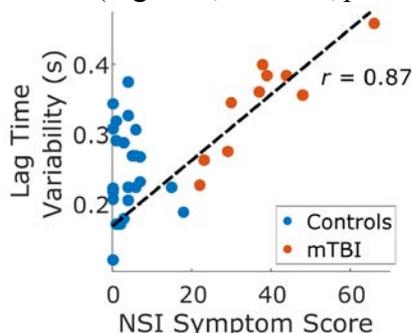

## RESULTS AND DISCUSSION

After adjusting for covariates of age, height, weight, walking speed, and turning angle, participants with mTBI had significantly slower peak angular velocities of the head (Figure 3,  $p < 0.01$ ,  $\beta = -0.30$ ,  $SE = 0.11$ ) and trunk ( $p < 0.01$ ,  $\beta = -0.31$ ,  $SE = 0.11$ ) compared with the control group. Lag time did not differ between groups, but lag time variability was significantly higher in the mTBI group compared with the control group ( $p < 0.01$ ,  $g = 0.58$ ).

**Figure 3:** Average peak yaw angular velocity of the head for each participant for each turn angle.

Within the mTBI group, NSI total symptom scores were associated with slower average peak angular velocities of the head and trunk during 90° turns ( $r = -0.77$ ,  $p < 0.01$ ;  $r = -0.71$ ,  $p = 0.02$ ). Lag time variability was strongly associated with NSI symptom scores (Figure 4,  $r = 0.87$ ,  $p < 0.01$ ).

**Figure 4:** Lag time variability was associated with NSI total symptom score in the mTBI group.

The slower peak velocities found in the mTBI group are consistent with previous reports of slower center-of-mass velocities in asymptomatic concussed

athletes during a 90° turn [3]. Notably, the slower angular velocities were significant after adjusting for walking speed, suggesting that the mTBI group may have cut corners to reduce the curvature [3] and angular velocity of each turn. Additionally, our results extend the evidence of increased segmental variability, previously reported during a light-induced turning task [2], to preplanned turns.

Importantly, measures of turning were associated with symptom scores. Standing balance and straight gait deficits are common after mTBI, but they have not been associated with symptom scores [4]. The association between higher symptom scores and measures of turning may be indicative of active avoidance of rapid rotations to prevent exacerbating symptoms. Alternatively, it could suggest symptoms are more apparent during specific dynamic activities such as turning, and such activities may heavily influence the self-reported symptom score given the high prevalence of turning in everyday locomotion. Further study of turning in symptomatic and asymptomatic individuals with mTBI is warranted.

## CONCLUSIONS

Individuals with mTBI adopted slower turning velocities across all turning angles, and exhibited more variable head-to-trunk coordination compared with controls. These results provide knowledge of how self-reported symptoms influence daily locomotor function in adults with mTBI. The association of turning velocity and head-to-trunk coordination variability to self-reported symptoms suggests individuals with mTBI change reorientation patterns to minimize the exacerbation of symptoms.

# INDIVIDUALS WITH A PRIOR TRAUMATIC BRAIN INJURY EXHIBIT DECREASED NEUROMUSCULAR COMPLEXITY DURING GAIT

<sup>1</sup> Samuel A Acuña, <sup>1</sup> Mitchell E Tyler, <sup>1</sup> Yuri P Danilov, and <sup>1</sup> Darryl G Thelen

<sup>1</sup> The University of Wisconsin–Madison, Madison, WI, USA  
email: saacuna@wisc.edu, web: <http://uwnmbl.engr.wisc.edu>

## INTRODUCTION

Gait and balance disorders are common among individuals who have experienced a traumatic brain injury (TBI). Prior studies have shown that TBI subjects tend to walk slower, take smaller steps, have increased mediolateral sway, and exhibit lower scores on the Dynamic Gait Index [1, 2]. Traditional rehabilitation protocols provide little improvement after the first few months post-injury, leaving many individuals with chronic balance impairments [3]. Interventions that target specific neuromuscular deficits may enhance recovery, but surprisingly little is known about how neuromuscular control of gait is altered following a TBI.

Synergy analyses have gained popularity as an approach for evaluating the complexity of neuromuscular control patterns in neurologically impaired populations. The analysis typically involves the use of matrix factorization algorithms to identify low-dimensional patterns, or synergies, that can describe the variability inherent in an individual's measured muscle activations. A synergy then represents a group of muscles that are generally co-activated, which may represent simplified control. Hence, the variance in muscle activity accounted for by a given number of synergies can provide a measure of the complexity of control used by an individual. Previous studies have shown that neuromuscular complexity, as measured by muscle synergies, is reduced after stroke, Parkinson's disease, spinal cord injury, and cerebral palsy [4, 5]. The goal of this research was to evaluate how the neuromuscular complexity of gait in persons with chronic TBI differs from unimpaired individuals. This synergy analysis provides insight into how leg muscles are controlled after TBI, and may provide a tool to assess changes with rehabilitation.

## METHODS

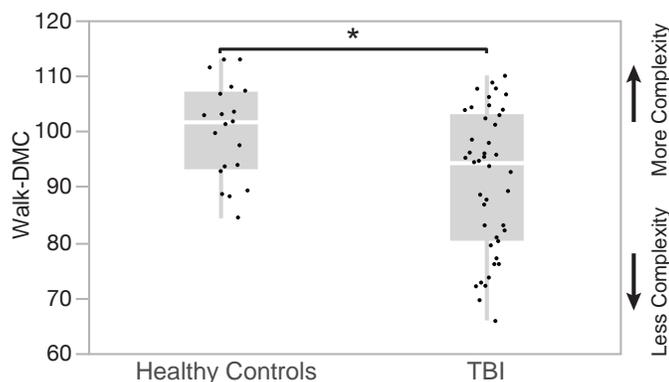

Twenty healthy young adults (25±3 years, 10 female) and forty-four ambulatory adults with a balance disorder due to a non-penetrative TBI participated in the study (53±9 years, 28 female). Each TBI participant was at least one year post-injury, had previously completed a focused physical rehabilitation program for their TBI, and had reached a plateau in their recovery. All TBI subjects had a dynamic posturography score at least 8 points below normal (Sensory Organization Test, NeuroCom<sup>®</sup>).

Lower extremity electromyographic (EMG) signals were collected bilaterally from six muscles (tibialis anterior, medial gastrocnemius, soleus, vastus lateralis, rectus femoris, semitendinosus) during treadmill walking (60 seconds). Each chronic TBI subject walked at his/her preferred speed (1.0±0.2 m/s). The protocol was repeated on the healthy young adults walking at a speed of 1 m/s. EMG signals were rectified and then low-pass filtered at 10 Hz. Ensemble EMG patterns were created by averaging signals over all gait cycles and normalizing the data to each muscle's root-mean-squared EMG. Non-negative matrix factorization was used to derive the synergies. The walking dynamic motor control index (walk-DMC) was then used to measure the complexity of neuromuscular control during gait [5]. Walk-DMC is a measure of the amount of variance in EMG accounted for in one synergy, relative to that in controls. Higher scores (>100) represent more complexity than the healthy controls, while lower scores (<100) reflect less complexity. For each subject, the walk-DMC score was averaged between left and right legs. A Mann-Whitney test compared the walk-DMC scores between healthy controls and the TBI subjects.

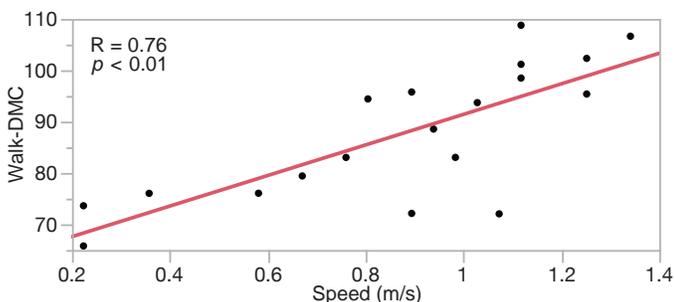

Additionally, a physical therapist evaluated the dynamic gait index (DGI) for each TBI subject. The DGI is an eight task battery (score: 0-24) that scores an individual's ability to walk normally, navigate obstacles, and turn. DGI scores  $\leq 19$  have been associated with fall risk in TBI subjects [2]. DGI was compared to walk-DMC using a Pearson correlation.

## RESULTS AND DISCUSSION

Walk-DMC was significantly ( $p = 0.015$ ) lower in individuals with chronic TBI ( $91 \pm 13$ ), compared to healthy controls ( $100 \pm 10$ ) (Fig. 1). DGI scores for the TBI averaged  $18 \pm 5$ , which is significantly lower than the DGI score of 24 seen in healthy control subjects [2]. As expected, walk-DMC and DGI scores were highly variable in the chronic TBI, with 45% of subjects exhibiting a DGI  $\leq 19$ . For those subjects, who would be classified as at risk for falls [2], walk-DMC was highly correlated with their preferred walking speed ( $R=0.76$ ) (Fig 2).

**Figure 1:** Walk-DMC scores for TBI and controls.

**Figure 2:** Walk-DMC and preferred walking speed were highly correlated for those subjects exhibiting a DGI  $\leq 19$ .

## CONCLUSIONS

This study is the first to show that the complexity of neuromuscular control of gait is permanently altered in many individuals who have previously experienced a TBI. Similar reductions in complexity have been reported in individuals who exhibit gait disorders due to other neurological impairments including stroke, cerebral palsy, and Parkinson's disease. This project is part of a larger neurorehabilitation study investigating the potential to use neuromodulation-enhanced gait retraining to normalize and improve walking in chronic TBI subjects [6]. Beyond simple spatiotemporal gait measures, synergy and walk-DMC metrics could provide greater insight into the underlying changes in coordination that may accompany effective approaches to gait rehabilitation. Further study will involve greater exploration of the synergy patterns and individual muscle weighting to identify the neuromuscular origin of abnormal control in individual subjects, which could be useful for targeting appropriate therapy.

# PLANTARFLEXOR REMODELING FOLLOWING ACHILLES TENDON RUPTURE REPAIR: A CASE STUDY

<sup>1</sup> Josh R Baxter, <sup>1</sup> Todd Hullfish, and <sup>1</sup> Wen Chao

<sup>1</sup> University of Pennsylvania, Philadelphia, PA, USA

email: [josh.baxter@uphs.upenn.edu](mailto:josh.baxter@uphs.upenn.edu), web: <https://www.med.upenn.edu/motionlab/>

## INTRODUCTION

Achilles tendon ruptures lead to elongated tendons and reduced patient function. Despite these clinical correlates, the link between muscular shortening constraints imposed by altered tendon properties and muscle remodeling remain poorly understood. Animal studies have shown that muscles rapidly remodel in order to maintain sarcomere shortening dynamics [1,2]. However, the muscular response to extreme changes in shortening demands have not yet been described, which may provide critical information for clinical decision making.

Therefore, the purpose of this study was to establish a framework for linking muscle remodeling and functional deficits in patients recovering from Achilles tendon ruptures. In particular, we aim to identify clinically relevant benchmarks that will guide treatment and better manage expectations. This case study presents a framework that is actively being utilized in a prospective patient registry to confirm a mechanism for muscle remodeling and establish clinical benchmarks for patient success.

## METHODS

A 27-year old male (1.83 m and 84 kg) presented with poor clinical outcomes 2.5 years following an acute Achilles tendon rupture that was surgically repaired by another provider using an open-reduction within 1 week of the initial injury. These poor outcomes were confirmed using a clinical outcome score (ATRS score of 49) [3], evaluation by a fellowship-trained foot and ankle surgeon, and inability to perform a single-leg heel raise. This functional assessment is part of an IRB approved research registry.

Plantarflexor architecture remodeling was quantified under ultrasonography by contrasting the medial gastrocnemius muscles of the affected and unaffected sides. Muscle thickness as well as fascicle

length and pennation were quantified by identifying the superficial and deep aponeuroses and clearly identifiable fascicles.

Plantarflexor function was assessed through a battery of tests including isometric strength testing, single-leg heel raise, and walking. During these activities, the ultrasonography probe acquired images synchronously with motion capture and force plate data. Plantarflexion motion, torque, and power along with fascicle shortening dynamics were calculated to establish the link between muscular and patient function. Fascicle dynamics were tracked using an automated tracking routine that utilizes MATLAB's Computer Vision System Toolbox.

## RESULTS AND DISCUSSION

Muscle remodeling was clearly evident and likely explained the patient's functional limitations observed in this case study. The medial gastrocnemius fascicles of the affected side were 59% shorter, 162% more pennated, and 24% less thick compared to the unaffected side.

Plantarflexor isometric torque was reduced by almost 50% on the affected side, however the percentage of fascicle shortening (41% – 46%) was similar between sides (Table 1). These results suggest that both the affected and unaffected plantarflexor muscles were operating on similar portions of the force-length curves during isometric strength testing.

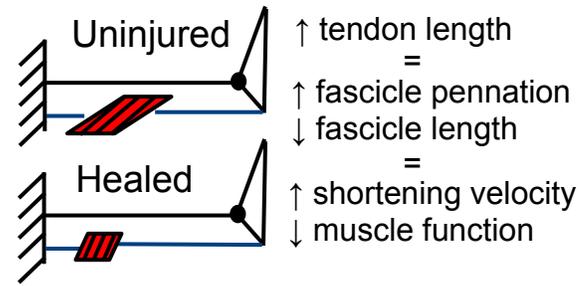

Despite drastic changes in muscle architecture and isometric strength, walking biomechanics did not differ between the affected and unaffected sides (Table 1). Toe off occurred at 15° plantarflexion with approximately 160 Nm of torque being generated. Gastrocnemius fascicles went through less than 1 cm of excursion, demonstrating how the Achilles tendon can efficiently store and return energy during cyclic tasks – even when constrained by muscular weakness.

**Table 1.** The affected side (surgically repaired tendon) demonstrated large reductions in plantarflexion torque, power, and fascicle shortening during non-cyclic tasks. (~) denotes small difference between sides.

		<b>Affected</b>	<b>Unaffected</b>	<b>% Change</b>
<b>Isometric</b>	Torque	70 Nm	133 Nm	-47%
	Shortening	41% (1.9cm)	46% (5.1 cm)	≈ (-63%)
<b>Walking</b>	Plantarflexion	16°	15°	~
	Torque	160 Nm	156 Nm	~
	Shortening	< 1 cm	< 1 cm	~
<b>Heel Raise</b>	Plantarflexion	12°	40°	-70%
	Torque	140 Nm	140 Nm	~
	Power	100 W	260 W	-62%
	Shortening	1.0 cm	5.4 cm	5 times

Single-leg heel raises are a common clinical exam that demonstrated high sensitivity for muscle structure and function in this case study (Table 1). The affected limb generated one-third as much ankle rotation compared to the unaffected limb. These functional deficits appear to be explained by a 5-fold decrease in fascicle shortening. This decrease in fascicle shortening seems to be compounded by increased shortening pennation (48° compared to 36°), which resulted in a 14% decrease in force transmission along the Achilles tendon line of action.

This case study proposes a framework to rigorously quantify muscle remodeling in response to Achilles tendon injuries – establishing a means to prospectively study the implications of injury and treatments on joint function. Decreases in heel-raise function have been linked to tendon elongation of 3 cm following rupture [4], and our current findings suggest that fascicle remodeling occurs to compensate for tendon elongation at the cost of shortening capacity (Fig. 1). Further, these adaptations appear to be consistent with prior animal work that shows muscle remodeling following acute changes imposed on tendon traveling requirements [1,2].

**Fig 1.** Achilles tendon lengthened following surgical repair [4], which appears to elicit muscle remodeling in order to maintain resting tendon tension. This muscle remodeling reduced muscle shortening and function in this study.

Early weight bearing and joint loading following tendon repair improves patient outcomes [5], which may be explained by reduced muscle remodeling and preserved joint function. Utilizing this framework, we have developed an Achilles tendon research registry to prospectively follow patients with tendinopathy and ruptures to develop predictors of success and clinical algorithms for identifying at-risk patients that require additional interventions. As this framework matures, we anticipate that regular patient visits will be completed in under 1 hour and the most descriptive measurements will be translated to clinical tools that can be integrated into the patient care experience.

## CONCLUSIONS

Skeletal muscle responds to tendon injuries in profound and deleterious ways. Utilizing a prospective approach to monitor patient progress may provide clinicians with additional information to tailor rehabilitation and return to activity timelines to optimize healing and long-term outcomes.

## INTRODUCTION

Human body posture is an important predictor of human health and as such, is often a target for clinical research, diagnosis, and intervention. For example, upright posture while sitting has been shown to improve stress resilience in asymptomatic patients [1], and to reduce the negative thought bias in depressed patients [2]. Biofeedback has been used to promote improved posture in persons with Parkinson's Diseases [3]. However, effective biofeedback for posture training requires characterization of human body posture outside of the clinic and in the context of specific activities of daily living (ADLs) such as sitting, standing, and lying down. Existing technologies do not provide the contextual activity information needed to interpret posture measurements, and are impractical to wear over multiple days.

To overcome these issues, we present a conformal, wearable sensor system to measure human body posture within the context of activities of daily living and demonstrate its use in the home over 48 hours in healthy subjects. With an eye toward identifying behavioral interventions for improving standing posture, we explore relationships between the time spent completing ADLs and posture, and examine whether particular types of activities could be used to predict improved standing posture.

## METHODS

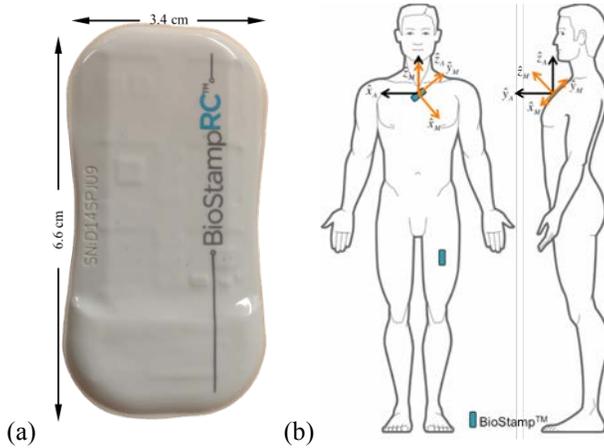

Data from N=28 subjects (13M/15F; 32+/-12 yrs; 1.72+/-0.11 m; 74.13+/-13.73 kg) over two days (49.34+/-5.42 hrs) were collected for analysis. Each subject was instrumented with BioStamp sensors (Fig. 1a, MC10, Inc. Lexington, MA, USA) affixed

to the skin of the chest and thigh as shown in Fig. 1b. Subjects performed a simple functional calibration (standing in a neutral posture), and then completed their typical daily activities. After 24 hours, subjects met with study staff to remove the BioStamp. This process was repeated on a subsequent day, within 1 week of the initial recording.

The activities completed by each subject are classified according to the machine learning approach described in [4]. Five-second windows of accelerometer data from each sensor are used to compute a set of 62 features which are used as input to a hierarchical tree of binary activity classification models. The output of this tree is an activity classification (Recumbent, Sitting, Standing, or Moving) for each five-second window of data.

Similarly, posture estimates are produced from five-second windows of accelerometer measurements. These measurements are reported in a reference frame ( $F_M$ ) aligned with the measurement axes of the sensor [5] (see Fig. 1b). The orientation of  $F_M$  is arbitrary relative to the anatomical frame of the body ( $F_A$ ). The mapping between  $F_A$  and  $F_M$ , for each subject, follows from the functional calibration activity [5]. Data during each window are averaged to yield the direction of gravity, and transformed into  $F_A$  using this mapping. The projections of gravity onto each axis of  $F_A$  are used to estimate posture angles in the sagittal and coronal planes following standard techniques.

We summarize subject activity patterns by computing the percentage of time spent in each ADL, and define posture quality as the average absolute angular deviation from a neutral standing

**Figure 1:** BioStamp sensors (a) deployed to the chest and thigh (b) on subjects to characterize posture and ADLs. Posture estimation requires a functional calibration to define the mapping between  $F_A$  (black) and  $F_M$  (orange).

posture in the sagittal plane. Relationships between subject demographics (age, gender, height, weight) and activity patterns are explored using Spearman's rank correlation coefficients. The association between activity patterns and standing posture quality is assessed with linear regression using the isometric log ratio transformation approach [6].

## RESULTS AND DISCUSSION

The correlation coefficients of Table 1 (statistical significance indicated with bolded text) reveal that older subjects spend significantly less time moving and more time sitting than younger subjects. This is especially important as we consider data from a relative young sample (oldest participant was 63 yrs. old), and yet these trends are already apparent.

**Table 1:** Spearman's rank correlation between demographics and percentage of time in each ADL.

	Moving	Sitting	Standing	Recumbent
Age	<b>-0.39</b>	<b>0.44</b>	-0.22	-0.24
Gender	-0.25	-0.07	-0.17	0.18
Height	-0.15	-0.07	-0.16	0.18
Weight	0.04	0.03	-0.13	-0.08

Controlling for age, linear regression reveals an association between standing posture quality and the percentage of time spent moving, sitting, and standing. Model coefficients ( $\beta$ ), standard error (std. err), t-scores ( $t$ ), and p-values ( $p$ ) for the regression are reported in Table 2.

**Table 2:** Regression parameters relating average sagittal standing posture angle and percentage of time spent completing activities.

	$\beta$ (std. err.)	$t$	$p$
Intercept	3.79 (3.94)	0.96	0.35
Age	-4.92 (4.07)	-1.21	0.24
Moving %	-11.75 (3.86)	-3.04	0.01*
Sitting %	8.95 (4.70)	1.90	0.07 <sup>†</sup>
Standing %	7.72 (3.22)	2.40	0.02*
$R^2=0.31$ , * $p < 0.05$ , <sup>†</sup> $p < 0.10$			

Subjects who exhibit better standing posture spend more time moving ( $\beta = -11.75$ ), and less time standing ( $\beta = 8.95$ ) or sitting ( $\beta = 7.72$ ). These results suggest that movement-based intervention programs could provide a means for improving standing posture. Moreover, they demonstrate that interventions that aim to elicit an increase in the percentage of time spent standing (e.g. standing desks), are unlikely to improve standing posture quality. Future studies should further explore these associations with an interventional study to assess the efficacy of behavioral changes (i.e. increased movement, increased standing, etc.) for improving standing posture. In the future, this type of study could further enable investigation of the efficacy of postural and behavioral intervention for improving mental health.

The results presented herein demonstrate that a new conformal, wearable sensor system is able to track activity patterns and posture noninvasively in the home across multiple days. In so doing, we identify relationships between age and activity patterns and between activity patterns and posture quality. These results point toward future interventional studies aimed at improving posture quality and, more generally, the use of this wearable sensor system for studying human behavior outside of typical clinical environments.

# QUANTIFYING THE SHOULDER MOVEMENT OF MANUAL WHEELCHAIR USERS IN THE REAL WORLD USING INERTIAL MEASUREMENT UNITS

<sup>1</sup> Stephen M. Cain, <sup>2</sup> Emma Fortune, <sup>2</sup> Meegan Van Straaten, and <sup>2</sup> Melissa M. Morrow

<sup>1</sup> The University of Michigan, Ann Arbor, MI, USA

<sup>2</sup> Mayo Clinic, Rochester, MN, USA

## INTRODUCTION

The shoulder is the most common site of musculoskeletal pain in people with spinal cord injury (SCI) who use manual wheelchairs (MWCs). Current understanding of shoulder pathology in MWC users points to a “wear and tear” etiology from overuse of an inherently unstable shoulder joint that is poorly designed for weight bearing, mobility, and performing tasks over-head from a seated position [1]. To better understand the mechanisms of shoulder overuse injury, shoulder function in the real world needs to be quantified.

Inertial measurement units (IMUs) provide a relatively inexpensive, robust, simple, and flexible way to measure the acceleration and angular velocity of objects and body segments. Unlike optical-based motion capture, IMUs do not confine data collection to a capture volume defined by camera placement and therefore enable measurement and quantification of human movement in the real world. IMUs can be used to accurately quantify shoulder angles [2]. However, demonstrations of accuracy have been limited to short data collections (< 2 minutes) and require a sequence of properly executed functional movements and/or careful measurement of link lengths to ensure accurate results [2, 3].

The purpose of this study was to develop a methodology to quantify the shoulder movement of MWC users with SCI during day-long data collections in their natural environments. We aimed to meet two criteria: 1) require only functional movements or static calibration postures that can be reliably achieved by all subjects and 2) outcome metrics should not be subject to drift.

## METHODS

In our IRB approved study, subjects ( $n = 5$ ) secured a total of three wireless IMUs (Opal, APDM, Inc.) to their left and right upper arms and thorax utilizing elastic hook and loop straps. For each IMU, we used a custom Kalman filter to estimate its orientation,  $R_{li}(t)$ , relative to an inertial frame defined by the direction of gravity and the initial orientation of the IMU. Because subjects are in a variety of unknown environments with potentially varying magnetic fields throughout the day, we only use accelerometer and angular rate gyro measurements for our orientation estimates. Therefore, we are confident our estimates of orientation relative to gravity are accurate and drift-free, whereas our estimates of the heading or yaw angle of each IMU are drift-polluted.

We instructed subjects to perform the following calibration static postures and dynamic movements after donning the IMUs for the day: 1) static upright posture, neutral shoulders, elbows 90° flexion, arms pressed against torso, 2) static arms straight out in front of body, shoulders 90° flexion, 3) static T-pose, shoulders 90° abduction, hands parallel to ground, 4) dynamic flexion/extension of the torso coordinated with shoulder flexion/extension, and 5) dynamic alternating flexion/extension of the left/right shoulders. All subjects were able to reliably perform calibrations 1 and 4; subjects had difficulty with the other calibrations due to arm movements being restricted by their wheelchairs, torso and abdominal strength, and/or available joint range of motion. Using data from calibrations 1 and 4, we calculated a body segment-to-IMU alignment,  $R_{bi}$ , using an approach similar to [4] for each IMU. The body segment-fixed axes for a given segment were defined as follows: Z-axis aligned with gravity and positive-up when in the calibration 1 posture, X-axis positive-

right and roughly aligned with the rotation axis during calibration 4, and Y-axis defined by the cross-product of the Z and X axes.

We calculated the orientation of each body segment in an inertial frame,  $R_{Ib}(t)$ , as follows:

$$R_{Ib}(t) = R_{Ii}(t)R_{bi}^T \quad (1)$$

Where the subscript  $T$  indicates the transpose of the matrix. The last row of the rotation matrix  $R_{Ib}(t)$  is a unit vector indicating the direction of gravity relative to the body segment,  $\hat{z}_{Ib}(t)$ . Segment elevation angle,  $\theta(t)$ , was calculated as follows:

$$\theta(t) = \cos^{-1}(\hat{z}_{Ib}(t) \cdot [0 \ 0 \ 1]) \quad (2)$$

Segment elevation angles are only dependent on the estimated direction of gravity relative to the body segment, and therefore are a drift-free metric for quantifying body segment motion. An elevation angle equal to zero indicates a body segment is in the same orientation as it was in during calibration 1; non-zero angles indicate deviations from the calibration 1 posture.

## RESULTS AND DISCUSSION

To illustrate the utility of our approach, we present sample results from one subject (male, 22 years, T5-T7 injury level, and 1.7 years post-injury) for a 7 hour long data collection (Fig. 1). The elevation

angle distributions contain several peaks, highlighting that different ranges of elevation angles are required for different tasks throughout the day, including propulsion, body transfer, and reaching tasks. This type of data can be used to determine if certain elevation angle daily distribution profiles are more likely to lead to shoulder pain and dysfunction.

## CONCLUSIONS

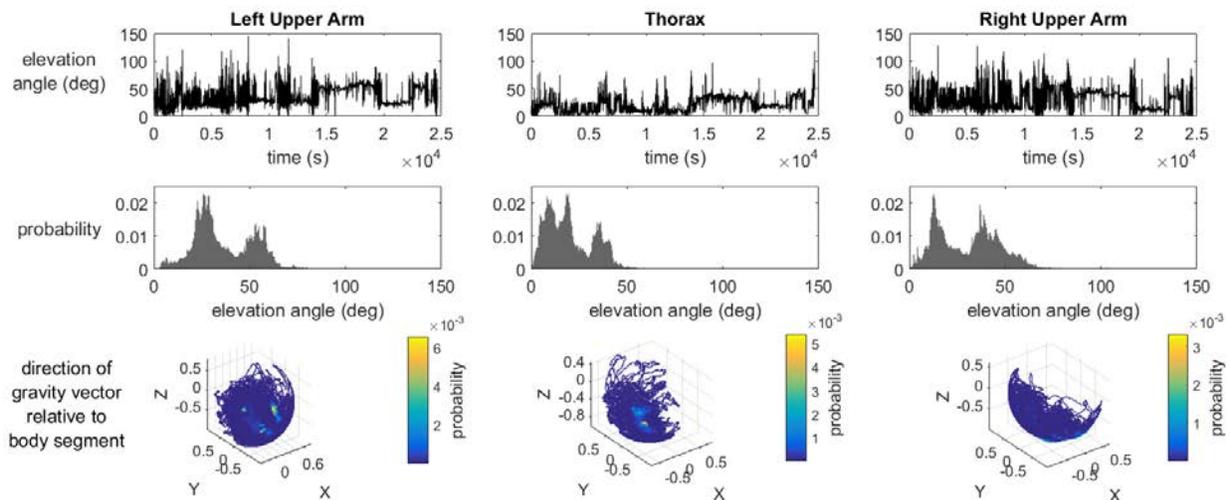

Thorax and arm movement can be meaningfully quantified using drift-free estimates of body segment elevation angles, which only require that a subject is able to sit upright and flex/extend the torso and shoulders. Future work will utilize relative orientations of body segments to resolve shoulder plane of elevation and angle of elevation.

# JOINT MOMENT ESTIMATION USING INERTIAL SENSOR MEASUREMENTS WITH GAUSSIAN PROCESS REGRESSION

Craig J. Simons<sup>1</sup>, Cory L. Christiansen<sup>2</sup>, and Bradley S. Davidson<sup>1</sup>

<sup>1</sup>Department of Mechanical & Materials Engineering, University of Denver, Denver, CO, USA

<sup>2</sup>Department of Physical Medicine & Rehabilitation, University of Colorado Denver, Denver, CO, USA

email: [cjsimons@gmail.com](mailto:cjsimons@gmail.com),

web: <http://www.du.edu/rsecs/departments/mme/biomechanics/labs/humandynamics.html>

## INTRODUCTION

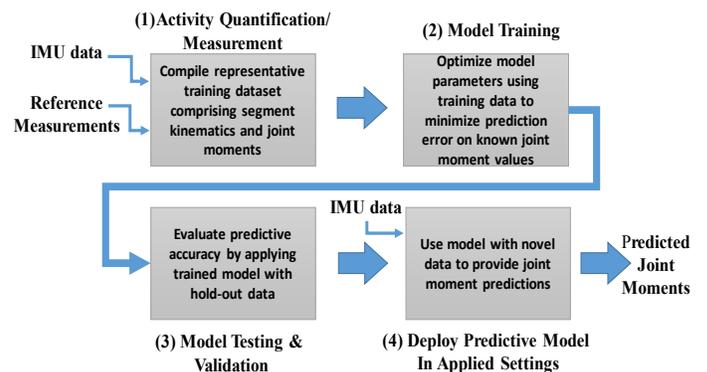

Joint moment measurements can provide unique insight into the mechanisms of human movement and thereby offer a powerful metric for clinical evaluation. [1] Traditional methods for determining joint moments require an instrumented gait lab, which limits the range of activities and the population that can be evaluated. Recent developments in the field of wearable inertial measurement units (IMUs) have expanded our ability to quantify human movement outside of traditional movement laboratories.

Because motion data measured with IMUs are typically limited to a subset of segmental kinematics, estimates of joint kinetics are not readily accessible. Conventional inverse dynamics methods provide clear theoretical frameworks enabling equations of motion to be solved for joint moments. However, inverse dynamics methods based exclusively on kinematics information can be insufficient for human motion because both kinematic measurement and parameter uncertainty create outputs that are error prone.

In this investigation, we explored an alternative to inverse dynamics, using IMU data directly with Gaussian Process Regression (GPR), a supervised learning technique, to predict joint moments. To avoid the effects of uncertainties in human data, we made use of a validated kinematic and kinetic dataset from an overdetermined, 7 degree of freedom (DOF) Barrett WAM robotic arm. The goal of the investigation was to establish foundational knowledge for developing a method to estimate joint moments in human movement based only on IMU data.

## METHODS

Gaussian Process Regression (GPR), a supervised learning algorithm, was used to establish a mapping relation from segmental kinematics (measured with IMUs) to the associated joint moments without explicitly modeling the original dynamic process. The GPR mapping relation was learned during a model training phase that uses example data with known kinematic and joint moment values to establish a correlation function between input measurements and target variables (Fig. 1). The training process identifies optimal model parameters for making future joint moment predictions using similar kinematic data.

**Figure 1:** Proposed work-flow for enabling joint moment predictions using GPR with IMU data

The 7-DOF robotic arm has two 3-DOF spherical joints (shoulder & wrist) and a 1-DOF elbow. Joints are labeled sequentially from proximal to distal (Fig 2-a). Each joint is individually actuated and the validation data was directly measured at each DOF. Validation kinematics originated as Z-X-Z Euler angles and were transformed into body fixed linear acceleration and angular velocity to simulate IMU data for each of the three arm segments (arm,

forearm, end effector). The simulated IMUs were positioned at the mid-point along the axial length of each segment and initially aligned with the global reference frame.

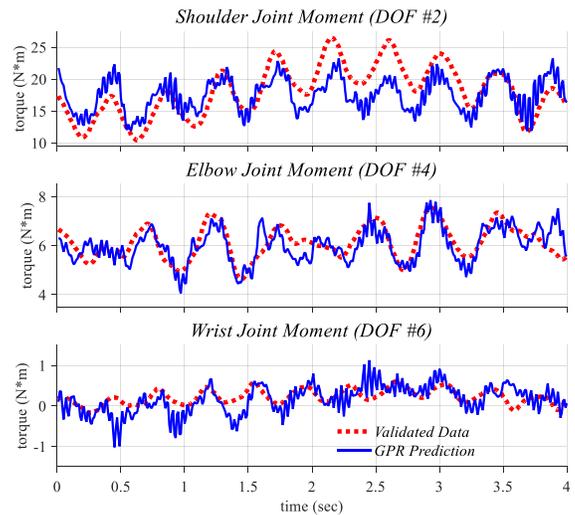

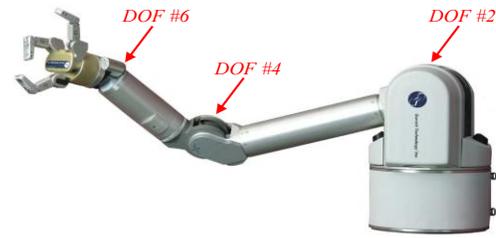

The validation dataset included 12000 samples (12 sec at 100 Hz) and spanned the range of joint motion using joint-level periodic motion that was phase-shifted at each joint to produce irregular system kinematics. The model was trained using the first 1200 samples and tested on 400 samples at the mid-point of the dataset. Input variables included 3 DOF acceleration and angular velocity from each IMU (18 total). The model predicted 7 joint torques.

## RESULTS AND DISCUSSION

Average moment, standard deviation of the prediction error, and root mean square error are reported for each DOF (Table 1). The ratio of RMS error to joint moment magnitude can be interpreted as prediction accuracy. Prediction results for the primary axes of rotation are displayed in Figure 2.

Within each anatomical joint (shoulder, elbow, wrist) the DOF associated with actuation in the plane of gravity demonstrates greater proportional accuracy than the joints responsible for axial rotation. This may reflect difficulty modeling the subtle dynamics associated with axial rotation.

GPR is well suited to modeling complex dynamic processes (such as human movement) that are difficult to model directly. The GPR model structure easily handles high-dimensional (many DOF) relations and effectively incorporates probabilistic relations embedded within the predictor variables. GPR provides a convenient framework for automating the data processing and results process when deployed for evaluations performed outside of the laboratory.

**Figure 2:** Barrett WAM robotic arm with primary rotational joint axes identified (top) and joint moment predictions using GPR with simulated IMU data (bottom)

## CONCLUSIONS

Additional development and refinement of the technique applied to human movement is important to determine the potential for use in achieving research-type kinetic measurements in applied and clinical settings.

Focus of future work will include determining specific training data requirements and establishing the accuracy and capabilities across a range of activities with human subjects.

## INTRODUCTION

Commercial availability of wearable fitness trackers has grown in recent years, and devices to track variables relating to physical activity have become popular. Some running-specific devices are able to collect sophisticated information relating to running injury and performance variables that have been identified in biomechanics research literature, such as cadence, ground contact time, and vertical oscillation. Additionally, running speed, step length, and loading rates have been associated with running performance, injury, or both [1,2,5]. The general population of runners does not have regular access to instrumented gait analysis, in which cases running-specific devices can provide an affordable and portable alternative for those interested in measuring, tracking, and improving these variables to reduce the high incidence of running-related injuries and improve performance.

Accuracy of measurement is an important factor of a device and may increase its use, in turn improving outcomes for users [3]. The purpose of this study was to compare the accuracy of running metrics from a shoe-worn accelerometer for fitness tracking (the Milestone Pod) to analogous running data from instrumented gait analysis. We specifically tested the accuracy of the Pod for running velocity (VEL), cadence (CAD), ground contact time (GCT), peak knee angle in swing (KA), and vertical average loading rate (VALR).

## METHODS

Institutional approval was obtained and each participant gave written consent. Thirty-nine healthy adults participated in the study (12 males, 27 females, age  $29 \pm 13$  yrs). Subjects were fitted with 33 reflective markers on the pelvis, lower

extremity of the dominant leg and non-dominant foot. The Pod (mass  $\sim 13$  g) was attached to the shoe on the dominant foot by a small rubber carriage. Kinematic data was captured using a 13-camera VICON motion capture system sampling at 200 Hz. Ten embedded force plates recorded ground reaction forces (GRF) at 1000 Hz. Subjects ran around a 50-m indoor track for 3 laps each at 3 speeds: self-selected “normal”, “slow”, and “fast” paces to capture a range of the subject’s typical running mechanics. Running trials were conducted while subjects wore their own running shoes (RS) and standard lab shoes (LS) (New Balance 780v5).

Kinematic and GRF data were processed using Visual3D and MATLAB to determine average VEL, CAD, GCT, KA, and VALR. Data were averaged over all speeds and both shoes to represent intra-subject variance in running training. Raw data were filtered using a Butterworth low-pass filter at 6 Hz for kinematic and 50 Hz for GRF. VALR was calculated as the change in force over the change in time between 20-80% of the time period between initial contact and impact peak and scaled by body weight [4].

A paired-samples *t*-test compared the measurement difference between the Pod and Lab data to zero for all variables ( $\alpha = 0.05$ ). Additionally, a paired-samples two one-sided test (TOST) of equivalence was done between Pod and Lab data ( $\alpha = 0.05$ ). The TOST allows a specified range of difference between variables known as the practical difference (PD). The within trial standard deviation was calculated for both the Pod and Lab system. The average standard deviation of Pod data was used for VEL, CAD, and GCT, and the average standard deviation of Lab data for KA and VALR. Finally, the percent of subjects whose measurement difference fell within the PD was determined.

## RESULTS AND DISCUSSION

Results of the t-test revealed:

- No significant difference between Pod and Lab measurements for GCT ( $p = 0.235$ ,  $ES = 0.12$ ) and KA ( $p = 0.770$ ,  $ES = 0.11$ ).
- Significant differences for VEL ( $p = 0.001$ ,  $ES = 0.41$ ), CAD ( $p = 0.001$ ,  $ES = -0.25$ ), and VALR ( $p < 0.001$ ,  $ES = -0.51$ ).

The TOST between Pod and Lab data showed equivalence for all variables tested:

- VEL, PD = 0.25 m/s ( $p < 0.001$ )
- CAD, PD = 7.83 steps/min ( $p < 0.001$ )
- GCT, PD = 20.0 ms. ( $p < 0.001$ )
- KA, PD = 3.03 deg. ( $p < 0.005$ )
- VALR, PD = 8.51 BW/s ( $p < 0.001$ )

Representative scatterplots of the variables that showed the smallest and greatest differences between Pod and Lab are shown in Fig. 1. The percentage of subjects whose difference between Pod and Lab measurements fell within the practical difference is shown in Figure 1c. The practical difference of KA captured the least number of subjects (17.1%), followed by VEL (52.1%) and VALR (40.6%). CAD and GCT both captured the highest percentage of subjects (both 69.8%).

These results support the general accuracy of the device. The Pod estimates of GCT and KA were most accurate, showing no significant difference from zero. Pod estimates of VEL, CAD, and VALR were equivalent, showing significant differences between Pod and Lab, but the size of the difference was on average smaller than natural within-subject

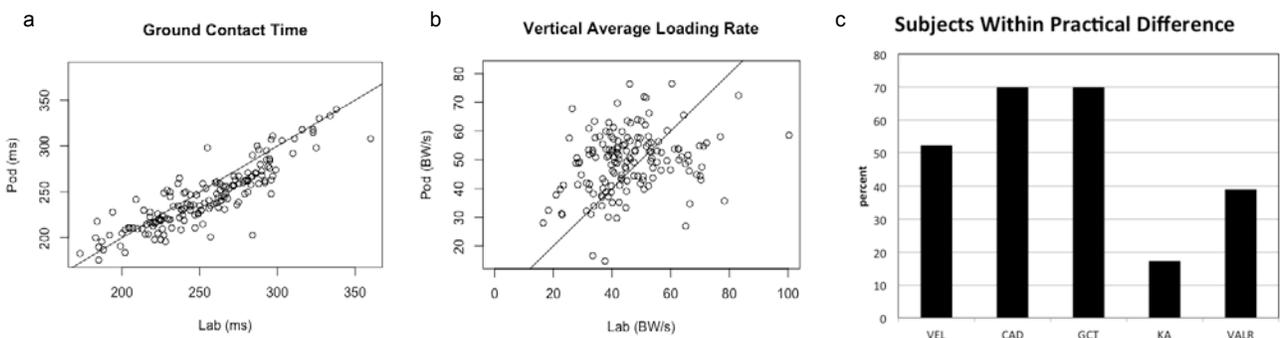

variance in running mechanics. Although there was no significant difference between the measurement difference and zero for KA, the percentage of subjects whose average KA fell within the practical difference was low. The means of Pod and Lab data were very similar which led to good performance in the  $t$ -test ( $93.7 \pm 9.1$  deg. and  $95.1 \pm 16.0$  deg., respectively). However there was a fairly large (10.3 degree) average within subject difference between Pod and Lab measurements compared to relatively low individual standard deviation within speed and shoe conditions from the Lab data that defined the practical difference (3.03 deg.).

## CONCLUSIONS

The Milestone Pod is effective for measuring kinematic and kinetic running variables. However, refinement of the Pod's capabilities to estimate VEL, CAD and VALR are necessary to improve its versatility and applicability to a greater percentage of users.

## INTRODUCTION

We present a method for using inertial measurement units (IMUs) to estimate stair climbing kinematics during running. Running on stairs can provide important insight into individual's athletic performance and health. In-depth biomechanical analysis of stair running is challenging using traditional optical-based motion capture systems, which are limited to relatively small capture volumes. Most studies that analyze stair climbing focus on functional walking pace [1]. In contrast, we propose using foot-mounted IMUs to capture the foot kinematic motion (acceleration and rotation) during stair running and over large climbing distances. Using this technology, we capture a relatively large number of steps to understand steady state running on stairs. Doing so further provides data essential for within-subject statistical analysis.

IMUs are portable, unobtrusive, and unconstrained (e.g. do not need external references) motion tracking devices. However, IMUs also suffer from several sources of error (e.g. bias instability, scale factor errors, g-sensitivity, temperature sensitivity) that must be accounted for motion tracking applications. When IMUs are mounted on feet, velocity drift error can be estimated using the fact that the foot is essentially stationary during specific times in the stance phase. This velocity error is used to compensate for other system states using a process known as zero velocity update (ZUPT) [2]. We employ this strategy in custom-developed algorithms to accurately reproduce the foot trajectories during stair climbing (see Fig. 1). From these trajectories, we determine important events. Specifically, we estimate stride, swing and stance durations, which reveal climbing speed. In addition, we estimate foot velocity, orientation and position during the entire gait cycle.

The objective of this study is to analyze stair climbing performance while running on stairs. We hypothesize that the stance duration will determine overall

climbing speed since the swing phase duration is largely dictated by the the physical constraints of the stair case (height of risers and width of treads).

## METHODS

We tested 11 healthy volunteer participants (3F, 8M; age: 25.6/3.7 years; mean, SD) The University of Michigan IRB approved the study and all subjects provided informed consent. Subjects were instructed to run up a long stair case at maximum speed, without skipping treads. After pausing for for about 10 seconds, the subjects ran down the same flight of stairs at maximum speed returning to the starting position. The subjects wore two IMU data loggers (Opals, APDM, 128Hz), one mounted on each shoe by attaching it with athletic tape to the top of the laces. Estimated foot trajectories were derived from IMU data according to an algorithm previously validated [2]. The method uses gyroscope and accelerometer data to estimate spatial orientation, and then integrates translational accelerations twice to yield foot velocities and position. Drift (and other inertial sensor errors) were reduced by applying the ZUPT algorithm [2]. Because the riser and tread dimensions of the stairs are known, we added a additional correction to our estimates. In particular, we designed a Kalman filter that uses the riser height as a measurement value that the filter uses to correct the vertical foot position, which is updated by the filter whenever the foot reaches a new tread during the foot fall. After the correction is computed, we used smoothing techniques to provide backward corrections to obtain the complete foot trajectory for each stride. All calculations were performed using custom software developed using MATLAB (MathWorks).

Using the computed foot trajectory and orientation estimations, we determined foot-strike and toe-off times. Foot-strike was defined as the time the foot first contacts a tread. For running on stairs, the toe is more likely to contact the tread first, whereas during normal walk the heel contacts the ground first. Toe-off

time is defined as the time when the foot first loses contact with the tread. Using these foot contact events, the stride duration was estimated as the time between consecutive foot-strike events. The stance time follows from the time between a foot-strike and the subsequent toe-off. Finally, the swing time follows from the time between a toe-off and the subsequent foot-strike (see Fig 1).

## RESULTS AND DISCUSSION

We computed the stance, swing and total stride time for all eleven subjects. We assume left-right symmetry and we combined the results from the left and right feet. During our analysis, we eliminated the first and the last step from each stair run, as we consider them to be transition steps that differ from the steady state stepping that is the focus of our study. In particular, the stair case provided 16 strides total during steady state (eight left and eight right).

Our data analysis shows that in either direction (running up or down the stairs), the stride time was mainly determined by the stance time (see Fig. 2) showing high correlation ( $R^2$  value: up stairs 0.84, down stairs 0.92). During running up stairs, the swing phase time was loosely correlated with the stride time ( $R^2$  value: 0.24), which can be explained by the fact that regardless of the subject speed, the feet must travel approximately the same distance between steps (imposed by the stair design). Subjects make fine adjustments to provide just enough speed to reach the next thread (see Fig. 1). When running down stairs, we found that faster subjects chose to use higher speed during the swing phase at the expense of suffering higher impacts during the foot-strike, as shown by the correlation between the swing phase and stride time ( $R^2$  value: 0.58). Overall, we conclude that stride time is highly correlated with stance time and therefore speed is determined largely by stance time.

In addition to the above conclusion, estimates of foot attitude angles, velocity, and position reveal provide many additional performance metrics that can yield valuable insights into athletic performance such stride variability, ankle flexion and foot clearance.

## INTRODUCTION

Measuring an athlete's sprint velocity in the field is important for evaluating performance and guiding training interventions [1]. Inertial measurement units (IMUs) are becoming increasingly popular for field-based human movement analyses and may have the means to estimate sprint velocity in the field. Velocity estimates made via integration of the accelerometer signal alone may be subject to error due to a biased signal and/or inaccurate orientation estimates. In this study, we develop and validate a velocity estimation algorithm that uses data from a single sacral worn IMU independent of any external measurement systems.

## METHODS

IMU data may be used to estimate sprint velocity by first expressing the sensor referenced acceleration vector in the world frame and then time integrating the forward component. Error in an estimate obtained this way may originate in the integration of a biased angular rate signal from the gyroscope, integration of a biased acceleration signal from the accelerometer, or an inaccurate estimate of the IMU initial orientation. To compensate for these potential errors, which are expected to increase with time, the algorithm we developed seeks to force constraints on the estimate given the following two assumptions:

(i) the runner's heading during the sprint is expected to be mean zero and

(ii) we expect the following velocity-time relationship as suggested by Furusawa et al. [1]:

$$v(t) = v_m \left(1 - e^{-\frac{t}{\tau}}\right) \quad (1)$$

where  $v$  is the velocity at time  $t$  and  $v_m$  and  $\tau$  describe the sprint running capabilities of the runner.

The quaternion is used to describe the IMU orientation and to express sensor referenced acceleration in the inertial track frame. The initial orientation is estimated during a standing static trial using the on-board accelerometer and magnetometer [2]. The algorithm follows the following steps:

1. Estimate instantaneous IMU orientation via gyroscope integration [3].
2. Decompose the composite quaternion to estimate the sensor's heading and attitude.
3. Linearly detrend the heading estimate to force the mean zero correction of assumption (i).
4. Time integrate the forward acceleration to provide an *a priori* estimate of sprint velocity ( $v^-$ ).
5. Find foot contacts using the forward acceleration signal as described in [4].
6. Fit  $v^-$  data at each foot contact to eq. (1) and determine the associated error ( $E$ ) in the curve-fitting.
7. Beginning with the foot contact where  $E$  was a minimum, determine the correction ( $d_v$ ) provided by the modeled velocity obtained from the curve fitting and the trust factor ( $G$ ) to be given to this correction according to,

$$G = \frac{E_k}{E_k + E_{k-1}} \quad (2)$$

where  $E_k$  and  $E_{k-1}$  are the curve fitting errors associated with  $v^-$  at foot contact  $k$  and  $k-1$  respectively.

8. Correct the *a priori* velocity estimate ( $v^-$ ) according to,

$$v = v^- + G(d_v) \quad (3)$$

9. Time integrate  $v$  to estimate position ( $p$ ) and repeat step 6 and 7 if  $p < 40$  m (sprint distance).

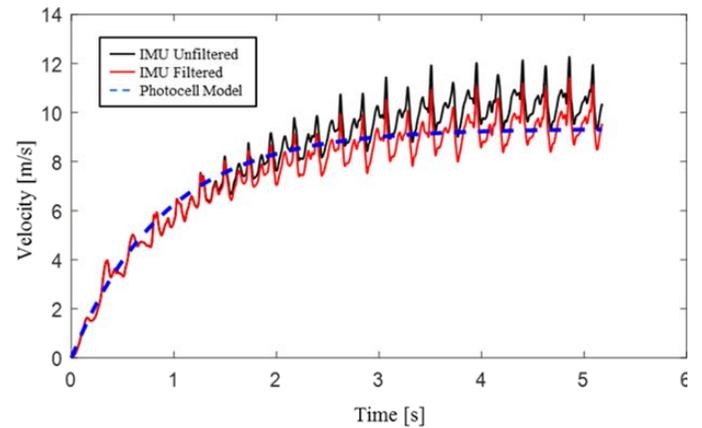

The validity of the velocity estimates from the proposed IMU method was determined by comparison to a previously validated position-time method using photocell data [1]. IMU and photocell data were collected on twenty-eight subjects (male and female sprinters and non-sprinters) for three maximal effort 40 m sprints. Each subject’s best sprint was used for analysis.

The velocity measures used for comparison were average interval velocity (0 – 10 m, 10 – 20 m, 20 – 30 m, and 30 – 40 m), maximal velocity, and instantaneous velocity. Error in the IMU velocity estimates was quantified using relative error (absolute percent difference), root mean square error (RMSE), and Pearson’s product moment correlation coefficient ( $r$ ).

## RESULTS AND DISCUSSION

Comparison of IMU and photocell estimates of average interval and maximal velocity is shown in Table 1. The validity of the IMU estimates may be suggested by significant ( $p < 0.01$ ) correlations with photocell measures, relative error less than 8%, and RMSE between 0.34 m/s and 0.67 m/s. The RMSE of the IMU estimate of instantaneous velocity was  $0.70 \pm 0.26$  m/s and showed strong correlations ( $r = 0.97 \pm 0.01$ ) with photocell estimates.

Fig. 1 shows an example of the result of the filter on the estimated velocity for a single subject. The sinusoidal nature of the true center of mass velocity (due to braking and propulsive impulse at each foot contact) is not expressed in eq. (1) nor in the photocell estimate, which may underlie some of the observed error.

**Figure 1:** Comparison of velocity estimates from reference photocell method (blue dashed line), raw velocity estimate from IMU (solid black line), and velocity estimate from proposed IMU algorithm.

The results of this study suggest IMUs may provide an appropriate means by which to assess sprint velocity. IMUs have been used to measure other variables that may be of interest in evaluating sprint performance (e.g. ground reaction force, joint angles, step frequency, etc.). Future research should investigate the use of IMUs to estimate these other performance variables during sprinting to be used along with sprint velocity in a performance evaluation.

## INTRODUCTION

By 2030, it is estimated that 1.92 billion people, worldwide, will be overweight or obese [1]. Physical activity can help individuals maintain healthy body mass and decrease risk of certain prevalent diseases (e.g., cancer and diabetes). Wearable devices that can measure activity-based outcomes (e.g., energy expenditure), in real time, can increase exercise motivation, physical activity levels, and weight loss [2]. The ability of commercially-available wearable devices to accurately predict energy expenditure, however, is currently poor enough to have implications for people who desire to use wearables to lose body weight [3].

In our lab, we have developed quasi-piezoelectric, nanocomposite, foam sensors that can be used to sense impact energy in three orthogonal planes. When inserted into the insole of a shoe (Figure 1), data from these sensors strongly correlates to energy expenditure with promising accuracy. These sensors are also robust and relatively inexpensive. The purpose of this study was to test the ability of these sensors, placed in a shoe insole, to predict energy expenditure during walking and running.

**Figure 1:** (A) the foam sensor; (B) locations of the foams sensors, within the insole; and (C) a photograph of the instrumented athletic shoe.

## METHODS

Six recreational runners (3 males and 3 female,  $24 \pm 1$  years,  $170 \pm 5$  cm, and  $61 \pm 11$  kg) participated in this study. We used a Cosmed K4b<sup>2</sup> portable metabolic analyzer (Cosmed K4b<sup>2</sup>, Cosmed, Rome, Italy) to measure energy expenditure. Subjects first provided informed consent, and then subject demographics were measured. During data collection, participants wore standardized running shoes, and the right shoe was instrumented with our quasi-piezoelectric, nanocomposite foam sensors. Participants completed a 15-min warm-up, at 2.68 m/s, and then completed 5 different trials in a randomized order. Each trial was 4 min of walking or running, at one of the designated speeds: 1.34, 2.23, 2.68, 3.13, or 3.58 m/s. A 1-min walk (1.34 m/s) was completed before and after every trial.

Data from the foam sensors and energy expenditure data were measured throughout the entire collection period (~50 min). Disregarding the transitory periods (first 2 min of each trial), mean energy expenditure was measured for each trial. Using participant weight, height, body mass index, and 8 characteristics of the foam sensor signals (average maximum voltage of the heel, arch, and toe sensor; average minimum voltage of the heel, arch, ball and toe sensor, and absolute integral of voltage curve from the toe sensor), we created a predictive model using a standard linear regression model.

To calculate the out-of-sample root mean square error (RMSE), we performed a cross-validation process where we removed data representing one subject (out-of-sample), fit our model using data from the other five subjects (within-sample), and predicted energy expenditure for the out-of-sample subject. We repeated this process six times, leaving

out each subject in turn, and computed the average RMSE for each walking/running speed, across all subjects.

## RESULTS AND DISCUSSION

Mean RMSE for six within-sample predictions and six out-of-sample predictions are shown in Table 1. Figure 2 shows the distribution of measured and predicted energy expenditure for all six subjects (within-sample subjects and out-of-sample).

Two common wearable devices that are now used to predict energy expenditure during physical activity are the Fitbit Charge HR (Fitbit Inc., San Francisco, USA) and Apple Watch (Apple Inc., California, USA). Our predictive model, based off only 6 subjects, shows somewhat promising results, that are comparable to the two aforementioned devices [3]. On average, the Fitbit Charge HR, which is more accurate than the Apple Watch [3], underestimates energy expenditure by 0.93 Kcal/min. On average, our within-sample RMSE is 0.78 Kcal/min, however, our out-of-sample RMSE is 2.88 Kcal/min. Unlike the Fitbit and Apple

Watch, the accuracies from our model are generally maintained at higher intensity levels. Additionally, we expect RMSE, associated with our model, to decrease, as we increase our sample size and add other independent variables (e.g., gender and accelerometer data, which is also collected from the shoe) to the model.

## CONCLUSIONS

The ability to predict energy expenditure via our novel piezoelectric sensors appears promising; however, more data is needed to create a more accurate model.

## INTRODUCTION

Load distribution shifts from the lateral to the medial compartment is related to an increase in knee adduction moment (KAM) [1] and is associated with knee osteoarthritis (OA) [2]. Previously, reductions in KAM occur when barefoot plantar pressure is medialized [3]. This supports the role of altering kinematics of the foot to redistribute loads across the knee joint.

Successfully gait retraining to medialize plantar pressure and lower KAM have been achieved in the laboratory via auditory feedback provided by a high-resolution insole with specifically arranged sensor areas [4]. However, such a plantar pressure-detecting system is comprised of multiple electronics and cables and therefore is unsuitable for gait training in the community. With the ultimate goal of translating pressure-based feedback training into the clinical setting for sufferers of knee OA, the current study employed a pair of fully integrated, slim 13-sensor insoles (OpenGo, Moticon GmbH, Munich, Germany) for measuring and recording real-time plantar pressure distribution (**Figure 1**). A smartphone receives sensor data via ANT wireless technology and provide instant, auditory feedback. Further exploration of using this sensor insole to provide auditory feedback to lower KAM outside of the laboratory is warranted.

In this study, we hypothesize that gait training using auditory feedback from a cable-less, commercially available insole in the in the community will reduce KAM.

## METHODS

This single-day, IRB-approved study tested 11 healthy subjects ( $25.64 \pm 4.67$  yrs; 5M, 6F;  $22.95 \pm 2.83$  kg/m<sup>2</sup>), who self-reported an absence of pain in their lower extremities during the last 48 hours. All subjects wore a pair of standardized, flexible shoes (Dr. Comfort, FlexOA, Mequon, WI, USA) that

contained the insoles. Kinematics, kinetics, and plantar pressure was evaluated for the dominant leg (all right sided).

**Figure 1.** Moticon OpenGo cable-less pressure insoles and their sensor distribution

The testing procedure included a baseline walking assessment, in-lab training and subsequent gait test with feedback, continuation of training outside the lab, and final assessment of memorized gait modification without feedback. For the baseline test, all subjects completed five walking trials at a self-selected speed with their normal gait pattern on a leveled 6-m walkway with their plantar pressure recorded using the insoles. The mean maximum pressure of both sensor S5 and S9 (**Figure 1**) on the lateral side of the foot was calculated. For both sensors, 75% of the mean maximum pressure was set as the training threshold. Each subject received instructions to subtly alter their walking style avoiding the auditory tone from the smartphone. Subjects practiced until they could successfully avoid the feedback tone for several consecutive steps. Then, three walking trials were assessed as the subjects were performing the modification with feedback. Each subject was then instructed to further practice the gait modification while going for a one-mile walk around campus. During this walk, feedback was received through headphones. Upon return to the lab, each subject was asked to walk with the internalized gait modification without

feedback. Five marker-based trials were completed while plantar pressure was recorded as well.

Motion capture was performed using a ground embedded force plate (Bertec, Columbus, OH, USA) to measure ground reaction forces and 12 optoelectric cameras (Qualysis, Gothenburg, Sweden) to capture lower extremity kinematics. A modified Helen Hayes marker set was applied to the lower extremities. Raw kinetics and kinematics were processed in Visual3D (C-Motion, Inc., Germantown, MD, USA) with model templates customized using joint offset for all subjects.

Statistical analyses were performed using IBM SPSS Statistics 22 (SPSS Inc., Chicago, IL). A *p*-value of 0.05 indicated significance. Descriptive statistics were calculated for variables of interest and one-way ANOVA with post hoc Bonferroni were used.

## RESULTS AND DISCUSSION

On average, subjects reduced lateral plantar pressure by 58.96% and 33.58% for S5 and S9, respectively (**Table 1**). Speed, stride, or cadence did not change across three tested conditions (**Table 2**). Compared with normal walking, subjects reduced KAM1 by 15.46 % (0.32%BW\*Ht, *p* = 0.051) and KAM2 by 25.18% (0.71%BW\*Ht, *p* = 0.017) while performing the gait modification cued by feedback. After the additional on-campus training and removing the feedback function on the phone, subjects maintained a 17.87% reduction of KAM1 (0.37%BW\*Ht, *p* = 0.010) and 25.53% of KAM2 (0.72%BW\*Ht, *p* = 0.009). It was encouraging that the KAM reduction was sustained

even without feedback after training. Additionally, knee flexion moment (KFM) did not change while subjects were modifying their gait.

Subject	Reduction of Pressure (%)	
	S5	S9

email: iyoun@unomaha.edu

## INTRODUCTION

Osteoarthritis (OA) of the knee is a debilitating condition that negatively affects ambulatory function [1]. Although no cure exists, Total Knee Arthroplasty (TKA) is a common procedure to reduce pain for individuals with end-stage OA [2]. Various functional and self-reported measures are used to assess functional ability and impairment before and after TKA. Although questionnaires are cost-effective and easy to administer, these are subjective and may not accurately reflect actual physical impairments or functional deficits. Performance tests can objectively capture mobility capability, but each test only addresses a small aspect of physical function.

Wearable sensor-based ambient gait monitoring is a promising approach that can address some of the limitations of clinical evaluation. This gait monitoring is low cost, portable, and can provide important objective information of mobility characteristics after unilateral TKA in a real-world setting [3]. To implement the wearable approach, effectiveness of the system needs to be carefully evaluated. Therefore, the purpose of this study was to determine if inertial gait features from wearable accelerometers were associated with self-reported and performance-based measures after unilateral TKA.

## METHODS

15 subjects (1.70±0.1m, 84.5±17.1kg, 67.1±7.5yr, speed=1.13±0.20m/s) after unilateral TKA participated in two data collection sessions. In the first session, subjects answered self-reported surveys including knee outcome survey (KOS) and knee injury and osteoarthritis outcomes score (KOOS). Functional testing included the stair climb test (SCT), 6-Minute Walking (6MW), and timed up and go (TUG). In the second session, acceleration data

were collected using two ankle-worn accelerometers. Accelerometers were attached above the lateral malleoli. Each subject walked at self-selected comfortable walking speed, as determined by a 6 meter walk test, for one minute.

**Table 1:** Eleven inertial gait features based on one all-step inclusive and three directional gait feature categories.

Category	Description
Inclusive	Step time
	Step vector magnitude
	Initial loading vector mag.
Lateral	Lateral heel-strike magnitude
	Lateral heel-strike impulse
	Lateral stance phase angle
Vertical	Vertical heel-strike magnitude
	Vertical heel-strike impulse
Anterior	Anterior heel strike magnitude
	Anterior heel-strike impulse
	Anterior stance phase angle

Eleven gait variables were extracted to estimate magnitude, impulse, and angles of initial loading from 3D-acceleration data. Then, the wearable sensor-based gait variables were compared to questionnaires and performance test outcomes. Hierarchical linear regressions were applied to determine contribution of directional gait variables from wearables for each biomechanical gait feature. To analyze directional effect of inertial gait variables, inclusive-, lateral-, vertical-, and anterior-gait inertial variables were sequentially appended to prior regression models.

## RESULTS AND DISCUSSION

Outcomes of the hierarchical linear regression indicated that inertial gait features significantly predicted performance tests (Table 2) and self-

reported measures (Table 3). All three models performed well at predicting performance measures. 70.1 % of TUG score was explained by vertical and anterior inertial variables. 67.6% of 6MW result was explained by anterior variables, and 68.4% of SCT result was explained by inclusive and anterior inertial variables. Self-reported measures were explained well by combinations of inertial gait features. Inclusive and anterior inertial gait features explained 89.0% of variance in KOS Activities of Daily Living Scale (KOS-ADLS). The variance explained for two KOOS subscales (KOOS-Pain and KOOS-Symptom) were 54.7% and 69.0%, respectively. Generally, anterior gait variables improved prediction of clinical measure outcomes. Since the two inertial sensors were attached on ankle, the magnitude of the anteroposterior acceleration is more dominant while walking compared to the other directions. The anterior inertial gait features worked better than inclusive variables including step time and vector magnitude.

## CONCLUSION

Although current results are challenging to generalize due to small sample size, prediction results are promising and may provide additional information about the TKA population. Additional gait characteristics such as symmetry will be analyzed to understand associations between inertial gait features and clinical scores to improve our understanding of the underlying mechanisms behind the observed relationships.

# A NEW MEASURE OF TRIP RISK INTEGRATING MINIMUM FOOT CLEARANCE AND DYNAMIC STABILITY ACROSS THE SWING PHASE OF GAIT

<sup>1</sup> Brian Schulz

<sup>1</sup> VA Office of Research and Development, Washington, DC  
email: Brian.Schulz@va.gov

## INTRODUCTION

Minimum toe clearance (MTC), or more generally minimum foot clearance (MFC) when the heel is also considered, is thought to quantify the risk of the toe or foot contacting the ground during the swing phase of gait and initiating a trip [1], but there are methodological issues with this measure and the risk of trip-related falls has been shown to also be associated with gait speed [2].

Proximity of the foot to the ground at midswing would be expected to increase trip risk, but the dynamic stability of the locomotor system would also be expected to relate to trip risk and thus far has not been considered in combination with MTC.

This paper proposes and evaluates a new measure, trip risk integral (TRI), that circumvents many issues with MTC as typically calculated at a single point by considering minimum foot clearance across the entire swing phase and taking into account dynamic stability to estimate risk of falling due to a trip rather than risk of the foot contacting the floor.

## METHODS

Shoes and floor surfaces were digitized and MTC and TRI calculated for unimpaired younger (N=14, age=26±5), unimpaired older (N=14, age=73±7), and older adults who had recently fallen (N=11, age=72±5) walking on surfaces with no obstacles, visible obstacles, and hidden obstacles at slow, preferred, and fast gait speeds.

MTC and MFC were calculated as described previously [3] and TRI was calculated using a version of the margin of stability [4] that was modified to provide a continuous trajectory during the swing phase of gait and negated to indicate the margin of instability (MoI).

To quantify the total trip risk across the swing phase, the integral of MoI/MFC was taken, but spikes in the trip risk trajectory would often occur at

foot liftoff or landing. To exclude these spikes when the foot was intentionally and necessarily in close proximity to the ground, the integral was taken between the time points of peak MFC acceleration to exclude these erroneous spikes and still capture all values between the initial liftoff acceleration of the foot and the terminal deceleration prior to foot contact. The resulting trip risk integral (TRI) is thus calculated as per equation 1:

$$TRI = \int_{FOacc}^{ICacc} \frac{MoI}{MFC} dt \quad (1)$$

A repeated-measures linear mixed model was used to test the effects of the three independent variables of subject group, flooring surface, and actual gait speed on two dependent variables (MTC and TRI) using SAS (SAS Institute Inc., Carey, NC). All interaction effects were also included in the model.

## RESULTS AND DISCUSSION

All subjects walked faster when instructed (F=580, p<0.0001) and slower on surfaces with obstacles (F=8.3, p=0.0006; **Table 1**). Fallers walked slower at all instructed speeds (F=14, p<0.0001).

**Table 1: Mean (SD) of actual gait speeds by instructed gait speeds**

Actual Gait (m/s)	Subject Group	Instructed Gait Speed		
		Slow	Preferred	Fast
Uncorrected	Younger Non-Fallers	0.83 (0.19)	1.19 (0.19)	1.98 (0.40)
	Older Non-Fallers	0.89 (0.25)	1.24 (0.25)	1.85 (0.40)
	Older Fallers*	0.80 (0.18)	0.94 (0.18)	1.18 (0.17)
Normalized (leg lengths/s)	Younger Non-Fallers	0.97 (0.24)	1.40 (0.26)	2.32 (0.52)
	Older Non-Fallers	1.15 (0.35)	1.59 (0.32)	2.38 (0.52)
	Older Fallers*	0.98 (0.23)	1.14 (0.23)	1.43 (0.24)

\* Group effect p<0.0001

MTC and TRI had significant (F≥5, p≤0.005) but differing effects of gait speed and floor surface (**Fig. 1**). As gait speed increased (which increases risk of trip-related falls [2]) MTC indicated less and TRI greater risk, indicating that TRI better quantifies risk of falling due to a trip. While MTC and TRI did

not differ by subject group, strong speed-related effects of TRI ( $F \geq 8$ ,  $p \leq 0.0007$ ) resulted in improved TRI for fallers due to their slower self-selected preferred gait.

### CONCLUSIONS

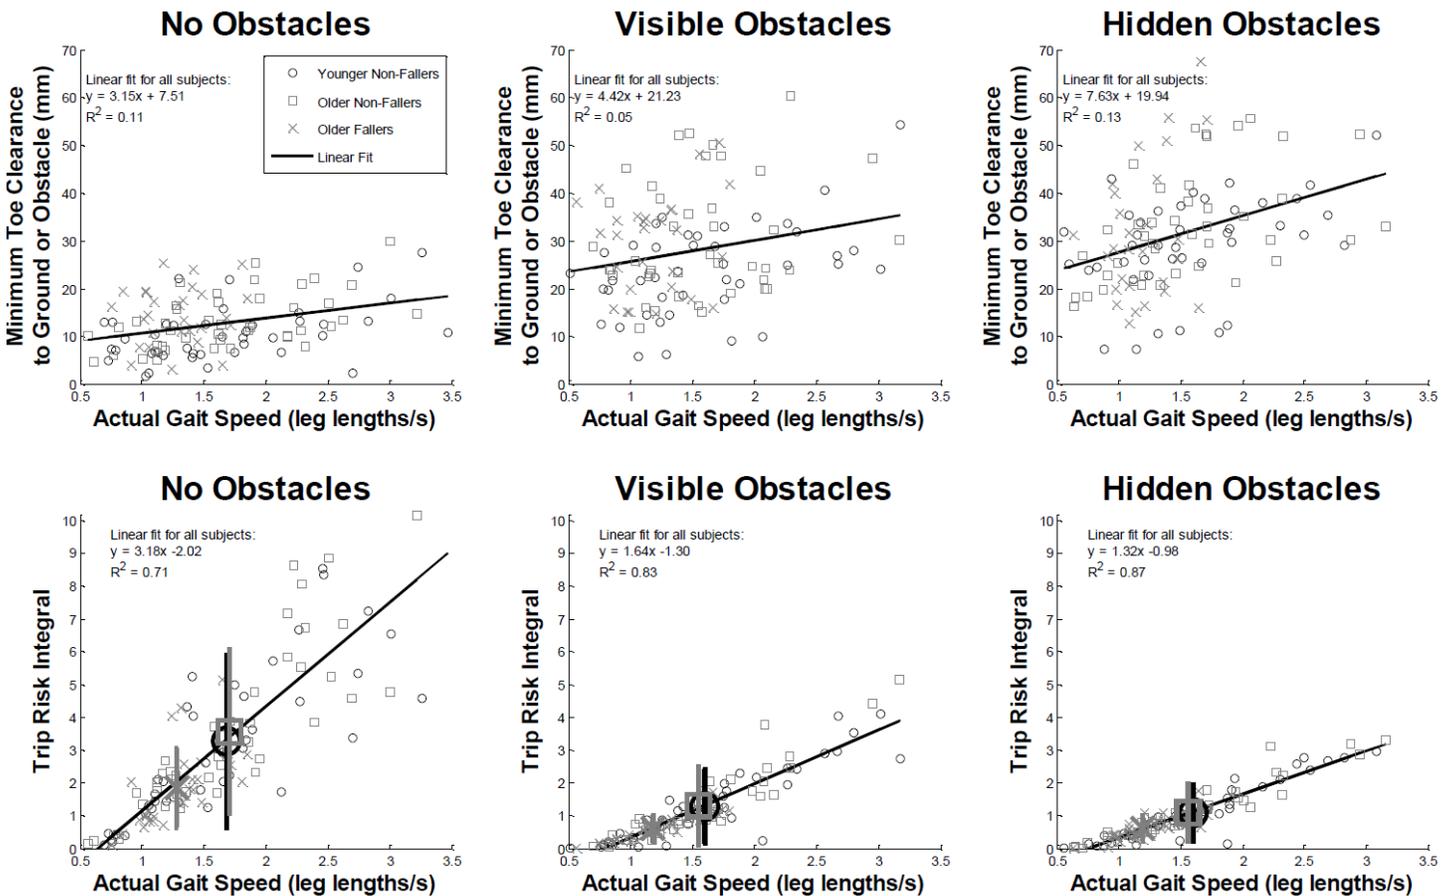

The proposed trip risk integral (TRI) successfully captures dynamic gait stability and MFC across the swing phase of gait in a single measure that circumvents many of the issues associated with MTC and may better quantify risk of falling due to a trip. These findings demonstrate that slower gait is both an important covariate and potential intervention for trip-related falls.

## INTRODUCTION

Despite extensive research efforts, global risk factors for running-related injury remain largely unidentified. This gap may be due to the traditional linear methods of analysis that comprise the majority of running investigation. These analyses rely on discrete mechanical variables and examination of time-invariant means and variances rather than acknowledging the non-linear dynamics of running in which numerous system components interact to achieve healthy gait. Thus, an alternative dynamical systems approach has been proposed to better elucidate the relation among running mechanics, motor behavior, and injury [1]. This analysis involves studying the adaptability of the motor system during running via concepts related to stability, complexity, and variability.

Stride-to-stride fluctuations in gait patterns have been used to indicate system complexity and adaptability. Detrended fluctuation analysis (DFA) is a common method for examining these deviations in gait and characterizes the statistical persistence (long-range correlation) of a time-series through a single value  $\alpha$ :  $\alpha = 0.5$  indicates no persistence (i.e., white noise);  $\alpha < 0.5$  indicates anti-persistent correlation, in which deviation in one direction is statistically more likely to be followed by deviation in the *opposite* direction, and  $\alpha > 0.5$  indicates persistence, with deviation in one direction statistically more likely to be followed by deviation in the *same* direction. A change in  $\alpha$  in response to a perturbation or a biological stressor may lend insight into motor system flexibility to environmental or task demands. The breakdown of long-range correlations (decreased  $\alpha$ ) in walking gait has typically been viewed as a loss of system complexity and global stability that contributes to functional deterioration often seen with aging and disease. Recently, long-range correlations have been examined in healthy and injured runners in response to changes in running

speed, fatigue, or footwear [2,3,4]. However, unlike walking, there is not a clear direction that delineates healthy versus at-risk (injured) runners. Likewise, interpretation of  $\alpha$  to indicate positive or negative gait adaptation remains unclear.

An important first step in applying these methods to running injury research is to clarify the interpretation of  $\alpha$ . Our primary purpose was to explore changes in long-range correlations in response to an enforced gait perturbation. We sought to determine the extent to which values were predictive of adaptive performance and whether experience (skill mastery) influenced adaptive performance or global system stability.

## METHODS

Forty distance runners (26 M;  $35.6 \pm 10.3$  years old) participated in this study. Runners were free of musculoskeletal injury and had not attempted gait retraining in the last 12 months preceding data collection. Runners were categorized into three groups based on years of distance running experience: 1) novice (0-3 years) 2) intermediate (4 – 10 years) 3) experienced (10+ years).

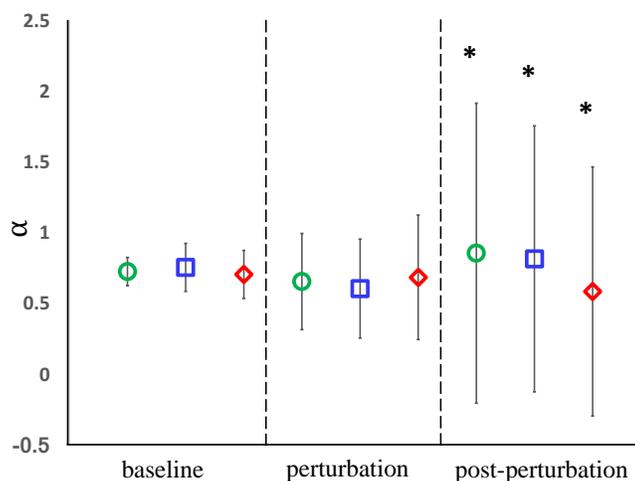

Participants ran on an instrumented treadmill (h/p/cosmos, Zebris Medical, Germany) at a self-selected speed. Five different step frequencies [150, 160, 170, 180, 190 beats per minute (bpm)] were enforced via an audible metronome and participants were asked to match their footfalls to the beat. Pressure data (120 Hz) were collected from the treadmill using commercial software (Noraxon MyoResearch 3.8) and used to calculate spatiotemporal measures. Metronome onset began after 1 min of free running and lasted for 3 min. The audible beat was washed out with 2 min of white noise and 1 min of silence, for a total trial duration of 7 min. Enforced step frequency order was randomized. Adaptation and de-adaptation were

measured as the time to reach a plateau after onset and cessation of the metronome, respectively.

Generalized linear mixed models were used to determine the extent to which the strength of long-range correlations changed from baseline measures during and following cessation of enforced step frequency perturbations. Additionally, the influence of running experience on  $\alpha$  was examined.

## RESULTS AND DISCUSSION

Baseline  $\alpha$  values did not predict adaptive performance ( $p = 0.30-0.88$ ). However, stride time  $\alpha$  was significantly different between the perturbation and post-perturbation periods ( $p = 0.001$ , Figure 1). All runners had lower  $\alpha$  values during the perturbation period compared to baseline levels. These changes are in line with previous work suggesting the metronome induces a less complex pattern or requires corrective action to maintain stability. Interestingly, values post-perturbation did not return to baseline for any group and were highly variable.

**Figure 1:** Strength of long-range correlations ( $\alpha$ ) for stride time across periods. Green circles: novice; blue squares: intermediate; red diamonds: experienced.

Experience appeared to positively influence adaptability. Baseline  $\alpha$  values were significantly influenced by experience ( $p < 0.05$ ). Likewise, more experienced runners had shorter adaptation times,

were better able to match the desired step frequency, were less perturbed (lower step frequency drift), and were able to successfully match enforced frequencies further away from their preferred step frequency. Experienced runners displayed weaker long-range correlations post-perturbation while correlations in the novice group became stronger.

There is debate about the interpretation of  $\alpha$  in relation to optimal function. Some suggest a higher correlated signal ( $\alpha = 1$ ) is optimal [5] while others suggest an increased correlation represents decreased dynamical degrees of freedom and less flexibility to adapt to perturbations [4]. Given that novice runners have a much higher rate of injury [6] and years of experience usually implies advanced motor skill, it would appear that weaker correlations (lower  $\alpha$ ) are more advantageous for injury resiliency in runners. This is supported by our findings that more running experience corresponded to better adaptive performance. However, the large variability during the post-perturbation period suggests that there is a subject-specific response that warrants further investigation.

## CONCLUSIONS

Nonlinear analysis of long-range correlations during continuous running gait detected changes in response to an external perturbation. This method has the potential to facilitate identification of injury-prone behavior patterns. More research is needed to confirm the appropriate  $\alpha$  interpretation, determine subject-specific responses, and assess sensitivity to specific perturbations.

## INTRODUCTION

Maintaining dynamic balance while walking on stairs is challenging, particularly for people with a transtibial amputation, who have lost the function of the ankle muscles. A previous study of the range of whole-body angular momentum ( $H$ ) found that powered prostheses do not substantially alter dynamic balance on stairs relative to passive prostheses [1]. Alternative measures of balance based on an inverted pendulum model, such as the extrapolated center of mass [2], foot placement estimate [3,4], and capture point [5,6], may provide new insights. However, muscle power generation/absorption and leg length changes that occur during stair walking may affect some models more than others. Thus, our goals in this study were to 1) compare the three inverted pendulum models and 2) correlate inverted pendulum models and  $H$  in people with a transtibial amputation using powered and passive prostheses on stairs.

## METHODS

Nine able-bodied people (7M/2F, 24.1±5.5 yrs, 92.6±9.2 kg, 1.80±0.10 m) and nine people with transtibial amputation (8M/1F, 30.0±5.6 yrs, 95.6±6.6 kg, 1.81±0.09 m) walked on a 16-step instrumented staircase at a controlled cadence while whole-body kinematics were collected (120 Hz).

We calculated the sagittal-plane extrapolated center of mass (XCOM, Fig. 1a, Eq. 1), with gravitational acceleration  $g$  and constant leg length  $L$  from a static trial.

$$XCOM = x_{COM} + v_x \sqrt{\frac{L}{g}} \quad (1)$$

The foot placement estimate (FPE, Fig. 1b) allows variable leg length (Eq. 2) and incorporates instantaneous  $H$ , expressed as  $J_{COM}\omega_1$ . Conservation of  $H$  about the FPE during foot contact is assumed (Eq. 3), and conservation of energy is applied so the COM comes to rest above the FPE (Eq. 4). Solving numerically for  $\phi$  gives the FPE location.

$$L(\phi) = \frac{h_n}{\cos\phi}, \quad (2)$$

$$mL(\phi)[v_x \cos\phi + v_y \sin\phi] + J_{COM}\omega_1 = [mL(\phi)^2 + J_{COM}]\omega_2 \quad (3)$$

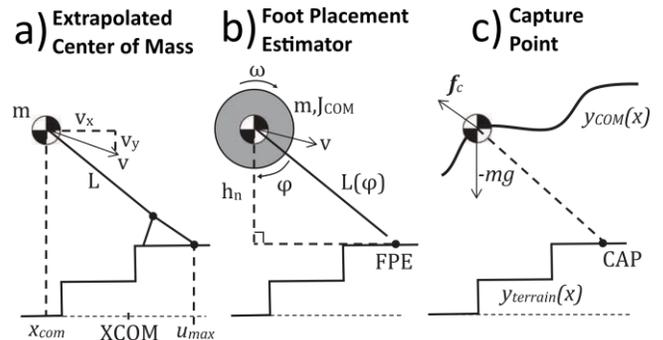

$$\frac{1}{2}[J_{COM} + mL(\phi)^2]\omega_2^2 + mgL(\phi) \cos\phi = mgL(\phi) \quad (4)$$

The capture point (CAP, Fig. 1c) was computed by numerically integrating the system equations of motion (Eqs. 5 and 6) so the center of mass (COM) follows its experimentally measured trajectory  $y_{COM}$  and comes to rest above the CAP location.

$$\ddot{x} = \frac{(x_{COM} - x_{CAP})(g + \frac{d^2 y_{COM}}{dx^2} \dot{x}_{COM}^2)}{(y_{COM} - y_{CAP}) - (x_{COM} - x_{CAP}) \frac{dy_{COM}}{dx}} \quad (5)$$

$$\ddot{y} = \frac{(y_{COM} - y_{CAP}) \frac{d^2 y_{COM}}{dx^2} \dot{x}_{COM}^2 + g(x_{COM} - x_{CAP}) \frac{dy_{COM}}{dx}}{(y_{COM} - y_{CAP}) - (x_{COM} - x_{CAP}) \frac{dy_{COM}}{dx}} \quad (6)$$

Stability metrics were computed as the distance between the XCOM, FPE, and CAP x-locations and the x-location of the leading toe at heel strike ( $u_{max}$ , Fig. 1a), normalized by static leg length.

**Figure 1:** Inverted pendulum model diagrams.

Results were compared with a three-factor, repeated measures ANOVA with walking condition, leg type, and metric as fixed effects and subject as a random effect. Pairwise comparisons were adjusted using Tukey's method when significant main or interaction effects were found. We also analyzed the correlation between each stability metric and the range of sagittal-plane  $H$ . All statistical tests had  $\alpha=0.05$ .

## RESULTS AND DISCUSSION

The main effects were all significant ( $p<0.001$ ), as were the interaction effects of condition by leg ( $p<0.001$ ) and condition by metric ( $p<0.001$ ). During stair ascent the effective leg length at heel strike was approximately 20% smaller than in static standing. However, during stair ascent the mean differences were  $0.009\pm 0.005$  (XCOM vs CAP) and  $0.02\pm 0.006$  (XCOM vs FPE), compared to level-ground where the differences were  $0.01\pm 0.006$  (XCOM vs CAP) and  $0.06\pm 0.008$  (XCOM vs FPE). Thus, inverted pendulum models were not highly sensitive to violations of leg length assumptions in stair walking.

There were significant, although small, correlations between the stability metrics and range of sagittal-plane  $H$  in stair descent ( $r\cong -0.19$ ,  $p\leq 0.008$ ), but not in stair ascent. However, a *post hoc* analysis revealed a stronger correlation between the instantaneous value of  $H$  at heel strike and the FPE metric ( $r=-0.50$ ,  $p<0.001$ ). This result indicates that foot placement is important for regulating  $H$  at heel-strike. However, mechanisms like muscle force generation are critical for regulating  $H$  throughout the gait cycle.

Stability metrics were generally more positive in the amputated versus the intact leg, suggesting a conservative prosthetic foot placement strategy. However, when using the powered prosthesis, the

metrics were not significantly different between the amputated and intact legs in stair ascent, suggesting that prosthetic ankle power may help restore bilateral symmetry of dynamic balance during this task.

## CONCLUSIONS

Inverted pendulum models of stability do not appear highly sensitive to leg length assumption violations in stair walking. Foot placement helps regulate  $H$  in early stance, but other mechanisms (e.g., muscle force generation to regulate the net external moment) are also important throughout the gait cycle. People with a transtibial amputation use a conservative prosthetic leg strategy, and powered prosthesis use increases step symmetry in stair ascent.

email: mgbrowne@email.unc.edu, web: http://abl.bme.unc.edu

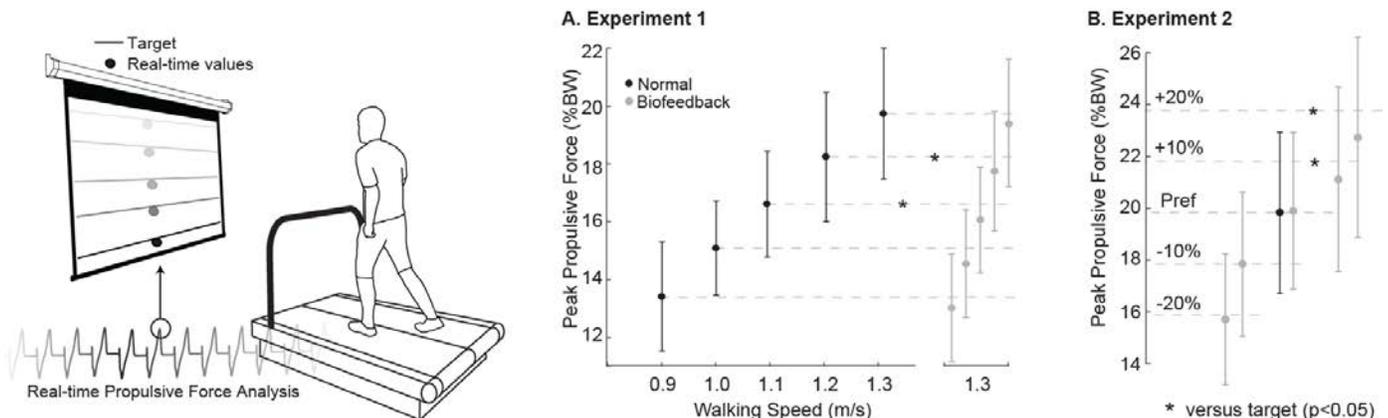

## INTRODUCTION

Older adults are at an exceptionally high risk of falls, and most of these falls occur during locomotor activities such as walking. Older adults may thus opt to walk slower to improve their resilience to unexpected balance challenges and mitigate their risk of falls. However, prior to eliciting slower preferred speeds, advancing age is accompanied by a precipitous reduction in propulsive forces ( $F_P$ ) exerted during the push-off phase of walking. Winter et al. (1990) originally proposed that many of the hallmark biomechanical features of elderly gait, including reductions in  $F_P$  generation during push-off, reflect the adoption of a safer, more stable pattern of movement [1]. Accordingly, older adults may walk with smaller propulsive forces even prior to walking slower to prioritize stability over mobility. However, direct evidence for tradeoffs between propulsive force generation and walking balance control, independent of changes in walking speed, has remained allusive. As an important first step, the purposes of this study were to investigate: (1) the independent effects of walking speed and  $F_P$  generation on dynamic stability in young adults, and (2) the extent to which young adults prioritize

dynamic stability in selecting their preferred combination of walking speed and  $F_P$  generation. We tested two intuitively sound, but mutually exclusive hypotheses: (i) that walking slower or with smaller  $F_P$  would improve dynamic stability, and (ii) that young adults prefer a combination of walking speed and  $F_P$  generation that maximizes dynamic stability.

## METHODS

Young adult subjects participated in two different but complementary experiments: 12 subjects participated in Experiment 1 (mean  $\pm$  standard deviation, age:  $26.2 \pm 3.1$  years, 6 males/6 females) and 10 subjects participated in Experiment 2 (age:  $24.8 \pm 5.4$  years, 5 males/5 females). Experiment 1 and Experiment 2 both utilized a novel visual biofeedback paradigm based on real-time force measurements from a dual-belt force measuring treadmill (Bertec, Corp., Columbus, OH) (Fig. 1). Specifically, for trials involving this biofeedback paradigm, a custom Matlab (Mathworks, Natick, MA) script continuously computed the average bilateral peak  $F_P$  during push-off from each set of four consecutive steps and projected a visual representation of those values as dots in real-time to

**Figure 1:** Visual biofeedback of  $F_P$  was used in Experiments 1 and 2. Experiment 1 targets were prescribed as  $F_P$  from the slower walking speeds. Experiment 2 prescribed  $\pm 10$  and  $\pm 20\%$  changes in  $F_P$  at preferred speed.

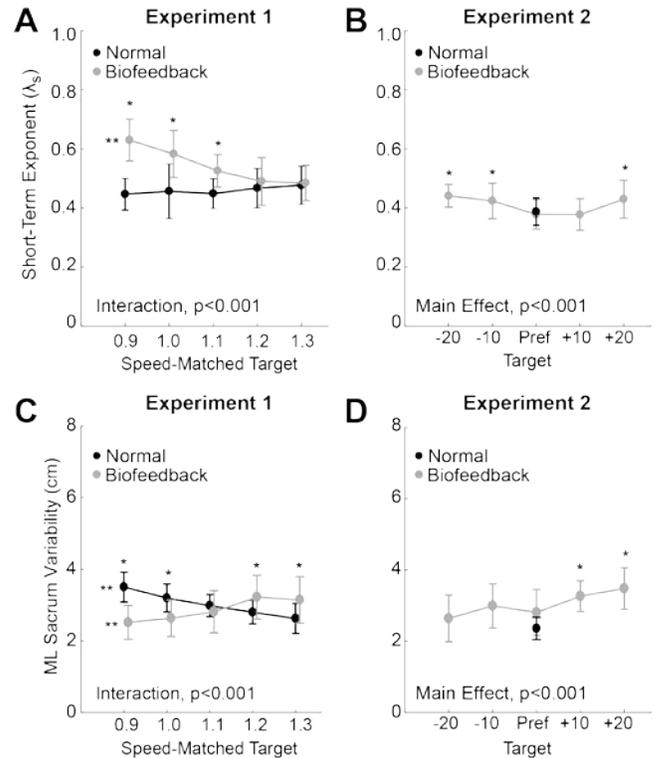

a screen positioned in front of the treadmill (Fig. 1). For Experiment 1, subjects first walked at a range of speeds, from 0.9 to 1.3 m/s in 0.1 m/s increments. Subjects then walked at 1.3 m/s while matching their instantaneous  $F_P$  to target values representing the average extracted from the slower speeds (Fig. 1A). In Experiment 2, subjects first walked at their preferred overground walking speed. Subjects then walked while matching target values representing  $\pm 10$  and  $\pm 20\%$  of preferred  $F_P$  (Fig. 1B). Using motion capture data, we constructed a state vector from the time series of sacrum position and velocity in the anterior-posterior (AP), mediolateral (ML), and vertical directions to calculate short-term maximum divergence (i.e., Lyapunov,  $\lambda_s$ ) exponents [2, 3]. Finally, we analyzed the variability of sacrum kinematics given its complement to dynamic stability within the context of balance control.

## RESULTS AND DISCUSSION

Subjects successfully modulated their  $F_P$  in accordance with all prescribed biofeedback targets (Fig. 1) and biofeedback itself (i.e., normal walking vs. walking with targets representing normal walking) had no discernible effect on dynamic stability. In Experiment 1, walking slower improved dynamic stability despite increasing ML variability. Walking with smaller  $F_P$ , however, increased  $\lambda_s$  by up to 30% (Fig. 2A), with the largest effects in the ML direction. In Experiment 2, increasing or decreasing the  $F_P$  subjects exerted when walking normally at their preferred speed negatively affected metrics of dynamic stability (Fig. 2B). Specifically, walking with 20% larger or smaller than preferred  $F_P$  increased  $\lambda_s$  by 14% and 17%, respectively. In contrast, all components of sacrum variability decreased monotonically with smaller  $F_P$  across the range of biofeedback targets presented (e.g., Fig 2D).

## CONCLUSIONS

Our findings provide the first empirical evidence that that walking slower and walking with smaller  $F_P$  elicit very different effects on local dynamic stability. Consistent with prior studies, walking slower improved dynamic stability despite

**Figure 2:** Group mean (SE) short-term divergence exponents and ML sacrum variability during walking in Experiment 1 and Experiment 2.

increasing movement variability in young adults. However, contrary to our first hypothesis, walking with smaller  $F_P$  reduced dynamic stability compared to walking normally. Rather, more consistent with our second hypothesis, our findings suggest that young adults adopt an  $F_P$  at their preferred walking speed that maximizes dynamic stability. The age-related reduction in propulsive force generation is likely multifactorial, but precedes the slowing of preferred speed. Winter et al. [1] originally proposed that older adults may reduce  $F_P$  to prioritize stability over mobility. Although an intuitively sound hypothesis, our findings instead allude to unfavorable consequences of reduced propulsive force generation on dynamic stability that may ultimately precipitate walking slower.

# AGING EFFECTS ON LEG JOINT VARIABILITY DURING WALKING IN THE PRESENCE OF OPTICAL FLOW PERTURBATIONS

Mu Qiao, Jody A. Feld, and Jason R. Franz

University of North Carolina at Chapel Hill and North Carolina State University, Chapel Hill, NC, USA

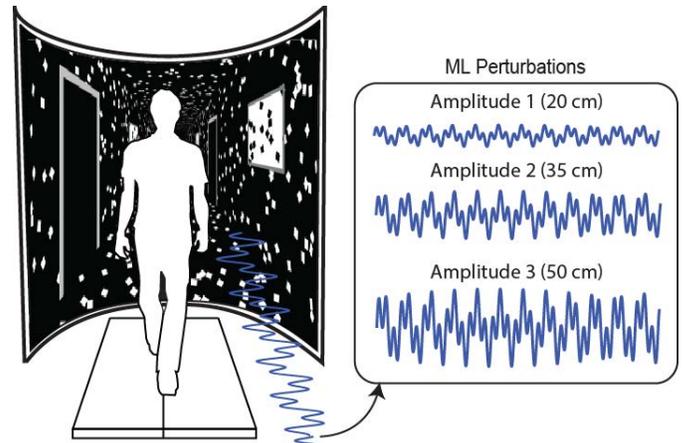

Email: [mu\\_qiao@med.unc.edu](mailto:mu_qiao@med.unc.edu), web: <http://abl.bme.unc.edu/>

## INTRODUCTION

Balance control in older adults is much more susceptible to optical flow perturbations during walking than in young adults, presumably governed by an age-related dependence on visual feedback for motor planning and execution [1, 2]. Balance corrections issued by the central nervous system manifest first at the individual muscle and joint levels before ultimately eliciting adjustments in foot placement from one step to the next. Kinematic variability can provide insight into the magnitude of these step-to-step corrections [3]. However, we currently lack an individual joint-level understanding of how aging affects the neuromechanical strategies used to accommodate optical flow perturbations. Therefore, our purpose was to investigate the effects of aging on leg joint kinematic variability during walking with and without optical flow perturbations of different amplitudes. First, we hypothesized that leg joint variability would: 1) vary across the gait cycle, and 2) increase in the presence of optical flow perturbations. We also hypothesized that, compared to those in young adults, the effects of optical flow perturbations on leg joint variability would be larger and more pervasive in older adults.

## METHODS

11 healthy young (mean±sd, age: 24.8±4.8 years, 5 male, 6 female) and 11 healthy older adults (age: 75.3±5.4 years, 5 male, 6 female) participated. Young subjects walked at 1.25 m·s<sup>-1</sup> and older subjects walked at their preferred overground speed (1.19±0.20 m·s<sup>-1</sup>,  $p=0.15$ ) on an instrumented dual-belt treadmill (Bertec Corp., Columbus, OH). While walking, subjects watched a speed-matched, virtual hallway rear-projected onto a semi-circular screen surrounding the treadmill both with and without continuous mediolateral oscillations of optical flow, applied as the sum of three sine waves (0.125, 0.250, and 0.442 Hz) (Fig. 1). In fully-randomized order, subjects walked for 2 min each with and without

**Figure 1.** Experimental setup and time series of the three optical flow perturbation amplitudes.

optical flow perturbations prescribed by three amplitudes (20, 35, and 50 cm, Fig. 1). A 14-camera, three-dimensional motion capture system (Motion Analysis Corp., Santa Rosa, CA) operating at 100 Hz recorded the trajectories of 33 retroreflective markers placed on the right and left foot, shank, and thigh, and on the pelvis. We calculated hip, knee, and ankle joint kinematics using a global optimization inverse kinematics routine. We calculated time series of sagittal plane hip, knee, and ankle joint angles, and coronal plane hip joint angle. From these, we calculated stride-averaged profiles and the variability of leg joint kinematics using the mean and standard deviation of each outcome measure over the gait cycle. A mixed design 3-way factorial ANOVA determined effects of and interactions between age (young vs. old), perturbation amplitude (0 vs. 20, 35, and 50 cm), and gait cycle (10% bins).

## RESULTS AND DISCUSSION

As hypothesized, during normal walking, hip, knee, and ankle variabilities differed significantly across phases of the gait cycle ( $p$ 's<0.001), and all joints reached their maximum variability immediately following toe-off (*i.e.*, 60-70% cycle) (Fig. 2). Compared to young adults, older adults walked

normally with 33% larger coronal plane hip variability ( $p=0.014$ , Fig. 2D), but no difference in sagittal plane hip ( $p=0.074$ , Fig. 2B), knee ( $p=0.091$ , Fig. 2F), or ankle ( $p=0.091$ , Fig. 2H) joint variabilities.

In young adults, we found a significant effect of perturbation amplitude only on coronal plane hip joint variability ( $p=0.014$ , Fig. 2C), which increased by 39% compared to unperturbed walking. However, in young adults, significant interactions in the sagittal plane revealed that perturbations increased hip joint variability only during midstance and ankle joint variability only at initial contact and terminal stance (hip:  $p=0.020$ , Fig. 2A; ankle  $p<0.001$ , Fig. 2G). As hypothesized, in contrast to their effects in young adults, the effects of optical flow perturbations on leg joint variabilities were larger and much more pervasive in older adults. For example, only in older adults did we find that the increase in coronal plane hip joint variability in the

presence of perturbations ( $p=0.016$ , Fig. 2D) was accompanied by larger sagittal plane hip ( $p=0.045$ , Fig. 2B), knee ( $p=0.048$ , Fig. 2F), and ankle ( $p=0.010$ , Fig. 2H) joint variabilities. These larger effects of perturbations in older adults also manifested over more phases of the gait cycle than in young adults. Moreover, in contrast to young adults who scaled their leg joint variabilities progressively with increasing perturbation amplitude, older adults did not scale their response and were instead disproportionately susceptible to even the smallest amplitude perturbation. Compared to young adults, 20 cm perturbations increased sagittal plane hip, knee, and ankle joint variabilities by an average of 211%, 88%, and 63% more, respectively, and coronal plane hip variability by an average of 68% more in older adults.

## CONCLUSIONS

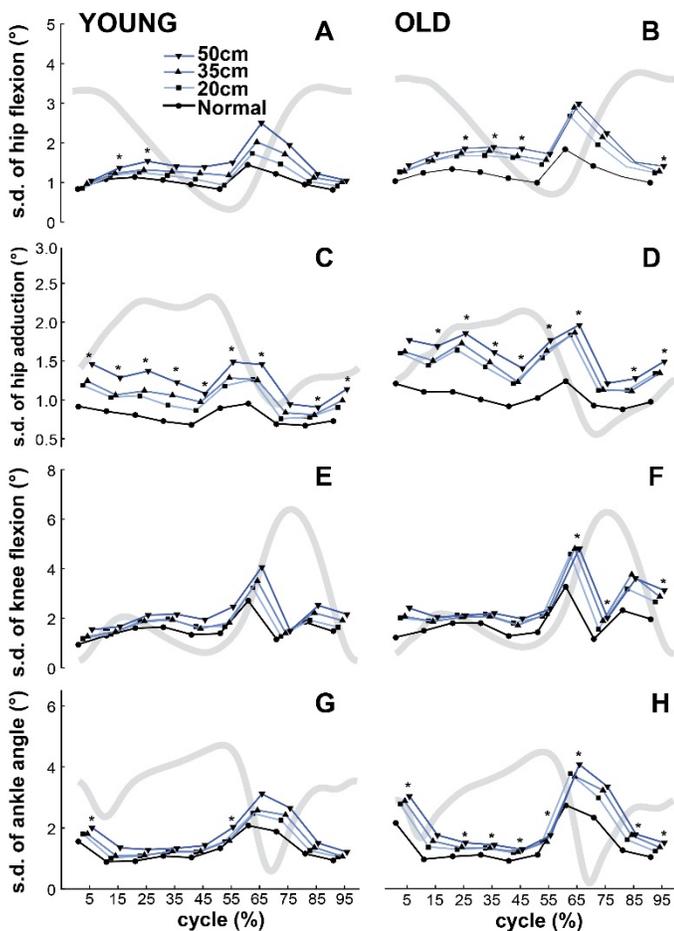

This study provides joint-level insight into aging effects on the neuromechanical strategies used to regulate walking balance. We first conclude that leg joint variability during walking is phase dependent, with step-to-step adjustments in hip, knee, and ankle joint kinematics occurring predominantly during push-off. Second, young adults accommodated mediolateral optical flow perturbations almost exclusively by increasing variability in coronal plane hip joint angle, likely to orchestrate step-to-step adjustments in lateral foot placement. Finally, in contrast to the localized adjustments in young adults, the same perturbations elicited larger and more pervasive increases in all joint variability outcome measures in older adults. This latter finding suggests that aging not only increases the susceptibility to optical flow perturbations but also negatively affects the joint-level neuromuscular control of walking balance.

## INTRODUCTION

Executive function (EF) encompasses multiple cognitive processes. A set of skills necessary to formalize goals, plan, strategize, and suppress task-irrelevant information [1]. In everyday life, EF may directly affect walking in contexts that challenge how individuals modify their stepping. Here, we manipulated the cognitive demand of walking by introducing virtual stepping objects (targets and obstacles) designed to disturb the normal walking pattern. We explored how both physical and EF measures affected stepping error performance.

## METHODS

Twenty-one young healthy adults (YH; age 18-29 years) and twenty-one older healthy adults (OH; age 60+ years) walked on a treadmill at  $v_w = 1$  m/s. In the first condition (NWalk), participants were instructed to simply walk. In following two conditions, virtual stepping objects appeared on the treadmill (Fig. 1); and in both conditions, 80% of the stepping objects were colored yellow. Participants were instructed to step on yellow objects (GoYel) while avoiding red objects, and then to step on red objects (GoRed) while avoiding yellow objects. The GoYel Condition accustomed participants to step on yellow objects 80% of the walking trial. The GoRed Condition required participants to *inhibit* this stepping response (i.e. step on yellow) 80% of the trial. Participants completed two 3 minutes trials per condition. Stepping errors partitioned into Go Errors (missed targets) and NoGo Errors (stepped on obstacles).

PHYSICAL AND EF ASSESSMENTS: Each participant also completed a cognitive battery (including MMSE, Go-NoGo Task and Stroop Task; Fig. 2) and several physical (including Timed Up And Go, overground Preferred Walking Speed, and isometric knee extension strength) assessments.

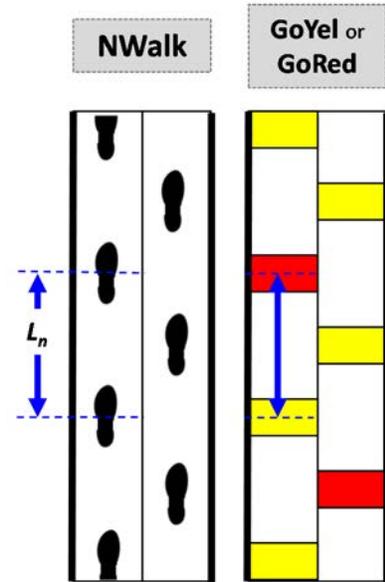

Figure 1: Three Experimental Walking Conditions

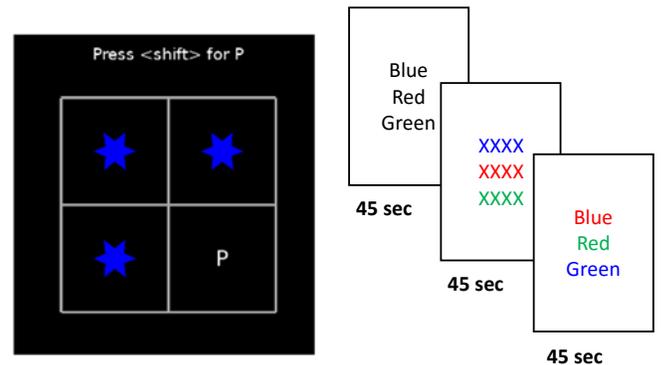

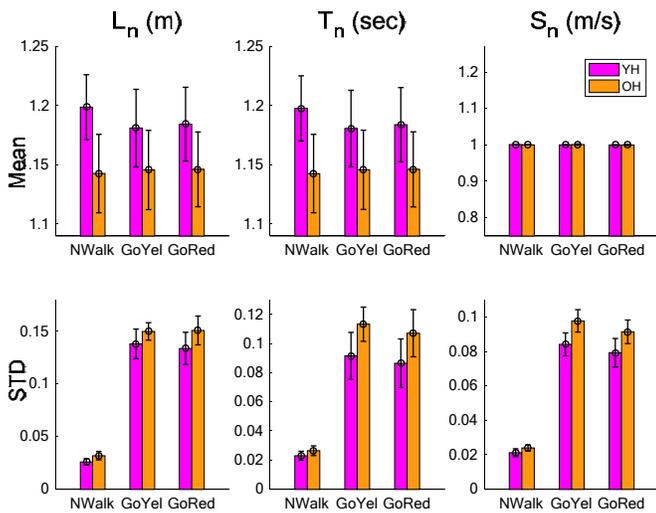

Figure 2: Go-NoGo (GNG) and Stroop Tasks (ST). These cognitive tasks evaluate response inhibition.

## RESULTS AND DISCUSSION

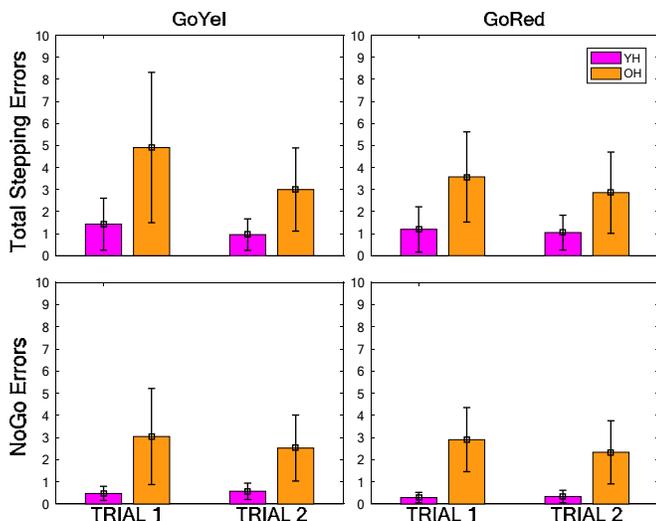

OH adults took shorter and faster strides compared to YH adults (Fig. 3) across all conditions. When virtual stepping objects were introduced (GoYel & GoRed), all participants exhibited increased stepping variability in stride length  $L_n$ , stride time  $T_n$  and stride

speed  $S_n$  (Fig. 3). However, across all conditions, OH adults exhibited greater stepping variability compared to YH adults.

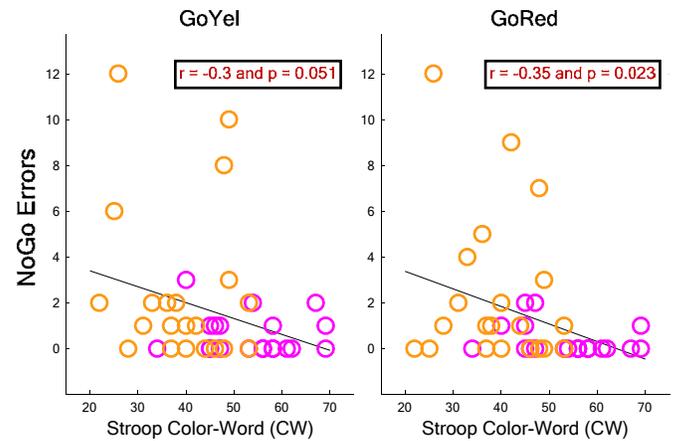

**Figure 3:** Stride Parameter Means and Variability for both YH and OH adults.

STEPPING ERRORS: OH adults made more total stepping errors in both GoYel and GoRed compared to YH adults (top row, Fig. 4).

**Figure 4:** Total Stepping Errors and NoGo Errors (stepping on an obstacle) in both object conditions (both Trial 1 and 2 shown).

However, when the total stepping errors were partitioned, OH adults made more NoGo Errors (stepping on an obstacle) compared to YH adults (bottom row, Fig. 4) in both object conditions.

**Figure 5:** Stroop Color-Word (CW) Performance versus stepping NoGo Errors during both object conditions (Trial 2 data shown).

PHYSICAL & EF: OH adults ( $1.48 \pm 0.1$  m/s) preferred slightly faster overground walking speeds compared to YH adults ( $1.33 \pm 0.1$  m/s). For Timed Up and Go (TUG) times, OH adults ( $7.87 \pm 0.4$  sec) were slightly slower than YH adults ( $7.32 \pm 0.5$  sec). OH adults demonstrated slightly less isometric quadriceps strength compared to YH adults. However, no associations were found between any of the physical measures and stepping errors (not shown).

Reduced response inhibition was observed in OH adults compared to YH adults in the Stroop CW condition (not shown). Further, Stroop CW performance was weakly associated with stepping NoGo Errors in the GoRed condition (Fig. 5).

## CONCLUSIONS

Introducing virtual stepping objects within the walking task disrupted the normal walking pattern and did significantly alter walking variability across all participants. OH adults were less successful at negotiating stepping *obstacles* compared to stepping targets. Stepping error performance appeared to be weakly associated to EF (Stroop CW), but was not associated to any of the physical measures

This session is dedicated to the memory of Jim Hay, a pioneer in the field of sport and exercise biomechanics and a founding member of ASB. The Jim Hay Memorial Award recognizes the originality, quality, and depth of biomechanics research that addresses fundamental research questions relevant to extraordinary demands imposed in sport and exercise. The Jim Hay Memorial Lecture will be followed by three invited presentations all on the topic of muscle-tendon unit mechanics in the context of sport. The following represents a brief summary of our discussion and the order of presentations for the 2017 meeting.

### **Biomechanical Studies of Muscle Injury**

Richard L. Lieber  
Shirley Ryan AbilityLab

This lecture begins with a brief review of biomechanical and biological studies of eccentric injury in animal models. Basic muscle physiological principles will be illustrated, as well as high-resolution tools to study muscle structure. These basic studies will be used to express a paradigm where high intensity muscle contractions serve as a model to understand normal function. This should set up succeeding talks who will use some of these ideas in more applied settings.

### **Relationship Between Hamstring Flexibility and Strain in Sprinting**

Bing Yu  
University of North Carolina – Chapel Hill

Hamstring muscle injury is one of the most common injuries in sports involving sprinting. Risk factors for hamstring muscle strain injury are still not clear. The literature demonstrates that muscle injury is due to mechanical strain. Our recent studies demonstrated that hamstring muscle-tendon optimal length is correlated with flexibility, and that

hamstring muscle tendon optimal length and flexibility are correlated to the maximal strain of hamstring in sprinting. These results filled gaps in our understanding of risk factors for hamstring muscle strain injury.

### **Modulation of Muscle-Tendon Kinetics with Running Cadence and Speed**

Darryl G. Thelen  
University of Wisconsin

An understanding of muscle-tendon mechanics during running is important for balancing the risk between performance, training and injury avoidance. This talk will review modeling studies we conducted on hamstring demands during high speed running and re-distributions of muscle loading with cadence. We will also introduce a novel shear wave measurement technology which may enable objective assessments of in vivo muscle-tendon kinetics. Such information can be used for biomechanical biofeedback on running form or for tracking recovery following soft tissue injury.

### **The Converging Fiber Hypothesis and Muscle Injury**

Silvia S. Blemker  
University of Virginia

Across the human body, there are several muscles in which fibers converge from a large cross-sectional area in the mid-belly of the muscle to a small cross-sectional area of attachment at the myotendinous junction. However, the classic descriptions of muscle fiber arrangements (e.g., fusiform, pennate, bipennate) do not address the biomechanical implications of this converging fiber phenomenon. Computer models and in vivo dynamic magnetic resonance imaging studies performed by our group have revealed that muscles

with this fiber converging phenomenon have elevated localized tissue strains generally near the myotendinous junction. In this talk, I will present the hypothesis that muscles with fibers that substantially converge to a narrow attachment site have an elevated susceptibility to localized damage during contractions. Further, I will discuss the implications of this concept on (i) strain injury susceptibility in athletes, and (ii) degeneration of muscles due to elevated susceptibility to contraction-induced injury in muscle diseases.

# Material Properties of Ankle Plantarflexor and Dorsiflexor Muscles – Effect of Aging

Sabrina Lee, Amy Xie, Ada Terman, Ricardo Santana, and Kristen Jakubowski

Northwestern University, Chicago, USA

email: [s-lee@northwestern.edu](mailto:s-lee@northwestern.edu), web: <http://www.feinberg.northwestern.edu/sites/pthms>

## INTRODUCTION

Decreased motor performance with increasing age is often associated decreased muscle strength, which in turn, has been attributed to muscle atrophy and changes in muscle architecture. Increased tendon compliance has also been shown to affect muscle mechanics and has been correlated with decreased joint power during push-off. Torque-angle-based estimates of passive muscle stiffness of the ankle are increased in older adults compared in younger adults [1]. However, these methods include contributions from ligaments, joint capsule, multiple muscles and tendons. Elastography is a method that allows quantification of material properties, specifically stiffness, of individual muscles. Shear modulus, as measured using magnetic resonance elastography, showed no significant correlation between age and tissue stiffness [2]. A recent study using shear wave (SW) ultrasound elastography reported increased shear modulus with increasing age in the upper extremity biceps brachii [3]; however, the effects of aging on the lower extremity ankle muscles are unknown.

Thus, the aim of this study was to compare the material properties measured using SW ultrasound elastography, specifically stiffness, of the medial gastrocnemius (MG) and tibialis anterior (TA) between younger and older adults. SW velocity was also compared to measures of joint stiffness, as well as muscle stiffness estimates from torque-angle measures.

## METHODS

Nine young adults (four males, five females,  $21.0 \pm 3.6$  yrs) and five older adults (four males, one female,  $68.8 \pm 5.4$  yrs) participated in the study. Subjects were seated with their knee in maximum extension and their foot secured to a platform of a

dynamometer (System3Pro, Biodex). B-mode and SW elastography ultrasound measurements (Aixplorer, SuperSonic Imagine) of MG and TA muscles were captured, as well as joint angle, torque, and electromyography (Delsys) with the ankle at different angles (0 degrees dorsiflexion (DF), 15 degrees plantarflexion (PF), maximum DF, maximum PF, and two other intermediary angles) while the muscle was passive. SW ultrasound elastography measures the velocity at which shear waves propagate through the tissue [4]. Shear waves will propagate faster in a tissue that has a higher elastic shear modulus. SW velocity was also compared to passive joint stiffness, which was calculated as the change in joint torque as a function of ankle angle. Estimates of MG stiffness from the torque and ankle angle measures were also calculated. The MG moment arm for the ankle range of motion of each subject was obtained from OpenSim using the lower extremity model by Arnold et al. (2010) [5]. The passive force shared by the lateral and medial gastrocnemius was assumed to be proportional to the cross-sectional area such that the passive MG muscle was determined as 61% of the total gastrocnemius force [6]. An Analysis of Covariance was used to compare the SW velocity and joint stiffness between younger and older adults, with ankle angle as the covariate. Correlation coefficient of determination was calculated between SW velocity, joint stiffness, and muscle stiffness estimates.

## RESULTS AND DISCUSSION

Our main findings show that SW velocity in the MG of younger adults was on average 36% greater than older adults ( $p < 0.001$ ) across the ankle range of motion and 54% greater at maximum DF (Fig. 1). There was no difference in SW velocity in the TA between the two groups. Joint stiffness was significantly greater in PF in older adults ( $p = 0.032$ )

and 0.042), but tended to be less in DF compared to younger adults. These results of decreased MG stiffness, as indicated from SW velocity, but increased joint stiffness (similar to the literature) was very surprising. This suggests that MG stiffness does not contribute to the increased joint stiffness of older adults and that other soft tissues and other muscles are the main contributors. This surprising result has substantial implications to our interpretation of joint stiffness and changes in muscle mechanics due to aging. Increased Achilles tendon compliance in older adults has been suggested to affect energy storage during shortening and lengthening cycles. This may also be the case for a more compliant muscle. However, it is unclear if this is an adaptation or a result of changes in muscle composition or structure (i.e. fiber type, collagen content, extracellular matrix).

Our results also indicate that there was a significant correlation between joint stiffness and SW velocity in the MG only in the younger adults ( $r^2=0.46$ ,  $p<0.001$ ); there was no significant correlation between joint stiffness and SW velocity of the TA in both groups. There was no correlation between SW velocity and muscle stiffness estimates from torque-angle measurements. This further suggests that changes in muscle stiffness may be muscle specific and that individual contributions of passive stiffness of muscles and other soft tissues to joint stiffness differ due to aging.

### CONCLUSIONS

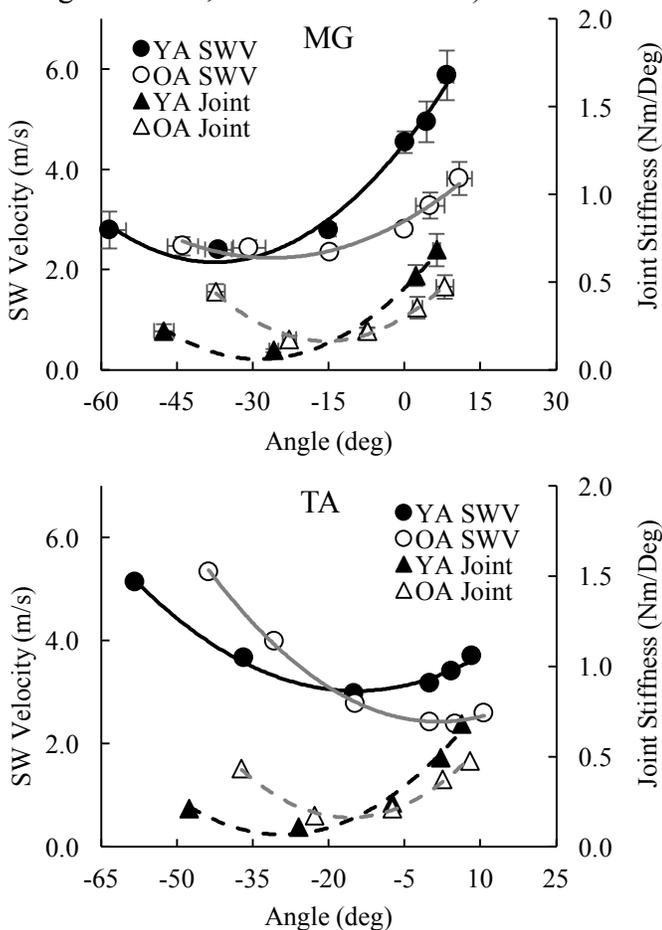

These findings indicate that muscle stiffness, as indicated by SW velocity, of the MG is greater in younger adults compared to older adults across the ankle range of motion with the largest difference when the muscle was at the longest. The lack of difference in SW velocity in the TA due to aging suggests that these changes may not be systemic such that all muscles are not affected equally. Tissues other than the primary plantarflexor and dorsiflexors of older adults may contribute differently to joint stiffness than in younger adults. This work has implications for refining and developing training programs focused on muscle properties to prevent mobility loss.

# DIFFERENCES IN HAMSTRING MUSCLE QUALITY BETWEEN HIGHLY ACTIVE AND SEDENTARY OLDER ADULTS

Erica Casto, Jocelyn Hafer, and Katherine Boyer

University of Massachusetts Amherst, Amherst, MA, USA  
email: [ecasto@kin.umass.edu](mailto:ecasto@kin.umass.edu)

## INTRODUCTION

Age-related decreases in muscular strength are associated with increased mortality and decreased quality of life (1,2). Knee extensor function is a well-documented determinant of mobility in older adults (1,2). The overall decline in strength with age can occur not only due to loss of muscle mass (sarcopenia), but also a decrease in muscle quality (strength/unit of muscle) (2,3). Few studies account for the potential interaction of age and physical activity on alterations in muscle function with age. While running has been shown to diminish the loss of muscle mass with age (4), the impact of running or high physical activity levels on muscle quality in the aged is not well characterized. A greater understanding of the impact of physical activity on muscle quality may be important as it could have implications for understanding and preventing the onset of age-related musculoskeletal disease.

Poor knee extensor muscle quality has been associated with increased prevalence of knee osteoarthritis in men and women (6). Little work has focused on the changes in hamstrings muscle quality and function with age or disease. Initial work suggests that strengthening of knee flexors may be equally as important as targeting the knee extensors in rehabilitation of knee osteoarthritis (8). A relationship between thigh (knee extensor and knee flexor) muscle strength and increased risk of knee osteoarthritis in women has also been reported (8). There is a need to better understand differences in hamstring function and quality with age as it may be a modifiable factor that influences age-related mobility declines and/or onset of degenerative conditions such as knee osteoarthritis.

The *purpose* of this study was to assess differences in hamstring muscle quality in vigorously active (runners) and sedentary older adults. We hypothesized that runners would have an increased muscle mass, accompanied by an increase in muscle quality.

## METHODS

14 healthy adults, 8 runners (running  $\geq 15$  miles/wk; 4M, 4F,  $62.9 \pm 3.8$  yrs, BMI  $23.2 \pm 2.1$ ) and 6 sedentary (exercising  $\leq 2$  times/wk; 2M, 4F,  $62.6 \pm 4.7$  yrs, BMI  $23.3 \pm 1.3$ ) were recruited to participate in this study. All participants had no history of lower extremity joint injury or surgery, chronic pain, neurological or musculoskeletal diseases. Participants completed two study visits. The first visit was to complete a health-screening questionnaire, assign activity monitors and undergo MRI for hamstring volume assessment. The second visit, 10-14 days later, was to quantify hamstring muscle function. Written informed consent was obtained from all participants as approved by the University of Massachusetts Amherst IRB.

Physical activity was quantitatively assessed using Actigraph GT3X triaxial accelerometers worn at the hip for 7-10 days. Muscle volume was assessed using a 1.5T Siemens MRI. The scan included the length of the thigh from fibular head to greater trochanter with T1 weighted scan sequence (6mm serial axial slice thickness). Hamstring area ( $\text{cm}^2$ ) was measured at 50% of the distance between the femoral condyles and femoral head using custom MATLAB code (Figure 1). Muscle tissue area was distinguished from other tissues based on pixel.

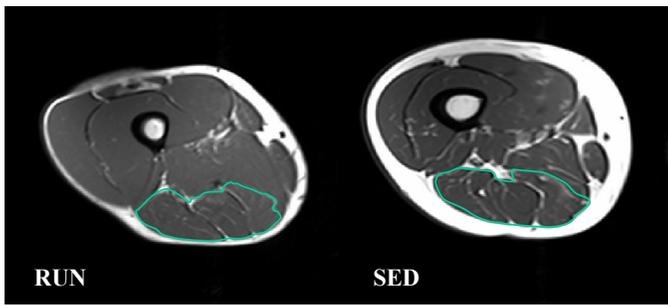

Figure 1: Hamstring muscle area (cm<sup>2</sup>) in RUN vs SED.

Hamstring function was assessed using a Humac Norm isokinetic dynamometer (Cybex, Medway, MA). The protocol included maximal knee flexion isometric contractions and concentric contractions at 90, 180, and 270°/sec throughout a 70° range of motion (20-90°). Two sets of 3 reps were completed at each contraction speed, with 30 seconds rest between sets, and 2 minutes rest between speeds. Peak torque was extracted from the isometric contractions and calculated at the time of peak power for concentric contractions. Muscle quality was then calculated as peak torque divided by the hamstring muscle area for each contraction speed.

A 2-way repeated measures ANOVA was used to compare muscle quality at each contraction speed in RUN vs SED (IBM SPSS software v24, Armonk, NY). An independent samples t-test was used to compare the total hamstring muscle area in the RUN vs. SED groups ( $\alpha=0.05$ ).

## RESULTS AND DISCUSSION

The total hamstring area was 25% greater for the RUN group as compared to the SED group ( $p=0.027$ ). However, despite the increased muscle mass, muscle quality in RUN (mean= 0.289) was lower than in SED (mean= 0.387) at each of the contraction speeds ( $p=0.057$ ), shown in Figure 2. The magnitude of the difference between groups was not different between contraction velocities.

Similar findings were reported for the differences in muscle volume and quality of the knee extensors in this population (9). Similar to the knee flexors, for the knee extensors there was also an inverse

relationship between muscle quality and muscle size. This suggests that although runners are able to mitigate loss of muscle mass with age, they may not maintain muscle quality within the hamstrings.

Figure 2: Muscle Quality: RUN vs SED,  $p=0.057$ .

## CONCLUSIONS

While running appears to be effective for limiting decreases in muscle mass, it may not be effective in maintaining overall muscle quality. Further investigation is needed to assess the mechanism for this unexpected impact of physical activity on muscle function in older adults.

# COGNITIVE AND NEUROPSYCHOLOGICAL DIFFERENCES BETWEEN ELDERLY POPULATIONS WITH GOOD AND POOR BALANCE AS DETERMINED BY THE FUNCTIONAL GAIT ASSESSMENT

<sup>1</sup> Kenneth Pechtl, <sup>1</sup> April J. Chambers, PhD, <sup>1</sup> J. Richard Jennings, PhD, <sup>1</sup> Mark S. Redfern, PhD

## INTRODUCTION

Understanding the cognitive changes that occur in the elderly population that put them at greater risk for poor balance and falls is necessary in order to implement appropriate interventions. Several studies have reported relationships between declining cognitive measures and increases in self-reported falls [1, 2, 3]. However, the falls measure is subject to participant bias that limits the validity of these associations.

Less work has been done on behavioral measures related to balance and falls. The functional gait assessment (FGA) is a measure of walking balance ability. The simple scale has 10 items, each on a 3-point scale with one overall sum. The measure has construct validity and is clinically appropriate for identifying different levels of walking balance [4].

The current study aims to define the neuropsychological and cognitive differences between elderly populations with good and poor balance, as differentiated by the functional gait assessment.

## METHODS

31 healthy elderly adults (18 females, 13 males) with no history of vestibular or neurological disorders were enrolled. Participants with a functional gait assessment score of less than 24 were placed in the Poor Balance group (“ELD-PB”,  $n = 11$ ), and participants with a score of 24 or greater were placed in the Good Balance group (“ELD-GB”,  $n = 20$ ). The ELD-GB group (10 females, 10 males) had an average age of  $75.5 \pm 3.9$ , while the ELD-PB group (8 females, 3 males) had an average age of  $76.9 \pm 4.3$ . Participants were

Caucasian except for 3 African Americans in the ELD-GB group and 2 in the ELD-PB group.

A set of tests ensured that participants were cognitively normal for age (Mini-Mental State Exam, MMSE) and free of major disabilities interfering with their performance (Duke comorbidity scale, Physical Performance Test, preferred gait speed, monofilament test of touch).

The participants then completed a battery of neuropsychological tests. These tests included CNS Vital Signs and the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS). Two tests often used in studies of aging were measured in addition: the digit symbol substitution test and the Trails test. Taken together, these tests assessed short and long term memory, verbal memory, visual memory, psychomotor speed, complex attention, cognitive flexibility, executive function, and simple attention. We also administered the Motor and Perceptual Inhibition Test (MAPIT), a performance measure of choice reaction time and ability to resist perceptual and motor interference, which was previously related to balance [5].

Statistical computations were conducted using Statistica software (Statsoft, Tulsa, OK). Independent samples t-tests were used to compare the cognitive measures between the ELD-GB and ELD-PB groups.

## RESULTS AND DISCUSSION

The ELD-GB and ELD-PB groups were similar in co-morbidities that would confound comparisons and were also similar in overall cognitive function as assessed by the MMSE. Specific

neuropsychological components were also largely similar between groups. This similarity did not extend to all domains, however.

The CNS Vital Signs finger tapping measure was significantly different between the ELD-GB (97.200) and ELD-PB (86.000) groups;  $t(29) = -2.38, p < .05$ , meaning that the ELD-GB group had better fine motor control and motor speed than the ELD-PB group. There is a rather direct relationship between motor control/regulation and balance during gait, which is of clear relevance to falls.

The CNS Vital Signs memory and visual memory domains were significantly different between the ELD-GB (112.150, 112.750) and ELD-PB (102.182, 100.182) groups:  $t(29) = -2.35, p < .05$ ;  $t(29) = -2.25, p < .05$ . Memory and particularly visual memory condition our expectations of the environment that we are moving through. Mild deficits in these domains might hinder anticipation of balance challenges.

The visuospatial constructional index of RBANS was also significantly different between the ELD-GB (100.400) and ELD-PB (88.545) groups;  $t(29) = -2.19, p < .05$ . Good balance relative to poor balance elderly performed better on tasks requiring processing and using visuospatial information.

Finally, susceptibility to perceptual interference as measured by MAPIT was significantly different between groups, where ELD-GB had lower scores (113.806) compared with ELD-PB (162.500);  $t(27) = -2.35, p < .05$ . Relative to the ELD-PB group, the ELD-GB group was slowed less by the perceptual displays, which at first glance would stimulate an incorrect response.

Elderly people with poor balance as determined by a FGA score less than 24 have worse balance because of deficits in basic motor speed combined with some visuospatial deficits appearing in memory, construction, and resistance to interference. This combination of deficits would seem to place them at risk due to slowed reactions to visually confusing challenges in their environment.

## CONCLUSIONS

Taken together, the results suggest a collection of mild deficits that together decrease stability during gait and likely increase risk for falls. When using the FGA as a criterion, a group of factors emerge that overlap only in part with those implicated in falls. Previous studies have found declines in inhibition for single fallers and recurrent fallers [1] as well as lower executive function and attention indices [3]. Similar to these studies, our study found perceptual inhibition differences, but attention and executive function remained similar between groups. This may be due to differences between the groupings using the FGA instead of the self-report falls measure, as well as a difference in the exact measures of attention and executive function.

This study was limited by a small sample size, so replication with larger samples to verify and enhance generalizability is required. Concurrent assessment of functional gait and incidence/prevalence of falls together with neuropsychological testing is needed in the future.

Possible interventions for the elderly population based on these findings include visuospatial training to reduce these deficits.

# THE RELATIONSHIPS BETWEEN PHYSICAL CAPACITY AND BIOMECHANICAL PLASTICITY IN OLD ADULTS DURING LEVEL AND INCLINE WALKING

<sup>1</sup> Daniel Kuhman, <sup>1</sup> John Willson, <sup>1</sup> J.C. Mizelle, and <sup>1</sup> Paul DeVita

<sup>1</sup> East Carolina University, Greenville, NC, USA

email: kuhmand15@students.ecu.edu, web: <https://www.ecu.edu/cs-hhp/exss/biomechlab.cfm>

## INTRODUCTION

Compared to young adults, old adults exhibit a distal-to-proximal redistribution of joint contributions to support phase mechanics of level walking. This age-associated biomechanical plasticity was quantified by DeVita & Hortobagyi (2000), who reported that hip and ankle joint contributions to total positive work were 16% and 73%, respectively for healthy, young adults and 44% and 51%, respectively for healthy, old adults [1]. Age-associated biomechanical plasticity has also been reported during incline walking. However, while young adults increased both hip and ankle joint torques during incline walking, old adults increased hip but not ankle joint torques [2] suggesting the magnitude of biomechanical plasticity may be task dependent.

Biomechanical plasticity is well established in healthy, old adults. However, not all adults age in a healthy and robust manner; old adults have a wide variation in physical capacity. Understanding the relationship between biomechanical plasticity and physical capacity in old adults may shed a brighter light on age-related declines in neuromuscular function and may lead to improved exercise and rehabilitation strategies for old adults. There is some indication that low- compared to high-capacity old adults exhibit increased magnitudes of biomechanical plasticity [3-5]. Based on these comparisons, we hypothesized that as physical capacity declines, age-associated biomechanical plasticity increases in magnitude. We also hypothesized that the magnitude of biomechanical plasticity would increase during incline compared to level walking; i.e. in the more difficult task.

The purpose of this study was to quantify the relationships between physical capacity and biomechanical plasticity in old adults during level and incline walking.

## METHODS

Data were collected on 32 old (22 female; age = 74.7  $\pm$  4.4 yr.) individuals. Written informed consent approved by the IRB of East Carolina University was obtained from all participants.

Physical capacity was measured using the Short-Form Health Survey Physical Component (SF-36 PC) score. Kinematic and GRF data for the pelvis and right leg were collected using motion capture (120 Hz, Qualisys AB) and force platforms (960 Hz, AMTI). Participants completed 5 successful trials of walking at self-selected speeds over level ground and up a 10° incline ramp.

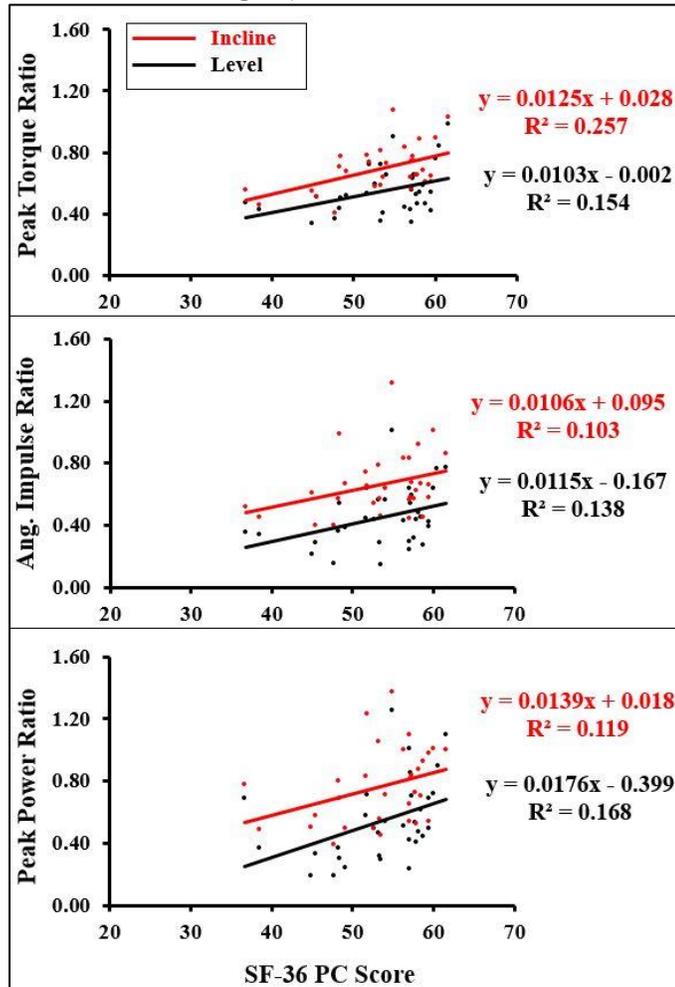

Kinematic and GRF data were filtered using second-order low pass Butterworth digital filters with cut-off frequencies of 6 & 45 Hz. Joint torques and powers were calculated using an inverse dynamics approach (Visual 3D, C-Motion). To define biomechanical plasticity, we created ratios of support phase hip extensor to ankle plantarflexor peak torques, angular impulses, peak positive powers, and positive work in both level and incline gaits.

Pearson product correlation coefficients were computed between SF-36 PC scores and the four biomechanical plasticity ratios during both walking gaits ( $p < 0.05$ ). In the cases where significant corresponding relationships existed during level and incline walking, 95% C.I.s of regression slopes were computed and compared to determine differences in the magnitude of plasticity in level and incline walking.

## RESULTS AND DISCUSSION

During level walking, significant positive relationships were observed between physical capacity and hip/ankle peak torque, angular impulse, peak positive power, and positive work ratios (Figure

1). During incline walking, significant positive relationships were observed between physical capacity and hip/ankle peak torque, angular impulse, and peak positive power ratios. No significant differences were observed in the magnitude of biomechanical plasticity between level and incline walking (i.e., the beta weights were statistically identical between gaits).

**Figure 1:** Correlations between SF-36 PC scores and biomechanical plasticity ratios and regression equations for each relationship.

**Table 1:** Pearson Correlation Coefficients (r) between biomechanical plasticity ratios and self-selected walking speeds during level and incline walking. Significant r-values are highlighted by **bold** font (p < 0.05).

Pearson Correlation Coefficients				
Plasticity Ratios	Self-Selected Level Walking Speed		Self-Selected Incline Walking Speed	
	r-value	r <sup>2</sup>	r-value	r <sup>2</sup>
Peak Torque	<b>0.518</b>	0.268	<b>0.453</b>	0.205
Angular Impulse	<b>0.353</b>	0.125	0.272	0.074
Peak Power	<b>0.352</b>	0.124	0.293	0.086
Work	0.087	0.008	0.007	0.000

Previous comparisons of high and low-capacity [3], strong and weak [4], and active and sedentary [5] old adults suggested an increased magnitude of biomechanical plasticity in low- compared to high-capacity old adults. Because of this, we hypothesized that an inverse relationship exists between physical capacity and age-associated biomechanical plasticity. Our results do not support this hypothesis. In fact, we report significant positive relationships between physical capacity and biomechanical plasticity during both level and incline walking. Positive relationships between plasticity ratios and self-selected walking speeds during level and incline walking suggest that biomechanical plasticity is an adaptation made by higher-capacity old adults to maintain better walking performance (Table 1). However, it should be noted that the magnitude of the relationships between biomechanical plasticity and physical capacity were moderate at best.

## CONCLUSION

Positive relationships exist between physical capacity and biomechanical plasticity during level and incline walking gait. Incline walking does not appear to increase the per unit magnitude of biomechanical plasticity per unit increase in physical capacity.

# AGING AND FALLS HISTORY EFFECTS ON THE MODULAR CONTROL OF WALKING WITH OPTICAL FLOW PERTURBATIONS

Jessica L. Allen<sup>1</sup>, Jessica D. Thompson<sup>2</sup>, and Jason R. Franz<sup>2</sup>

## INTRODUCTION

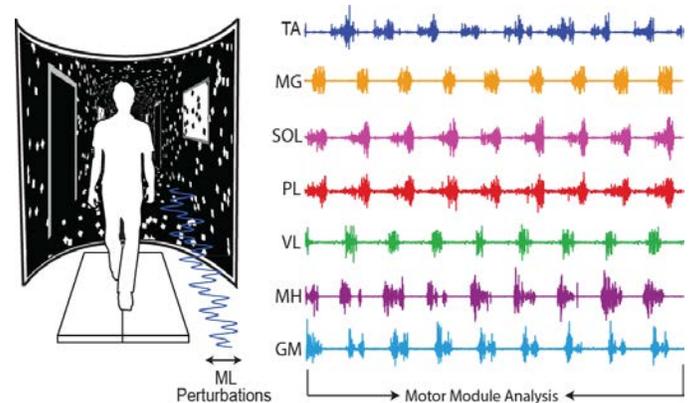

Older adults are at an exceptionally high risk of falls, and most falls occur during locomotor activities such as walking. We recently revealed that gait kinematics in older adults are more susceptible to optical flow perturbations than those in young adults [1], such that balance perturbations during walking could serve as an early identification for falls risk. Altered neuromuscular control of walking balance likely plays an important role in governing an individual's response to balance perturbations. Therefore, the purpose of this study was to investigate aging and falls history effects on the neuromuscular control of leg muscles during walking with and without optical flow perturbations of different amplitudes applied using a custom virtual environment. We used a motor module analysis [2,3] to quantify the complexity and consistency of neuromuscular control underlying walking balance and response to perturbations. We hypothesized that: (i) compared to young adults, aging and falls history would decrease module complexity and consistency, with (ii) larger effects in the presence of balance perturbations.

## METHODS

12 healthy young adults (mean±s.d., age: 24.8±4.8 years, 5M/6F), 11 healthy older adults (75.3±5.4 years, 5M/6F) and 11 older adults with a history of falls (78.0±7.6 years, 4M/7F) walked on an instrumented dual belt treadmill. We defined "falls history" as one or more falls within the last year. Young adults walked at 1.25 m/s while older adults walked at their preferred walking speed (Non-fallers: 1.19±0.20 m/s, Fallers: 1.03±0.22 m/s). Subjects walked while watching a speed-matched, virtual hallway (Fig. 1) with and without continuous mediolateral perturbations of optical flow, applied as the sum of three sinusoids (0.125, 0.250, 0.442 Hz).

In fully randomized order, subjects walked for two minutes with optical flow perturbations of amplitudes 0, 20, 35, and 50 cm.

We collected electromyographic (EMG) at 1000 Hz from seven right leg muscles (Fig. 1) during the second minute. EMG data were high-pass filtered (35 Hz) demeaned, rectified, and low-pass filtered (10 Hz) before being resampled at every 0.5% of the gait cycle. This resulted in an  $m \times t$  matrix for each perturbation condition, where  $m$  is the number of muscles and  $t$  is the time base (i.e.,  $t = \#$  of strides\*201). EMG from each muscle was normalized to the maximum observed across all conditions. We extracted motor modules from each EMG matrix using non-negative matrix factorization, which decomposes EMG such that  $EMG = W * C$  [2,3].  $W$  is an  $m \times n$  matrix and  $C$  an  $n \times t$  matrix of motor module recruitment coefficients, where  $n$  is the number of motor modules and was chosen for each condition such that the 95%

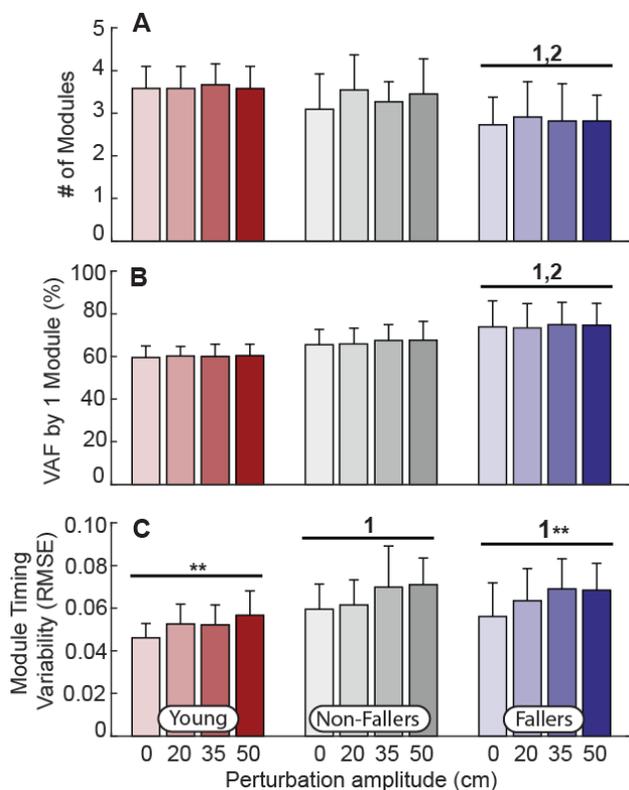

**Figure 1.** EMG was recorded from right leg tibialis anterior (TA), medial gastrocnemius (MG), soleus (SOL), peroneus longus (PL), vastus lateralis (VL), medial hamstring (MH), and gluteus medius (GM) while subjects walked in a custom virtual environment with/without mediolateral optical flow perturbations.

confidence interval of the variability accounted for was > 90% [2]. As a secondary analysis of module complexity we compared the variability accounted for by one motor module [3]. Finally, we examined step-to-step variability of motor module recruitment timing using the average RMSE of the module recruitment coefficients, C [2]. A two-way (group × perturbation) repeated measures ANOVA determined main effects and interactions between factors using alpha=0.05.

## RESULTS AND DISCUSSION

In partial support of our hypothesis, we found that falls history (but not age) was associated with reduced motor module complexity, and that age (but not falls history) was associated with increased step-to-step variability of module recruitment timing. In normal walking, older fallers averaged fewer motor modules ( $2.7 \pm 0.6$ ) than both young adults ( $3.6 \pm 0.5$ ;  $p < 0.001$ ) and older non-fallers ( $3.1 \pm 0.8$ ;  $p < 0.05$ ;

**Figure 2.** Results across all conditions for A: module number, B: variance accounted for by one module, and C: step-to-step module timing variability. Numerical values indicate significant pairwise comparisons between groups (1: vs. young, 2: vs. non-fallers;  $p < 0.05$ ). \*\* indicates significant effects of perturbation amplitude ( $p < 0.05$ ).

Fig. 2A). Similarly, the variance in leg muscle recruitment accounted for by one module was reduced in older fallers compared to young adults ( $p < 0.01$ ) and older non-fallers ( $p < 0.05$ ; Fig. 2B). The step-to-step variability of module recruitment timing in normal walking was on average 25% higher in older compared to younger adults regardless of falls history ( $p < 0.05$ ). This suggests that reduced neuromuscular complexity but not variability is associated with a risk of falling.

Further, we found that step-to-step variability of recruitment timing (and not module complexity) was altered by optical perturbations during walking regardless of age or falls history. Neither measure of module complexity was altered in the presence of optical flow perturbations, which is consistent with prior work suggesting that module complexity is preserved across a variety of walking conditions [4]. In contrast, step-to-step variability of module recruitment timing was increased in the presence of perturbations in both young adults ( $p = 0.02$ ) and older fallers ( $p < 0.01$ ).

## CONCLUSIONS

Here we provide compelling evidence implicating altered neuromuscular control as a mechanism for age-associated falls risk. Moreover, that module complexity was invariant even in the presence of perturbations suggests that the motor repertoire of older adult fallers is a constraint on their ability to appropriately respond to balance challenges during walking. Indeed, only the recruitment timing variability of their available motor modules increased in the presence of balance perturbations.

## INTRODUCTION

Beyond the visible hallmarks of aged gait, i.e., slowed walking speed, shorter steps, and increased cadence [1], aging also affects the neuromuscular control of gait and old compared with young adults typically walk with greater levels of agonist activation and particularly antagonist coactivation in the lower extremity muscles [2]. Disproportional levels of coactivation are associated with increased metabolic costs and reduced net force [3].

A form of resistance training known as power training incorporates exercises with moderate-to-high loads performed at maximal movement velocities during the concentric phase. It is well-established that power training in old adults results in increased maximal voluntary agonist activation, which contributes to training-induced gains in muscle strength and power [4]. The results on antagonist coactivation after power training are less consistent, as both increased and decreased coactivation were reported when measured during a maximal effort contraction on an isokinetic dynamometer [4]. It is unknown if power training-induced neuromuscular adaptations are also present during walking.

Therefore, for the first time, we examined the effects of 10-weeks of lower extremity power training on neuromuscular activation during walking in community-dwelling old adults. We hypothesized that power training produces correlated improvements in muscle power and gait velocity and increases in agonist activation or decreased antagonist coactivation.

## METHODS

Participants were community-dwelling old adults without mobility limitations who volunteered to participate in the Potsdam Gait Study (POGS). We included data from thirteen participants as a non-exercise control group (age  $69.7 \pm 5.0$  years, Body Mass Index  $25.1 \pm 3.2$  kg/m<sup>2</sup>), and data from twelve participants for the analysis of power training effects (age  $72.1 \pm 5.4$  years, Body Mass Index  $26.2 \pm 4.1$  kg/m<sup>2</sup>). Three participants from the power-training group first had completed the control period.

The power-training program consisted of 30 sessions whereby participants performed leg press, ankle press, knee extension, and knee flexion exercises at 40-60% of their three-repetition maximum (3-RM). Participants were instructed to move the weights rapidly and at high movement velocities during the concentric phase and training progression was based on biweekly measured 3-RM.

Testing was performed before and after the 10-week interventions. We affixed surface electromyographic (EMG) electrodes on five muscles of the right leg, i.e., vastus lateralis (VL), vastus medialis (VM), biceps femoris (BF), gastrocnemius medialis (GM), and soleus (SL).

Participants performed three maximal isometric knee flexor, knee extensor, and plantarflexor contractions while fixed in an isokinetic dynamometer. We recorded torque and EMG activity and took the trial with the highest torque for further analysis. We also recorded EMG activity at a sampling frequency of 1000 Hz during habitual, fast, and standardized walking speeds while participants walked over a 6.5 x 1.5-meter level walkway.

We used the Teager-Kaiser Energy Operator [5] to determine the onset and offset of the main EMG burst for each muscle. We bandpass-filtered the raw-EMG (20-450 Hz) and applied a root-mean-square (RMS) envelope using a 40-ms smoothing window. Next, we performed an amplitude analysis to determine the magnitude of agonist activation and antagonist coactivation. We averaged EMG data from GM and SL to characterize plantarflexor activation and we averaged EMG data from VL and VM to characterize knee extensor activation. We computed gait velocity from kinematic marker data.

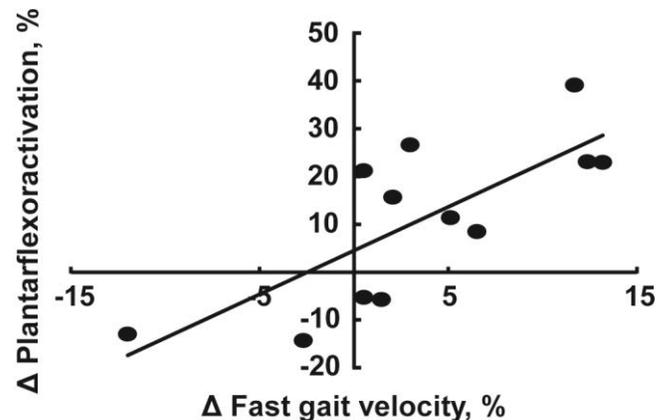

Variables were statistically analyzed using a paired t-test comparing pre-post values for power training and control due to the fact that subjects from the control group were included in the intervention group after completion of the control period and subsequent performance of power training. We used simple linear regression analysis to predict changes in isometric torque and gait velocity from changes in neuromuscular activation.

## RESULTS AND DISCUSSION

For all muscle groups, power training increased maximal isometric muscle strength (15-93%,  $p \leq 0.05$ ) and agonist activation (31-53%,  $p \leq 0.05$ ), while antagonist coactivation was unchanged ( $p > 0.05$ ). Changes in agonist activation correlated with changes in muscle strength ( $r = .58$ ,  $p = 0.049$ ), confirming previous findings [4] that mechanisms through which power training improved muscle strength involve increased agonist activation.

Power training non-significantly increased habitual (5%,  $p = .079$ ) and fast (4%,  $p = 0.059$ ) gait velocity. At all speeds, old adults walked with greater knee extensor activation during early stance post-training (16-21%,  $p \leq 0.05$ ). Knee extensor coactivation measured during the main knee flexor burst also increased (19-28%,  $p \leq 0.05$ ). These adaptations did not correlate with changes in habitual or fast gait velocity. We interpret these data to mean that power training increased knee extensor activation and coactivation during heel contact and early stance to stabilize the knee during the loading response.

Power training also increased plantarflexor activation during push-off at all speeds (11-28%,  $p \leq 0.05$ ). At fast speed, changes in plantarflexor activation correlated with changes in gait velocity ( $r = .760$ ,  $p = .004$ , Fig. 1). These data suggest that improved neuromuscular activation of the plantarflexors underlies in part the gains in fast gait velocity.

**Figure 1:** Association between power-training induced changes in fast gait velocity and changes in plantarflexor activation during push-off. The association is characterized by  $y = 1.83x + 4.5$ ,  $R^2 = 0.57$  ( $p = 0.004$ ).

## CONCLUSIONS

Power training-induced neuromuscular adaptations included an increase in agonist activation without reductions in antagonist coactivation. Power training may improve healthy old adults' walking performance by increasing neuromuscular activation of the extensor muscles.

## INTRODUCTION

An open question in motor control is how the brain selects the duration of a movement. We recently proposed a theory capable of explaining both the actions one prefers to take, as well as the speed of the movement that follows [1]. Each movement is assigned a utility consisting of the reward to be acquired minus the effort cost to acquire it, both discounted by time. Critically, the effort cost required to make the movement is represented objectively by its metabolic cost. Previous modeling efforts have assumed that effort costs in reaching scale quadratically with mass [2]. In contrast, empirical measurement of metabolic cost (i.e. objective effort cost) in locomotion suggests a linear scaling [3]. For reaching, the effect of mass on metabolics has not been measured. Here, we quantified metabolic cost of reaching as a function of mass, and then measured how preferred reach speed varied with mass. We asked if changes in speed were consistent with the theoretical predictions of a movement utility where effort of reaching depended on its metabolic cost.

## METHODS

Experiment 1: Metabolic cost of reaching with added mass. We measured the metabolic cost of reaching via expired gas analysis. Eight subjects made horizontal reaching movements while holding the handle of a robotic arm. We computed net metabolic power in four mass conditions: effective mass of robot+human arm of 2.5, 4.5, 6.5, and 10.4 kg. For each condition, subjects performed 5 minutes of reaching at six different movement durations, ranging from 0.4s to 1.3s. A single reach required moving 10cm from a starting circle to a target at the specified duration. Targets were oriented at 45°, 135°, 225°, and 315° in a pseudorandom order. We fit subject data to

determine the relationship between net metabolic power ( $\dot{e}$ ), effective mass of the arm ( $m$ ), reach distance ( $d$ ), and movement duration ( $T$ ) according to the equation:  $\dot{e} = a + bm^i d^j T^{-k}$  Eq. (1).

Experiment 2: Preferred reaching duration with added mass. Twelve additional subjects performed reaches with a similar target set-up but without duration requirements. Subjects were instructed to move at a comfortable speed, and they completed 200 trials in four mass conditions (effective masses of 2.5, 3.8, 4.7, and 6.1kg) in a randomized order. The effect of added mass on preferred movement speed was assessed using a linear mixed model.

## RESULTS

Experiment 1: The metabolic power curves for each mass condition are given in Fig. 1A, with  $i=0.7$  ( $p<10^{-9}$ ),  $b=15.5$  ( $p=0.02$ ),  $a=31.4$  ( $p<10^{-8}$ ),  $k=5$  ( $p<10^{-9}$ );  $j=1.1$  was fit in previous work [1];  $R^2=0.994$ . As expected, increasing mass increased the metabolic cost of reaching, and this effect was more pronounced for faster movements. Importantly, increased mass had a roughly linear effect on the metabolic cost of reaching, consistent with measures in locomotion. We quantified the effect of mass on endpoint variability for fixed movement durations. As expected, variability increased with shorter durations (Fig. 1B,  $p<0.001$ ), but variability did not change with mass ( $p=0.27$ ).

Experiment 2: Added mass increased movement duration (Fig. 2A;  $p<2e-16$ ), decreased peak velocity (Fig. 2B;  $p<2e-16$ ), and did not affect maximum excursion (Fig. 2C;  $p=0.09$ ). To determine if the movement slowing was in response to reduced accuracy with added mass, we turned to the Exp. 1 data (Fig. 1B). In the range of durations that people chose to reach (0.9-1.2sec), there was no discernable effect of mass on variability.

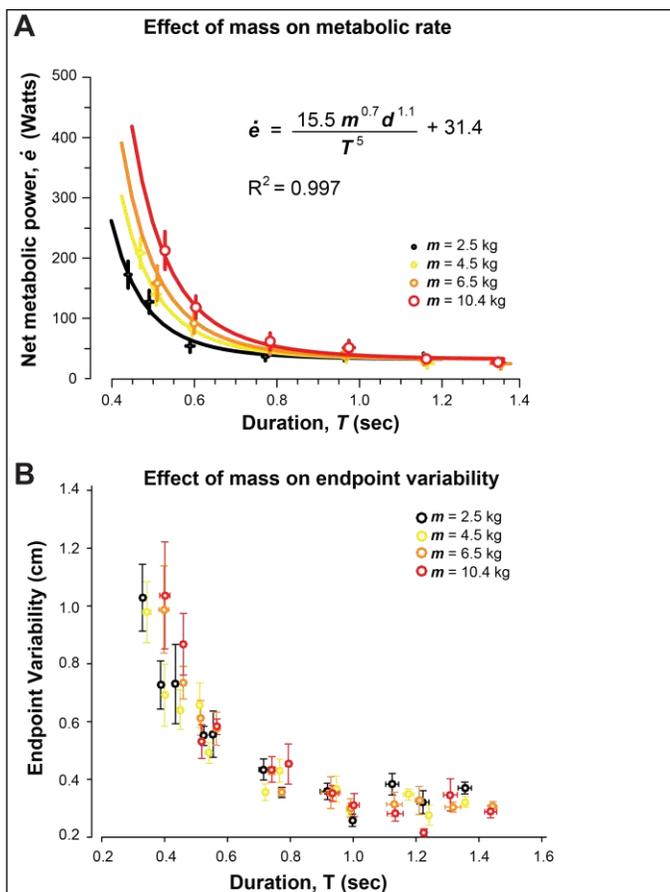

Figure 1. Experiment 1. A: Relationship between net metabolic power and movement duration. Subject data shown by open circles, with standard error. Model fits as curves, resulting in equation. B: Effect of mass on endpoint variability (std). Variability increases with shorter duration ( $p < 0.05$ ), but unaffected by mass ( $p = 0.27$ ).

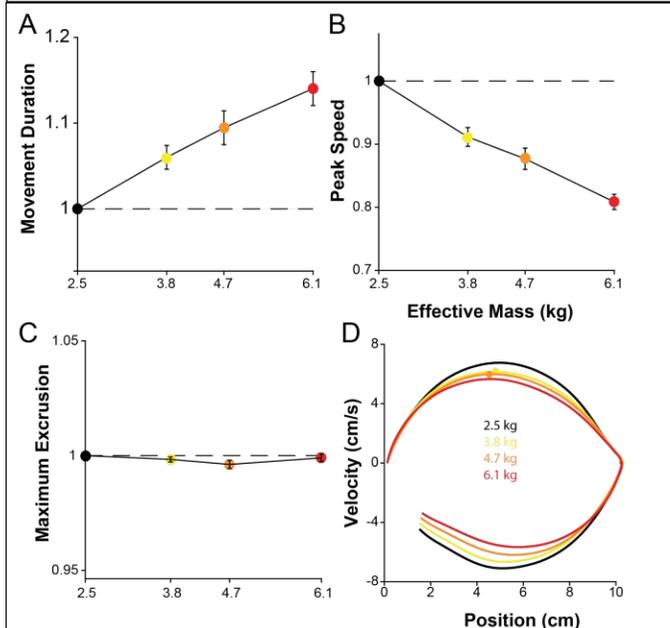

Figure 2. Experiment 2: Effect of mass on preferred duration. Movement duration (A) and Peak Speed (B) decreased with increasing mass at the hand. (C) Maximum Excursion shows no significant effect of mass. All metrics are normalized to the 0 added mass condition, which corresponds to an effective mass of 2.5 kg. (D) Velocity-Position profiles averaged over all subjects for each mass condition. Error bars represent 1 s.e.m..

**Model Predictions.** By integrating Eq. (1) over movement duration ( $T$ ) we have an estimate of effort. We write the utility of that movement as:  $J = (\alpha - aT - bm^i d^j T^{-k})(1 + \gamma T)^{-1}$  Eq. (2), where  $\alpha$  is reward, and  $\gamma$  is the temporal discount factor. To find the models predictions regarding the relationship between movement duration and mass, we set the derivative of Eq. (2) equal to zero and solve for  $T$ . The results are shown in Fig. 3 in both normalized and absolute units (the only free parameter is  $\alpha$ ,  $\gamma$  was set to 1). A model where effort increases linearly with mass ( $i=1$ ) also performs well. In contrast, quadratic scaling ( $i=2$ ) is inconsistent with the data and overestimates the effect of mass on preferred duration.

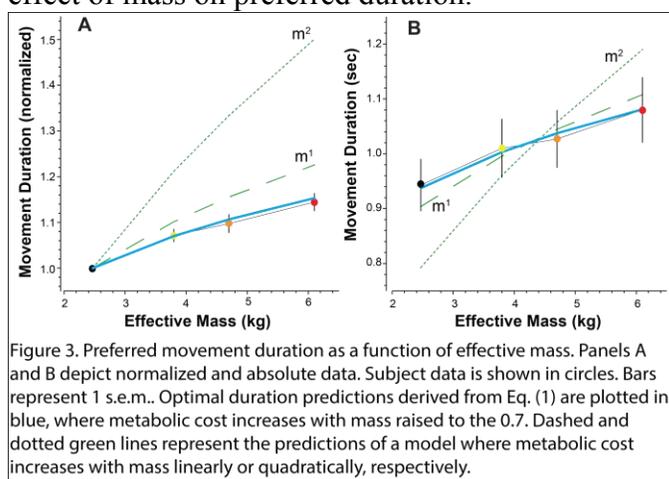

Figure 3. Preferred movement duration as a function of effective mass. Panels A and B depict normalized and absolute data. Subject data is shown in circles. Bars represent 1 s.e.m.. Optimal duration predictions derived from Eq. (1) are plotted in blue, where metabolic cost increases with mass raised to the 0.7. Dashed and dotted green lines represent the predictions of a model where metabolic cost increases with mass linearly or quadratically, respectively.

## CONCLUSIONS

In many models of motor control, effort scales quadratically with mass. Here, we measured metabolics of reaching and found that it increased approximately linearly with mass. Using a model of movement utility where effort was represented objectively as metabolic cost, we found that the speed with which people chose to reach increased at a rate that was consistent with a linear increase in effort as a function of mass.

# MECHANICS & ENERGETICS OF WALKING WITH A FLAT CENTER OF MASS TRAJECTORY

Russell T. Johnson and Brian R. Umberger

## INTRODUCTION

The sinusoidal pathway of the whole-body center of mass (COM) in the sagittal plane during walking has been a topic of study for many years. Early researchers argued that reducing the vertical displacement of the COM should lower the metabolic energy cost of walking [1]. However, recent experimental studies have shown that reducing COM excursion such that it follows a flat trajectory doubles the metabolic cost of transport (COT) [2,3]. These previous studies have shown that humans adopt a flexed limb posture in order to walk with a flat COM trajectory. This flexed posture may explain much of the greater COT, independent of COM motion [4].

One limitation of acute experimental studies is that subjects may not have optimized their gait to novel walking conditions, exaggerating the metabolic penalty. Musculoskeletal modeling and optimal control techniques present a unique way of exploring the influence of walking with a flat COM trajectory without the confounding influence of human adaptation. When viewed together with experimental studies, the modeling approach may provide additional insight on the role of COM motion in locomotor energetics. Thus, our purpose was to investigate the mechanics and energetics of walking with flat and normal COM trajectories using a musculoskeletal modeling approach.

## METHODS

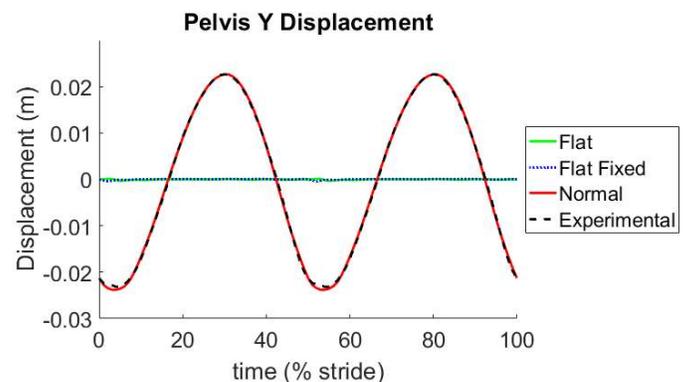

A two-dimensional, 12 degree-of-freedom, 48 muscle model [5] was used within the OpenSim software package. Optimal control simulations of walking (1.3 m/s) with flat and normal trajectories were generated using a direct collocation approach. A weighted multi-objective function was used to minimize the sum of cubed muscle activations plus the deviation from the desired pelvis segment

trajectory, which was used as a surrogate for COM motion as in experimental studies [2,3]. As the pelvis vertical displacement was the only variable that was tracked it allowed the other degrees of freedom, including pelvis segment height and hip, knee, and ankle joint angles, to vary freely within the optimization.

The three specific cases were a normal condition that matched experimental pelvis vertical displacement (Normal), a flat pelvis trajectory matched for final time with the Normal solution (Flat Fixed), and a flat pelvis trajectory where the final time was allowed to vary (Flat) (Fig. 1). The free final time solution allowed the optimization to change stride length and frequency, while the matched final time case had to maintain the stride length and frequency from the Normal condition. The results of the three optimizations were used to compare the COT using a muscle energetics model [6].

## RESULTS AND DISCUSSION

The model was able to produce the desired pelvis displacement trajectories for each of the three conditions (Fig. 1). The joint angles for the Normal condition, despite not being tracked, showed broad

**Fig. 1:** Pelvis vertical displacement. The Normal condition reproduced the experimental mean and Flat conditions kept the pelvis trajectory nearly flat.

agreement with experimental values, with the greatest deviation being relatively less ankle plantar flexion at push off (Fig. 2). The Flat Fixed condition necessarily had the same final time, stride length and frequency as the Normal condition (Table 1). The Flat condition reduced the stride time, resulting in a ~10% shorter stride length.

The Flat Fixed and Flat condition joint angles were similar to each other and represented a more flexed-limb posture around mid-stance than the Normal condition or experimental means (Fig. 2). However, the limb was considerably more extended in the Flat conditions than the postures chosen by humans walking with a flat COM trajectory [2,3]. Thus, the pelvis height was maintained at a relatively high position in these simulations, within a few cm of the mean vertical position of the Normal condition.

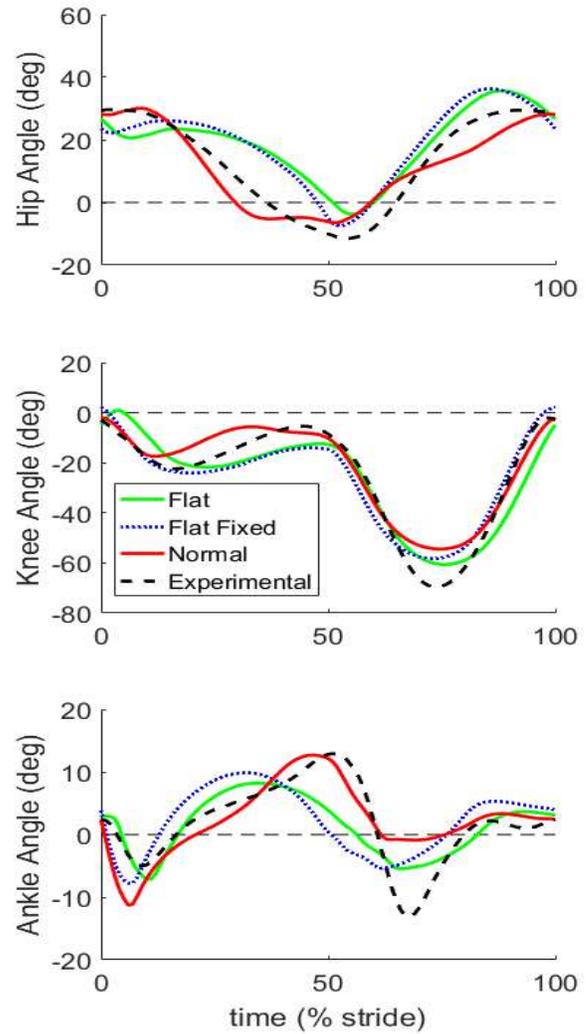

The net COT was 11-23% greater in the two Flat trajectory conditions than in the Normal condition (Table 1). This modest increase in COT is considerably less than the ~100% increase reported in experimental studies [2,3]. The model was able to produce a flat pelvis trajectory with a relatively upright posture, avoiding a large increase in energy demands. With feedback or a longer adaptation period, subjects might be able to learn to walk with a flat COM trajectory at relatively low cost by flexing the limbs less. It appears that maintaining a sinusoidal path of the COM in the sagittal plane is energetically beneficial, yet much of the increase in COT reported experimentally may be due to adopting a couched posture rather than the flat COM trajectory, *per se*.

**CONCLUSIONS**

Humans should be able to walk with a flat COM trajectory with only a modest increase in COT. This prediction should be tested experimentally.

**Table 1:** Output variables for the three conditions.

	Flat	Flat Fixed	Normal
Stride Time (s)	0.89	0.99	0.99
Stride Length (m)	1.16	1.28	1.28
Net COT (J/kg/m)	3.11	2.81	2.52

## INTRODUCTION

Humans have evolved the ability to walk very efficiently [1]. We choose to walk at approximately the speed which minimizes the cost of transport (COT) [e.g. 2], where COT is the metabolic energy expenditure per distance  $\left[\frac{\text{Joules}}{\text{kg}\cdot\text{meter}}\right]$ . The COT for walking on level ground at different speeds can be represented using the following equation form:

$$COT = \frac{b}{v} + mv, \quad (1)$$

Where  $v$  is the speed  $\left[\frac{\text{m}}{\text{sec}}\right]$ , and  $b$  and  $m$  are the equation's constants [2].

However, humans did not evolve to only walk on smooth, level ground, and therefore it is interesting to investigate how different walking surfaces might affect the relations between the energy expenditure and speed. For example, while walking on sand, the relation between COT and speed is linear [3], which means that an optimum COT speed does not exist.

This study investigated the relation between COT and speed for walking on natural outdoor rough terrain to test if there is an optimum speed and if people naturally choose to walk at that speed. Further, we compared our rough terrain results to smooth, level ground walking.

## METHODS

Subjects were 5 males, age 24-29, mass 65-85 kg, height 1.65-1.85 m who gave informed consent to participate. For the rough terrain, subjects walked on a trail 67 m long with small changes in elevation (+/- 1 m). The trail was strewn with rocks and boulders and was relatively straight. The control surface was a 44-meter straight, smooth flat tile floor. The gross energy expenditure rate, was measured with a Cosmed K4b<sup>2</sup> telemetric system.

Two experimental sessions were performed on the rough terrain trail and a third on the level floor. To

allow subjects to adapt to walking on the trail, subjects performed two similar sessions of walking on rough terrain. Here, we report only the results of the second session.

Prior to the first trail session, the subjects were shown the trail and they practiced wearing the metabolic measurement system. The subjects walked out and back on the trail at various speeds. Then, the subjects were asked to walk for 7-9 minutes at their preferred speed. From the time for completion of the trail, average speed was calculated (i.e. the preferred speed). Next, the subjects performed 6-8 trials at different speeds relative to their preferred speed (approximately 50, 75, 100, 125% and 150%), with 5-min rest between trials. Some of the speeds were performed more than once. The order of speeds was randomized for each subject, to avoid adaptation or fatigue effects on metabolic rate. Measurement of the metabolic rate began only after at least 3 min of walking, to capture steady-state energy expenditure. Further, to eliminate the effect of local terrain variation, metabolic rate was averaged over full laps. Only trials with RER (respiratory exchange ratio) < 1 were analyzed. The same procedures were repeated for the floor trials.

*Analysis* We calculated the COT  $\left[\frac{\text{Joules}}{\text{kg}\cdot\text{m}}\right]$  by dividing metabolic rate by the speed and the subject's body mass, we tested several variations of equation (1) and found that the best fit for each of the two-experimental condition was in the form of:

$$COT = a + \frac{b}{v} + mv, \quad (2)$$

To test whether there was a difference in COT between the two surfaces, we used the Chow test using the two equation:

$$COT_{\text{rough terrain}} = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \varepsilon, \quad (3)$$

$$COT_{\text{floor}} = \alpha_0 + \alpha_1 x_1 + \alpha_2 x_2 + \varepsilon \quad (4)$$

where  $x_1$  is speed<sup>-1</sup> and  $x_2$  is the speed and we fitted 3 parameters for each equation based on 30 valid

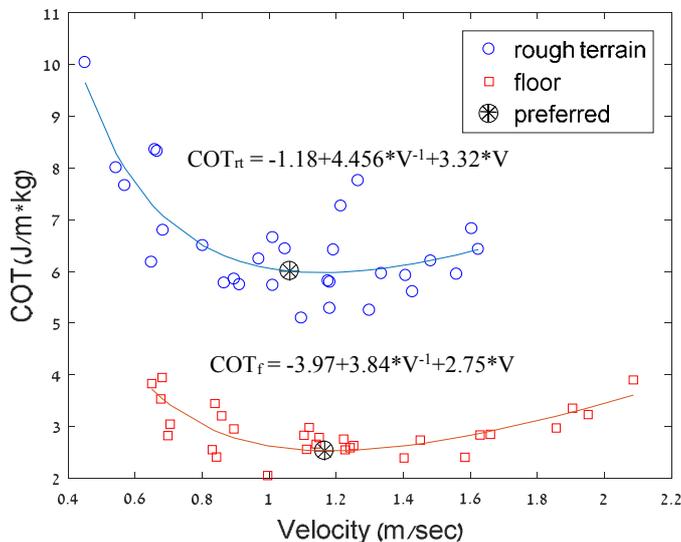

observations from the trials on the rough terrain surface and 29 observations from the floor surface.

$$F_{statistic} = \frac{(SSE_a - (SSE_{rt} + SSE_f))/6}{(SSE_{rt} + SSE_f)/(30 + 29 - 2 * 3)}, \quad (5)$$

where  $SSE_a$  is the SSE (sum square of error) calculated on all the observations,  $SSE_{rt}$  is the SSE of the observations from the rough terrain experiments, and  $SSE_f$  is the SSE of the observations from the experiments on the floor surface.

## RESULTS AND DISCUSSION

The COT as a function of speed was 200%-230% greater for the rough terrain surface compared to the smooth, level floor (Table 1) at equivalent relative speeds (Table 1). Further, there was a significant difference in the shape of the COT-speed relations between the two surfaces (Figure 1). While the COT functions were different, both functions have very similar minimum points (1.16 m/sec on rough terrain and 1.18 m/sec on the floor). Further, the subjects' preferred speeds (1.06 m/sec on the rough terrain and 1.17 m/sec on the floor) were very close to the energetic optima (Figure 1).

**Figure 1:** COT as a function of velocity. The trend lines were estimated using least squared error minimization.

**Table 1:** Average COT (J/kg•m) for different normalized speed bins and comparing rough terrain to floor.

Normalized speed	50%	75%	Preferred	125%	150%
Average COT rough terrain	7.97(±1.38)*	6.96(±1.15)	5.76(±0.52)	6.20(±0.59)	6.63(±0.63)
Average COT floor	3.44(±0.44)	2.91(±0.39)	2.52(±0.24)	2.65(±0.20)	3.36(±0.34)
Difference (percentage)	231.9%	238.8%	228.2%	234.4%	197.0%

\* Average (±std)

## CONCLUSIONS

The aim of this study was to investigate human walking on rough terrain. When walking on rough terrain, the COT was more than 200% greater than for walking on a smooth floor surface. The preferred walking speed was slower on rough terrain. Interestingly, even on challenging terrain, with considerations such as foot placement, stability, and slipping, there was a speed that minimized the COT and the subjects' preferred speed corresponded to the optimum speed. These findings strengthen the notion that humans sense and prefer speeds that minimize the COT.

*Future work:* Future, experiments should examine different trails, with different terrain roughness. In addition, future research that examines the kinetics and kinematics of the locomotion might explain why the COT is different for walking on different surfaces.

## INTRODUCTION

The relationship between the gross energy expended per unit distance traveled (i.e. metabolic cost) and the speed of progression in human walking typically appears U-shaped. In addition, the speed that incurs the lowest metabolic cost is often at or near the individual's preferred walking speed, with faster and slower speeds incurring exponentially greater costs. This result was first reported by Ralston [1] and has been frequently replicated. However, it has not been fully explained why the energy-speed relationship exhibits its characteristic U-shape.

An obvious contributor to the U-shaped curve at slow speeds is the energy cost of basal metabolism, which is an inverse function of walking speed. Thus, basal metabolic cost progressively decreases with increasing speed, suggesting the rise in gross metabolic cost at faster speeds results primarily from muscle energetics. Walking simulations at a range of speeds indicate the iliopsoas and glutei muscle groups are unique compared to other major muscle groups in that they are active primarily during energetically-costly concentric contractions and have little opportunity to store and return elastic strain energy during the stride [2]. The metabolic cost of using iliopsoas and glutei may therefore be expected to increase more dramatically with increasing walking speed than other muscles that can take advantage of energy savings through lengthening contractions and elastic energy return.

Therefore, we hypothesized that the shape of the gross energy-speed curve would be determined primarily by the cost (energy per unit distance) of basal metabolism at speeds slower than preferred, and by the cost of iliopsoas and glutei muscles at speeds faster than preferred.

## METHODS

Optimal control simulations of walking were performed using a 2D musculoskeletal model with 26 Hill muscle models (Fig. 1) [3]. An implicit direct collocation method was used to find the states and controls of the model that minimized the sum of a tracking error plus the gross metabolic cost [3], at five speeds from 0.72-1.67 m/s.

The tracking targets were joint angles and ground reaction forces from 10 healthy young male military service members [4]. Basal metabolic rate was assumed to be 1.0 W/kg. Gross metabolic cost was the sum of the basal and muscle metabolic rates, divided by speed and body mass.

The contribution of each muscle (and of the basal metabolic rate) to the shape of the gross energy-speed curve was determined by calculating the muscle's individual metabolic cost at each speed, then subtracting the cost of the same muscle in the 1.20 m/s simulation, which had the lowest gross metabolic cost.

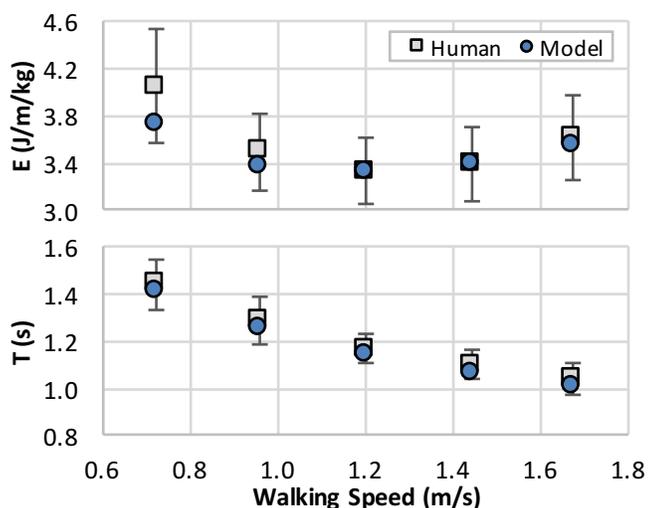

## RESULTS AND DISCUSSION

The model's metabolic cost and stride duration were within one standard deviation of the human mean at all five speeds, with a U-shaped energy-speed curve (Fig. 2). The model's joint angles and ground reaction forces deviated from the human means by 0.9 standard deviations on average.

No individual muscle had a U-shaped energy-speed curve. Basal metabolism and the energy cost of

**Figure 1:** Model

**Figure 2:** Metabolic costs (E) and stride durations (T) at each speed for the model and human data [4].

vasti and hamstrings increased the gross cost at slow speeds, but their contributions were minimal beyond the optimal speed, where the energy cost of iliopsoas and glutei made the greatest contributions (Fig. 3). The other 18 muscles combined made a contribution similar to the iliopsoas (Fig.3).

## CONCLUSIONS

The shape of the gross energy-speed curve in walking is due primarily to basal metabolic rate at slower speeds and to the uniaxial hip muscles at faster speeds. The effect of speed on these muscles is likely due to their architecture (long fibers, short tendon), limiting storage and return of elastic tendon energy, and the fact that they are primarily

used to perform energetically costly shortening contractions. Muscles with similar architecture (e.g. vasti) are activated during less costly lengthening contractions, and other muscles activated during shortening tend to have relatively short fibers and long tendons to take better advantage of tendon elastic energy storage and return (e.g. soleus).

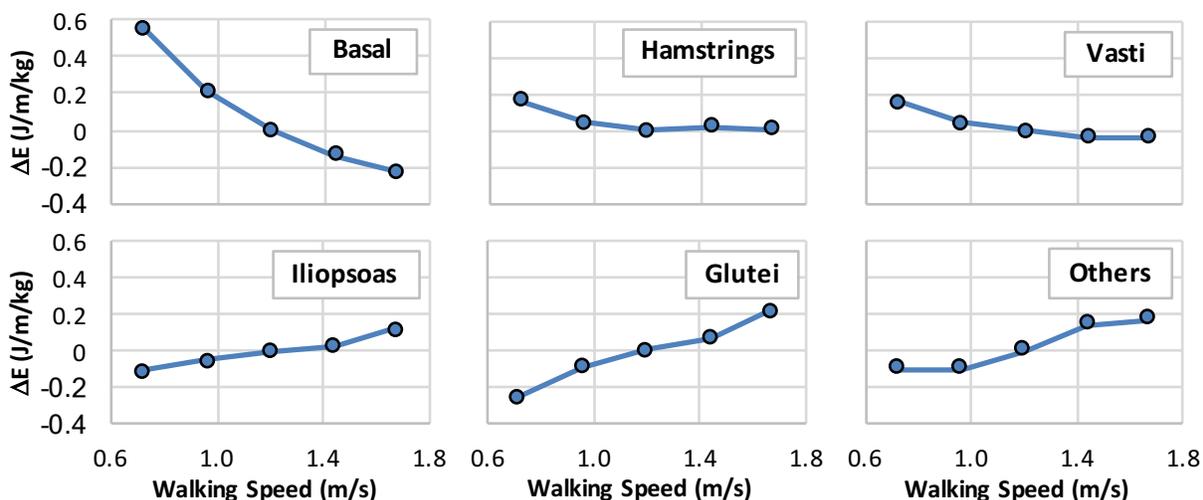

The metabolic costs of individual muscles were not minimized near a common speed (Fig. 3), similar to EMG data from [5], and no muscle had a U-shaped energy-speed curve. Thus, perhaps muscle activity is coordinated to minimize the effect of speed on gross metabolic cost, such that the average cost over the range of typical walking speeds is minimized.

The translational potential of the present results is that individuals who struggle to walk comfortably at moderate speeds or faster may be limited by their uniaxial hip muscles, which are not targeted in strength training as often as other major groups like the quadriceps, hamstrings, and plantarflexors.

# A PASSIVE HIP EXOSKELETON FOR REDUCING METABOLIC COST OF WALKING: A SIMULATION STUDY

Mohammadhossein Saadatzi and Ozkan Celik

Department of Mechanical Engineering, Colorado School of Mines, Golden, CO, USA  
email: msaadatz@mymail.mines.edu, web: brl.mines.edu

## INTRODUCTION

Wearable robots are recently being explored to make walking more efficient, through replacing part of metabolic energy requirement with power provided by exoskeletons. It is shown by Quinlivan et al. [1] that an active exoskeleton with an offboard actuation and power supply system has the capability of reducing metabolic cost of walking up to 23%. However, the weight of such a system that needs to be carried by the wearer in a completely wearable application is a real barrier to net metabolic energy savings during walking. On the other hand, it is shown by Collins et al. [2] that the metabolic cost of human walking can be reduced about 7.5% using an unpowered, clutch-and-spring ankle exoskeleton. This exoskeleton works based on the principle that clutch and spring sustain force passively, unlike muscles and tendons.

In this study, based on the same principle, we have evaluated the feasibility of using a passive hip exoskeleton to reduce the metabolic cost of walking within a predictive simulation framework. Simulations suggest that the proposed hip exoskeleton can reduce the metabolic cost of walking by 10.3% through replacing the power of Iliopsoas muscle group during walking.

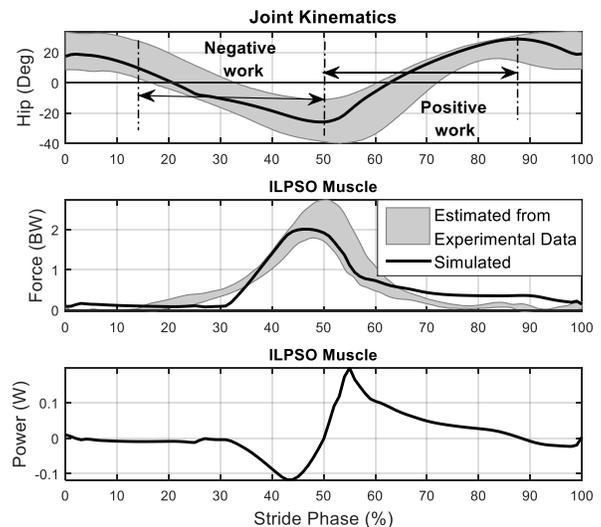

## METHODS

In this work, we are using a predictive simulation framework which is created using OpenSim API in C++. In this framework, bipedal walking is generated through optimization of muscle actuation profiles for a musculoskeletal model with 9 sagittal degrees of freedom and 18 muscles.

The actuation profiles for the muscles are determined by minimizing a cost function which

consists of several terms, including target velocity error, metabolic expenditure of muscles, and excessive alternating motion of the upper body. Ten parameters define an actuation profile for each muscle during a gait cycle (90 parameters for all muscles).

Figure 1 shows the results of our predictive simulation framework, and human experimental data (which is taken from [3]) for walking at speed 1.5 m/s. In this figure, the top panel depicts the kinematic trajectory of hip during a stride cycle, the middle panel indicates the Iliopsoas muscle force, and the bottom panel shows Iliopsoas muscle power. According to the depicted experimental data, in the beginning of the gait cycle (from about 15-50% of the gait stride), the Iliopsoas performs negative work (it applies flexion torque while the hip joint is extending). Hence, a torsional spring during this first half of the stride can replace the

**Figure 1:** Hip angle and Iliopsoas muscle force and power during a gait stride. Experimental data are represented by the shaded region ( $\pm 1$  SD). The solid line represents our predictive simulation results.

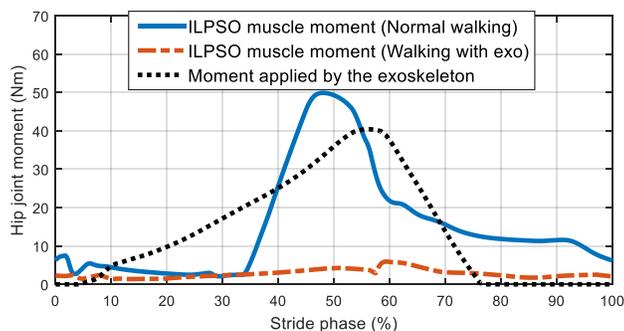

negative work done by the Iliopsoas. Also, the energy stored in the spring during the first half of the stride can be used during the rest of the stride to fulfill the positive work normally done by Iliopsoas.

We used our framework to determine the optimal spring parameters around the hip joint to minimize the energetics of walking. Two spring parameters are considered in our optimizations: the optimal stiffness and the equilibrium (free) angle of the torsional spring. The framework optimizes the muscle actuation profiles (90 parameters) and the two exoskeleton parameters simultaneously.

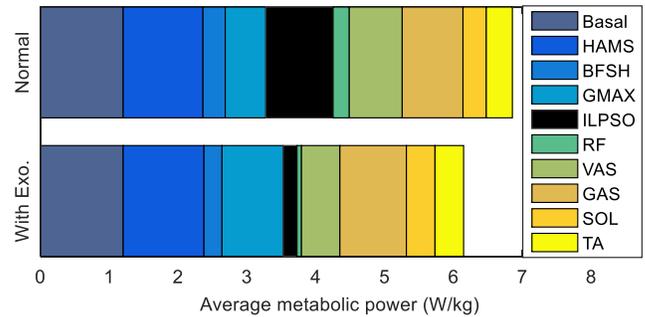

## RESULTS AND DISCUSSION

Based on our framework, an optimal spring (having stiffness of 0.99 (Nm/deg) and equilibrium angle of 10.04 (deg) flexion) is predicted to decrease the metabolic cost of walking by 10.3%. Figure 2 shows the moment generated by Iliopsoas muscle for a stride cycle, during normal gait and during gait with the optimized passive hip exoskeleton. It also shows the moment generated by the proposed exoskeleton if it is worn during walking. It is clear from this figure that the hip exoskeleton has replaced majority of the work done by the Iliopsoas muscle.

Figure 3 shows the metabolic expenditure of walking during normal gait and during gait with the hip exoskeleton. The muscle energetics model proposed by Umberger et al. [4] has been used to compute the metabolic cost of walking (OpenSim API probe class has been used). We note that the

**Figure 2:** Hip joint moment by the Iliopsoas muscle during gait with and without exoskeleton, and the moment generated by the exoskeleton during gait with exoskeleton.

**Figure 3:** Metabolic cost of walking during gait with and without the exoskeleton.

computed metabolic cost of walking is overestimated for either case [4], due to the musculoskeletal parameters and simplifications contained in our model. The hip exoskeleton has changed the metabolic energy expenditure for the muscles, and mainly affected the Iliopsoas. The change in energy expenditure of other muscles originates from the coupled structure of the human musculoskeletal system and multi-articular muscles, which was also noted by Uchida et al. in [5].

## CONCLUSIONS

Our simulation results suggest that it would be feasible to reduce metabolic cost of walking using a passive hip exoskeleton. Verification and tuning of the exoskeleton design through data collection from human subjects constitute our next step.

While current device design efforts have utilized repeated human subjects testing when device parameter values are being explored [6], a predictive simulation framework can be used to explore the device parameter space and to determine the most promising design solutions/parameter values that can be used to inform the human subject experiment design.

## INTRODUCTION

Passive-elastic lower-limb exoskeletons aim to reduce metabolic costs by taking advantage of elastic springs that both provide assistive passive torque and work. While there have been approaches to store and return energy passively across the entire limb [1], the majority of passive-elastic exoskeletons have drawn inspiration from the spring-like mechanics of the human triceps surae. These devices are typically designed with an external spring that parallels the Achilles tendon that stores and returns energy during the stance-phase of walking or hopping.

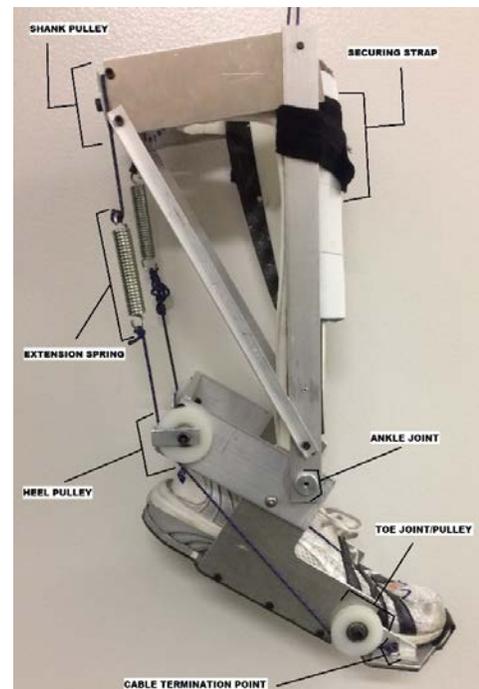

Emulating the elastic role of the human triceps surae is proving a successful means by which to augment human walking. Indeed, the metabolic energy saving of one such lightweight passive-elastic ankle exoskeleton has recently been shown to lower the metabolic cost of walking below that of normal, instrumented, walking [2]. Here we propose that further advances in passive-elastic assistive exoskeletons may be achieved by drawing inspiration from non-human species that exemplify elastic gait mechanics. Unlike humans that move in a plantigrade posture, the majority of cursorial species walk and run in a digitigrade posture (toe running). This mode of locomotion facilitates elastic energy storage and return in multi-joint muscle-tendon units that cross both the ankle and the metatarsophalangeal (MP) joint. For example, the ostrich has been shown to produce nearly fifty percent of the positive mechanical work of the stance phase of running through elastic recoil at the tarso-metatarsophalangeal joint [3]. This feature of ostrich running is thought to be the main

explanation for how they run with half of the metabolic energy compared to humans [3].

The purpose of the present study was to design and test a biologically-inspired human exoskeleton that emulates the storage and return of elastic energy at both the ankle and MP joints typical of the gait mechanics of efficient non-human cursorial species.

## METHODS

### Exoskeleton Design:

**Figure 1:** Passive-elastic ankle-MP exoskeleton

We designed a passive-elastic exoskeleton (EXO) that was based on a two-joint (ankle and MP)

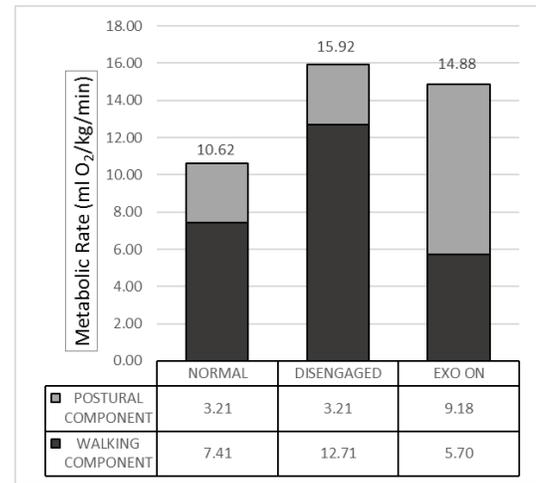

passive spring design. The EXO consisted of three segments fabricated out of carbon fiber and aluminum: (1) a shank frame; (2) a rear-foot frame mounted directly to a lightweight running shoe that articulated with the shank frame; and (3) a fore-foot plate that was mounted to the sole of the running flat under the toe box (Fig. 1).

The proximal section of the spring cord (Paracord) was aligned in parallel with the triceps surae muscles and ran to a pulley situated on the rear-foot frame behind the ankle. The distal section of the spring continued to a second pulley mounted on the rear-foot frame near the MP joint and terminated on the fore-foot plate. The spring cord looped between the left and right side of the EXO across two pulleys mounted at the top of the shank frame. Two parallel linear steel springs (7 kN/m each) were positioned in the spring cord line behind the calf. This design provided a simultaneous passive-elastic joint moment at the Ankle and MP joints and was capable of transferring energy between the joints.

Metabolic Testing: Pilot experiments measured rates of oxygen consumption (Vista VO2 Lab, Ventura California) in multiple walking trials (1.25 m/s) under three conditions; (1) a control walking condition without the EXO; (2) walking with the EXO but without the passive elastic component engaged; and (3) walking with the EXO fully functional. Standing trials, both under normal and EXO conditions, were collected to determine the net cost of walking (gross metabolic rate minus standing rate). A training period of 20 minutes was used to allow for familiarization with walking in the device both with the spring engaged and when the spring was disengaged.

## RESULTS AND DISCUSSION

The metabolic rates (ml O<sub>2</sub>/kg/min) for walking and standing in the control (no EXO) condition, in the EXO with the spring disengaged, and in the EXO with the spring engaged are presented in Fig. 2

**Figure 2:** The gross oxygen cost measured during walking is represented by the sum of the black and grey bars (standing postural cost). The black bars represent the net oxygen cost of walking.

The gross oxygen cost of walking with the EXO was substantially elevated over the control condition, and is likely explained by the substantial mass of the EXO. Nevertheless, the gross cost of walking in the EXO with the spring engaged was reduced by 6.5%, indicating that the two-joint passive-elastic spring mechanism can reduce walking cost. The net oxygen cost of walking was, surprisingly, 23% lower than the control condition. This value is impressive, but must be viewed cautiously since this arises due to the high cost of standing in the EXO. It is unclear if the same postural cost is present during gait. In summary, pilot data indicate that a biologically-inspired ankle-MP EXO may provide a novel approach for reducing the metabolic cost of human walking.

## INTRODUCTION

Osteoarthritis is the most prevalent cause of mobility dependency and disability in the United States and its prevalence is expected to increase over the coming decades. Its etiology and progression involve complex interactions among biomechanical and physiological factors and any cure currently remains elusive. Consequently, OA is an important research focus in both the ASB and the Osteoarthritis Research Society International (OARSI). We now combine researchers from both Societies to identify current practice, experiment, and theory in the scientific investigation and medical treatment of OA. Additionally, our goal is to stimulate increased collaboration between members of ASB and OARSI and between the Societies themselves.

The symposium will follow this schedule:

Introduction – Paul DeVita – 5 mins

Movement Analysis and Gait Retraining – Cara Lewis – 15 mins

Knee Modeling & Cartilage Conditioning – Ross Miller – 15 mins

Overview of OARSI – Tim Griffin - 5 mins

Cartilage Mechanical Environment – Lou DeFrate – 15 mins

Inflammation, Oxidation & Mechanobiology of the knee – Tim Griffin – 15 mins

Discussion – 15 mins

## MOVEMENT ANALYSIS & GAIT RETRAINING – Cara L. Lewis

Evaluating movement kinematics through a visual assessment is an essential part of physical therapy practice. This qualitative assessment of movement, however, does not provide easily quantifiable metrics and is often practitioner-specific. Movement analysis within a three-dimensional motion capture laboratory enhanced with force platform capacity provides a precise quantification of movement as well as the ability to analyze joint forces, moments and powers. These data further combined with electromyography data provide an accurate and sophisticated description of a patient's movement capacity and his or her kinesiological movement solution to the task demands. This added information enables the investigation of the mechanism of injury and potentially successful rehabilitation protocols.

From a clinical standpoint, pain is often used to indicate if the current movement pattern is adaptive or maladaptive. For example, if gait biomechanical changes reduce pain, then those changes are assumed to be favorable and the previous pattern assumed to be detrimental. From a biomechanical standpoint, however, we can investigate why and how those changes may have reduced the pain. This important step allows the physical therapist to not only quantify the alterations for a single individual or group of individuals, but also extrapolate to other groups who may similarly benefit. Thus the combination of the clinical perspective with the biomechanical tools facilitates the development of movement-based physical therapy interventions supported by an understanding of the underlying biomechanical mechanisms.

## **BIOMECHANICAL KNEE MODELING & CARTILAGE CONDITIONING – Ross Miller**

Modeling the loads on the knee during activities of daily living is a growing topic of interest in clinical biomechanics, often motivated by the assumption that relatively high loads prompt the development of knee osteoarthritis under the “wear-and-tear” paradigm. Common approaches include static optimization, reduction models, EMG-driven models, and finite element models. Knee osteoarthritis is notable for the large number of special populations with a relatively high prevalence of the disease, including older adults, obese adults, African Americans, women, individuals with contralateral limb loss, and individuals with prior traumatic knee injuries. This presentation will compare and contrast joint loading in these seemingly disparate populations and will ask how (or if) common features of joint loads may predispose them all to the same chronic disease. The author’s central hypothesis is that if these populations are linked by a primarily-biomechanical factor in their risk for knee osteoarthritis, that factor is likely the conditioning of their cartilage earlier in life affecting their cartilage metabolism and sensitivity to “excessive” or “unusual” joint loads later in life. Thus, predicting the risk for developing OA requires data and models beyond the current loading of the joint.

## **DIVING INTO DIARTHRODIAL JOINTS: IDENTIFYING CARTILAGE MECHANICAL ENVIRONMENT – Lou DeFrate**

Mechanical loading plays an important role in maintaining cartilage health. Altered mechanical loading (potentially due to factors such as joint injury, obesity, and mal-alignment) may contribute to the development of osteoarthritis. However, there are currently limited tools available to quantify the local in vivo mechanical environment of cartilage in humans. While measures of joint alignment on x-ray and gait analysis techniques using markers attached to the skin can provide insights into the amount of force distributed between medial and lateral compartments, it may be difficult to predict the local cartilage tissue response based on these measurements. We now explore how risk factors for

osteoarthritis such as joint injury and obesity influence the local mechanical environment of cartilage during activities of daily living using novel techniques which incorporate MR imaging, biplanar radiography, and 3D modeling tools. Additionally, we will demonstrate the use of imaging biomarkers quantifying changes in cartilage thickness and composition. Together, these measurements can provide new insights into the changes associated with the initiation and progression of OA. Understanding these changes is essential to developing new interventions aimed at the prevention of osteoarthritis.

## **INFLAMMATION, OXIDATION, AND THE MECHANOBIOLOGY OF A RESILIENT JOINT – Tim Griffin**

A central characteristic of OA is the imbalance in the synthesis and degradation of articular cartilage, resulting in the net loss of tissue. This imbalance is attributed in large part to two processes that activate cellular catabolic pathways and impair cell function: inflammation and oxidation. Yet these processes are themselves normally maintained in a balance, for example, by pro- and anti-inflammatory cytokines or endogenous pro-oxidant molecules and anti-oxidant enzymes. Understanding how different types of biomechanical stress sway the balance of joint tissue inflammation and oxidation can provide a more comprehensive understanding of the beneficial and detrimental aspects of biomechanical factors in altering OA risk.

We examined this question in two joint tissues--the infrapatellar fat pad (IFP) and articular cartilage. The IFP is a source of pro-inflammatory cytokines in end-stage OA knees, but it is not known if it is a source of inflammation early in the disease process. We found that the IFP becomes fibrotic without increased inflammation prior to the development of knee OA in obese mice. We hypothesized that the increase in IFP fibrosis was the result of increased joint loading. We tested this hypothesis in non-obese mice following voluntary wheel running. IFP fibrosis and inflammation increased after 3 days of running but resolved by 14 days, indicating that increased loading induces a transient inflammatory response in a healthy knee. In cartilage, we tested

the hypothesis that physiologic levels of cyclic loading improve cellular oxidative balance by enhancing antioxidant capacity. Using *in vitro* compressive loading models with bovine cartilage explants, we found that cyclic loads of 50 and 300 kPa (1 Hz, 12 hrs/day, 2 days) induced a significant increase in total cartilage antioxidant capacity (15% and 115% increase, respectively, over unloaded controls,  $p < 0.05$ ). We are investigating the cellular mechanisms responsible for these load-induced responses that promote oxidative balance.

## **The OSTEOARTHRITIS RESEARCH SOCIETY INTERNATIONAL**

The [Osteoarthritis Research Society International \(OARSI\)](http://www.oarsi.org) is the premier international organization for scientists and health care professionals focused on the prevention and treatment of OA through research, education, advocacy, and the worldwide dissemination of new knowledge. The complexity of OA prevention and treatment requires a multi-disciplinary effort, which includes you! Get involved by participating in OARSI's annual meeting and sponsored workshops. The 2018 and 2019 OARSI World Congresses will be in Liverpool, England and Toronto, Canada in April and May of those years. In fact both Societies hope to have a second combined ASB-OARSI symposium at the 2019 OARSI meeting. Consider the society's journal, [Osteoarthritis and Cartilage](http://www.oarsi.org), for your next publication; it is a highly respected multidisciplinary journal for all OA-related original research articles and reviews. Learn more about OARSI and consider becoming a member by visiting their website at [www.oarsi.org](http://www.oarsi.org).

The ASB gratefully acknowledges the enthusiasm and support of this symposium by OARSI and its Board of Directors.

# THE EFFECT OF ACHILLES TENDON MOMENT ARM LENGTH ON STRETCH-SHORTENING CYCLE PERFORMANCE IN THE VERTICAL JUMP

Thomas Madden, Thanh Tran-Vi, Katherine Knaus, Geoffrey Handsfield, Joseph Hart, and Silvia S. Blemker  
University of Virginia, Charlottesville, VA, USA  
email: tsm3me@virginia.edu

## INTRODUCTION

The enhancement of human movements involving the stretch-shortening cycle (SSC) is evident in motions such as running and jumping. However, the mechanism behind the enhancement is unclear, and less clear are the factors affecting SSC performance. Active force development and elastic energy recoil are thought to be responsible for the increased power output in SSC movements [3]. During the stretch portion, elastic energy is stored in tendons such as the Achilles tendon (AT). Stored energy is potentially reutilized during shortening to augment the power of the motion. For a given joint moment, musculoskeletal modeling illustrates that the amount of energy stored is most sensitive to moment arm (MA) length, and that the two are related inversely [8]. A shorter MA may also aid force and power development by allowing the muscle to shorten at a slower velocity. Observations indicate a shorter AT MA length promotes sprinting ability [2].

The purpose of this study was to determine the effect of MA length on the enhancement of power output in the SSC during vertical jumps. Because a shorter MA may lead to greater elastic energy storage in the tendon [8], we reasoned that AT MA length would correlate inversely with SSC performance in vertical jumping. To test this hypothesis, we used MRI and performance data to determine the relation between MA length and SSC performance in collegiate basketball athletes.

## METHODS

Ten NCAA Division 1 male basketball athletes served as subjects ( $20.1 \pm 1.9$  years,  $198 \pm 7$  cm,  $101 \pm 8$  kg). SSC performance was assessed by comparing peak power output of a jump from a static squat position (squat jump, SJ) to that of a jump with a countermovement (CMJ) [6]. The subjects kept

their hands on their hips during the SJ; in the CMJ, subjects were allowed arm swing in addition to a countermovement. Jump heights were measured using a Just Jump Mat (Probotics, Inc., Huntsville, AL). The best of three jumps were taken as the SJ and CMJ height for each subject. Jump powers (W) were calculated using previously developed equations depending on each subject's jump heights (cm) and body mass (kg) [7]:

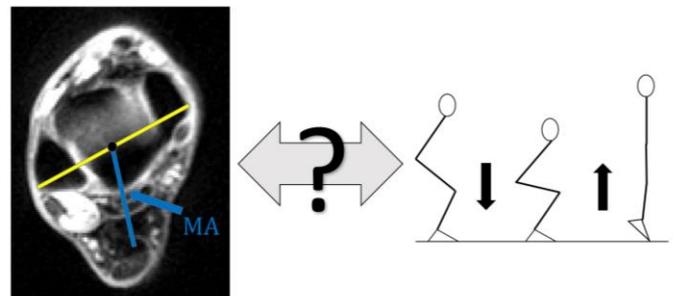

$$P_{SJ} = 60.7h_{SJ} + 45.3m - 2055 \quad (1)$$

$$P_{CMJ} = 51.9h_{CMJ} + 48.9m - 2007 \quad (2)$$

SSC performance was quantified as the prestretch augmentation (PA), the increase in jump power from SJ to CMJ relative to SJ [6]:

$$PA = \frac{P_{CMJ} - P_{SJ}}{P_{SJ}} 100\% \quad (3)$$

To produce axial MR images of the lower limbs, subjects were scanned using a 3T Siemens Trio MRI Scanner with a 2D multi-slice spiral gradient echo sequence. AT MA length was approximated as the distance from the center of the ankle joint, defined by the midpoint of a line between the medial and lateral malleoli [5], to the AT (Fig. 1). Measurements were made for the right leg.

**Figure 1:** (Left) AT MA length was approximated from axial MR images of the ankle joint. (Right) The downward and upward phases of a CMJ is illustrated. The relation between PA and MA length was determined by correlation analysis.

To assess the relationship between MA length and PA, a curve was fit to the data based on an expression for energy stored in a stretched tendon, derived from the tendon force-elongation curve ( $F = ku^n$ ) for a musculoskeletal model [8]. With  $n = 2$  and a given moment,  $M$ , the energy,  $E$ , stored in a stretched tendon depends inversely on MA length,  $r$  [8]:

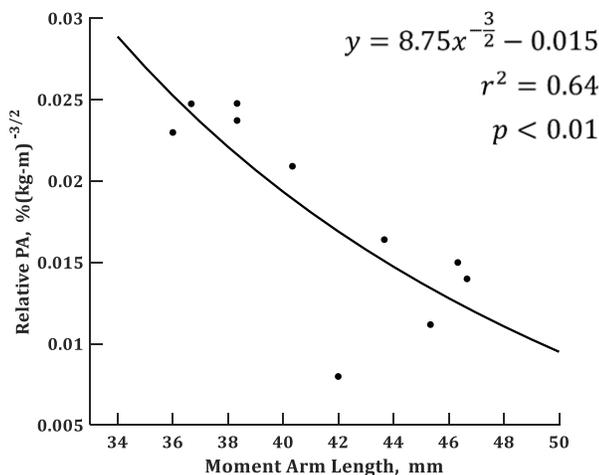

$$E = \frac{1}{3} k^{-\frac{1}{2}} M^{\frac{3}{2}} r^{-\frac{3}{2}} + C \quad (4)$$

To account for the variation of peak ankle joint moment across subjects, PA was normalized by the product of each subject's mass ( $m$ ) and CMJ height ( $h_{CMJ}$ ), raised to the power of  $3/2$ . This product represents the total work performed during the CMJ, defined as the increase in potential energy of the mass center from take-off to the maximum height of the jump. Because each subject exhibits a similar kinematic pattern, the variation in total work performed accounts for the variation in ankle joint moment. This resulted in the following model equation for relative PA:

$$\frac{PA}{(m \times h_{CMJ})^{\frac{3}{2}}} = Ax^{-\frac{3}{2}} + B \quad (5)$$

## RESULTS AND DISCUSSION

Consistent with our hypothesis, there was an inverse relationship between MA length and relative PA (Fig. 2). Fitting the model curve (Eq. 5) to the data resulted in a significant correlation between MA length and relative PA ( $p < 0.01$ ).

**Figure 2:** A curve, based on Eq. 4, could be used to fit the relative PA vs. AT MA length data.

Vertical jump SSC performance and AT MA length exhibit an inverse relation in the form of the expression for energy stored in a stretched tendon (Eq. 4). This result suggests elastic energy recoil appreciably contributes to SSC performance. Although MA length does not correlate with absolute CMJ height ( $p > 0.10$ ), a shorter MA may allow individuals to perform more efficient movements by reducing the work required of muscle. During the CMJ, subjects were allowed arm swing. While this has been shown to increase CMJ height as compared to no arm swing [4], we reason the difference is not enough to change the outcome of this study because the relative PA still correlated with MA length ( $p < 0.05$ ). Further, the results of this study are consistent with experimental data showing AT MA length to be inversely correlated with running economy [1, 8].

## CONCLUSIONS

Previous research has indicated sprinting ability [2] and running economy [1, 8] to be associated with a shorter AT MA length. In this study, we demonstrated that SSC performance in vertical jumping correlates inversely with AT MA length in collegiate basketball athletes. This relation exhibits the form of the expression for energy stored in a stretched tendon (Eq. 4), suggesting elastic energy is a crucial contributor to SSC performance. Athletic movements involving the SSC appear to favor individuals who have shorter MA lengths.

## INTRODUCTION

Leg stiffness ( $K_{LEG}$ ) is thought to contribute to an athlete's risk for lower-extremity (LE) injury [1]. However, the potential mechanism(s) by which an athlete's  $K_{LEG}$  contributes to their risk for LE injury is poorly understood. Although several biomechanical characteristics have been identified as prospective risk factors for LE injury [2, 3], the extent to which athletes with varying levels of  $K_{LEG}$  also display differences in biomechanical movement strategies remains unknown. Thus, gaining an understanding of whether differences in  $K_{LEG}$  are accompanied by differences in movement biomechanics is an important first step towards elucidating the potential mechanism(s) by which an athlete's  $K_{LEG}$  may contribute LE injury risk. Therefore, the purpose of this study was to compare differences in sagittal- and frontal-plane biomechanics between adolescent female athletes with varying levels of  $K_{LEG}$ .

## METHODS

Ninety-seven females ( $15.5 \pm 1.3$  years,  $1.7 \pm 0.1$  m,  $60.6 \pm 9.8$  kg) performed a repetitive (i.e. 2.2 Hz), single-leg, vertical hopping task atop a force platform integrated with a 14-camera motion capture system. Three 10-sec trials were recorded on both the dominant and non-dominant leg. Using data from the 6<sup>th</sup> to 10<sup>th</sup> hop of each trial,  $K_{LEG}$  was calculated as the ratio between peak vertical ground reaction force (PvGRF) and maximum center-of-mass (CoM) displacement for each hop [4]. The instants of initial ground contact (IC;  $GRF > 10$  N) and toe-off (TO;  $GRF < 10$  N) for each hop were then used to calculate stance time (from IC to TO), flight time (from TO to IC). Sagittal- and frontal-plane trunk, hip, knee, and ankle biomechanics were also extracted from each

hop. Our biomechanical variables of interest included joint angles at the instant of IC, peak angles and moments throughout stance (from IC to TO), and angular excursions (i.e. peak value – IC value).  $K_{LEG}$ , PvGRF, and moments were normalized to body mass ( $kN \cdot m^{-1} \cdot kg^{-1}$ ), body weight ( $N \cdot N^{-1}$ ), and the product of body height and mass ( $Nm \cdot m^{-1} \cdot kg^{-1}$ ), respectively.

A preliminary repeated-measures ANOVA revealed no significant differences in  $K_{LEG}$ -related variables between dominant and non-dominant legs ( $P > .05$ ). Thus, all variables were averaged across legs for subsequent analyses. Tertiles (i.e. low-, moderate-, and high-stiffness groups) were then established using  $K_{LEG}$  values, and between-group differences in demographics,  $K_{LEG}$ -related variables (i.e. stance and flight times, hopping frequency, CoM displacement, and PvGRF), and hopping biomechanics, were then evaluated using separate one-way ANOVA models.

## RESULTS AND DISCUSSION

Participant demographics, CoM displacement, and hopping frequency, were not statistically different between groups ( $P > .05$ ). However,  $K_{LEG}$ , PvGRF, and flight time significantly increased, and stance time significantly decreased, from the low- to moderate- to high-stiffness group ( $P < .001$ ), indicating that the high-stiffness group experienced higher peak forces and loading rates. Given that performing activities with high GRFs is a risk factor for LE injury, due to higher loading [2], athletes in the high-stiffness group may be producing the very forces in which they should be attempting to avoid. However, we are unaware of any studies that have examined whether healthy athletes with higher  $K_{LEG}$  also display higher peak forces and loading rates during other dynamic tasks. Thus, future work examining such relationships is warranted.

At IC, the high-stiffness group landed with greater lateral trunk-flexion (relative to the stance leg;  $5.3\pm 3.6$  vs  $2.6\pm 3.2^\circ$ ,  $P=.009$ ) and lesser hip-adduction ( $1.4\pm 3.3$  vs  $3.7\pm 2.9^\circ$ ,  $P=.022$ ) angles compared to the low- and moderate-stiffness groups, respectively. Following IC, the high-stiffness group displayed less lateral trunk-flexion excursion compared to the moderate-stiffness group ( $0.8\pm 2.3$  vs  $2.7\pm 3.7^\circ$ ,  $P=.046$ ), greater ankle-dorsiflexion moments compared to the moderate- ( $1.70\pm 0.25$  vs  $1.56\pm 0.17$   $\text{Nm}\cdot\text{m}^{-1}\cdot\text{kg}^{-1}$ ,  $P=.002$ ) and low-stiffness ( $1.70\pm 0.25$  vs  $1.52\pm 0.12$   $\text{Nm}\cdot\text{m}^{-1}\cdot\text{kg}^{-1}$ ,  $P=.022$ ) groups, and greater peak hip-flexion ( $0.59\pm 0.17$  vs  $0.40\pm 0.12$   $\text{Nm}\cdot\text{m}^{-1}\cdot\text{kg}^{-1}$ ,  $P<.001$ ) and ankle-eversion ( $0.48\pm 0.14$  vs  $0.41\pm 0.09$   $\text{Nm}\cdot\text{m}^{-1}\cdot\text{kg}^{-1}$ ,  $P=.038$ ) moments compared to the low-stiffness group. The moderate-stiffness group also displayed greater peak hip-flexion moments compared to the low-stiffness group ( $0.57\pm 0.22$  vs  $0.40\pm 0.12$   $\text{Nm}\cdot\text{m}^{-1}\cdot\text{kg}^{-1}$ ,  $P=.001$ ). Together, these findings suggest that athletes in the high-stiffness group displayed a much more “rigid” hopping strategy compared to athletes in the low-stiffness group, which may help explain why these athletes also displayed greater PvGRF.

While we observed differences in hip and ankle moments, there were no kinematic differences at these joints in their respective planes of motion. As such, the larger hip and ankle moments displayed by the high-stiffness group may be attributed to differences in PvGRF rather than differences in body positioning. In contrast, the larger ankle-eversion moments in the high-stiffness group may be due to the combination of higher PvGRF and greater amounts of lateral trunk flexion. Positioning the trunk lateral to the stance leg can cause the GRF vector to shift laterally, thereby increasing the lever arm relative to the ankle-joint center. Thus, landing with greater lateral trunk flexion at IC, and greater PvGRF, may help explain why the high-stiffness group also displayed greater ankle-eversion moments compared to the low-stiffness group.

The greater lateral trunk flexion observed in the high-stiffness group may be clinically relevant, as this may be a compensatory mechanism for hip-abductor muscle weakness [5]; particularly during single-leg tasks, where adequate neuromuscular control of the hip abductors is essential in positioning the body's

CoM over the base of support to maintain stability. While positioning the trunk lateral to the stance leg can be an effective strategy for reducing hip-abductor demand, the concomitant shift of the GRF vector lateral to the knee-joint center may increase the externally-applied abduction moment, which has been identified prospectively as a risk factor for noncontact ACL injury and patellofemoral pain [2, 3]. While not statistically significant, the high-stiffness group displayed 53% greater peak moments than the low-stiffness group. Our lack of statistically significant findings for frontal-plane knee kinematics and kinetics is likely due to the use of a submaximal hopping task and large variability surrounding group means. Therefore, future studies examining whether  $K_{\text{LEG}}$  is predictive of knee-abduction angles and moments during single-leg tasks with greater frontal-plane demands may clarify how the  $K_{\text{LEG}}$  assessment could identify athletes at increased risk for LE injury. Additionally, because hip-abductor strength was not assessed, it is unknown whether the greater lateral trunk-flexion in the high-stiffness group was due to hip-abductor weakness; thus, future investigations examining this relationship are needed.

## CONCLUSIONS

Healthy, adolescent, female athletes with varying levels of  $K_{\text{LEG}}$  display differences in sagittal- and frontal-plane biomechanics during single-leg hopping. Future studies are needed to determine whether athletes with varying levels of  $K_{\text{LEG}}$  display similar biomechanical differences during more demanding tasks. Because of the large amount of variability in  $K_{\text{LEG}}$  observed in a relatively homogenous sample, future studies examining how  $K_{\text{LEG}}$  contributes to LE injury risk should focus on smaller group subsets that participate in similar activities and have similar training experience.

# MODIFIED HOCKEY SKATE BLADE PROFILES AFFECT SKATING BIOMECHANICS AND PERFORMANCE

<sup>1</sup>Jordyn Vienneau, <sup>1</sup>Aimée C. Smith, <sup>1</sup>Sandro R. Nigg, and <sup>1</sup>Benno M. Nigg

<sup>1</sup>University of Calgary, Calgary, Alberta, Canada  
email: javienne@ucalgary.ca

## INTRODUCTION

Biomechanical differences exist between recreational and high caliber ice hockey players [1]. Specifically, high caliber players are able to 1) generate greater total plantar force, 2) extend their hip more at toe-off, and 3) generate a larger hip flexion/extension range of motion during skating maneuvers than their recreational counterparts. These biomechanical differences may help explain the improved skating performance (faster) in high caliber players. However, limited research has been conducted on hockey skates and whether modified skate properties will influence players' performance or biomechanics. One modifiable skate property is the longitudinal radius of the blade, which defines the amount of blade/ ice contact [2]. It has been speculated that a shorter radius allows a player to be more agile in turning movements, while a longer radius enables faster skating due to the increased blade/ ice contact [2].

The purpose of this study was to quantify selected effects of different hockey skate blade profiles on skating performance and skater biomechanics.

## METHODS

Ten male university and collegiate level hockey players participated in this study (Mean  $\pm$  SD: 25.9  $\pm$  6.2 years, 90.2  $\pm$  4.9 kg, 185.2  $\pm$  3.9 cm). All players wore the same CCM Ribcor 44K hockey skate model with three interchanged skate blades. The blade profile conditions were 1) the standard CCM 44K Ribcor profile (Standard), 2) a test profile with a shorter radius than the Standard profile (Agility), and 3) a test profile consisting of two combined radii; a shorter radius for the anterior aspect, and a longer radius for the posterior aspect of the blade (Combo).

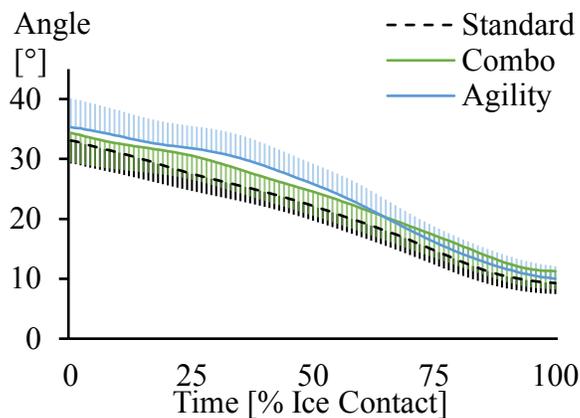

Players performed a standardized hockey protocol consisting of forward crossovers, backwards crossovers, and a sprint. Only the data from the backwards crossovers are presented here. Players were instrumented with electro-goniometers to measure hip flexion/extension (Biometrics, AG1500), pressure-sensing insoles to measure in-skate total and regional plantar forces (Pedar-X, novel), and a 3D accelerometer (ADXL 78, Analog Devices USA) on the skate holder for stride detection. Timing lights (TC Timing System, Brower Timing System) were used to measure performance times for each skating maneuver.

## RESULTS AND DISCUSSION

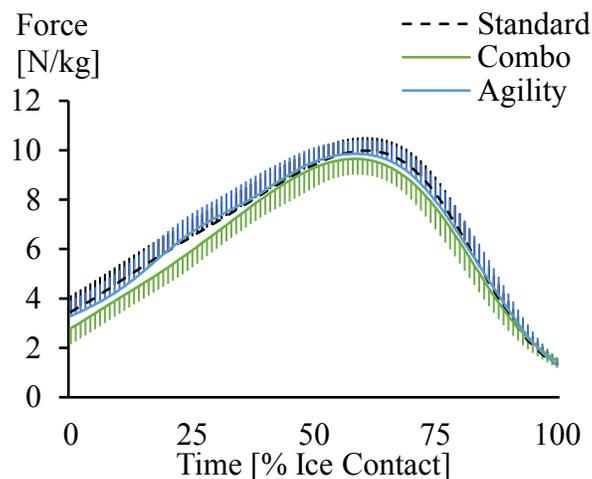

Performance time for backwards crossovers was the best using the Agility blade profile, as the time was 2.3% faster than the standard profile. The combo profile was the slowest with a performance time of 3% slower than the standard profile.

The greatest hip flexion range of motion was observed when skating in the Agility profile (Mean  $\pm$  SE: 25.3°  $\pm$  2.7), followed by the Standard (23.9°  $\pm$  2.0) and the Combo (23.1°  $\pm$  1.9) profiles (Fig. 1). The greatest hip extension at toe-off was observed using the Standard profile (9.3°  $\pm$  1.8), followed by the Agility (10.0°  $\pm$  2.1) and the Combo (11.3°  $\pm$  3.0) profiles.

Players generated greater total plantar force when skating in the Agility and Standard profiles than in the Combo profile (Fig. 2). The increased total force in the Agility profile corresponded to a 2% greater force in the heel region than the Combo profile.

**Figure 1:** Mean  $\pm$  SE hip flexion angle for the inside (left) leg during a backwards crossover.  $0^\circ$  corresponds to full extension.

**Figure 2:** Mean  $\pm$  SE total plantar force for the inside (left) leg during a backwards crossover.

It has previously been suggested that a shorter radius would improve a player’s agility [2], which would be beneficial for maneuver such as crossovers. This speculation is supported in this study, where players improved their performance during backward

crossovers in the Agility profile compared to both the Standard profile offered with CCM Ribcor 44k skates, and the Combo profile.

The performance benefits of the Agility profile are supported biomechanically. The Agility blade profile most emulated the elite skating style with an increase in heel force application, and an increase in the hip flexion range of motion [1]. Increased plantar force may allow players to generate more explosive movements, and increasing the hip range of motion maximizes the players blade/ice contact time.

Findings from this study suggest that skate manufacturers should focus on optimizing the skate blade radius, as this parameter appears to positively affect skating performance. Specifically, defenseman perform significantly more backwards skating than offensive players [3], and therefore may benefit most from skates with a shorter radius.

## CONCLUSIONS

In conclusion, changes to hockey skates appear to affect the skating performance of high caliber hockey players, and these enhancements can be supported by biomechanical variables.

## INTRODUCTION

Swinging a bat and hitting a ball is a complex task requiring exquisite timing and strength to be successful. In general, at the point of impact, the bat is horizontal and has reached its maximum speed just prior to impact. Increasing a player's maximum bat swing speed is the focus of much instruction and training. The benefit of greater bat swing speed is supported by research studies that have demonstrated that increasing bat swing speed linearly increases batted ball speed, and hence distance. To increase swing speed for a given bat, a player must increase the forces and moments he applies with his hands to the bat during the swing. In a previous study [1], we tracked the full 3-D kinematics of baseball bat swings during a batting cage study of bat performance. We found that bat moment of inertia about the knob (MOI) was the best predictor of the ideal batted ball speed. In this study, we analyze the kinetics of bat swings using those bat kinematics. Specifically, we examined the effects of bat MOI on force impulse and bat speed, and the forces and moments during swings.

## METHODS

Twenty-two ( $n = 22$ ) right-handed male players (mean age: 16, range 13-18) participated in a batting cage study after IRB approval and informed written consent/assent were obtained. Thirteen bat models from six different manufacturers were used in the previous study [1], but only three were selected for this study (Table 1). Five bats of each model were prepared for testing by applying square markers (13mm×13mm) of retro-reflective tape (3M Scotchlite High Gain Reflective Sheeting 7610) along the length of the bat. Four markers were

evenly-spaced circumferentially at approximately 0, 9, 28, 38 and 76 cm from the tip. Baseballs (R100, Rawlings, St. Louis, MO,  $n = 300$ ) were prepared with six uniformly arranged square retro-reflective markers (13mm×13mm).

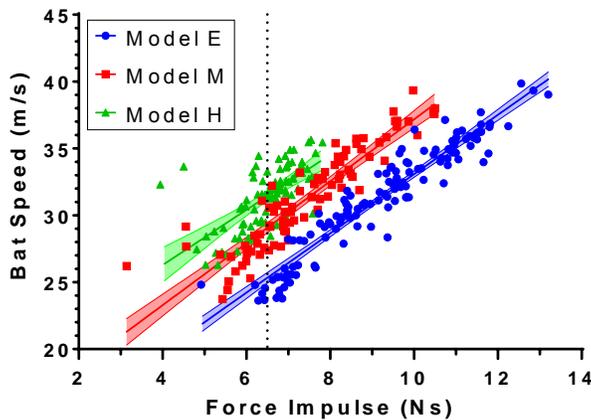

Testing was held indoors in the Brown University Athletic Center (Providence, RI) over a two-day session. A portable batting cage was assembled (15.2 m×3.0m×4.3m) on the gymnasium floor. The pitching machine (Iron Mike MP5, Master Pitching Machine Kansas City, MO) was positioned within the cage 12.2m from the hitter. Balls were pitched at a speed comfortable to the hitter (range 21.5 – 26 m/s) to maximize the number of hits. Players participated in multiple batting sessions consisting of approximately twenty-five pitches with a single bat. The order of bat models swung by players was selected randomly. Not all bat models were swung by all players.

The pitched ball, batted ball and bat swing were tracked at 300 Hz using an eight-camera Qqus 5-series infrared sensing system (Qualisys, Gothenburg, Sweden). The cameras were mounted on tripods approximately 2.4 m (8 ft) high and positioned behind and to the right side of the batter. Pitched and batted balls were tracked within 3 m (6 ft) of the front of home plate. The system was recalibrated following every 100 pitches, resulting in calibration tolerances less than 0.7 mm. Ball and bat markers were identified within Qualisys Track Manager and exported to Matlab (Mathworks Inc., Natick MA) for subsequent analysis. Ball and bat positions and velocities were calculated using previously developed algorithms [2]. Bat swing speed was computed as the speed of the bat at the tip of the bat.

The forces and moments generated by the hands throughout the duration of the swing were estimated by inputting each bat's physical properties and the 3-D kinematics into Visual3D (C-Motion, Germantown, MD). Linear regression was used to determine if force impulse predicted bat speed. Within each swing, the force and moment time series curves were normalized by their peak value. The normalized curves were then averaged over all players, swings, and bats for qualitative examination. Time of 50% peak values were compared using a paired t-test.

## RESULTS AND DISCUSSION

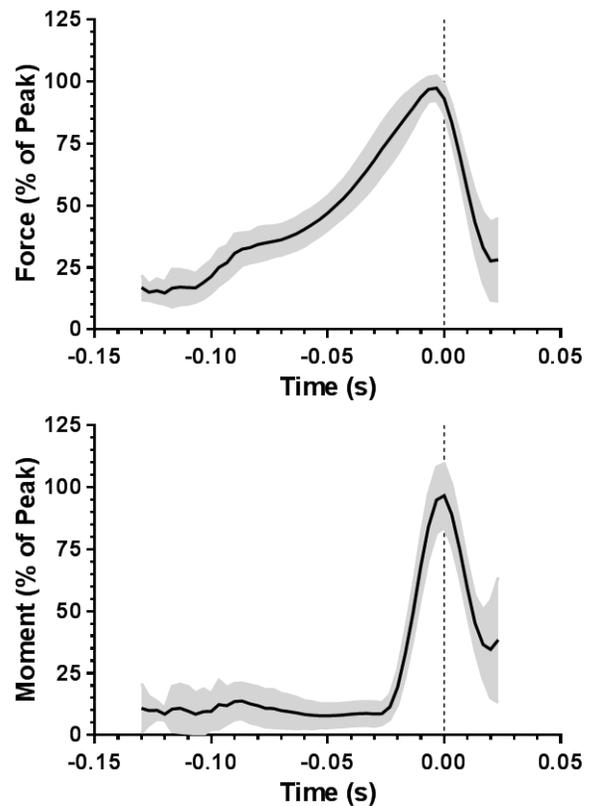

Force impulse predicted bat speed ( $R^2 = 0.91, 0.84, 0.43$ ) and this linear correlation was constant for each bat model (Fig.1). For the same impulse (e.g. 6.5 Ns) bat speed was significantly ( $P < 0.0001$ ) faster with decreasing MOI.

**Figure 1.** Bat speed correlations with force impulse differed (offset, not slope) with bat MOI.

The normalized time series were consistent with a mean standard deviation of 8% and 9% for force and moments, respectively. Additionally, force rose significantly ( $P < 0.001$ ) sooner in the course of the swing than moment, with force reaching 50% of peak at a mean time of 0.045s before ball impact, as

compared to 0.017s for 50% of the peak moment (Fig. 2).

**Figure 2.** Mean (black) and SD (grey) ( $n = 306$ ) of the swing force and moment time series across all bat models, normalized by peak force and peak moment. Time series were synchronized at ball impact (Time = 0.0s).

# ENERGY GENERATION STRATEGIES RELATED TO PEAK ELBOW VARUS TORQUE IN HIGH SCHOOL BASEBALL PITCHERS

<sup>1</sup> Michael P. McNally, <sup>1</sup> James A. Oñate, <sup>1</sup> Ajit M.W. Chaudhari

<sup>1</sup> The Ohio State University, Columbus, OH, USA

## INTRODUCTION

Elbow injuries in high school pitchers are an issue of increasing prevalence, with the number of ulnar collateral ligament injuries increasing nearly 10x in a high school aged population from 2002 to 2011. (Hodgins, 2016). These injuries are often attributed to a combination of overuse, poor conditioning, and/or poor mechanics. While relatively little is known about biomechanical risk factors in high school pitchers, professional pitchers who suffer a serious elbow injury have been shown to have both a greater average pitch velocity (Bushnell, 2010) and greater peak elbow varus torque (Anz, 2010). While there are mixed results on the relationship between ball velocity and elbow varus torque (Hurd, 2012; Post, 2015), theoretically, increasing velocity places more force on the distal end of the kinetic chain, which may result in greater joint torque at the elbow. However, the variance in elbow torque is only partially explained by elbow velocity ( $R^2 = 4.0-37.3\%$ ), and thus is affected by other factors independent of ball velocity.

A common theory among coaches and practitioners is that generating more energy with the lower body, and having sufficient ability to transfer energy through the trunk to the upper body, may aid in reducing load on the arm while improving ball velocity. While plausible, increasing energy transferred from the trunk and legs also results in a greater elbow torque to transfer energy across the elbow (McNally, 2015). Understanding how energy generation strategies during the pitching motion affect elbow load independent of ball velocity are important for practitioners seeking to minimize potential for injury with a neutral or positive effect on performance. Therefore, the purpose of this study was to determine if energy generated by the lower body, trunk, and upper body affects elbow varus torque independent of the effect caused by increased

ball velocity. We hypothesized that energy generated by the legs and trunk would result in reduced elbow varus torque beyond that caused by an increase in hand velocity, while upper body energy generation would result in an increased elbow varus torque.

## METHODS

47 high school baseball pitchers between the ages of 15 and 18 were recruited for participation in this study. After performing a self-selected warm-up, pitchers were recorded using an optical motion capture system (Vicon Inc., Oxford, UK) capturing at 300 Hz while throwing five fastballs at “game like effort” towards a target. Synchronized ground reaction forces were recorded from a custom built pitcher’s mound bolted into four force platforms (Bertec, Co, Columbus, OH, USA), which recorded drive and stride leg ground reaction forces independently at 1500 Hz. The pitch with the highest hand velocity was used for analysis. If full body data were not available due to excessive marker occlusion or markers falling off, the pitch with the next highest velocity was chosen, continuing until the trial with the highest velocity with complete data was determined.

Joint torques and joint powers were calculated using standard inverse dynamics equations using Visual3D software (C-Motion Inc., Germantown, MD, USA). The pitching motion was analyzed from peak knee height to ball release. Peak knee height was determined as the point when the lateral knee joint marker reached its highest vertical position, and ball release was determined as the point 7 ms after the forearm passed a position perpendicular to the ground. Energy generation was calculated for the trunk, and bilaterally for the hip, knee, ankle, shoulder, elbow, and wrist. Energy generation was defined as the amount of positive work – the integral of joint power when joint power is greater than zero

- performed from peak knee height to ball release. Positive joint work was then summed to calculate lower extremity energy generation (hip, knee, and ankle;  $LE_{work}$ ), and upper extremity energy generation (shoulder, elbow, and wrist;  $UE_{work}$ ).

A simple regression was performed to estimate peak elbow varus torque as a function of peak hand velocity. Separate linear regression models were then used to determine the increase in  $R^2$  when including  $LE_{work}$ ,  $Trunk_{work}$ , and  $UE_{work}$ .

## RESULTS AND DISCUSSION

Complete model descriptions including the model input, standard error of estimate,  $R^2$  value, and  $R^2$  increase are shown in Table 1. On average, pitchers generated  $290.6 \pm 72.5$  J of energy with the lower extremity,  $52.7 \pm 24.3$  J with the trunk, and  $104.0 \pm 31.8$  J with the upper extremity. There was a significant association between ball velocity and peak elbow varus torque, with peak hand velocity explaining 56.6% of the variance in elbow varus torque (Table 1, Model A;  $p < 0.0001$ ). Lower extremity work explained an additional 5.4% of the variance in elbow varus torque (Model B;  $p = 0.009$ ), while upper extremity work explained an additional 4.2% (Model D;  $p = 0.020$ ). Trunk work was not associated with an increase in elbow varus torque (Model C). As a secondary analysis, a linear regression was performed to estimate peak elbow torque as a function of peak hand velocity,  $LE_{work}$ , and  $UE_{work}$ . The combined model resulted in an additional 6.45% of variance explained, though neither  $LE_{work}$  or  $UE_{work}$  were independently significant predictors of elbow varus torque.

In contrast to our hypothesis, energy generation by the lower extremity and upper extremity explained only a small amount of the variance in peak elbow varus torque independent of hand velocity. While the inclusion of both lower extremity and upper extremity energy positive work resulted in similar increases in  $R^2$  independently, when considered together, they were not significant predictors of elbow torque independent of ball velocity. Energy generated by the trunk was also not associated with peak elbow torque, which suggests that energy generation strategy may not substantially affect elbow torque above and beyond the effect due to increased hand velocity in high school baseball pitchers. Energetic strategies which emphasize the transfer or control of energy (segment torque power and negative joint torque power, respectively), and energetic transition strategies between fatigued and non-fatigued states, may play more of a role in injury potential, and warrant further investigation.

## INTRODUCTION

Shoulder and elbow injuries are common for baseball pitchers and are becoming more common for youth pitchers as well. Some of the most common injuries are the result of high torques on the elbow and shoulder causing damage to the ulnar collateral ligament (UCL) in the elbow.

Studies have primarily shown pitchers who throw with lesser velocity or have smaller body size encounter less stress [1] and the timing of sequences is important in energy flow especially in reference to pelvic rotation [2].

These findings are important but not always coachable. Arm slot has been defined in a previous study as the combination of trunk tilt, shoulder abduction, and elbow flexion [3]. This same study determined elbow stress increased with elbow flexion and when the arm was more horizontal. While trunk tilt may affect perceived arm slot, we hypothesized that varying degrees of shoulder abduction and elbow angle could impact the UCL. The purpose of this study was to examine arm slot in relation to pitch efficiency and upper extremity moments in the throwing arm.

## METHODS

Fourteen youth baseball pitchers (age: 11.6±1.3 years, height: 1.59±0.12 m, mass: 48.5±13.4 kg, velocity: 56.6±6.9 mph, 11 right-handed/3 left-handed) were recruited for this study. All testing occurred in an indoor research lab equipped with a custom built pitcher's mound with two embedded force plates; one under the rubber and one under the landing area. Reflective markers and marker clusters were attached to each pitcher's upper and lower body. Kinematic data was recorded with a 14-camera motion capture system at 250Hz, kinetic data of the drive (rear) and stride (front) leg were sampled at

1000Hz, and a radar gun was used to record velocity. Each pitcher threw 15 maximal effort fastballs toward a hanging strike zone 46ft from the rubber. The fastest strike thrown for each pitcher was chosen for analysis.

Trunk rotation was positive when rotation passed the point of being square with home plate or being neutral in relation to the pelvis. This is according to the right hand rule about a vertical z-axis.

Correlation was tested using Pearson correlation coefficients. The shoulder, elbow, and trunk orientations were compared to pitch velocity and upper extremity moments normalized for body mass and height. Additionally, upper extremity moments were normalized by velocity to assess the efficiency of the pitch effectively as load/mph [4]. Angles generated from left-handed pitchers were changed in sign to match standard convention used for right-handed pitchers.

The joint angles tested were elbow flexion, shoulder abduction, shoulder elevation, shoulder external rotation, trunk rotation relative to the pelvis, pelvis orientation, and trunk orientation. Additionally, the distance towards home plate between the shoulder and the ball at release was also tested. Outcome variables tested were shoulder abduction moment, shoulder internal rotation moment, and elbow valgus moment. All angle and positioning measurements were collected at ball release.

## RESULTS AND DISCUSSION

The correlations coefficients for all statistically significant relationships are shown in Table 1.

Greater shoulder abduction angle was negatively correlated with increased pitch velocity. Greater external rotation moment significantly correlated with both valgus moment efficiency and shoulder

internal rotation moment efficiency. Values of joint moment efficiency decrease when pitch efficiency increases since the variable is normalized (joint moment per mile per hour pitch velocity). This trend is evident in Figure 2.

Increased transverse plane trunk rotation angle relative to the pelvis correlated with an increased normalized shoulder abduction moment. Increased values of contralateral tilt correlated with increased normalized shoulder abduction moment. Increased trunk rotation relative to the laboratory correlated with less normalized shoulder internal moment.

An interesting correlation is the relationship between greater shoulder abduction and higher velocity. The degree of shoulder abduction is a coachable characteristic and this may suggest arm slot can assist in producing a faster pitch. Also notable is contralateral tilt, which led to increased normalized shoulder abduction moment. This could suggest a more upright trunk during delivery is favorable. The two trunk rotation results had effects on normalized moments of the shoulder. With regards to previous studies' results relating trunk rotation and energy transfer, these may have more to do with the kinematic sequence of the pitch and the degree of trunk opening present at ball release.

Greater external rotation of the shoulder at ball release correlated with improved pitch efficiency for both elbow valgus moment and the shoulder internal rotation moment. This may suggest an earlier release point is favorable, or that greater initial external rotation is a mechanical method for generating more velocity with less stress even without proper kinetic sequencing.

## CONCLUSIONS

The results of this study show the varying factors of arm slot have an effect on the efficiency of a pitch with regards to velocity of the pitch and safety of the pitcher. Because arm slot is a coachable factor and many youth pitchers sustain arm injuries, this topic is deserving of further investigation.

## INTRODUCTION

Despite continual research and development in the field of Biomechanics, several aspects of muscle force production and muscle control remain to be answered or adequately understood. How is force shared among muscles? How do muscle contractile properties and muscle architecture influence the force exerted by muscles? How are motor units controlled to exert muscle force? These are fundamental questions that provide insight into the organization and control of human movement. The symposium will present recent research findings that attempt to resolve current controversies or shed light on these fundamental questions and their impact in sport performance and rehabilitation.

The symposium will follow this schedule:

Introduction – Walter Herzog – 5 mins

The distribution problem in biomechanics – Walter Herzog – 20 mins

Muscle architecture and material properties:  
Influence on muscle function – Sabrina Lee – 20 mins

Neural strategies of muscle force productions:  
controversies and evidences from studies of motor unit behavior – Paola Contessa – 20 mins

Discussion – 25 mins

## THE DISTRIBUTION PROBLEM IN BIOMECHANICS – Walter Herzog

The distribution problem in biomechanics is defined as the determination of the forces of musculo-skeletal structures crossing a joint from the known intersegmental resultant force and moment. The primary musculo-skeletal structures thought to contribute to the intersegmental resultant forces and moments are the muscles, ligaments and bony contact forces. Unfortunately, these forces are hard (not to say impossible) to measure accurately in humans non-invasively, thus only the crudest experimental data are available, typically obtained without proper calibration (in terms of muscle forces), or for non-physiological conditions (contact forces obtained in artificial joints).

However, animal models allow for the accurate measurement of muscle forces and the validation of predicted muscle forces based on musculoskeletal models. This technology has been available for almost forty years now (e.g. (Walmsley et al., 1978)) but has only been used sporadically for validation purposes (e.g. (Herzog et al., 1993; Liu et al., 1999)).

Static optimization algorithms, forward dynamic simulations, and EMG driven musculoskeletal models of muscle force prediction and synergistic force sharing among muscles are used in abundance (for a review see for example (Erdemir et al., 2007; Herzog, 1996)) often with little validation and questionable justification.

Here, I will be showing the wide variety of synergistic force-sharing of the cat triceps surae muscles, and specifically identify surprising results. For example, the result that the smallest muscle of

the group (soleus) contributes the most force for static, and many dynamic movement conditions. Or, that during standing one synergist (soleus) may be highly active and produce great force, while another (medial gastrocnemius) is completely silent, while for a paw shake response, the complete opposite is true, the medial gastrocnemius is highly active while the soleus is silent merely contributing minor passive forces to the movement. It is this complexity of synergistic force sharing that has eluded satisfactory explanation ever since first attempts at muscle force predictions were made (Penrod et al., 1974).

Although I do not have the full solutions to the distribution problem in biomechanics, I sincerely hope that my talk will revive this area of prime importance in biomechanics and movement control research, and might inspire some young scientists to tackle this problem once more with the improved techniques we have available today.

### **MUSCLE ARCHITECTURE AND MATERIAL PROPERTIES: INFLUENCE ON MUSCLE FUNCTION – Sabrina Lee**

Classic research in comparative functional morphology suggests that muscle properties are often optimized to achieve maximal performance for specialized functions. This may include locomotor speed, jump height or distance, and endurance (Hildebrand, 1960; Alexander, 1981; Lieber and Boakes, 1988; Lutz and Rome, 1994). Force modulation, the timing of force generation, and the force-generating capacity of muscle all greatly contribute to the many factors that affect performance. This optimizing of muscle properties for specialized tasks becomes unclear, challenging, and very intriguing in humans as we're not specialized for any movement task, at least not as a species. However, there are examples where groups of individuals may have optimal muscle properties to achieve specialized movements such as in sports (Abe et al., 2001; Kumagai et al., 2000). In particular, the investigation becomes even more intriguing when investigating muscular changes what muscular changes occur in impaired movement.

Muscle plasticity has both its advantages and disadvantages. On one hand, muscle properties can be altered negatively due to injury or pathology. Changes include muscle mass (Malaiya et al., 2007), sarcomere number and length (Lieber et al., 2002), fascicle length (Gao et al., 2008; Barber et al., 2011), pennation angle (Barber et al., 2011; Mohagheghi et al., 2008), stiffness (Sinkjaer et al., 1994; Lee et al., 2015). On the other hand, the muscular system can adapt positively to these disruptive changes, and rehabilitation treatments have great potential to revert these changes or allow muscle properties to adapt in manner such that movement becomes less impaired.

I will discuss how muscle properties such as muscle architecture (e.g. sarcomere length, fascicle length, pennation angle, moment arm) and material properties such as stiffness influence muscle function in healthy and pathologic muscle. With advancement of non-invasive techniques to quantify muscle properties, we are able to glean further insight into the human muscular system. This will help to bridge our knowledge of animal and human muscle mechanics and to decrease assumptions or estimations about muscle properties in humans. This becomes important for aiding clinicians in decision making about diagnosis and treatment-planning.

### **NEURAL STRATEGIES OF MUSCLE FORCE PRODUCTION: CONTROVERSIES AND EVIDENCES FROM STUDIES OF MOTOR UNIT BEHAVIOR – Paola Contessa**

The mechanisms by which the central and peripheral nervous systems control motor units to produce force are still subject to debate. Over the past five decades, the notion that higher-threshold motor units have greater firing rates than lower-threshold ones has been commonly accepted. This notion was derived from electrically stimulated motoneurons in cats (Eccles et al., 1958; Kernell, 1965), and supports the assumption that the firing rates of motoneurons match their mechanical properties to optimize force production. That is, higher-threshold motor units have shorter and bigger force twitches that require higher firing rates to tetanize (Kernell, 2003). Recent empirical data

from voluntary contractions in human subjects (De Luca and Hostage, 2010; among others) have provided abundant evidences in support of a competing theory of motor unit behavior, known as the Onion-Skin scheme (De Luca and Erim, 1996). This construct describes an inverse hierarchical arrangement of motor unit firing rates, where lower-threshold motor units maintain higher firing rates than higher-threshold ones at any time and force during a contraction. This control scheme seems to have evolved not to maximize force, but a combination of force magnitude and duration, thereby proving the capacity to generate muscle force and to sustain it over time.

This symposium will discuss the competing theories of motor unit control, and the empirical data in support of the Onion-Skin scheme. It will also present recent evidences indicating that the Onion-Skin scheme of motor unit firing remains invariant with muscle fatigue.

Conflicting observations on the adaptations of motor unit firing behavior during muscle fatigue have been reported in the literature. This symposium will address some of the discrepant findings, and present several confounding factors in the analysis of motor unit data that can obscure the underlying firing adaptations during muscle fatigue. When these confounding factors are mitigated, empirical data show that motor unit firing rate increases, motor unit recruitment threshold decreases and higher-threshold motor units are recruited during fatiguing contractions. These adaptations can be explained by increasing excitation to the motoneuron pool that compensates for the fatigue-induced decrease in muscle force generation capacity (Contessa et al., 2016), and highlight the influence of mechanical adaptations on motor unit firing behavior during fatigue. Throughout these complementary adaptations, the Onion-Skin scheme that governs motor unit firing behavior appears to be maintained with muscle fatigue.

## INTRODUCTION

A segmental power and energy analysis can be a powerful biomechanical tool for understanding the mechanism driving human movement. Segmental power calculations are traditionally performed using segment endpoint dynamics (traditional kinetic method), but a theoretically equivalent method is to measure changes in the segment's energy state (kinematic method) [1]. Using the change in energy and power relationship, researchers have related work performed by the lower limbs to changes in the energy state of the body [e.g., 2].

However, the traditional kinetic and kinematic methods do not provide experimentally equivalent results for segments proximal to the foot during stance phase of gait [3]. This has been deemed a "power imbalance" and is due to modeling segment endpoints as fixed in the traditional kinetic method. We derived a correction term to account for movement at segment ends to be included in segmental power calculations (corrected kinetic method) [4]. Capturing the magnitude of power imbalance is imperative to effectively interpreting energetic measures in the study of human movement. The purpose of this study was to document the power imbalance between the traditional and corrected kinetic methods to the kinematic method for a whole-body analysis over a gait cycle.

## METHODS

A subset of the data collected by Goldberg and Stanhope was used for data analysis [5]. Eight unimpaired adult subjects (height  $177 \pm 7.5$  cm, mass  $74 \pm 13.1$  kg) walked on a calibrated instrumented split-belt treadmill (Bertec, Columbus, OH) at height-normalized velocities of 0.8 statures/s. Three-dimensional movement data were collected via a six-camera system (Vicon, Los Angeles, CA).

At the segment level, the kinematic method sums the rate of energy change of the segment's gravitational

potential energy, rotational and translational kinetic energy to find segmental rate of energy change. The traditional kinetic method calculates segmental power ( $\vec{P}_m$ ) as the product of net joint moment and joint angular velocity summed with the product of joint intersegmental force and segment endpoint velocity at both distal and proximal segment ends. Distal foot power is calculated as defined previously [6]. The corrected kinetic method includes a derived correction term ( $\Delta\vec{P}c_m$ ) which accounts for movement at segment ends. The correction term is defined in equation 1, where  $\vec{F}_{grf}$  is the ground reaction force,  $\vec{\omega}_m$  is the segment angular velocity of the  $m^{\text{th}}$  segment, and  $\vec{r}_{m/(m-1)}$  is the vector from the distal end of the  $m^{\text{th}}$  segment to the proximal end of the adjoining segment ( $m-1$ ). The corrected kinetic method calculates segmental power as  $\vec{P}_m - \Delta\vec{P}c_m$ .

$$\Delta\vec{P}c_m = \vec{F}_{grf} \cdot (\vec{\omega}_m \times \vec{r}_{m/(m-1)}) \quad (\text{eq. 1})$$

The body was modeled as bilateral feet, shanks, and thighs, with a pelvis and trunk. For each method, body power or rate of energy change was calculated as the sum of the eight segment-level calculations combined. Powers were scaled to body mass.

Power imbalance is defined as the difference between the kinematic method and the traditional (PI<sub>tr</sub>) or corrected (PI<sub>co</sub>) kinetic methods. Two measures were used to capture the magnitude of this difference. First, the root-mean-square error was calculated over the gait cycle using PI<sub>tr</sub> (RMSE<sub>tr</sub>) and PI<sub>co</sub> (RMSE<sub>co</sub>). Second, the percent difference (% Diff) was calculated by taking the portion of absolute PI<sub>tr</sub> or PI<sub>co</sub> work (integration of positive and absolute negative power) divided by the absolute work over the gait cycle using the kinematic method. The % Diff was calculated over the gait cycle (GC) and five intervals of gait: (1) initial double support (DS), (2) first half of single support (SS), (3) second half of SS, (4) terminal DS, and (5) swing (Sw).

## RESULTS AND DISCUSSION

The root-mean-square error reduced from  $0.16 \pm 0.06$  W/kg (RMSE<sub>tr</sub>) (mean  $\pm$  SD) to  $0.03 \pm 0.01$  W/kg (RMSE<sub>co</sub>) with the correction term. In context, the % Diff with PI<sub>tr</sub> can over- or underestimate the work on the body by  $12.3 \pm 4.3\%$  over the gait cycle compared to  $2.8 \pm 0.9\%$  with PI<sub>co</sub>. Figure 1 shows a representative subject's power and rate of energy change for the three methods over a gait cycle. Note that the PI<sub>tr</sub> during swing can be attributed to having the contralateral limb in stance during that phase. The % Diff between absolute work performed during the five intervals of gait are shown in Table 1.

**Table 1:** Percent difference (% Diff) between kinematic and traditional (PI<sub>tr</sub>) or corrected (PI<sub>co</sub>) kinetic methods (mean  $\pm$  SD).

% Diff.	Interval					GC
	1	2	3	4	Sw	
PI <sub>tr</sub>	1.2 $\pm$ 0.8%	2.5 $\pm$ 1.2%	2.0 $\pm$ 1.0%	1.6 $\pm$ 0.3%	5.0 $\pm$ 2.9%	<b>12.3 <math>\pm</math> 4.3%</b>
PI <sub>co</sub>	0.5 $\pm$ 0.3%	0.4 $\pm$ 0.1%	0.5 $\pm$ 0.1%	0.5 $\pm$ 0.2%	0.9 $\pm$ 0.3%	<b>2.8 <math>\pm</math> 0.9%</b>

Researchers have noted two main causes for the lack of equivalence in power and rate of energy change calculations: (1) noise in kinematic data due to a series of differentiations, or (2) accessory motion of skin-mounted markers due to soft tissue movement making segment endpoints inaccurate (violating rigid body assumptions) [1, 3]. While the power correction cannot parse between these two causes, it does account for them to a substantial extent.

Traditional motion capture systems cannot precisely measure real joint translations from surface markers,

which would be necessary to fully interpret the power correction term. However, these results have important implications for the interpretation of power and energy data. Using the power correction term in inverse dynamics calculations can nearly eliminate the power imbalance when tracking power and energy flow through the segments.

## CONCLUSIONS

With the inclusion of a power correction term in the corrected kinetic method, root-mean-square error between the kinetic and kinematic methods decreased by an order of magnitude with the correction term. Power imbalance as a percent difference of absolute kinematic work was reduced from an average of 12% (PI<sub>tr</sub>) to less than 3% (PI<sub>co</sub>) over the gait cycle. The corrected kinetic method facilitates improved accuracy in whole-body energetic analyses.

# LOWER EXTREMITY JOINT KINETICS IN YOUNG ADULTS WALKING WITH VARIED STEP LENGTHS

Rebecca L. Krupenevich and Ross H. Miller

University of Maryland, College Park, MD, USA  
email: rlkrup@umd.edu

## INTRODUCTION

The ability to walk greatly influences quality of life, particularly in the aging population, but many older adults report difficulty when walking short distances. This difficulty may be reflected by older adult gait mechanics, which differ from the gait of young adults. Specifically, older adults take shorter, more frequent steps when walking at the same speed as young adults, and exhibit greater hip joint torque and power, and less ankle joint torque and power compared to young adults [1]. The cause of this age-related distal to proximal shift in joint kinetics is unknown. Identifying how and why older adults walk differently than young adults may contribute to improving mobility in this population. Previous studies have found that ankle plantarflexor power is a strong predictor of step length [2], and in young adults, walking with longer step lengths results in greater plantarflexor torque [3]. However, the effect of increasing or decreasing step length on joint kinetics in young adults is not clear. Understanding the effect of step length on joint kinetics in young adults is a first step towards identifying factors contributing to the age-related changes in walking mechanics.

Therefore, the purpose of this study was to determine if changes in step length can cause young adults to walk with joint kinetics characteristic of older adults. Previous studies have found reduced ankle joint moments in young adults walking with a shorter step length [3]. Therefore, we hypothesized that ankle plantarflexor moment and power would increase at longer step lengths and decrease at shorter step lengths relative to preferred step length, and hip joint torque and power would decrease at longer step lengths and increase at shorter step lengths, relative to preferred.

## METHODS

Five healthy young adults (4 male, 1 female,  $21 \pm 0.54$  yrs,  $71.6 \pm 15.5$  kg,  $1.73 \pm 0.13$  m) participated in this study after providing written informed consent. Participants performed seven step length conditions: walking with a preferred step length (PSL) and walking with step lengths of  $\pm 5$ , 10, and 15% of step length. Participants adjusted step length by stepping to a metronome beat. Infrared timing gates were used to constrain speed to  $\pm 3\%$  of 1.3 m/s in all conditions. Since walking speed is equal to the product of cadence and step length, holding speed constant and adjusting cadence resulted in changes to step length.

Kinematic data were captured using a 13-camera motion capture system and kinetic data were captured using eight force platforms. Marker position and ground reaction force data were smoothed using a 4<sup>th</sup> order dual-pass Butterworth filter with cutoff frequencies of 6 Hz and 45 Hz, respectively. Knee joint kinetics were calculated by 6DOF inverse dynamics using Visual3D software.

A one-way repeated measures ANOVA ( $\alpha = 0.05$ ) tested for the effect of step length on peak hip and knee flexion and extension moments, and peak ankle plantarflexion moment with a Bonferonni correction in post-hoc testing. Only the PSL and  $\pm 15\%$  conditions were included in the ANOVA due to the small sample size to date.

## RESULTS AND DISCUSSION

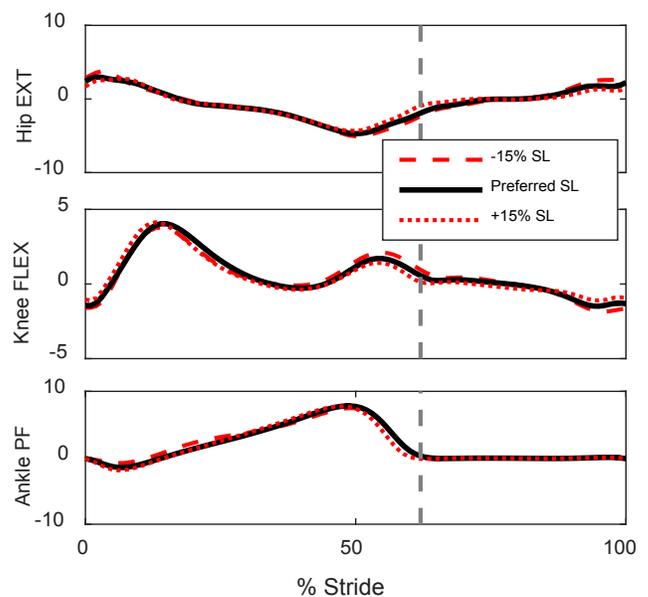

Joint moment and power waveforms are presented in Figures 1 and 2. Average stride lengths were 1.26 m, 1.46 m, and 1.63 m for -15% SL, PSL, and +15% SL, respectively. There was a significant effect of step length on peak hip extension ( $p =$

0.003) and flexion moments ( $p = 0.03$ ), peak hip positive power ( $p = 0.03$ ), peak knee flexion moment ( $p = 0.01$ ), and peak knee positive ( $p = 0.49$ ) and negative power ( $p = 0.01$ ). Peak hip extension moment was greater for -15% SL compared to PSL ( $3.83 \pm 0.54$  vs.  $3.24 \pm 0.76$  %BW\*Ht,  $p = 0.03$ ). Peak knee flexion moment was smaller for +15% SL compared to PSL ( $-1.22 \pm 0.19$  vs.  $-1.46 \pm 0.11$  %BW\*Ht,  $p = 0.03$ ), peak negative knee power was smaller for +15% SL compared to preferred and -15% SL ( $-1.17 \pm 0.37$  vs.  $-1.37 \pm 0.15$  and  $-1.71 \pm 0.21$  W/kg, all  $p \leq 0.04$ ). There were no significant pairwise comparisons for peak hip flexion moment (all  $p \geq 0.16$ ) or positive power, or peak knee positive power (all  $p \geq 0.16$ ). There was not a significant effect of step length on peak hip negative power ( $p = 0.82$ ), knee extension moment ( $p = 0.75$ ), peak plantarflexor moment ( $p = 0.39$ ), or peak plantarflexor power ( $p = 0.61$ ).

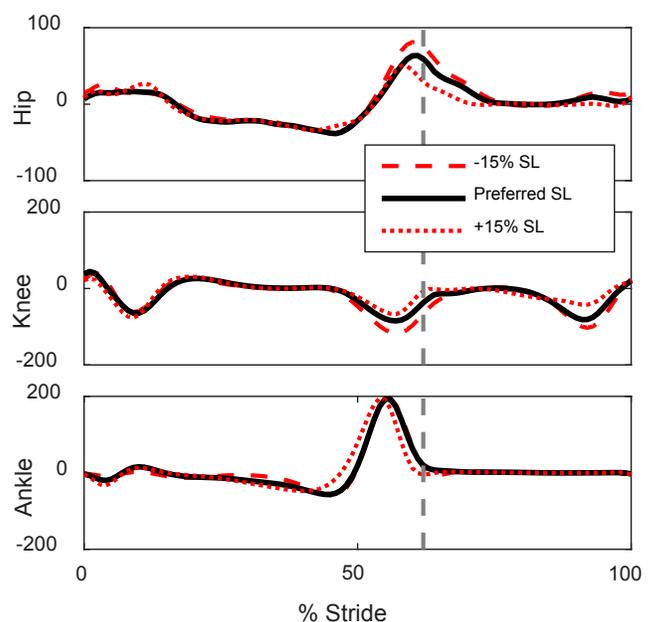

The kinetic strategies young adults use when walking with different step lengths did not involve adaptations at the ankle. Specifically, peak hip extension moment increased by 18% at shorter step lengths (-15% SL) compared to PSL, and peak knee flexion moment decreased by 16% at longer step lengths (+15% SL) compared to PSL. Similarly, at shorter step lengths, more energy was generated at the hip and absorbed at the knee.

## CONCLUSIONS

Young adults respond to walking with different step lengths by altering hip and knee, but not ankle, joint moments and powers. These findings suggest step length alone does not explain differences in joint kinetics between young and older adults and highlight the need for a similar experiment in older adults to further explain age-related distal to proximal redistribution of joint kinetics. Future work will expand upon these preliminary findings with a larger sample size, more subtle changes in step length, and alternative explanations for the age-related changes in gait mechanics, such as differences in muscle architecture characteristics.

# THE FUNCTIONAL UTILIZATION OF PROPULSIVE CAPACITY DURING HUMAN WALKING

Katie A. Conway, Randall Bissette, and Jason R. Franz

University of North Carolina at Chapel Hill and North Carolina State University, Chapel Hill, NC, USA  
email: kaconway@email.unc.edu, web: <http://abl.bme.unc.edu>

## INTRODUCTION

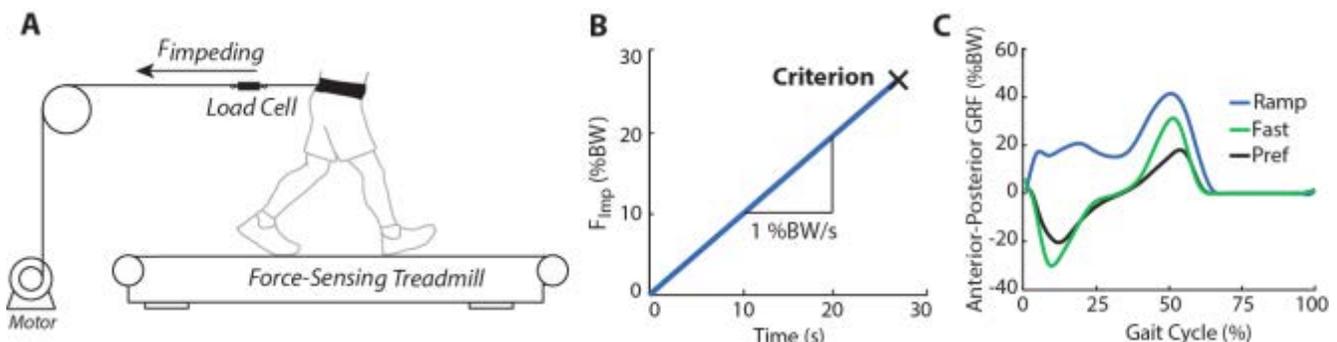

Reduced propulsive forces, arising in part from reduced net ankle joint moment and power generation during the push-off phase of walking, are thought to play an important role in age-related mobility impairment [1]. However, despite their deficits to young adults, older adults retain the capacity to enhance push-off performance, for example during uphill walking [2] and in response to biofeedback [3]. Thus, our ongoing research is based on the working hypothesis that older adults have a considerable but underutilized propulsive reserve available during walking. Conventional methods used to assess neuromuscular reserves (i.e., dynamometry) generally fail to effectively predict age-related changes in plantarflexor performance and/or yield implausible (i.e.,  $\geq 100\%$ ) values of functional capacity utilized (FCU) in walking [4].

As an important first step, the purpose of this study was to gain an improved joint-level understanding of the functional utilization of propulsive capacity during human walking in young subjects, with a special emphasis on the plantarflexor muscles. Ultimately, we intend to test the hypotheses that: (i) young adults' reserve capacity for walking faster

than preferred would correlate with their reserve capacity for increasing propulsion at a preferred walking speed, and (ii) both would yield plantarflexor FCU (%) values less than those obtained using conventional dynamometry.

## METHODS

Seven healthy young adults have thus far participated (age:  $25.6 \pm 7.0$  years, height:  $1.8 \pm 0.1$  m, body mass:  $74.0 \pm 9.7$  kg, 5M/2F). We first recorded subjects' preferred ( $1.3 \pm 0.1$  m/s) and maximum ( $2.6 \pm 0.2$  m/s) overground walking speeds as the time taken to traverse the middle 2 m of a 10 m walkway. Subjects then walked on a dual-belt force measuring treadmill (Bertec, Corp.) for 1 min at their preferred walking speed ("Pref"). Subjects then donned a waist belt that connected to a feedback-controlled, motor-driven system that prescribed horizontal impeding forces according to instantaneous measurements from a load cell (Fig. 1A). Specifically, while subjects walked at their preferred speed on the treadmill, a real-time controller increased the impeding force at a constant rate of 1 %BW per second (Fig. 1B, "Ramp"). Subjects were instructed to maintain their position on the treadmill throughout the ramped protocol while avoiding excessive forward lean. The

**Figure 1.** (A) Feedback-controlled impeding force system including load cell and motor. (B) Impeding force ( $F_{imp}$ ) ramp condition at 1 %BW/s. (C) Group mean anterior-posterior ground reaction forces (GRF) for preferred (Pref), maximum ramp (Ramp), and maximum walking speed (Fast) trials.

trial was ended following a 0.35 m inexorable posterior translation of the subjects' center of mass, monitored using the motor's encoder. In another trial, subjects walked on the treadmill at their maximum overground walking speed, which they maintained for approximately 10 s ("Fast").

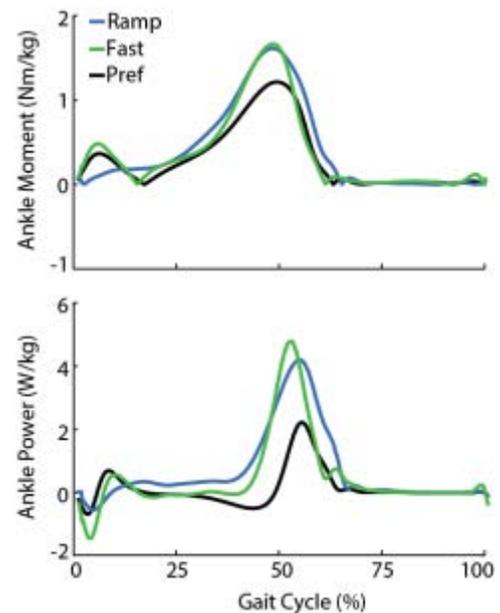

For all treadmill trials, we recorded the 3D trajectories of retroreflective markers on the pelvis and lower limbs (Motion Analysis, Corp.) in synchrony with 3D ground reaction force (GRF) data. Finally, we estimated leg joint moments and powers using inverse dynamics. For the "Ramp" and "Fast" conditions, we extracted all outcome measures from the stride associated with the largest peak anterior (i.e., propulsive) GRF. To compare to more conventional assessments, we also recorded subjects' maximum voluntary isometric ankle moment and maximum isokinetic ankle power at relatively slow (30°/sec) and fast (90°/sec) angular velocities using a dynamometer (Biodex).

## RESULTS AND DISCUSSION

Compared to normal walking, peak propulsive force, ankle moment, and ankle power increased by an average of 68%, 33%, and 115%, respectively, when subjects walked at their maximum speed ( $p$ 's<0.01) (Fig. 1C, Fig. 2). These values also increased by 123%, 35%, and 89%, respectively for the maximum ramp condition ( $p$ 's<0.01). Very surprisingly, peak ankle moment and power generation during the maximum ramp condition were nearly indistinguishable from those during maximum speed walking (Fig. 2) ( $p=0.29$  and  $p=0.21$ , respectively). Finally, isometric plantarflexor testing would have otherwise yielded the incomplete conclusion that subjects utilized, on average, 94% of their maximum available ankle moment when walking at their preferred speed. Rather, true ankle moment utilization resolved in this study averaged only 72-74% of subjects' maximum functional capacity.

## CONCLUSIONS

We present important reference data for the functional utilization of propulsive capacity during

**Figure 2.** Ankle moments and powers over an averaged stride for preferred (Pref), maximum ramp (Ramp), and maximum walking speed (Fast) trials.

walking in young adults. Using a novel ramped impeding force protocol, we discovered that young subjects walking at their preferred speed retain a functional reserve for propulsive forces of 55%, peak ankle moment of 26%, and peak ankle power of 47% during push-off that may not be fully elucidated using conventional dynamometry. Our data also suggest that plantarflexor mechanical performance may be a governing factor in regulating both maximum speed and maximum propulsive force generation during walking. Finally, we introduce a highly functional approach to the assessment of maximum propulsive capacity in walking that may have implications for the tailored prescription of interventions for individuals with propulsive deficits.

# JOINT POWER GENERATION DURING GAIT ACROSS MOOD PHASES IN BIPOLAR DISORDER

<sup>1</sup> Gu Eon Kang, <sup>1,2</sup> Brian Mickey, <sup>1</sup> Barry Krembs, <sup>1</sup> Melvin McInnis, and <sup>1</sup> Melissa Gross

<sup>1</sup> University of Michigan, Ann Arbor, MI, USA

<sup>2</sup> University of Utah, Salt Lake City, UT, USA

## INTRODUCTION

Bipolar disorder (BD) is characterized by unusual changes in mood, energy and daily tasks [1]. For example, patients with BD experience “high energy” in hypomanic phase and “low energy” in depressed phase [1]. However, these clinical characteristics are described only qualitatively, and have not yet been quantified. Gait is a daily task that requires energy generation for maintaining speed [2], and is altered by emotion in healthy people [3,4]. Since the amount of energy per unit time is power, and power generation in the lower limb is critical for gait [5], investigating joint power generation in gait may fill the gap between qualitative and quantitative descriptions of “energy” that patients with BD experience, which may help to understand more precisely the heterogeneous nature of BD. We aimed to investigate “energy” by quantifying joint power generation in gait across mood phases in BD.

## METHODS

Bipolar patients (n=21) and healthy controls (HC; n=14) recruited from the Prechter Longitudinal Study of Bipolar Disorder at University of Michigan Depression Center were included in this study. All participants had no history of neurological or orthopedic illnesses. HC had no history of personal or familial psychiatric illnesses. The Altman Self-Rating Mania Scale (ASRM) and the Patient Health Questionnaire (PHQ-9) were used to classify bipolar patients by mood phase into hypomanic phase (HM; n=4; ASRM=12.5±5.2; PHQ-9=1.8±1.5), euthymic phase (EU; n=7; ASRM=2.0±1.6; PHQ-9=13.8±7.1) and depressed phase (DP; n=10; ASRM=2.0±1.6; PHQ-9=13.8±7.1).

Marker and ground reaction force (GRF) data were obtained using an optoelectronic motion capture technology with 16 cameras (Motion Analysis, Santa Rosa, CA) at 120 Hz and two force plates (AMTI,

Watertown, MA) at 1200 Hz, respectively. Participants performed level gait for five trials at each of comfortable, slow and fast speeds. Marker and GRF data were low-pass filtered at 6 Hz and 50 Hz, respectively. We used Visual3D (C-Motion, Germantown, MD) to compute kinematic and kinetic variables. One-way ANOVA with Tukey correction was used to compare differences in mean between groups. Then, a linear mixed model with random effects of participants and fixed effects of gait velocity and groups was used to compare differences between groups while accounting for gait velocity.

## RESULTS AND DISCUSSION

Age (39.9±11.7 years) and BMI (25.8±5.3 kg/m<sup>2</sup>) were not different among groups ( $p>.05$ ). Gait velocity was significantly different between groups at comfortable speed (Table 1). Gait velocity was greatest for HM at comfortable speed ( $p<.05$ ), and also tended to be greater than other groups at slow and fast speeds. Gait velocity tended to be least for DP compared to other groups at comfortable speed.

Peak ankle power generation at all speeds, and peak knee power generation at comfortable and fast speeds, were significantly different between groups (Table 1). Peak ankle power generation was greater for HM than for EU, DP and HC at comfortable speed, greater for HM than for EU and HC at slow speed, and greater for HM than for EU at fast speed ( $p<.05$ ). Peak knee power generation was greater for HM than for EU, DP and HC at comfortable speed ( $p<.05$ ), and greater for HM than for HC at slow speed ( $p<.05$ ). Peak knee power generation tended to be the greatest for HM at fast speed. Although peak hip power generation tended to be much greater for HM than all other groups at comfortable and slow speeds, the differences were not significant.

The effects of gait velocity and mood phase on joint powers were separated statistically using a linear

mixed model (Table 2). Peak hip, knee and ankle power generation depended on gait velocity at all speeds ( $p < .05$ ). After accounting for the effects of gait velocity, however, peak ankle power generation was greater for HM than for all other groups at slow and fast speeds, and EU at comfortable speed.

## CONCLUSIONS

Individuals in the HM phase tended to walk faster than other groups at all speeds even though the difference was significant only for comfortable speed trials. Accordingly, peak joint powers also tended to be greatest for HM at the hip, knee and ankle. When the effects of gait velocity were controlled with the linear mixed model, however, group differences in peak joint power generation emerged. Peak ankle power generation was greater for HM than any other group at all speeds. These findings are consistent with qualitative observations of “high energy” for the

HM phase and suggest that biomechanical measures can contribute to the understanding of motor manifestations of BD.

## INTRODUCTION

Falls are common and perilous events in the lives of the elderly (age  $\geq 65$ ) [1]. Falls to the side are especially dangerous [2] and walking humans are inherently more unstable laterally [3,4]. Most walking environments (sidewalks, store aisles, treadmills, etc.) have finite width. It is unclear how people *regulate* lateral stepping movements in such contexts. Here, we extend a previous framework [5,6] to demonstrate how humans exploit available redundancies to achieve lateral stepping control strategies.

## METHODS

When walking on any defined path (Fig. 1), the only lateral requirement is to not step off the path:

$$-W/2 < [z_L \ z_R] < +W/2$$

where  $W$  is the path width. Due to biomechanical redundancy [6], there are *infinite* choices for each successive step,  $[z_L, z_R]$ . Likewise, our feet are not independent: they are connected to our body. Thus, we presume  $[z_L, z_R]$  act as effectors that enact control over some combination of body position ( $z_B$ ), heading ( $\Delta z_B$ ), or step width ( $w$ ) (Fig. 1). Further:

$$\begin{bmatrix} z_B \\ w \end{bmatrix} = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} \\ -1 & 1 \end{bmatrix} \begin{bmatrix} z_L \\ z_R \end{bmatrix}$$

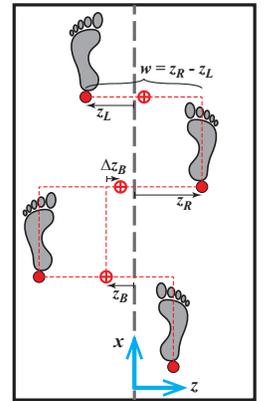

Since this relationship is invertible, specifying either  $[z_B, w]$  or  $[z_L, z_R]$  fully specifies the other. Thus, *position* ( $z_B$ ), *heading* ( $\Delta z_B$ ), and *step width* ( $w$ ) span the set of all possible variables that can be controlled: i.e., all strategies to control lateral stepping when walking on any defined path can be constructed as some combination of *position*, *heading*, and/or *step width* control. We then seek to find the most parsimonious control strategy that captures the variability and step-to-step dynamics we observe in experiment.

Models that control only a single variable ( $z_B$ ,  $\Delta z_B$ , or  $w$ ) do not work (ASB 2016). Likewise, it is impos-

sible to fully control 2 variables simultaneously because each control strategy predicts a *different* foot placement and you cannot put your foot in two places at the same time. Here, we show that multi-objective control models that *balance* control of 2 variables do replicate experimental observation.

**Figure 1:** Candidate variables for lateral stepping control:

- $\{z_L, z_R\} \equiv$  Left & Right lateral foot placements
- $z_B = (z_L + z_R)/2 \equiv$  Absolute lateral deviation of the body
- $\Delta z_B = z_{Bn} + z_{Bn-1} \equiv$  Change in lateral position of the body (a.k.a., “heading”)
- $w = z_R - z_L \equiv$  Step width.

Stochastic control computational models were developed from pre-defined goal functions [5,6]:

$$F = (q_{1n} - q_1^*) + (q_{2n} - q_2^*), \quad q_{1,2} \in \{z_B, \Delta z_B, w\}$$

where each  $q_n$  is a different state variable and the goal was to drive  $F \rightarrow 0$  (i.e., try to satisfy both goals at the same time). The process of regulating step-to-step walking dynamics was modeled as a 2D discrete map, or step-to-step update equation [5]:

$$\begin{bmatrix} q_{1n+1} \\ q_{2n+1} \end{bmatrix} = \begin{bmatrix} q_{1n} \\ q_{2n} \end{bmatrix} + \begin{bmatrix} 1 + \xi_{1m} & 0 \\ 0 & 1 + \xi_{2m} \end{bmatrix} \begin{bmatrix} u_{q1} \\ u_{q2} \end{bmatrix} + \begin{bmatrix} \xi_{1a} \\ \xi_{2a} \end{bmatrix}$$

where the  $\xi$ . were noise terms and the control inputs,  $[u_{q1}, u_{q2}]$  were derived analytically [5] to satisfy:

$$C = \alpha_1 e_1^2 + \alpha_2 e_2^2 + \gamma_1 u_{q1}^2 + \gamma_2 u_{q2}^2$$

where  $e_1$  and  $e_2$  were the errors with respect to each corresponding goal. Thus, these controllers minimized errors in each variable, while also minimizing corrections needed to achieve control. This yielded:

$$\begin{bmatrix} u_{q1} \\ u_{q2} \end{bmatrix} = \begin{bmatrix} -1/(1 + \sigma_{1m}^2 + \gamma_1/\alpha_1) & 0 \\ 0 & -1/(1 + \sigma_{2m}^2 + \gamma_2/\alpha_2) \end{bmatrix} \begin{bmatrix} q_{1n} - q_1^* \\ q_{2n} - q_2^* \end{bmatrix}$$

This control thus takes each new step as a weighted average of the 2 foot placements predicted by each

individual controller. For each possible pair of 2 candidate control variables,  $\{z_B, \Delta z_B, w\}$ , we varied this weighting (from 0% to 100%) and simulated walking for twenty trials of 1000 steps each.

In humans, stepping kinematics were recorded (Vicon) from 13 able bodied participants (age 22-40) who walked in a “CAREN” virtual reality environment [4]. Each participant completed five 3-minute walking trials at a comfortable speed [4].

Stepping parameters analyzed included time series of left ( $z_L$ ) and right ( $z_R$ ) foot placements, lateral position ( $z_B$ ), heading ( $\Delta z_B$ ), and step width ( $w$ ). Means, standard deviations, and Detrended Fluctuation Analysis (DFA)  $\alpha$  exponents [5] were calculated for each time series to compare step-to-step dynamics predicted by each controller to experiment.

## RESULTS AND DISCUSSION

Humans exhibited variability in all stepping variables (Fig. 2; Left). Control models that tried to control either heading & position or heading & step width failed to replicate experimental findings, regardless of the relative proportion of control.

However, the model that traded-off control of absolute position ( $z_B$ ) and step width ( $w$ ) was able to replicate all relevant experimental stepping dynamics when the proportion of control was weighted ~85%-95% towards  $w$ -control, with ~15%-5% towards  $z_B$ -control (Fig. 3).

## CONCLUSIONS

Computational control models yielded directly testable predictions that demonstrate humans adopt *multi-objective* lateral stepping control that prioritizes step width, while trading-off some step width control to maintain lateral position control. Prioritizing step width helps maintain lateral balance [3,4], which is highly relevant for those prone to falling [1,2].

## INTRODUCTION

Although 85% of individuals post-stroke regain some level of steady-state walking function, over one third of these individuals are unable to walk in the community (e.g., [1]). Walking in the community involves performance of adaptability tasks such as obstacle negotiation, stepping up a curb and changing walking direction [2]. Successful performance of these tasks requires the control of dynamic balance, which is a major challenge post-stroke.

Prior studies have shown that the regulation of whole-body angular momentum ( $H$ ) is essential to controlling dynamic balance. For example, older fallers have shown insufficient regulation of angular momentum after a trip [3]. Further, poor regulation of  $H$  during steady-state walking results in a higher peak-to-peak range of  $H$ , which has been associated with lower clinical balance scores in individuals post-stroke [4].

$H$  is primarily regulated by muscle forces through the generation of ground-reaction-forces (GRFs). Simulation analyses of healthy adults during steady-state walking indicate that soleus (SOL), gastrocnemius (GAS), and gluteus medius (GMED) are the primary contributors to the regulation of  $H$  in the frontal plane during late stance [5]. However, plantarflexor weakness is a common impairment post-stroke. Thus, muscle weakness and altered activation may contribute to poor regulation of  $H$  during walking and more challenging adaptability tasks. Further insight into the regulation of  $H$  and the underlying muscle activations post-stroke can contribute to the development of training programs targeted to improve walking adaptability.

Thus, the purpose of this study was to assess the regulation of  $H$  during a variety of walking adaptability tasks in individuals post-stroke and to examine the corresponding changes in the muscle activations relative to steady-state walking.

## METHODS

Three-dimensional kinematics and bilateral surface electromyogram (EMG) data were recorded from 16 individuals with post-stroke hemiparesis (11 left hemiparesis; age:  $60 \pm 12.5$  years; 5 female; self-selected walking speed:  $1.08 \pm 0.29$  m/s). Data was collected during a variety of walking adaptability tasks: self-selected (SS), fastest-comfortable (FC) and backward (BW) walking as well as obstacle negotiation and step up, which were divided into leading and trailing limb phases. These phases included obstacle leading (OBL), obstacle trailing (OBT), step up leading (SUL) and step up trailing (SUT). No orthotics were used. Additionally, data from 10 healthy individuals (age:  $23 \pm 2.9$  years; SS walking speed:  $1.35 \pm 0.13$  m/s) were collected to provide a basis for comparison.

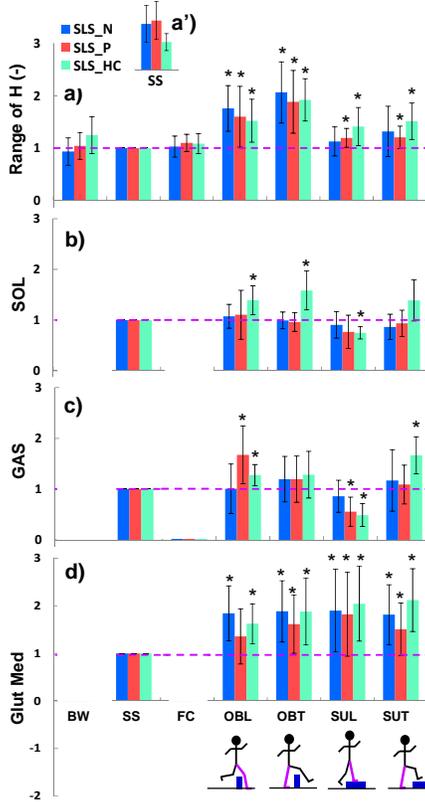

Whole-body  $H$  was calculated in the frontal plane using kinematic data [4]. The regulation of  $H$  was assessed using the peak-to-peak (max-min) range of  $H$  in the frontal plane during single-limb stance (SLS). This phase was selected because  $H$  is regulated by the stance leg through the generation of GRFs, which may be challenging post-stroke. EMG data from SOL, GAS and GMED were high-pass filtered at 30Hz, demeaned, rectified and low-pass filtered at 10Hz using a 4<sup>th</sup>-order Butterworth filter. Muscle activation in each task was quantified by averaging EMG amplitudes of each muscle

during SLS, normalized by the mean amplitude of the same muscle during the SS task.

Significant differences in the regulation of  $H$  between each task versus SS were identified using a paired t-test with Bonferroni adjustment within each condition: paretic SLS, nonparetic SLS, and average of both legs during SLS in healthy controls (HCs). In cases where significant differences were found, comparisons were conducted between the muscle activations during that task relative to the SS task.

## RESULTS AND DISCUSSION

The range of  $H$  in the frontal plane significantly increased during the obstacle and step up tasks relative to the SS task both in individuals post-stroke and in HCs (Fig. 1a). However, note that the baseline range of  $H$  during the SS task is over 65% higher in individuals post-stroke than in the HCs (Fig. 1a'). Thus, overall individuals post-stroke demonstrated higher ranges of whole-body angular momentum during all movement tasks than the HCs. This was particularly evident during the adaptability tasks, which required increased generation of  $H$ .

**Figure 1:** Normalized mean ( $\pm$ SD) a) range of  $H$  in the frontal plane, EMG amplitudes of b) soleus, c) medial gastrocnemius, and d) gluteus medius muscles are shown. All figures are normalized with respect to the SS condition and correspond to the single leg stance of the nonparetic leg (blue), paretic leg (red), and average of both legs in healthy controls (green). Significant differences within each group between each task and the SS task are shown with '\*'. Fig. 1a' shows the baseline range of  $H$  in the frontal plane in individuals post-stroke and in healthy controls during the SS task.

For the tasks where the range of  $H$  increased relative to the SS, with the exception of SUL, the

HCs demonstrated a concurrent increase in plantarflexor (SOL, GAS) and hip abductor (GMED) activation (Fig. 1b-d). Interestingly, while individuals post-stroke increased their hip abductor activation, minimal changes in the plantarflexors were evident (Fig. 1b-d). Based on their high range of  $H$  during the SS task (Fig. 1a'), one explanation could be that the individuals post-stroke recruited SOL maximally during the SS task and thus were unable to increase its activation to meet the increased task demands. In the case for GMED, adjustments in muscle activation were more evident across tasks post-stroke. It is possible that this proximal muscle contributed to a lesser extent to the SS task. Further, during the adaptability tasks, the higher pelvic and trunk control requirements along with the commonly used hip strategy post-stroke, may have collectively contributed to the increased GMED activations.

Prior simulation analyses of healthy adults during SS walking have shown the importance of the plantarflexors and the hip abductors in controlling dynamic balance in the frontal plane [5]. Specifically, SOL and GAS act to rotate the body towards the contralateral leg, while GMED acts to rotate the body towards the ipsilateral leg [5]. During these more challenging adaptability tasks, the contributions from these muscles may be even more important for balance control.

In summary, quantifiable deficits in the regulation of  $H$  and muscle activation levels were identified in individuals post-stroke during walking adaptability tasks. Rehabilitation focused on improved muscle activation during such tasks may contribute to recovery of home and community mobility in individuals post-stroke.

## INTRODUCTION

Athletes are at an increased risk of ACL injury during landing tasks, particularly at or immediately following the time of ground contact [1]. Differences in landing mechanics have been reported following ACL-R [2-4]. These movement differences have been proposed as risk factors for subsequent injury to either the ipsilateral or contralateral limb [2]. Asymmetry between limbs is common following ACL-R and has been cited as a potential risk factor for secondary injury [2,3]. Asymmetries in knee flexion angle, and vGRF have been reported in ACL-R populations, and asymmetries in knee extension moment and in frontal plane range of motion have been associated with an increased risk of sustaining a secondary ACL tear following return to sports [2,4].

Symmetry measures such as the Symmetry Index (SI), Ratio Index (RI), Gait Asymmetry (GA) and the Symmetry Angle (SA) have been used in the literature for years to quantify the extent of asymmetry between limbs at different joints. While each of these indices is useful, they all have limitations. For instance, RI tends to very large values as the denominator approaches zero, irrespective of the value of the numerator. The GA uses the natural logarithm and hence is useful only for positive quantities, which may be an issue based on the biomechanical axis system that is defined. The SI is the most generalizable of these indices, but it tends to saturate at its maximum value (max value = 200) when the measured variables are opposite in sign, which is again an issue depending on the variable of interest as well as the type of population being studied.

Another general issue with all these indices (apart from the SI) is that they cannot be used universally across different variables. For the same subject, a

high value of asymmetry in the knee might not be comparable to a high value of asymmetry in the ankle because the symmetry indices in the literature are not standardized, making clinical comparisons more challenging.

Therefore, the purpose of this study was to develop a new symmetry index, based on the SI, which addresses the weaknesses of the other measures in the literature. In addition, this study will demonstrate how this new symmetry measure will allow for comparison across different variables and will demonstrate the advantage of this new symmetry measure when compared to currently available measures.

## METHODS

23 ACL-R athletes (9 males, 14 females, 16.0±1.3 years, 1.69±0.09 m, 72.0±15.7 kg) and 12 control subjects (9 male, 3 female, 22.2±2.2 years, 1.76±0.01 m, 75.6±13.8 kg) participated in the study. All subjects underwent an ACL tibial tunnel-independent reconstruction with a hamstring graft. All subjects signed an approved assent or consent form prior to testing.

46 retro-reflective markers were placed on specific lower extremity landmarks by a single researcher as previously described [4]. An 8-camera motion capture system collected three-dimensional data at 120 Hz (Motion Analysis Corporation, Santa Rosa, CA). Ground reaction forces were measured with two embedded force plates collecting at 2400 Hz (AMTI, Watertown, MA). Each subject performed five vertical stop-jump tasks. The stop-jump task involved a running approach of several steps, a jump off one foot, a two-footed landing, and a subsequent two-footed jump. Subjects were told to approach as quickly as possible and to jump as high as was safely possible. No instruction on landing was given.

Kinematic and kinetic data were collected bilaterally during all trials.

The three-dimensional data was filtered with a 12 Hz low-pass Butterworth digital filter and ground reaction forces (GRF) were filtered at 100 Hz. Time-series curves were generated with Visual 3D software (C-Motion, Bethesda, Maryland, USA) and Matlab (MathWorks, Natick, MA) was used to extract the variables of interest.

Data from the surgical and non-surgical limbs (dominant and non-dominant) of each subject were used to calculate limb symmetry using the previously published SI as well as the newly developed Normalized Symmetry Index (NSI) for each variable using the following formula:

$$NSI = \frac{X_{NSx} - X_{Sx}}{|max(X_{Sx}, X_{NSx})|} * 100\%$$

where  $X_{Sx}$  and  $X_{NSx}$  denote data for the surgical and non-surgical limbs, respectively. An NSI of 0 would represent perfect movement symmetry between limbs. Since repeated measurements were available for each subject, the NSI was calculated using individual measurements and then the mean NSI was calculated. This allowed for the computation of the (intra-class correlation) ICC to evaluate the within and between subject variability in the NSI. A series of independent samples Wilcoxon signed rank tests was performed to compare the NSI in the control and treatment groups for the different variables ( $\alpha=0.05$ ). The non-parametric test is used due to the non-normal nature of the data. Statistical analysis was performed in R.

## RESULTS AND DISCUSSION

To better describe the differences that result from these various measures, we have provided subject specific examples as well as the group comparisons results. The peak valgus angles for the landing trials for a representative ACLR subject (Table 1) demonstrate the between trial variability that exists in this sample. In the calculation of the SI, the large differences between trials has a disproportionate effect resulting in a SI of -200. This difference is reflected when the mean of the SIs and NSIs are computed, yielding a mean SI of -64.17, and a mean NSI of -38.08. If trial 1 is dropped, however, the

mean SI reduces to -37.00, and the mean NSI reduces to -23.2. This illustrates the problem of the robustness of SI as a measure to use in clinical applications.

Table 1: Differences between SI and NSI for a representative subject from the ACLR group

Surgical Peak Valgus	Non-Surgical Peak Valgus	SI	NSI
0.70	-5.57	-200	-112.49
-4.54	-4.45	2.03	2.01
-0.89	-5.54	-144.56	-83.91
-4.73	-3.95	18.07	16.57
-3.50	-3.99	-13.21	-12.39
-3.51	-5.68	-47.33	-38.28
Mean= -2.74	Mean= -4.86	Mean= -64.2	Mean= -38.1

When comparing the two study groups it is clear that the NSI will allow for detection of asymmetries that are not as drastically impacted by between trial variability in joint position.

Table 2: Median Symmetry Measure comparison between the ACL-R and treatment groups using the NSI

	ACLR	Control	p-value
Frontal Plane Knee ROM	17.04	31.25	0.019*
Peak Vertical GRF	17.23	8.96	0.014*
Peak Knee Valgus	42.28	21.60	0.490
Peak Knee Ext Moment	23.87	8.19	0.003*

## CONCLUSIONS

The NSI as a measure of symmetry will allow for the detection of differences between groups as well as allowing for the comparison of the amount of asymmetry across various variables, which is not possible with the previously defined measures of asymmetry due to their measurement limitations.

## INTRODUCTION

250,000 ACL injuries occur annually and incur over \$2 billion in reconstructive and rehabilitative cost. Hence, it is essential that the orthopedic community better understand the underlying mechanisms that contribute to ACL rupture. A number of impact simulators were developed over the past decade to investigate intra-articular biomechanics at the knee [1]. Most of these platforms were used to investigate the effects of individual elements such as internal tibial torsion, quadriceps force, or hamstrings force on ACL strain during impulse loading. More recently, an impact simulator was designed that was capable of consistently inducing failure on the ACL [2]. However, these failures were mainly tibial avulsions or eminence fractures. Unfortunately, this does not correlate well with the clinical modality of failure observed in surgery. Accordingly, we designed a novel mechanical impact simulator with the intention of addressing this issue. It was hypothesized that our novel impactor design could reproducibly produce ACL failures on cadaveric specimens in modalities that correlate well with clinically observed failures.

## METHODS

35 cadaveric specimens were tested in our novel mechanical impact simulator. Detailed description of the simulator protocol is available in the literature [3]. Briefly, the simulator delivered a series of gravity-driven impulse forces into a ground platform that was aligned with the tibia of lower-extremity cadaveric specimen. Pneumatic actuators simultaneously applied external anterior tibial shear (ATS), knee abduction (KAM), and internal tibial rotation (ITR) forces and torques to the knee joint. All of these applied loads were derived from *in vivo* motion analysis and corresponding biomechanical assessment of athletes performing a drop vertical

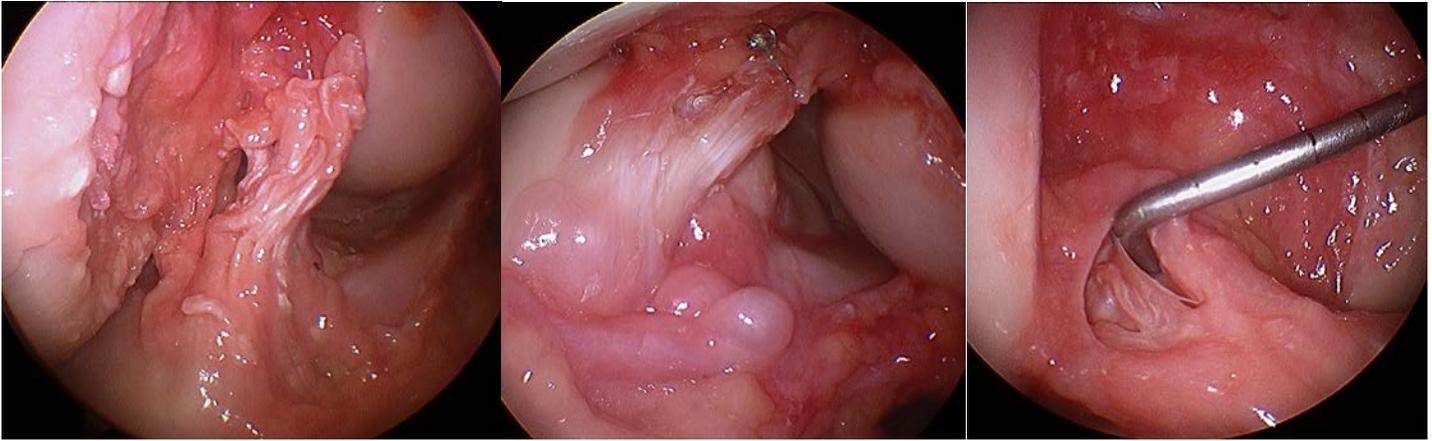

jump task off a 31 cm box. A 6-DOF load cell aligned with the long axis of the femur and affixed 20 cm proximal to the joint center point reported loads at the knee. DVRT strain gauges implanted on the ACL and MCL reported ligament strain. A board certified orthopedic surgeon performed clinical and arthroscopic exams pre- and post-testing to assess functional and structural integrity. Injury was attributed to the simulator if exam grades changed between pre- and post-testing. Six specimens were excluded due to unsuitable tissue quality or complications during the testing protocol. 29 specimens remained for analysis (age =  $42.0 \pm 8.5$  years; mass =  $87.6 \pm 21.7$  kg; height =  $175.6 \pm 8.9$  cm; 11 females; 18 males).

## RESULTS AND DISCUSSION

Of the 29 specimens tested, 27 experienced soft tissue failures, of which 25 were ACL failures and 2 were isolated MCL failures (Table 1). The remaining 2 specimens failed via femoral fractures. There was one specimen that received a grade 2 MCL laxity score prior to testing; and thus, was not considered and MCL injury induced by the impact simulator. None of the 29 specimens completed testing without sustaining any injuries. Within the ACL injured specimens, 9 (31%) also expressed concomitant MCL failure induced by the mechanical impact simulator. Twenty of the ACL injuries were complete tears, while 3 were partial tears (Table 2). 17 ACL ruptures were proximal on the femoral side, 6 occurred midsubstance, and 2 were distal on the tibial side (Figure 1). All but one injury reported on the specimens were attributed to the mechanical impact simulations (Table 3).

**Table 1:** Specimen failure modalities.

ACL Rupture	MCL Rupture	Other Soft Tissue	Femur Fracture
86%	38%	3%	7%

**Figure 1:** Image frames depicting various ACL rupture modalities from the mechanical impact simulator. From left to right, these frames exhibit 1.) a complete femoral avulsion, 2.) a complete midsubstance tear, 3.) a partial midsubstance tear. During a Lachman’s exam, both complete tears were grade 3, while the partial was grade 2.

**Table 2:** ACL rupture locations.

Femoral Avulsion	Mid-Substance	Tibial Avulsion	Complete	Partial
72%	24%	8%	80%	12%

**Table 3:** Number of specimens that recorded positive grades during pre- and post-testing clinical exams. Mean grade for all specimens is in parentheses.

	Lachman	PCL	MCL	LCL
Pre-Test	0 (0.0)	0 (0.0)	1 (0.1)	0 (0.0)
Post-Test	25 (2.5)	0 (0.0)	12 (1.2)	5 (0.4)

The mean peak ACL strain prior to failure in all specimens was  $14.5 \pm 9.0\%$  with a mean peak MCL strain of  $6.8 \pm 8.2\%$ . The mean peak ACL strain prior to failure in the 25 specimens that failed via ACL rupture was  $13.5 \pm 8.2\%$ , with a mean peak MCL strain of  $6.3 \pm 8.7\%$ . The mean peak ACL strain prior to failure in the 10 specimens that sustained MCL injury was  $17.1 \pm 8.6\%$  with a mean peak MCL strain of  $10.5 \pm 9.0\%$ . These values are similar to the peak strain reported in uniaxial ACL failure testing. However, the present ACL strains are smaller than those from a previous injury impactor [2]. This could be a result of the more physiologic loading conditions of our novel device that presented more clinically representative modalities of ACL failure. The increased ACL strain in MCL-injured specimens indicated that the ACL likely compensated for some of the knee restraint lost during MCL injury. Further, the higher strain observed in the ACL vs. MCL is

supportive of literature that indicates the ACL makes greater contributions to knee restraint than the MCL [4, 5].

The injury pattern demonstrated in the 25 specimens that exhibited ACL failure was representative of that which is observed clinically. Femoral side ACL tears are most common, followed by mid-substance tears, followed by tibial avulsions [5].

## CONCLUSIONS

The hypothesis that our novel mechanical impactor would reproducibly create clinically representative modalities of ACL failure was accepted and all results were confirmed by a board certified orthopedic surgeon. The presented simulator is optimized for the study of ACL injury, reconstruction and deficiency in cadaveric models.

## INTRODUCTION

Females have an increased risk of injury to the anterior cruciate ligament (ACL) compared to their male counterparts [1]. Additionally, 75% of these ACL injuries are non-contact in nature, demonstrating that biomechanical kinetics and kinematics are significant risk factors to this injury. Consequently, it is important to understand the underlying mechanisms of ACL injury to determine the factors that increase ACL injury risk in females. Improved knowledge of the mechanisms of ACL will enhance injury prevention, rehabilitation, and return to sport (RTS) criteria for these athletes.

This current study was designed to specifically determine the mechanisms of loading at the knee that cause ACL failure during a common athletic task – a drop vertical jump (DVJ). It was hypothesized that female limbs would demonstrate differences in knee forces and moments that predispose females to ACL injury compared to males, especially with frontal plane knee abduction.

## METHODS

A custom-designed cadaveric impactor was utilized to simulate athletic DVJs in lower extremities of 35 specimens (22M:13F). Ages of specimens ranged from 24 to 52. Inclusion criteria of the specimens include: no evidence of significant trauma/surgery to lower extremity and no evidence of extended chemotherapy. Specimens were prepared according to specifications outlined in a recent methodology manuscript [2].

*In vivo* kinetics and kinematics of 70 subjects were calculated to determine tertiles of risk (i.e. low, medium, and high) in three degrees of knee forces/moments [i.e. knee abduction moment

(KAM), anterior tibial shear (ATS), and internal tibial rotation (ITR)]. Pneumatic cylinders then applied the designated knee forces/moments to the tibia calculated from the *in vivo* subjects and then a gravity-driven drop sled of 0.5 body weight (34 kg) was released from a height of 31 cm with quadriceps and hamstrings co-contracted with a 1:1 ratio. Single axis and 6-axis load cells recorded vertical ground reaction forces (vGRF) and forces/moments at the knee, respectively. Additionally, two differential variable reluctance transducers (DVRTs) were implanted into the medial collateral ligament (MCL) and the ACL for measurements of ligament strain during loading. Six specimens were excluded for unsuitable tissue quality or complications that arose during the experimental protocol. Four additional specimens were excluded as they did not experience ACL rupture. Twenty-five specimens remained for analysis (16M:9F; **Table 1**).

Statistical analyses were performed with JMP 10 (SAS Institute Inc., Cary, NC) with utilization of one-way ANOVA.

**Table 1:** Specimen Demographics by Sex.

	Males	Females	<i>p</i> -value
<b>Age</b>	42.6 ± 8.1	41.7 ± 8.3	0.7813
<b>Mass (kg)</b>	94.3 ± 17.8	72.5 ± 19.6	0.0094
<b>Height (cm)</b>	180.6 ± 4.9	165.9 ± 3.1	<0.0001

## RESULTS AND DISCUSSION

The cadaveric impactor reliably reproduced clinical ACL ligament ruptures in the 25 specimens included in this analysis (i.e. 17 femoral avulsions, 6 mid-substance ruptures, and 2 tibial avulsions). The vGRF was consistent across all randomized trials. Statistical comparison of vGRF demonstrated no significant difference between males and females with minimum values, maximum values, initial

contact, or 33 msec, 66 msec, or 100 msec post-contact. This is important as significant differences in vGRF would increase forces/moments at the knee. However, consistency of the vGRF across trials demonstrates that biomechanical mechanisms other than vGRF influenced forces and moments at the knee more significantly to induce ACL injury.

With maximum values between sex, females demonstrated a significant increase of maximum knee compression ( $F_{1,24}=6.6497$ ;  $p=0.0168$ ) and a significant difference of maximum knee extension moment ( $F_{1,24}=8.1078$ ;  $p=0.0091$ ). There was a trend towards significance for females to have an increase KAM ( $F_{1,24}=4.0761$ ;  $p=0.0553$ ) compared to males. Normalization of maximum values by body weight and height demonstrated significantly increased KAM ( $F_{1,24}=9.1274$ ;  $p=0.0090$ ) and a significant trend with ITR ( $F_{1,24}=3.4408$ ;  $p=0.0765$ ) of females in comparison to males.

At initial contact compared to males, females exhibited significant more compression of the knee ( $F_{1,24}=12.8497$ ;  $p=0.0016$ ) and significantly greater extension moment ( $F_{1,24}=4.5796$ ;  $p=0.0432$ ). At 33 msec post-impact compared to males, females demonstrated significant trends in lateral translation ( $F_{1,24}=3.2485$ ;  $p=0.0846$ ) and compression ( $F_{1,24}=3.6331$ ;  $p=0.0692$ ). At 66 msec post-impact compared to males, females demonstrated significant trends in lateral translation ( $F_{1,24}=3.5165$ ;  $p=0.0735$ ) and compression ( $F_{1,24}=3.2832$ ;  $p=0.0831$ ). At 100 msec post-impact compared to males, females demonstrated significantly increased knee extension moment ( $F_{1,24}=14.1998$ ;  $p=0.0010$ ) and KAM ( $F_{1,24}=6.6006$ ;  $p=0.0172$ ) (**Table 2**).

These data indicate that with ACL failure trials, females exhibited significantly greater knee

extension moments and compression. When normalized to height and body weight, females exhibited significantly greater KAM compared to males. Relative to load timing characteristics, females exhibited significantly greater knee compression and extension moment at initial contact. At 100 msec post-impact, females demonstrated significantly greater knee extension moment and KAM. Knee extension and KAM are theorized mechanisms that load the ACL and can consequently lead to rupture.

## CONCLUSIONS

Females exhibit greater forces and moments at the knee that predispose them to ACL injury compared to males. Our unique cadaveric simulator reproduced clinical ACL ruptures in both sexes with demonstrations of increased aberrant loading of forces and moments of the knee for females. This evidence indicates that the previous theorized mechanisms of ACL injury [3] (i.e. knee extension, KAM, and ITR) are significant contributors to ACL injury.

## INTRODUCTION

Magnetic resonance (MR) T<sub>2</sub>\* is an imaging property that reflects collagen organization, with lower T<sub>2</sub>\* relaxation times corresponding to more aligned fibers [1]. The purpose of this study was to develop a T<sub>2</sub>\* relaxometry-based statistical model to predict the structural properties of the healing anterior cruciate ligament (ACL) over a 24-week (w) healing period in a preclinical model of ACL repair. Two hypotheses were tested: (1) that a multiple linear regression model based on both short and long T<sub>2</sub>\* relaxation times would outperform a competing model based on short T<sub>2</sub>\* relaxation times only; and (2) that an optimized prediction model would be capable of predicting ACL structural properties between 6 and 24 weeks post-repair.

## METHODS

Subjects: Twenty-four 15±1 month old (12 castrated males, 12 females; Sinclair Bio Resources, MO) Yucatan minipigs were randomized to receive primary suture repair with (n=12; 6 female) or without (n=12; 6 female) a scaffold to enhance primary healing [2]. All animal procedures were approved by the Institutional Animal Care and Use Committee. In vivo MR imaging: ACLs were imaged (8 per group) at either 6, 12, or 24w after ACL repair using a 512x512 acquisition matrix (voxel size=0.31x0.31x0.8mm) and a 3D gradient 4-echo sequence. Animals were euthanized immediately after imaging, and the hind limbs were harvested and kept frozen until tensile testing. ACL T<sub>2</sub>\* estimation: ACLs were segmented manually by

a single segmenter (Mimics v16, Belgium). T<sub>2</sub>\* relaxation times were calculated on a voxel-wise basis by fitting a monoexponential function to the signal decay across the four echoes. The segmented ACL voxels were then binned into four sub-volumes based on their T<sub>2</sub>\* relaxation times: Vol<sub>1</sub>=0-12.5ms; Vol<sub>2</sub>=12.6ms-25ms; Vol<sub>3</sub>=25.6-37.5ms; Vol<sub>4</sub>=37.6-50ms [3]. Vol<sub>1</sub> is the sub-volume (in mm<sup>3</sup>) of the ACL voxels containing the most organized collagen, whereas Vol<sub>4</sub> is the sub-volume containing the least organized collagen. ACL structural properties: Hind limbs were thawed, dissected leaving only the ACL, and then tensile tested. ACL maximum load, yield load, and linear stiffness were calculated from the load-displacement data determined from the tensile tests [4]. Statistical models: For each structural property, two competing multiple linear regression models were fitted to the data:

1. A 6-parameter model = Vol<sub>1</sub> at 6w, 12w, 24w and (Vol<sub>1</sub> x healing time) interaction

2. A 12-parameter model = the same six parameters as (1), with the addition of Vol<sub>4</sub> at 6w, 12w, 24w; (Vol<sub>1</sub> x Vol<sub>4</sub>) interaction; and three-way (Vol<sub>1</sub> x Vol<sub>4</sub> x healing time) interaction

The Akaike Information Criterion (AIC), which provides an objective measure of the trade-off between goodness of model fit and model complexity, was used to test the first hypothesis by comparing the AIC values of the 6- and 12-parameter models. Lower AIC values indicate superior model performance [5]. To test the second hypothesis, model predictions for each structural property were compared to the measured values in

separate optimized models. The slopes of the optimized models at 6, 12 and 24w were then evaluated to determine whether the slopes contributed significantly to the model predictions at each of the healing time points.

## RESULTS AND DISCUSSION

The AIC values for the multiple linear regression models that were based on both short and long  $T_2^*$  relaxation times were lower than the models based on the shortest relaxation times only (Table 1).

**Table 1.** Regression model AIC values (unitless).

	6-Parameter Model	12-Parameter Model
Failure Load	28.4	23.8
Yield Load	28.6	23.3
Stiffness	29.2	22.0

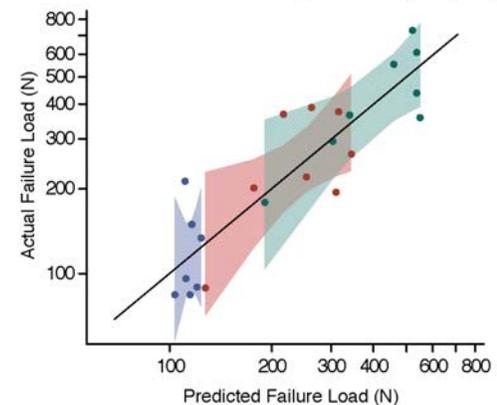

In the optimized 6-parameter ( $Vol_1$ ) only models, the slopes were significant at 12 and 24w, but not at 6w for all structural properties. Conversely, slope was significant at all time points in the 12-parameter ( $Vol_1 + Vol_4$ ) optimized models (Fig 1).

The results supported our hypotheses: the AIC values were lowest in the 12-parameter ( $Vol_1 + Vol_4$ ) models, and the ACL structural properties could be predicted throughout the 24w healing period using this model. Including  $Vol_4$  and its interaction terms had the effect of spreading out the values of the predicted ACL structural properties at 6w, making the slopes significant throughout the 24w healing period. This finding suggests that in addition to the quantity of organized collagen, the amount of disorganized tissue encompassed by the  $Vol_4$  sub-volume is especially important at early time points. We believe that  $Vol_4$  could reflect compositional elements related to the sub-acute healing process that may then modulate collagen organization at later phases of healing following primary ACL repair.

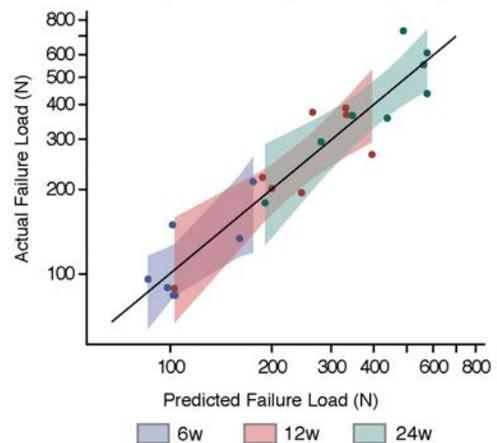

## CONCLUSIONS

Our time-specific,  $T_2^*$ -based prediction model may allow us to estimate the structural properties of ACL repairs in vivo longitudinally.

a. Failure load at 6, 12 and 24w predicted by  $Vol_1$  only

b. Failure load at 6, 12 and 24w predicted by  $Vol_1$  and  $Vol_4$

**Figure 1.** Actual versus predicted failure load for (a) the 6-parameter ( $Vol_1$ ) model and (b) 12-parameter ( $Vol_1+Vol_4$ ) model. Shaded regions encompass the 95% confidence intervals of the estimated slopes at each time point. Each circle corresponds to one animal.

# THE EFFECT OF RETURN-TO-SPORT TRAINING ON GAIT MECHANICS AND KNEE LOADING IN MEN AND WOMEN AFTER ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION

Jacob J. Capin, Ashutosh Khandha, P. Michael Eckrich, Ryan Zarzycki, Amelia J. H. Arundale, Kurt Manal, Thomas S. Buchanan, Lynn Snyder-Mackler

## INTRODUCTION

After anterior cruciate ligament (ACL) reconstruction (ACLR), individuals often walk using a “stiff-knee” gait in their involved (ACLR) limb. While gait symmetry (involved vs. uninvolved limb) likely improves over time, gait asymmetries may persist 2 years after ACLR [1]. Moreover, gait asymmetries may be related to poor functional performance [2] and the development of early knee osteoarthritis (OA) after ACLR [3]. Therefore, it is critical to investigate gait mechanics over time after ACLR and the influence of rehabilitation on the presence of gait asymmetries. The purpose of this study was to analyze gait mechanics, including medial compartment tibiofemoral loading, and the presence of gait asymmetries in men and women after ACLR, before and after return-to-sport training. We hypothesized that this training would improve gait symmetry in men and women.

## METHODS

This is a preliminary analysis of an ongoing study that will have 80 participants (40 M, 40 F). Forty-four athletes (age:  $21.1 \pm 7.7$  years, range: 13-54 years; sex: 26 men, 18 women) in jumping, cutting, and pivoting sports participated after primary ACLR when they achieved impairment resolution including quadriceps strength index of  $\geq 80\%$  (post-operative time:  $22.8 \pm 7.4$  weeks, range: 13-40 weeks). All participants underwent motion analysis testing during overground gait with bilateral surface electromyography (EMG). We conducted testing at two post-operative time points: before (pre-training) and after (post-training) a return-to-sport (RTS) training program including strength, plyometric, agility, and secondary prevention exercises.

We used a previously-validated, EMG-informed musculoskeletal model [4,5] to estimate medial tibiofemoral joint contact force. This patient-specific model uses a Hill-type muscle fiber model and establishes optimal muscle parameters (within  $\pm$

20% of normative values) via simulated annealing, in which the squared difference between the internal and external sagittal plane knee moment curves is minimized. Joint contact forces are determined using a frontal plane moment algorithm that balances external knee adduction moment with internal muscle forces. We averaged three predicted walking trials per limb, per subject for analysis. Self-selected gait speed was controlled within subjects to  $\pm 5\%$  across trials and time points. We calculated joint kinematics and kinetics via inverse dynamics using commercial software (Visual3D; C-Motion, Germantown, MD). Knee flexion and adduction moments were normalized by mass\*height ( $\text{kg}\cdot\text{m}$ ) while joint contact forces were normalized by body weight (BW).

We analyzed peak tibiofemoral medial compartment contact force (pMCF), peak knee flexion angle (pKFA) and moment (pKFM), and peak knee adduction moment (pKAM) using 2x2x2 ANOVAs ( $\alpha=0.05$ ): sex (male vs. female), limb (involved vs. uninvolved), and the repeated measure of time (pre-training vs. post-training). We also calculated the proportion of men and women who walked with meaningful gait asymmetries at each time point: we trichotomized participants as overloaders, symmetric, or underloaders by comparing inter-limb differences (involved – uninvolved) to minimal detectable change (MDC) values [6].

## RESULTS AND DISCUSSION

Women walked using larger pMCF ( $p=0.017$ ) compared to men (Table 1). There were main effects of limb for pMCF ( $p=0.003$ ), pKFA ( $p=0.001$ ), and pKFM ( $p<0.001$ ) with smaller values for each variable in the involved versus uninvolved limb. Interestingly, when comparing group mean differences to MDC values [6], both men and women walked with symmetrical joint loading at pre-training. However, at post-training, women as a group underloaded their involved versus uninvolved

medial tibiofemoral compartment while men continued to load symmetrically. This change in loading was due to 9 (of 18) women who had a meaningfully smaller inter-limb loading difference at post-training compared to pre-training. At pre-training, an equal number of women overloaded (N=5) versus underloaded (N=5) their involved knee, while at post-training, all but one women loaded symmetrically or underloaded. In contrast, the proportion of men in each loading classification remained stable over time (Table 2). There were no statistically significant main effects of time, 2-way interactions, or 3-way interactions for any of our variables (kinematic, kinetic, or joint loading).

Our preliminary findings refute our hypothesis and suggest that an RTS training program does not restore gait symmetry. Unexpectedly, while similar proportions of men and women walked symmetrically at pre- and post-training, there was a shift toward underloading among women at post-training. This shift did not occur in men, who remained relatively stable over time: 16/26 (61.5%) men remained in the same loading category, while only 8/18 (44.4%) women were consistent across time. Thus, women and men may respond differently to RTS training.

These differing responses among women and men could influence their subsequent risk for OA. While some studies suggest overloading may place

individuals at risk for OA, other findings indicate underloading 6 months after ACLR may be a risk factor for developing radiographic OA 5 years postoperatively [3]. It is possible that women who initially overload their involved knee may benefit from this type of training while those who underload may benefit from alternative interventions. Further research is warranted.

## CONCLUSIONS

Our preliminary findings suggest RTS training after ACLR does not restore gait symmetry, and men and women respond differently. Surprisingly, women underloaded their involved limb after RTS training, but not before. Further research is needed to fully investigate gait mechanics in men and women after ACLR, and the implications for OA development.

## INTRODUCTION

The posterior tibial slope has been discussed as a potential risk factor for anterior cruciate ligament (ACL) injuries [1] due to the anteriorly directed force vector on the knee with axial loading [2]. Video analyses investigating the motion pattern and body position at the time where an ACL injury occurs found that typically subjects land on their heels or the flat foot with the center of gravity being behind the knee joint [3]. In such a position, the effective posterior tibial slope relative to the ground is increased as compared to a static upright standing, where commonly the posterior tibial plateau is measured [3]. Thus, the relationship between the tibial plateau orientation and knee force vector may affect ACL injury. Although computational models to estimate compressive and shear forces at the knee are common (such as inverse dynamics models), no study has investigated the relationship between the knee force vector and subject-specific tibial plateau orientation during dynamic loading. The purpose of this study was to determine the angle between the proximal tibia force vector and the tibial plateau during the early stance phase of walking in ACL-reconstructed and contralateral intact knees. We tested the hypothesis that there are knee (recon vs. intact), compartment (medial vs. lateral) and time related differences in the angle between the knee force vector and the tibial plateau during walking.

## METHODS

Eighteen participants (12 M/6 F, 23.8±9.7 y.o.) who were a part of a larger IRB-approved study of knee kinematics after ACL-reconstruction were included in the present analysis. Six months after

ACL-reconstruction, subjects walked on an instrumented treadmill (Bertec Corporation, Columbus, OH, 1000 Hz) at 1.3 m/s while biplane radiographs of the knee were collected at 100 images per second and overall lower body kinematics were determined using conventional motion analysis (Vicon MX, 100 Hz). Precise kinematics of the tibia and femur were determined using a validated volumetric model-based tracking of the biplane radiographs [4]. Subject-specific inverse dynamics computational models were developed to calculate the forces applied to the tibia from heel-strike through the first twenty percent of the single support phase of the gait cycle. Subject-specific 3D models of the femur and tibia were created from high-resolution CT scans of each knee. Vectors determining the tibial plateau orientation on the medial and lateral compartments of each 3D tibia model were created. The angle between the proximal tibia force (determined through inverse dynamics) and the tibia plateau vector (determined thorough biplane radiographic tracking) was determined.

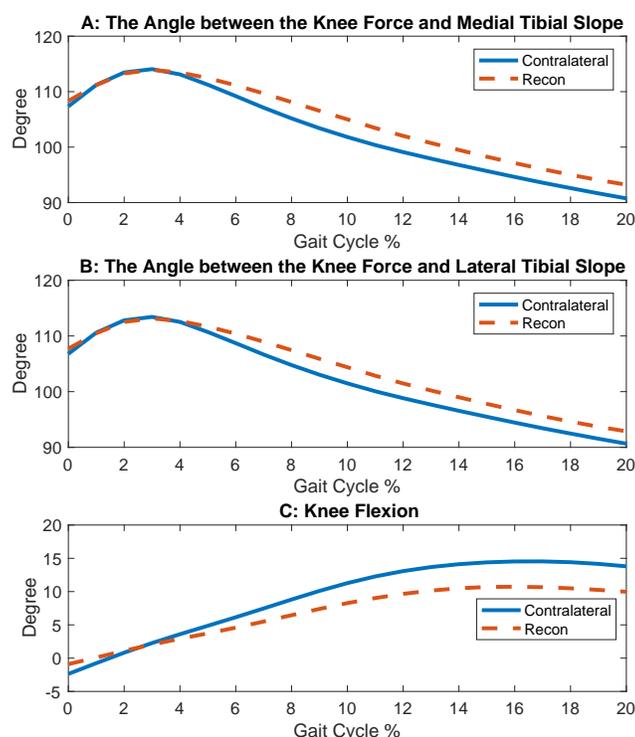

**Figure 1:** The angle between the knee force vector and the tibial plateau.

Statistical analysis was performed every 5% of the gait cycle from foot strike (0%) to midstance (20%). Repeated measures analysis of variance with a post-hoc Sidak test was used to identify differences between legs, compartments, and time instants.

## RESULTS AND DISCUSSION

The results indicate that the angle between the knee force and the tibial plateaus was large during the initial loading phase (0% to 5% of gait cycle) and gradually reduced to approximately 90° at midstance (Figure 2). The angle between the knee force vector and tibial plateau was slightly larger in ACL-R knees, however, this difference was not significant ( $p = 0.179$ ). Likewise, there were no differences between medial and lateral compartments ( $p = 0.21$ ). The angle between the knee force vector and tibial plateaus changed significantly from early stance (0% to 10%) to midstance (15% and 20%) (all  $p < .001$ ). The reconstructed knee tended to be more extended over the first 20% of the gait cycle (Figure 2C).

**Figure 2:** A & B: The average angle between the knee force and the medial (A) and lateral (B) tibial plateaus during gait. C: Group average knee flexion.

These results suggest that the proximal tibia force vector has a slightly larger (although non-significant) shear component in ACL-R knees during the initial loading phase of gait. It is possible that walking with more knee extension 6 months after surgery is a coping mechanism to limit the tibial shear force in the ACL-R knee.

## CONCLUSIONS

The most important finding of this study is that the angle of the force vector relative to the tibial plateau surface changes during the initial loading phase of the gait cycle, with a greater portion of the tibial force directed parallel to the tibial plateau during the early loading phase. This result corresponds well to previous research into the common injury mechanism of ACL tears occurring with the knee near full extension [3]. Contrary to our hypotheses, there were no differences between the ACL reconstructed and contralateral healthy knee or between the medial and lateral joint compartments. This novel study, combining surface-based kinematics and kinematics obtained from biplane radiography, is limited by the use of a basic inverse-dynamics model to estimate forces at the knee. More complex musculoskeletal modeling may produce different results. Future analysis will include more complex musculoskeletal modeling and the use of the biplane radiography data (rather than skin-based markers) to estimate joint centers during gait.

## INTRODUCTION

Mobile computing and the use of touchscreens has become common for business and personal use [1]. Touchscreen users actuate mobile computing technology by using their fingers. However, the amount of force applied by the fingers during touchscreen gestures is unknown. Exposure to fingertip forces during repetitive touchscreen interaction could potentially increase risk for musculoskeletal injury or disability [2,3]. Also, characterization of fingertip forces and impulses could be used to optimize software design and touchscreen interfaces.

Touchscreen interaction often involves tapping as well as other gestures such as swiping and pinching. The overall goal of this study was to determine the forces and impulses generated by the index finger or index finger and thumb during seven common touchscreen gestures. We hypothesized that compared to tapping, sliding and two-fingered gestures such as pinch and stretch would have smaller resultant forces per finger but larger force impulses. Specifically, based on finger kinematics during touchscreen use [4], we expected tapping to demonstrate the shortest completion time but the highest force.

## METHODS

Thirteen unimpaired participants (6 male, 7 female; age 21-33 years) used a 10.1-inch tablet computer (Galaxy Tab 2, Samsung, Seoul, South Korea) to complete repetitions of touchscreen gestures. All participants provided consent for protocols approved by California State University, San Marcos. Gestures were completed with the dominant hand (11 right-, 2 left-handed). Participants were seated with the touchscreen tablet positioned on a table in front of them. The

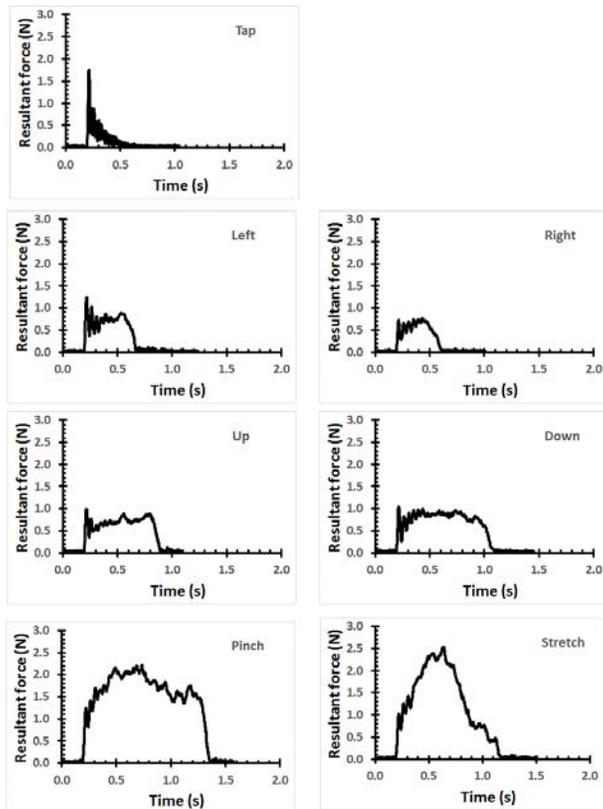

participant's sternum was aligned to the center of the tablet computer. The touchscreen computer dimensions were 25.7 x 17.5 x 0.97 cm. A custom software application displayed 6x6 cm square buttons to complete each gesture. The gestures included index finger tap, slide right, slide left, slide up, slide down and index finger and thumb used for pinch (zoom out) and stretch (zoom in). Each of the 7 gestures were presented in randomized order with subjects completing 11 consecutive repetitions. We instructed participants to complete the gestures at a moderate, self-selected pace. The tablet computer was fitted into a rigid plastic case and securely mounted on 6 degree-of-freedom load cell (JR3 Inc., Woodland, CA). calibrated for this study. Calibration and validation of the touchscreen indicated that the measured forces were accurate to within 4% in the range associated with gestures. The 3-dimensional forces and torques applied to the touchscreen were measured at 1000 Hz and were recorded using Labview software (National Instruments, Austin, TX). A manual trigger was used to mark the beginning and end of each gesture during data collection. We calculated forces from the transducer output using the calibration matrix in MATLAB (MathWorks, Natick, MA).

Data were analyzed using Microsoft Excel (Microsoft, Redmond, WA). We computed mean resultant force, impulse for resultant force and coefficient of variation (CoV) for resultant force for each gesture. For pinch and stretch, we calculated force per finger as resultant force divided by two. Gesture completion time was calculated as the duration that a 9-ms moving average of the resultant force was greater than a threshold of 0.2 N. Impulse was computed for resultant forces using the trapezoid rule approximation for the area under the force-time curve. Gestures were compared using repeated measures analysis of variance and Bonferonni's post-hoc comparison.

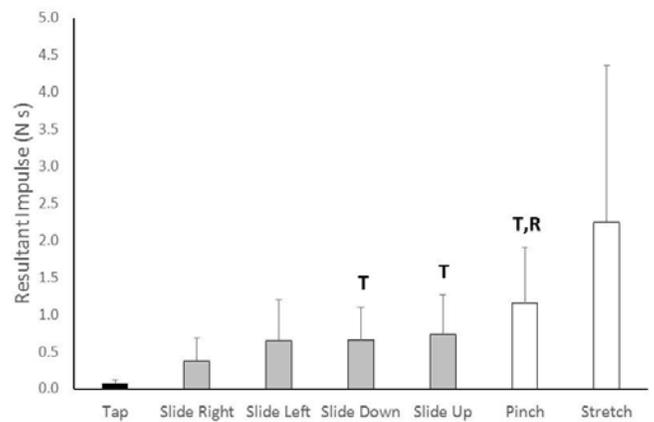

## RESULTS AND DISCUSSION

Mean( $\pm$ SD) resultant force was greatest for the stretch gesture at 2.05(1.13) N. However, stretch and pinch did not have more average resultant force per finger than single-finger gestures ( $p > 0.05$ ). Contrary to our hypothesis, tap had the lowest mean force of all 7 gestures at 0.50(0.09) N. Resultant force for tap was significantly less ( $p < 0.04$ ) than resultant force for all gestures except slide right. Consistent with our hypothesis, tap had significantly faster completion time than all other gestures studied ( $p < 0.004$ ). Additionally, tap had the lowest CoV for mean resultant force at 18%. CoV for other gestures ranged from slide up at 40% to stretch at 55%.

Each touchscreen gesture had a characteristic impulse profile (Fig. 1). Impulse for the tap gesture 0.07(0.05) Ns was significantly less ( $p < 0.03$ ) than slide up, slide down and pinch (Fig. 2). Stretch had the largest impulse at 2.25(2.11) Ns.

**Figure 1.** Representative force-time profiles for one participant for tap, slide left, right, up, and down with the index finger and pinch and stretch with the index finger and thumb on a touchscreen.

**Figure 2:** Mean resultant impulse for index finger tapping (black bar), index-finger sliding (gray bars), and for two-finger gestures (white bars). Values are mean with error bars for SD for 13 subjects. T and R denote significant difference from tap and slide right, respectively.

The touchscreen gestures studied differed in mean resultant force and impulse measurements. Both the magnitude and duration of force application could potentially influence musculoskeletal exposure during touchscreen use. These findings could be used to optimize design of touchscreen software to minimize the forces and duration of force application. Specifically, these results suggest that to reduce force application to the fingers, index finger tapping could be selected in touchscreen software design over two-finger gestures such as pinch. These data provide a first step toward assessing the potential differences in force and impulse associated with repetitive interaction of the fingers with a touchscreen for tapping, sliding, pinch and stretch gestures.

# GENDER DIFFERENCES IN UPPER LIMB JOINTS CONTRIBUTIONS DURING A LIFTING TASK

<sup>1</sup> Romain Martinez, <sup>1</sup> Jason Bouffard, <sup>1</sup> Mickael Begon

<sup>1</sup> Université de Montréal, Département de kinésiologie, Québec, Canada  
email: martinez.staps@gmail.com

## INTRODUCTION

The occurrence of upper limb injuries has been associated with work factors such as overhead work, heavy lifting, repetitive movements and bad postures, but also with individual risk factors including gender. Indeed, even if women are underrepresented in manual handling work, the prevalence of their upper extremity injuries is greater than in men [1].

Differences in motor behavior between women and men have been identified and may contribute to the increased risk of upper limb musculoskeletal disorders among women [2]. Recent studies identified sex differences in trunk and lower limb coordination during manual handling tasks [3]. However, the sex-specific kinematic strategy of the upper limb during a lifting task remains unknown.

This study investigated sex differences in upper limb joints' contribution during a lifting task. Exploring these differences would help us understand the reasons behind the higher prevalence of upper extremity injuries in women.

## METHODS

In total, 25 women (21 ± 2 years; 1.68 ± 0.7 m; 61 ± 8 kg) and 25 men (24 ± 3 years; 1.79 ± 0.8 m; 75 ± 12 kg) took part in this study. The experimental task consisted of moving one box between three adjustable shelves located at hip, shoulder and eye levels. Different box masses were used for men (12 kg) and women (6 kg) to adjust for sex-related differences in maximal force.

Kinematics of the upper arm were recorded with VICON Motion Analysis cameras and the markers set described in [4]. A 25 degree-of-freedom (DoF) kinematic model was constructed using a static trial

(pelvis & trunk [PE/TR; 6 DoF each], sternoclavicular & acromio-clavicular [SC/AC; 3 DoF each], glenohumeral [GH; 3 DoF], elbow & wrist [EL/WR; 2 DoF each]). Centres of rotation was determined using the SCoRE/SARA algorithms (for PE, TR, EL and WR joints) and bony landmarks (for SC, AC and GH joints). Inverse kinematics was performed during lifting trials using an extended Kalman filter algorithm [4].

Then, the contribution of each joint ( $H|_i$ ) to the box elevation was computed by successively resetting joint angles to their reference orientation ( $q_i^{REF}$ ) [5]. Joint contribution refers to the amount of box height achieved by each group of DoF (Algorithm 1).

**Algorithm 1.** Calculation of the joint contributions.  
At time t:

$$\begin{aligned} \text{calculate height}(\mathbf{q}) &= H|_{WR/EL+GH+SC/AC+TR/PE} \quad (1) \\ q_{WR/EL} &= q_{WR/EL}^{REF} \end{aligned}$$

$$\begin{aligned} \text{calculate height}(\mathbf{q}) &= H|_{GH+SC/AC+TR/PE} \quad (2) \\ H|_{WR/EL} &= (1) - (2) \end{aligned}$$

$$\begin{aligned} q_{GH} &= q_{GH}^{REF} \\ \text{calculate height}(\mathbf{q}) &= H|_{SC/AC+TR/PE} \quad (3) \\ H|_{GH} &= (2) - (3) \end{aligned}$$

$$\begin{aligned} q_{SC/AC} &= q_{SC/AC}^{REF} \\ \text{calculate height}(\mathbf{q}) &= H|_{TR/PE} \quad (4) \\ H|_{SC/AC} &= (3) - (4) \end{aligned}$$

$$\begin{aligned} q_{TR/PE} &= q_{TR/PE}^{REF} \\ \text{calculate height}(\mathbf{q}) &= 0 \quad (5) \\ H|_{TR/PE} &= (4) - (5) \end{aligned}$$

Contributions of men's and women's joints were compared using statistical parametric mapping (ANOVA 2-way: sex × height [repeated measures]) for each group of joints.

## RESULTS AND DISCUSSION

A significant main effect (Fig. 1, panel A) of sex on the contribution of the GH joint was found (4-7 and 79-90% of the trial), highlighting a contribution 14% higher for women than for men. Moreover, a significant main effect of sex on the SC/AC joints (11-27% of the trial) and TR/PE (8-32 and 55-100% of the trial) shows those groups of joints contributed 8% and 5% more to box height in men than women.

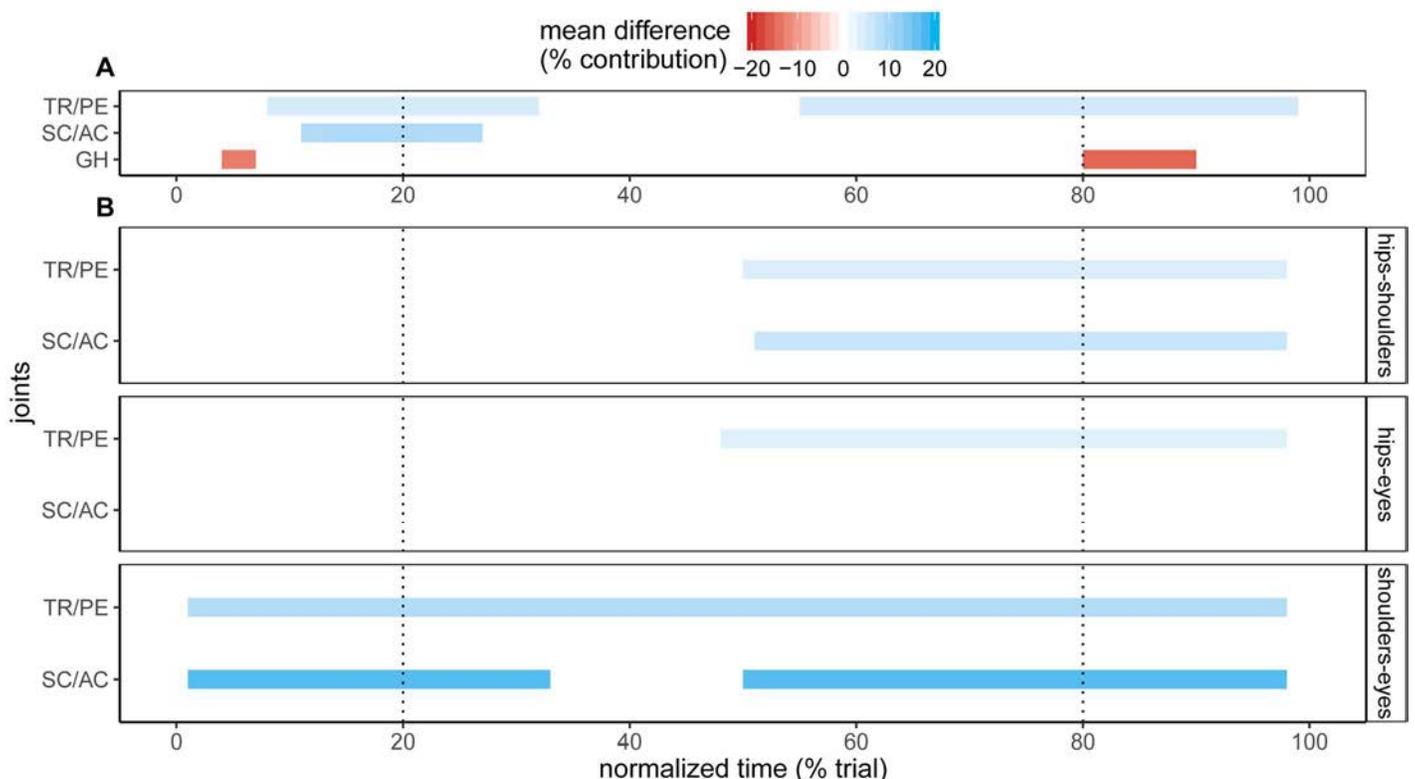

An interaction between the two factors was found on the SC/AC joints (0-34 and 51-100%) and TR/PE (0-100%). The post-hoc tests (Fig. 1, panel B) revealed that the most significant difference related to the SC/AC joints, with men contributing 18% more than women at the shoulders-eyes condition, followed by the TR/PE at the same height.

Our results support the perspective of a sex-specific kinematic strategy of the upper limb during a lifting task. In particular, we showed that men tend to use a technique which share the motion, and eventually the load, between different groups of joints (GH, SC/AC,

TR/PE) when lifting the box, while women mobilize mainly the glenohumeral joint. We can therefore hypothesize that the force applied to the shoulder is higher in women, thus increasing the risk of injury [6]. The implications of such results argue for a careful consideration of sex during ergonomic interventions, but also during research studies focusing on the upper limb.

## INTRODUCTION

An object's inertial properties influence the forces and torques required to move the object. The rotational inertia values can be visualized in tensor form as the axes describing an inertia ellipsoid. From the inertia ellipsoid, scalar properties can be calculated which represent the volume (overall object inertia) and symmetry of inertia (Fig. 1). Objects with larger overall inertia require greater torque and muscle forces, while the symmetry of the inertia affects the diversity and patterning of the torque and forces. Previous work in ecological psychology has demonstrated that the relationship between the symmetry and volume of an object's inertia ellipsoid influences effectiveness as a hammering tool [1]. When the magnitude of overall inertia was increased relative to the symmetry of inertia, hammers were more effective. However, these studies did not investigate biomechanics or motor control for functional tasks and did not describe or interpret the entire movement, but only measured outcomes of the task (number of objects hammered in a specific time period) and vertical hammer motion in accomplishing the task.

**Figure 1:** Inertia ellipsoid, volume  $V = (4\pi/3)(I_1 I_2 I_3)$  and symmetry  $S = 2I_3/(I_1+I_2)$ .

The purpose of this study was to use principal components analysis (PCA) to characterize upper-extremity kinematics while subjects performed functional hammering with hammers of varying

properties. The goal was to examine the role of hammer symmetry of inertia. The hypothesis was that hammers with greater symmetry of inertia would result in an overall more complex motion as represented by the number of principal components required to explain variance in the motion.

## METHODS

Data were collected with VICON as described previously [2]. Male subjects (N=19) made single strikes of nails using hammers (Fig. 2). Three trials were performed with each hammer. Overall inertia for pairs of hammers (1-2 and 3-4, respectively) were approximately equal. The symmetry of hammers 2 and 4 were 3 and 7 times the symmetry of 1 and 3 (equal symmetry), respectively (Fig 3).

**Figure 2:** Hammers of varying inertial properties.

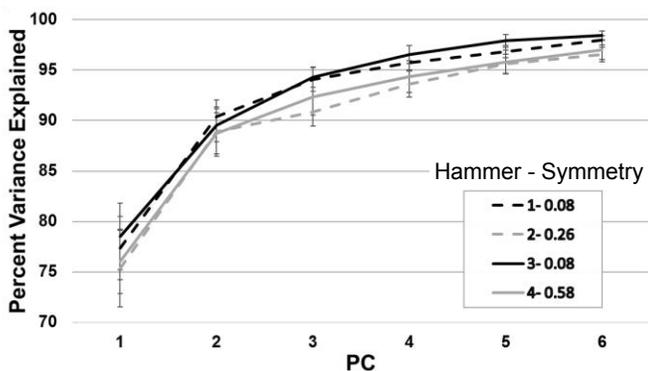

Coordinates of 16 markers on upper-extremity and hammers were linear-length-normalized from swing initiation to strike/follow-through (trials equal length, 101 points from 0-100% of motion). Data were normalized by the mean marker and norm of the mean in each trial to remove inter-subject anthropometric variation as described in [3]. For each hammer, PCA was performed on the covariance matrix of concatenated data of all trials (19 subjects x 3 trials).

The contribution of each principal component (PC) to the movement of a subject in each trial was

calculated from the normalized variance of the time-series marker data projected onto the principal components. The cumulative normalized variance represents the percentage of variance explained by a given number of PCs for a trial. Differences in cumulative normalized variance for each PC were detected with ANOVA. Additionally, reconstruction of the motion for each PC was performed by projecting marker data onto the principal component and then performing Inverse-Kinematics analysis with OpenSim to calculate joint angles. This analysis allowed for potential qualitative interpretation and visual representation and understanding of how components of the motion variance are partitioned to individual PCs.

## RESULTS AND DISCUSSION

At PC1 and PC2 there were no differences in percent variance explained. For PC3 through PC6 significant differences were found in the percentage of explained variance between the hammers ( $p < 0.001$ ), although significance, differences and effect sizes varied between the different hammers across principal components (Fig. 3). For a given variance level, hammers with greater symmetry of inertia required more principal components to explain the motion.

**Figure 3:** Cumulative PC for hammer motion data.

Most of the hammering motion variance is associated with shoulder and elbow flexion and is represented by PC1 (Fig. 4). Other PCs account for less variance indicating subtle differences in secondary degrees of freedom that contributed small but potentially important variations to the motions. For example, PC2 generally corresponded to the reaching involving thorax flexion and elbow extension

required for striking the nail, while PC4 relates to the wrist flexion-extension required for accurate hammer control within the hand.

These results indicate that hammers with greater symmetry of inertia result in a more complex motion as evidenced by the greater number of principal components required to explain variance in motion. These findings confirm results of previous studies [1] which found objects with greater symmetry of inertia were less effective hammers and adds to the understanding of how the symmetry relates to the kinematics of the motion during the entirety of the hammering trial.

These findings have implications for understanding the role of inertial properties of hand held objects in contributing to motion variability as related to difficulty of the task or motion and how control of upper-extremity kinematics, as well as resulting joint and tissue loadings, may be affected.

The model of adding a segment to the upper-extremity with alterable inertial properties presents an intriguing paradigm for understanding not only the role of inertial properties of hand-held objects, but also how inter-subject variability and other situations involving altered segment properties, e.g. obesity, reconstructive surgery/salvage, limb replacement, or prosthesis/exoskeleton, can affect biomechanics and motor control.

## INTRODUCTION

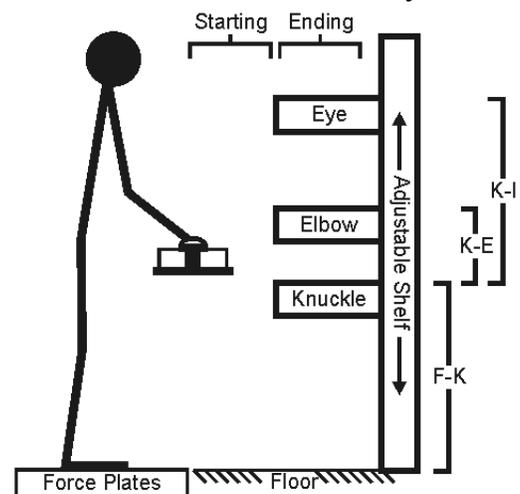

To combat the high incidence of workplace injuries caused by lifting overexertion [1], ergonomists often rely on tables of maximal acceptable weight limits (MAWL) [2]. Such tables reflect MAWLs for various lifting situations, deemed safe and reasonable by experienced manual materials handling (MMH) workers through an arduous psychophysical research protocol [3]. Application of MAWL tables has demonstrated reductions in workplace injury [4], but their subjective basis provides an intriguing dichotomy between an individual's perception of safe lifting loads and the underlying biomechanical capabilities upon which the perception is based.

Despite advances in motion detection and modeling, there have been a limited number of studies aimed at describing MAWLs in relation to full-body joint demands. Such analysis could identify limiting joints, improve intervention strategies, allow for more personalized MAWLs obtained with less difficulty, and improve our understanding of musculoskeletal safety perception [5, 6].

Therefore, to better understand the psychophysical selection process for safe working loads, a full-body rigid-link joint kinetics model was applied to three different sagittal lifting tasks. Each lifting task was performed at an individually determined MAWL. Our objectives were to examine 1) whether psychophysically determined MAWLs could be characterized by joint kinetics, 2) if individual task MAWLs were linked to the strength of a specific limiting joint, and 3) whether MAWLs across tasks were related by a universal limiting joint strength threshold irrespective of the limiting joint location.

## METHODS

18 healthy, young, fit male participants ( $25 \pm 5$  years;  $178 \pm 6$  cm;  $80 \pm 10$  kg;  $BMI \leq 30$ ) with MMH experience participated in a two-visit protocol designed to minimize the effects of fatigue. During visit 1, following informed consent, an abridged psychophysical protocol consisting of two 20-minute trial-and-error selection periods was used to find individual MAWL loads for three randomly presented lifting tasks: 1) Floor-to-Knuckle (F-K), 2) Knuckle-to-Elbow (K-E), and 3) Knuckle-to-Eye (K-I). For each lift, a custom-built robotic lifting shelf was designed to repeatedly return a 34 x 56 x 16 cm instrumented (AMTI, Watertown, MA) box to the initial position (Fig. 1). Participants were instructed to lift at their own comfortable speed [3], but were paced at 4 lifts/minute with an auditory cue.

**Figure 1:** Experimental set-up of the starting and ending positions of lifts F-K, K-E, and K-I.

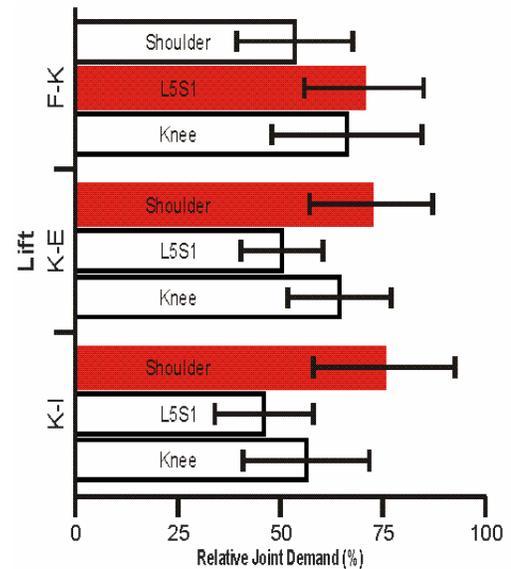

In visit 2, kinematics and kinetics of the three tasks with loads based on the subject-specific MAWLs from visit 1 were recorded. Each lifting motion was recorded at 100Hz using 8 cameras and reflective markers on body segments and the lifting box (Motion Analysis Corporation, Santa Rosa, CA),

along with the ground reaction forces of each foot (Kistler Instruments Corporation, Amherst, NY). Data from three representative lifts for each task are reported. Visit 2 concluded with static maximal voluntary contractions (MVCs) that isolate the shoulder, L5S1, and knee joints, performed at the floor, knuckle and eye lifting positions.

A 3D inverse dynamics model was coded in Matlab (Mathworks, Natick, MA) to determine sagittal joint moments using established body segment characteristics and joint centers [7-9]. Computed external moments were reported relative to their proximal segment's coordinate system. Lift durations were defined by the interval when the measured hand force exceeded 5N. For each participant, shoulder, L5S1, and knee joint moments were normalized to their respective peak MVC values. Peaks for all normalized moments during each lift were extracted. Average MAWLs for the three lifting tasks were calculated and ANOVA tested ( $p < 0.05$ ). A repeated measures ANOVA and Tukey HSD post-hoc test examined differences in normalized peak moments and in the limiting joints for each lift (lift x joint). Limiting joints were identified by the highest normalized peak joint moments for a lift.

## RESULTS AND DISCUSSION

The average MAWLs obtained from the three lifts were:  $19 \pm 5$ ,  $17 \pm 3$ , and  $14 \pm 2$  kg for F-K, K-E, and K-I, respectively (F-K = K-E > K-I). There was a significant joint x lift interaction ( $p < 0.01$ ), with both joint moment patterns and the limiting joint varying by lift (Fig. 2). The lower starting position for F-K challenged the L5S1, whereas the more upright starting postures (K-E & K-I) concluded with a more extended reach that stressed the shoulder. Despite the varied MAWL loads and limiting joints, the normalized peak moments of the limiting joint were similar across the three lifts at ~73% of the joint MVC (F-K = K-E = K-I). These results suggest that a lifter selects a safe MAWL by considering a limiting joint for a particular lifting task. Further, the consistent normalized moment values for the most stressed joints across lifting tasks suggest a universal limiting joint threshold in the MAWL selection process.

**Figure 2:** Peak normalized shoulder, L5S1, and knee joint moments for each lift. The limiting joint is indicated in red.

The consistent average relative load on the most stressed joint across lifting tasks agrees with a previous study of controlled static postures at a comparable level [5]. This agreement suggests that a universal limiting threshold may hold for both static and dynamic efforts. Future work should examine joint stresses at dynamic loads below and above MAWLs to better understand the MAWL selection process.

Limitations of this study include: 1) participant's interpretation of the psychophysical protocol in MAWL selection, 2) normalizing dynamic joint moments to selected static MVCs, and 3) use of a single nominal lifting frequency.

# FORCE REDISTRIBUTION FOR SEATED INDIVIDUALS VIA REPOSITIONING

Justin Scott, Tamara Reid Bush

Michigan State University, East Lansing, MI, USA  
email: reidtama@egr.msu.edu

## INTRODUCTION

Most people know someone using a wheelchair, as there are 2.2 million users in the United States [1]. Wheelchair users are at a heightened risk for developing pressure ulcers (PUs) as the tissue in their buttocks is loaded all day with little shifting of this load. PUs are wounds that form when tissue dies, and this death occurs through malnourishment due to lack of blood flow. External pressure on tissue, such as seated loads, diminishes blood flow to the area, putting the area at risk for a PU if the load is not relieved. PUs are costly, painful, and are prone to infection.

Able bodied individuals shift their position or get up if they feel discomfort due to a high pressure on their body. But relief options are limited for wheelchair users. Those with a spinal cord injury (SCI) are not able to feel discomfort [2]. This work investigates loading on the buttocks and back to see what position changes relieve areas of concentrated load, such as the ischial tuberosities (ITs) which is a body region prone to PUs. Our goal is to redistribute the loads occurring on PU prone areas (particularly the ITs) through the development of an articulating chair.

## METHODS

To reach our goal, we developed an articulating chair with independently moving parts to simulate different seated positions [3]. The chair back reclined around the hip joint center. Posture change and leg position were also tested. Rotating the thorax and pelvis supports created 1) kyphotic, 2) neutral and 3) lordotic postures (Figure 1). Two leg positions were tested, a ninety degree knee bend and a straight leg position, each supported by a footrest in front of the chair. A Tekscan mat obtained pressure distributions and center of pressure data on

the seat pan. Pressure measurements were taken at recline angles of 0, 10, 20, and 25 degrees for each leg position and posture.

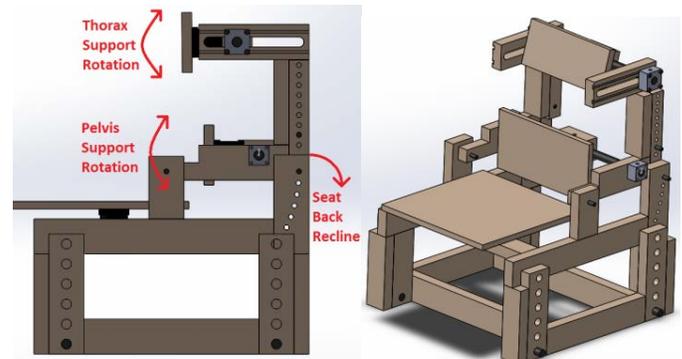

Figure 1. Movement mechanisms of the articulating chair (left) and isometric view (right).

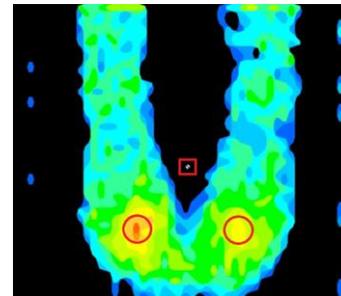

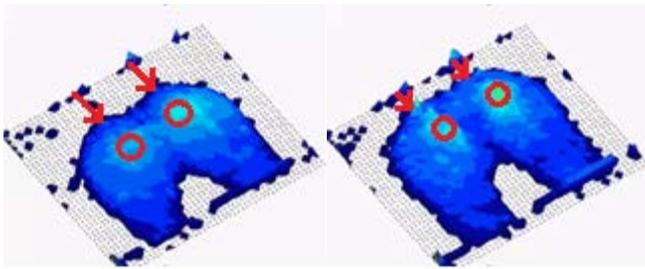

Figure 2. Snapshot from Tekscan mat with Center of Pressure (COP) in the box and ITs circled.

## RESULTS AND DISCUSSION

The pressure data was split on the midline of the participants to consider the left and right sides separately. Values in the y-direction are distances from the back of the buttocks forward, and values in the x-direction are distances from the midline to the left or right. We identified the position of the center of pressure (COP) using the x and y coordinates. On average, a 28 millimeter posterior shift occurred in the COP when reclining from 0 degrees to 25 (Table 1). A 12.7 millimeter posterior shift occurred when changing posture from the lordotic to kyphotic position (Table 2). Both recline and

posture positions show little change in the x direction. When moving the legs from a bent to straight position, a 23.5 millimeter posterior shift in the COP and a 15.6 millimeter shift toward the midline occurred (Table 3).

These COP shifts were measured from the rearmost contact of the buttocks. However, if we look at dynamic movements (Figure 3), we see that in the lordotic posture as compared to the kyphotic posture 1) the full contact area of the buttocks is reduced, 2) the IT pressure is lower, and 3) the IT pressure shifted forward. So, measurement of COP shift from the rearmost position of the buttocks may not truly reflect changes occurring.

**Figure 3.** Pressure distributions on the seat pan for two postures, lordotic on the left (lower IT pressure peaks shifted forward) and kyphotic (higher pressure peaks shifted rearward) on the right.

Although our numerical data indicate a single motion does not produce a large enough shift in pressure to completely unload the ITs, our measurement approach may not be capturing some of this movement. Additionally a combination of these movements in concert, such as a straightening of the legs while reclining and changing posture,

will create an even larger shift, removing the loading from the ITs. Our long-term goal is to apply these movements to wheelchairs and have them cycle through different postures after a duration of time to automatically shift loads and reduce the risk of PUs.

## CONCLUSIONS

Our initial results have shown a positional shift of the COP when looking at recline, posture change, and foot position while seated. Most movement occurs in the anterior posterior direction. Such movements can be used to load and unload different tissues while in a seated position. A limitation of this study is the small sample size (n=4) and that we have only tested able bodied individuals. Prior to testing people with disabilities, we will incorporate a whole body tilt in addition to articulation and recline to further change loading. Furthermore, we will see if any differences exist between able bodied individuals and those with disabilities.

# EFFECTS OF HEAD-WORN DISPLAY USE ON OBSTACLE CROSSING PERFORMANCE IN A SIMULATED OCCUPATIONAL TASK

Sunwook Kim, Sophia Ulman, and Maury A. Nussbaum

Industrial & Systems Engineering, Virginia Tech, Blacksburg, VA, USA  
Email: sunwook@vt.edu

## INTRODUCTION

Slips, trips, and falls (STFs) continue to be a major cause of occupational injuries and fatalities. For example, STFs accounted for 16.5% of fatal occupational injuries and 27% of lost workday cases in 2015 [1]. The occupational application of smart glasses, or head-worn displays (HWDs), has been explored in diverse applications [2], and may lead to potential benefits since a HWD can project diverse, real-time information in front of one (monocular) or both eyes (binocular) of a user. Though broad evidence supports that an increase in attentional demand and/or cognitive distraction can reduce gait performance [3], there is limited evidence that has been reported regarding the potential impacts of HWD use on gait performance, particularly with respect to obstacle crossing (OC). This study thus assessed the effects of different HWD technologies and information presentation types on OC performance. Two commercially-available HWDs were used, representing binocular (Epson Moverio BT-200) and monocular (Vuzix M100) technologies. Based on earlier work, we hypothesized that the use of a HWD would deteriorate OC performance.

## METHODS

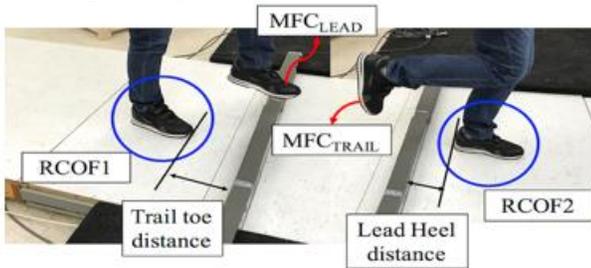

This study involved 12 gender-balanced participants, with self-reported normal or corrected-to-normal vision (contact lenses only), and no recent or current musculoskeletal disorders or injuries. The mean (SD) age, stature, and body mass were 25.3 (6.0) yrs, 177.2 (6.2) cm, and 74.2 (8.3) kg, respectively for males; and 30.2 (14.3) yrs, 164.2 (4.8) cm, and 55.8 (5.4) kg, respectively, for females. Testing was performed with IRB approval, and informed consent was obtained.

A 3×2×2 repeated measures design was used to assess the effects of *Information mode* (paper list, binocular HWD, monocular HWD), *Information type* (text- vs. graphic-based instructions for a simulated assembly task), and *Gender* on OC performance. Participants were provided with consistent shoe types and asked to walk on a linear gait track at a “purposeful” walking speed [4]. After familiarization, participants completed three gait trials to establish a baseline (i.e., no info. mode) and then all the experimental conditions. The order of experimental conditions was counter-balanced.

Triaxial ground reaction forces (GRFs) were collected from two force plates (AMTI, OR-6). Gait kinematics were collected using a 10-camera motion capture system (Vicon, Vero), using passive reflective markers placed on select anatomical landmarks. Eight markers were also placed around the shoe outsole [5], and four markers were placed on each corner of the obstacle (made of dense foam, see Figure 1).

Minimum foot clearance (MFC) and peak required coefficient-of-friction (RCOF) between the shoe and floor surface were used to assess OC performance. RCOF was obtained from each force plate as:  $\sqrt{F_X^2 + F_Y^2}/|F_Z|$  where  $F_X$ ,  $F_Y$ , and  $F_Z$  are the shear and normal GRFs, respectively. Peak RCOF was then extracted [6]. MFC was defined as the lowest location among the reconstructed shoe outsole markers near the mid-swing phase of gait, and was calculated separately for the lead and trail feet over the obstacle [5]. Foot placement location around the obstacle was obtained [7], including the trail horizontal toe and the lead horizontal heel distances (Fig. 1). Obstacle crossing speed (OCS) was estimated as the mean velocity of four pelvis markers during the obstacle crossing step. Mixed-factor analyses of variance were performed on OC

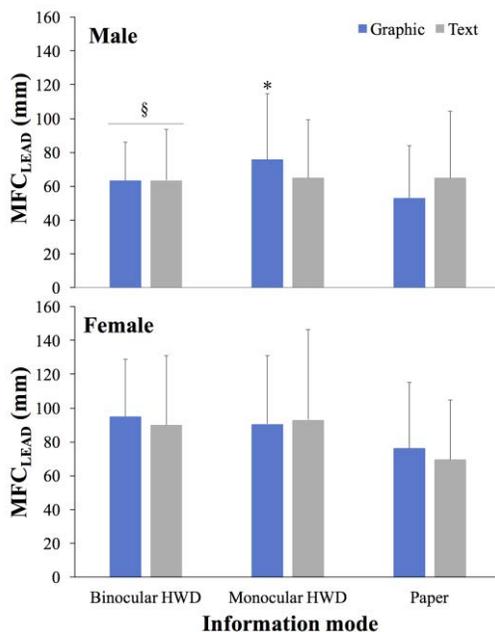

performance measures to assess the effects of gender, *Info. mode*, and *Info. Type*, while including the corresponding baseline measure as a covariate.

**Figure 1:** OC performance measures obtained.

## RESULTS AND DISCUSSION

Participants exhibited significant changes in some OC performance measures (i.e., RCOF2 or lead heel distance) relative to baseline measures. Additionally,  $MFC_{LEAD}$  was significantly affected by a main effect of *Info. Mode*, and an *Info. Mode*  $\times$  *Info. Type*  $\times$  *gender* interaction effect (Fig. 2).  $MFC_{LEAD}$  was generally comparable between *Info. type* conditions with one exception, and larger for females vs. males.

**Figure 2:** Three-way interaction effect of *Info. mode*, *Info. type*, and *gender* on  $MFC_{LEAD}$ . Note: \* and § indicate significant differences between *Info. type* conditions and between genders, respectively.

When attentional demand increases, reducing the OCS may have been a strategy to maintain postural stability (i.e., cautious gait). Use of a HWD resulted

in a slight decrease (~4%) in OCS compared to the baseline, but such a decrease was not apparent for the paper list condition. This may suggest that visuospatial attentional demands were higher with HWD use (vs. the paper list), given that walking/obstacle crossing requires visual and visuospatial information to control limb trajectories [8]. Also, HWD use seemed to cause more conservative obstacle crossing behaviors, which may be gender specific. Common strategies to reduce trip risks include decreasing OCS, increasing  $MFC_{LEAD}$ , and/or increasing the trail toe distance while reducing the lead heel distance [3]. Here, when using the monocular HWD or paper list, males increased the trail toe distance while reducing the lead heel distance. When using a HWD, females exhibited increased  $MFC_{LEAD}$  values.

In summary, we examined the effects of HWD use on OC performance. Our results demonstrate that the use of HWDs may cause the adoption of specific gait strategies. Yet, given potential study limitations (i.e., young participants, rather optimal walking condition), future efforts are needed to understand more completely how HWD use might affect gait performance of diverse working populations, for longer-term use, and under suboptimal or more challenging walking conditions.

# CONTACT FORCE DISTRIBUTION ON THE FINGERS DURING SPHERICAL GRIPPING

Erik W. Sinsel, Christopher M. Warren, Daniel E. Welcome, and John Z. Wu

National Institute for Occupational Safety and Health, Morgantown, WV, USA  
email: ESinsel@cdc.gov

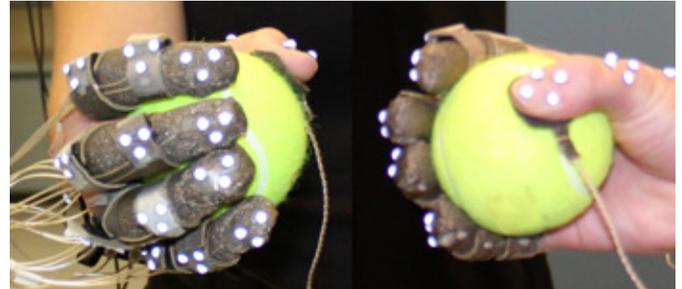

## INTRODUCTION

Tool handles are the interfaces between human hands and the tools being operated. The contact conditions in the hand/handle interface may play a role in the comfort and efficiency of the tool operation, as well as in the fatigue of, and injury to, the upper extremity musculoskeletal systems [1]. The size of the handles of power tools has been a major ergonomic consideration for designers wishing to minimize the operating effort and maximize the grip force and torque strength [2]. Previous studies indicate that grip force depends strongly on the handle diameter [3]; the grip effort and injury potential can be reduced by using handles of suitable diameter [4]. However, only cylindrical gripping was considered in the previous studies. The purpose of the current study is to investigate contact force distributions within and across the fingers when gripping a spherical object.

## METHODS

Eight female adults [age 29 (9.1) years, mass 64.6 (7.1) kg, height 163.5 (1.9) cm, hand length 17.2 (0.7) cm] participated in the study, providing informed consent under protocol IRB 11-HELD-02XP approved by the Centers for Disease Control and Prevention. In order to measure contact force, normal force sensors (FingerTPS, Pressure Profile Systems, Los Angeles, USA) were attached to the distal, middle, and proximal phalanges of the four fingers, excluding the thumb (Fig. 1). Each sensor was then individually calibrated at intervals up to 15 N, where an error greater than 2 N prompted a new calibration.

Subjects performed two maximum exertion gripping tasks on a standard tennis ball. A quasi-static portion of each trial was selected and the mean total force across the two trials was used to establish the subject's maximum voluntary exertion (MAX) force value. The subject then performed a random ordering

**Figure 1.** Test setup. The subject grips a tennis ball (65 mm diameter); force sensors are located on the palmar aspects of the finger phalanges.

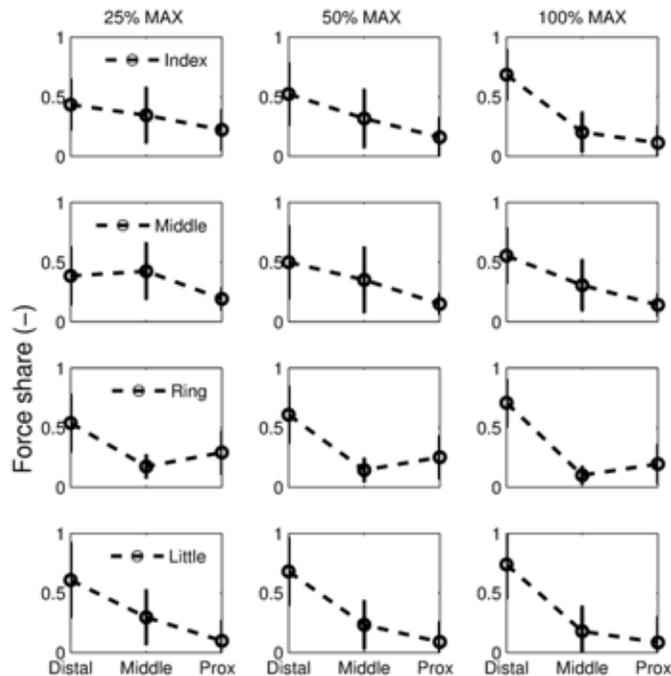

of two trials each at 50% and 25% of MAX. Subjects rested at least 2 minutes between trials. In each trial, an experimenter placed the ball in the subject's instrumented hand; subjects were instructed to not greatly adduct the fingers, avoiding a claw-like posture while gripping.

Sensor data were collected at 40 Hz. During each trial, tare offset data were collected with the sensors not externally loaded; the mean of a one-second range was used to apply a tare to each sensor's data and a zero flooring operation was applied. The mean force for each sensor was calculated over a four-second range with the minimum variance of total finger force.

## RESULTS AND DISCUSSION

The force share among the distal, middle, and proximal phalanges for three grip force levels are shown in Fig. 2. The results show that across all force levels the distal phalanges share approximately 50% of the total force. The proximal phalanges shared approximately 10% of the total force for all grip force levels. Force share for the proximal phalanges was the lowest within the fingers with the exception of the ring finger, where the middle and proximal shares were approximately equal. The grip force level affects the force distributions on the phalanges, however the general trends are not changed.

The force sharing characteristics across fingers are presented in Fig. 3. At all force levels the middle and ring fingers share approximately 50% more force than the other two fingers. The force shares in the middle and index fingers increase with increasing total force level, while the shares in the ring and little fingers decrease.

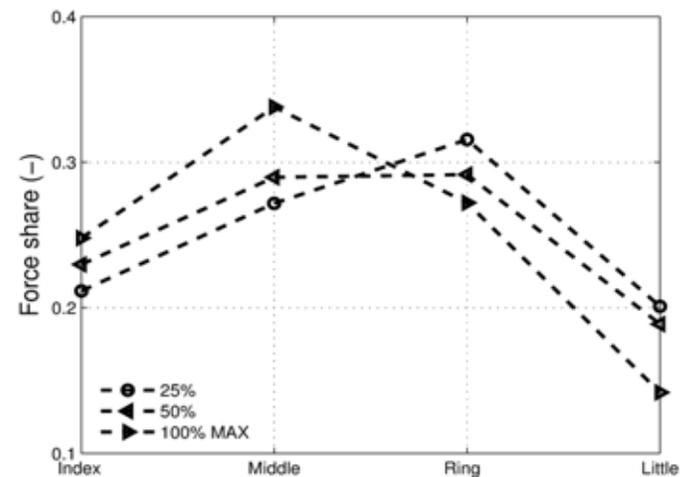

**Figure 2.** Force sharing across the distal, middle, and proximal phalanges for three levels of total finger force (n=8).

In the current study we utilized sensors which were mounted on fingers to evaluate the force on each phalanx when gripping a spherical object. In previous studies [5, 6], contact pressure was measured by using pressure sensor film wrapped on the cylindrical contact surface. It is technically difficult to wrap a pressure sensor film on a spherical surface, while the application of the sensors used in this study is independent of the curvature of the contact surface being gripped.

## CONCLUSIONS

About 60% of the force on the fingers is contributed by the middle and ring fingers and about 40% by the index and little fingers. These characteristics are independent of the total force levels and stiffness of the contact surface (results not shown).

For each of the fingers, the contact force is concentrated mostly on the distal phalanx, independent of the total force. This phenomenon is similar to that observed during cylindrical gripping [5], where the maximal pressure was found on the distal phalanx of the index finger. However, the observed force share pattern in the fingers differs from the previous study: the majority of the finger force is contributed by the middle and ring fingers in spherical gripping, while in cylindrical gripping it is contributed mainly by the index finger [5].

**Figure 3.** Force sharing across the fingers for three levels of total finger force (n=8).

# IN VIVO QUANTIFICATION OF MUSCLE FATIGUE IN UPPER EXTREMITY DURING PULLING AND GRIPPING USING REGIONAL OXIMETER: A FEASIBILITY STUDY

\*Liyong Zheng, Xueyan S. Xu, Erik W. Sinsel, Daniel E. Welcome, Ren G. Dong, and John Z. Wu

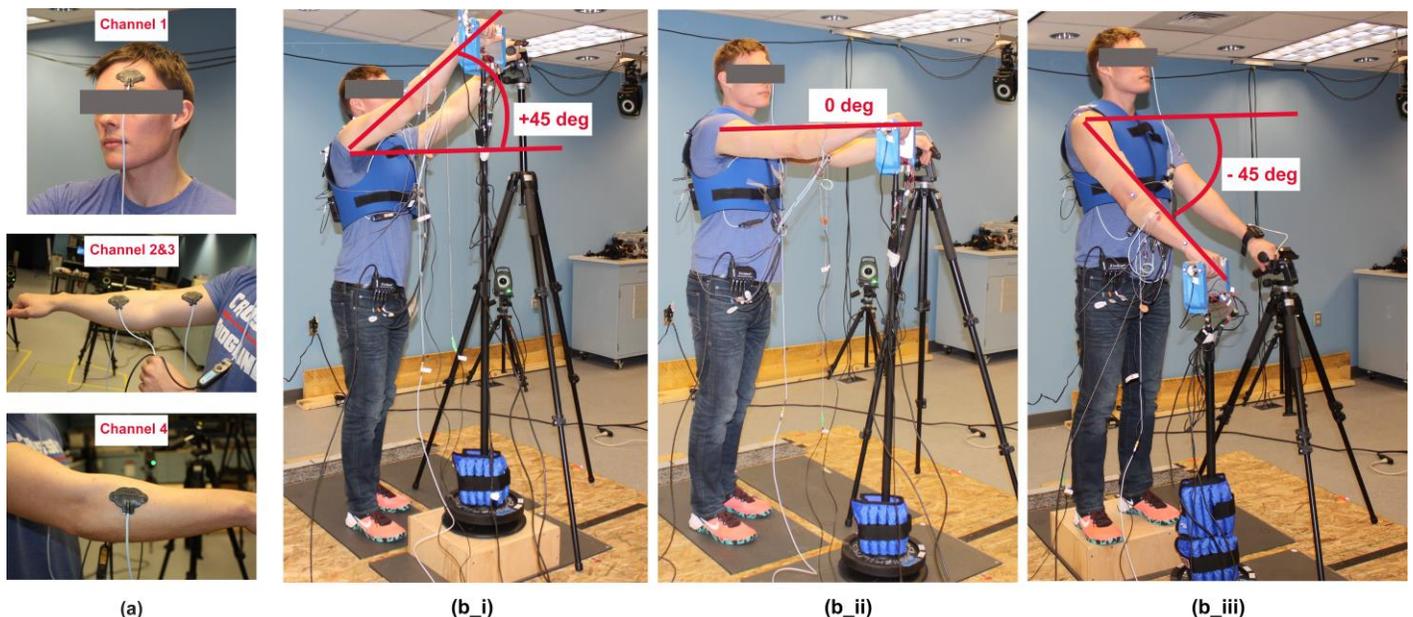

National Institute for Occupational Safety and Health, Morgantown, WV, USA.

\*email: lzheng2@cdc.gov

## INTRODUCTION

Musculoskeletal disorders (MSDs) are responsible for over a third of all sick leaves lasting over nine days in the construction industry [1]. The MSDs in the upper extremity are the second most prevalent type of MSDs [2,3]. It is well accepted that the initiation and development of the MSDs are associated with the muscle fatigue induced by awkward working posture, extended and/or repetitive loading. Ergonomic devices such as wearable robotics or exoskeletons (many specifically focus on the upper extremity) are promising solutions to reduce fatigue and lower risks of the work-related MSDs. To assess effectiveness of those ergonomic products, the first critical step is to quantify fatigue-related changes in the musculoskeletal system *in vivo* and noninvasively and to have a comprehensive understanding of muscle fatigue.

Electromyography (EMG) is commonly used to measure neuromuscular response of muscle fatigue and the median frequency of EMG signals is expected to drop when fatigue occurs. Nevertheless, several studies commented that surface EMG might not be sensitive enough to record low-level muscle activity and the median frequency changes were rather small [4,5]. Recent advances in near infrared spectroscopy (NIRS) technology have provided a noninvasive approach to measure muscle oxygenation and oxidative metabolism, which is believed to investigate a different aspect of the physiological process of fatigue [5]. Previous studies also reported that NIRS results were task- and muscle-dependent [6]. This feasibility study is to test if NIRs is a viable means to quantify fatigue-related oxygenation changes, specifically in upper extremity muscles during pulling and gripping at different postures.

**Figure 1.** (a): Four regional oximetry sensors (channels) were placed on the contralateral forehead (cerebral) and three muscles on the right arm—biceps brachii, flexor carpi radialis, extensor carpi radialis; (b\_i-iii): a subject pulls on an instrumented handle at three different postures (arm angles: +45, 0 and -45 degrees).

## METHODS

A healthy subject (male, 24 years old, 77.6 kg, and 1.75m) was consented to participate in this ongoing NIOSH IRB-approved study. Four regional oximeter sensors (Nonin, SenSmart Model X-100) were placed on the subject's forehead and forearm (Fig. 1a) to measure the oxygenation levels (Oxy). The pulling force was recorded by the force plate (Bertec, 4080-10) and the grip force was measured by the instrumented handle equipped with a pair of force sensors (Interface, SML-100).

Prior to the hold-until-fatigue testing, two types of reference trials—resting and maximum voluntary contraction (MVC)—were recorded at three postures (Fig. 1, b\_i-iii). Three events (Fig. 2) were labeled for the following fatigue tasks in the oximeter: initiate to target two levels of pulling exertions ('a', 30% MVC and 60% MVC), verbally signal the examiner when the subject could not maintain the desired pulling force ('b'), keep the force level as high as possible for about extra 5 seconds, and relax ('c'). The targeted pulling force level was shown on the monitor next to the subject.

## RESULTS

The NIRS measures were found to be markedly responsive to the changes in exertion levels and upper extremity postures (Fig. 2). For the same posture, the muscle oxygenation changes in the 30% MVC trials were noticeably lower than those in the 60% MVC ones; the endurance time was relatively

longer and the force levels remained steadier in the 30% MVC trials as expected [7]. Changes in muscle recruitment were detected when the postures were different: less muscle oxygenation changes were found in the forearm muscles in the overhead posture (Fig. 2, the leftmost column), presumably due to the involvement of the shoulder muscles initiated in the overhead exertions.

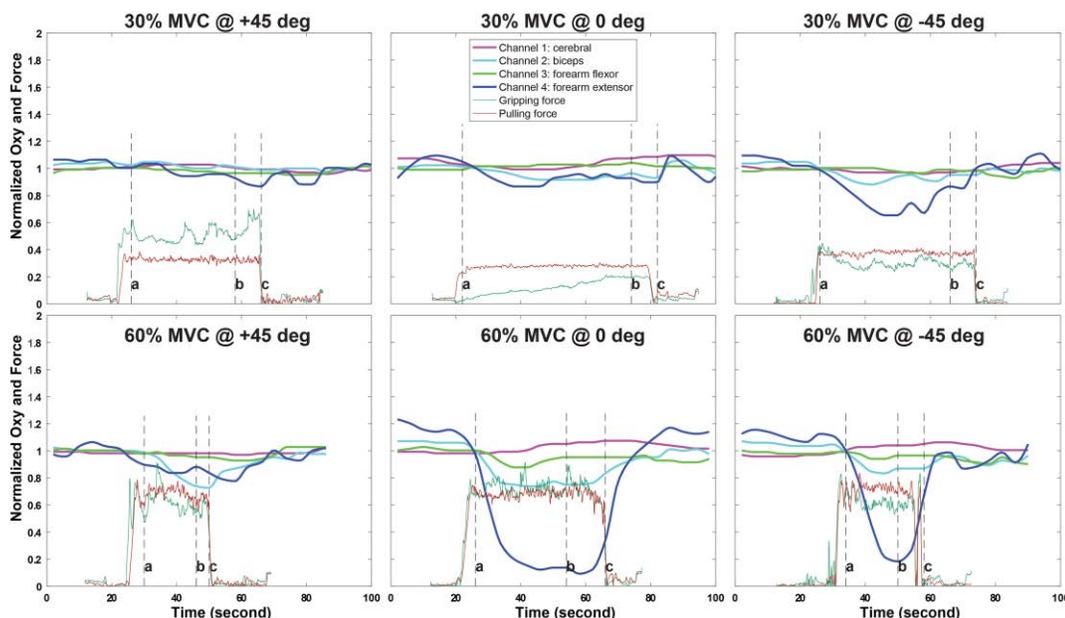

## DISCUSSION

These preliminary results demonstrate the promise of NIRS as a feasible approach to quantify muscle fatigue response during functional upper extremity tasks. Further integrative analyses which will also include EMG and vibromyography may provide a complete characterization of onset and progression of muscle fatigue, leading to better assessments and improvement of ergonomic interventions.

## INTRODUCTION

Transitional periods of dynamic movement, such as transitioning from a run to a walk (RTW) or a walk to a run (WTR) are maneuvers common to military training. In the military, these maneuvers are commonly performed while donning body borne load, sometimes in excess of 45kg. These loads alter lower limb biomechanics causing a significant reduction in performance, as well as increased incidence of musculoskeletal injury. More than 75% of military-related musculoskeletal injuries occur in the lower limb and primarily occur at the knee (1). Donning body borne load, elevates this injury risk and may compromise performance by increasing the mechanical load placed on the joint (2). Load carriers reportedly exhibit increased ground reaction forces and knee joint moments during military activities. But, to date, it is unclear if body borne load increases the frontal and transverse plane knee moments thought to contribute to joint pain, instability and soft-tissue injury (3), particularly during transitional movements common to military training. With that in mind, this study investigated the impact of body borne load on knee joint kinetics and ground reaction force during RTW and WTR transitional movements.

## METHODS

Twenty-one male military personnel (age:  $21.6 \pm 3.1$  yrs, height:  $1.77 \pm 0.56$  m, weight  $79.9.0 \pm 11.6$  kg) participated in this study. For the WTR trials biomechanical data was unavailable for 2 subjects and a reduced sample size of 19 was used. Each participant completed the study maneuvers with three different load configurations: light (LL, ~6kg), medium (ML, 15% of BW) and heavy (HL, 30% of

BW). For the LL, participants wore military equipment (helmet, boots and mock weapon), while for the ML and HL participants added a weighted vest (WeightVest.com Inc. Rexburg, ID, USA) to the LL equipment. The weighted vest was adjusted to have the total load equal either 15% or 30% of participant BW. With each load, participants completed five successful RTW and WTR maneuvers. The RTW consisted of the participant running down a 10m platform at 4 m/s and then transitioning into a 1.5 m/s walk when their dominant leg contacted a force platform (Optima, AMTI, Watertown, MA, USA). Likewise, the WTR required the participant to walk at 1.5 m/s down the platform and transitioning to a 4 m/s run when their dominant limb struck the force platform.

Knee biomechanics were quantified from 3D trajectories of 36 reflective markers. A high-speed stationary recording (240 fps, Opus, Qualysis AB, Gothenburg, Sweden) of each participant was taken to create a kinematic model using Visual 3D (C-Motion, Rockville, MD). The kinematic model consisted of seven skeletal segments (bilateral foot, shank and thigh, and pelvis segments) with 24 DoF. For each trial, synchronous GRF data and marker trajectories were low pass filtered with a fourth-order Butterworth filter (12 Hz). Then, joint rotations were processed using the filtered marker trajectories, while knee joint moments were obtained by processing the filtered kinematic and GRF data.

Peak knee joint moments and GRFs exhibited during stance phase were normalized to BW and submitted to a repeated measures ANOVA to test the effect of load configuration (LL, ML, HL) during the RTW and WTR transitions. Where statistically significant

differences were observed ( $p < 0.05$ ), a modified Bonferroni procedure was used. Where sphericity failed, a Greenhouse- Geisser correction was used.

## RESULTS AND DISCUSSION

Body borne load had a significant effect on peak vertical GRF during the WTR ( $P < 0.001$ ). During the WTR, participants significantly increased vertical GRF from  $1.89 \pm 0.13$  BW with the LL to  $1.92 \pm 0.23$  BW and  $2.04 \pm 0.18$  BW with the ML ( $p = 0.005$ ) and HL ( $p < 0.001$ ) conditions, respectively. However, despite the increased vertical GRF, participants did not exhibit a similar increase in knee joint moments when transitioning from WTR when donning body borne load. Specifically, body borne load had no main effect on peak knee joint flexion ( $p = 0.687$ ), abduction ( $p = 0.92$ ), or internal rotation ( $p = 0.117$ ) moments during the WTR (Table 1). When participants donned body borne load during the WTR, it appears they did not adopt hazardous knee kinetic changes, such as larger knee abduction or internal rotation moments that would increase the injury risk of the acceleration task. Further work, however, is warranted to determine if participants adopted significant kinematic changes that enabled the successful performance, and minimized injury risk, of the WTR.

Body borne load had a significant effect on peak vertical GRF during the RTW tasks ( $P < 0.001$ ). Participants exhibited a peak vertical GRF of  $2.49 \pm 0.25$  BW,  $2.58 \pm 0.25$  BW and  $2.77 \pm 0.25$  BW with the LL, ML and the HL, respectively, during the deceleration of the RTW task. Specifically, during the RTW, the participants exhibited significant increase in peak vertical GRF with the addition of the ML ( $p = 0.025$ ) and HL ( $p < 0.001$ ) compared to the LL configuration.

To maintain lower limb stability and help attenuate the elevated GRFs that resulted with the addition of

load during the RTW, participants increased knee joint moments (Table 1). Participants exhibited a significant increase in peak knee abduction ( $P = 0.006$ ) and internal rotation ( $P = 0.029$ ) moments, but not the peak flexion moment ( $P = 0.415$ ) during the RTW. Specifically, participants increased peak knee abduction moment with the HL ( $p = 0.016$ ) and ML ( $p = 0.008$ ) compared to the LL, and increased the peak internal rotation moment with ML ( $p = 0.050$ ) compared to the LL. These elevated out of plane moments may be indicative of increased risk for injury, as well as instability at the knee. Previous studies have reported a correlation between internal rotation and knee abduction moments and soft tissue injury (4). Further study needs to be done to understand how to minimize these hazardous biomechanical adaptations at the knee during deceleration.

## CONCLUSIONS

Body borne load had a significant effect on knee joint moments when decelerating during the RTW, but not when accelerating during the WTR task. In order to decelerate with body borne load, participants exhibited larger frontal and transverse plane knee moments. These elevated moments may increase injury risk, as well as instability at the knee during the RTW task. Interestingly, participants did not exhibit a similar increase in knee joint moments when performing the WTR with body borne load. Further work is needed to determine if participants can adopt biomechanical patterns that enable successful performance, minimize injury risk, and improve lower limb stability during all military activities.

# THE INFLUENCE OF HAND LOCATION AND EXERTION TYPE ON LUMBAR TWIST DURING SIMULATED INDUSTRIAL TASKS

<sup>1</sup> Colin D. McKinnon, <sup>1</sup> Clark R. Dickerson, and <sup>1</sup> Jack P. Callaghan

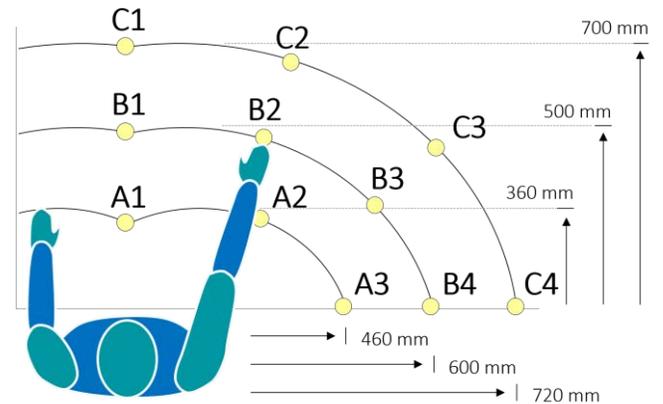

<sup>1</sup> University of Waterloo, Waterloo, ON, Canada  
email: colin.mckinnon@uwaterloo.ca

## INTRODUCTION

Current workstation design guidelines include recommendations for forward and lateral reach distances during occupational tasks based on task frequency and anthropometry. Forward reach guidelines focus on maintaining a neutral shoulder posture since large reaches create large shoulder loads, cause people to fatigue more quickly, and cause more reporting of shoulder pain [1–3]. For lateral reaches, current guidelines are underdeveloped and do not have the same research-based foundation. Rather, lateral reach guidelines generally apply forward reach concepts to the lateral reach envelope determined by worker size and arm length. Low back twisting has been strongly associated with low back pain and injury development [4,5], and the relationship between reaching task hand location and low back twist is currently unknown. The purpose of this study was to investigate low back twist during simulated manual labour tasks across a range of forward and lateral reach distances, task heights, and exertion directions.

## METHODS

Twenty-four (12 male, 12 female) right-handed participants performed single-handed exertions against a load cell (MSA-6, AMTI, USA) attached to the end of a 6-DOF robotic arm (Motoman HP50, Yaskawa, USA). Eleven (11) right-hand target locations (Figure 1) corresponded to Canadian Standards Association forward and lateral reach guidelines for frequent, infrequent and occasional tasks [6]. Exertions were performed at each hand location in all combinations of three directions (forward push, upward exertion, downward exertion), two heights (standing acromion and olecranon heights), and two load magnitudes (40 N, 60% of forward push strength) for a total of 132

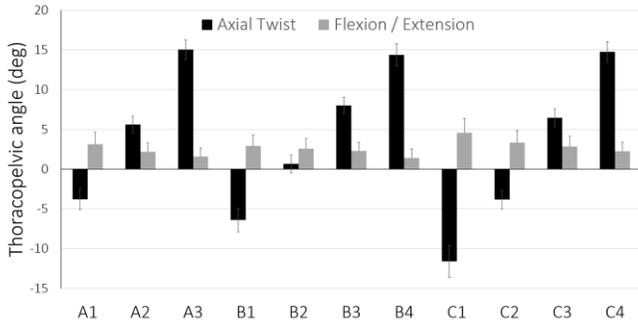

**Figure 1:** Eleven hand target locations used for manual exertions. Targets correspond to current ergonomics reach guidelines (CSA, 2012).

1-second isometric exertion trials. Participant thoracopelvic and right upper limb postures were recorded using 14 reflective markers on bony landmarks and an optical motion capture system (MX20+, Vicon, USA). Thoracopelvic angles (YZX Euler sequence) and right upper arm angles (YXY Euler sequence) were calculated using custom-written Matlab software. Thoracopelvic angles were normalized and expressed relative to a static upright standing trial. Joint angles were compared using a mixed general linear model (RStudio 1.0.136) with sex (M/F), target location (11 levels), height (elbow/shoulder) and direction (up, down, push) as factors ( $\alpha = .05$ ). A Tukey HSD post hoc test tested levels within significant main and interaction effects.

## RESULTS AND DISCUSSION

Significant *target-by-direction* ( $p < .003$ ) and *direction-by-height* ( $p < .03$ ) interactions were observed for all three axes of thoracopelvic motion (axial twist, flexion/extension, lateral bend). These motion axes also showed *target* ( $p < .0003$ ) and

direction ( $p < .007$ ) main effects. Post hoc analyses showed axial twist angle increased with more lateral hand targets, and this increase was generally similar regardless of reach distance (A vs. B vs. C, Fig. 2). Thoracopelvic flexion showed the opposite response, with less flexion at more lateral targets and more flexion with increased reach distance (Fig 2).

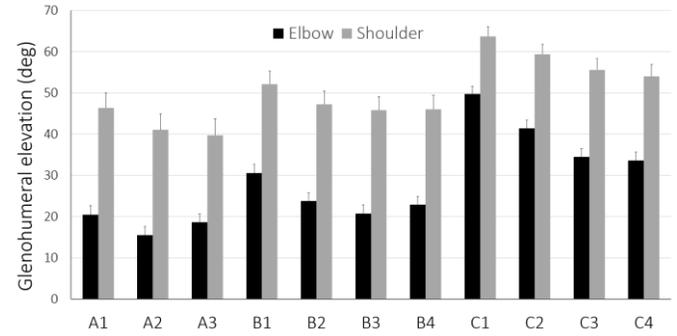

**Figure 2:** Thoracopelvic axial twist angle and flexion angle by hand target location. Positive values show rightward twist and flexion.

These results indicate a trade-off between the twist and flexion motion axes, with opposing postural demands for forward and lateral reaches. It should be noted that mean flexion angle was less than 5 degrees across all hand targets (around 13% of flexion range of motion [7]), whereas axial twist angle was approximately 15 degrees for the most lateral locations, which is nearly 40% of maximum twist range of motion in an upright, neutral posture [8].

Significant *target-by-direction-by-height* ( $p = .01$ ), *direction-by-height* ( $p < .0001$ ), *target-by-height* ( $p < .0001$ ), and *target-by-direction* ( $p < .0001$ ) interactions were observed for glenohumeral elevation angle. Elevation was highest for straight forward targets and decreased laterally (Fig. 3).

Elevation showed similar levels with A and B reached, but increased for C reaches. Plane of elevation showed several significant 2-factor and 3-factor interactions including *direction-by-height* ( $p = .003$ ) and *target-by-direction* ( $p < .0001$ ). Plane of elevation tended to be closer to shoulder abduction for lateral targets and closer to shoulder flexion for forward targets, as expected.

**Figure 3:** Glenohumeral elevation angle by hand target and by target height. Positive values indicate abduction from neutral (arms at sides).

## CONCLUSIONS

The opposing conditions associated with maximum motion for axial twist (lateral, shoulder height, close targets) and glenohumeral elevation (forward, shoulder height, far targets) indicate a complex relationship between thoracopelvic twist and upper limb motion. While close and medium distance targets are reached primarily using lumbar spine motion, farther targets are reached using a combination of lumbar spine motion and increased upper limb elevation. Future work comparing the linear increase of axial twist angles with laterality of hand target and the associated injury risk will assist in definition of safe guidelines for reaching task hand targets.

# TRACING ON A TOUCH SCREEN: INFLUENCE OF AGE, IMPLEMENT, HAND, AND FRICTION

Brittany D. Heintz and Kevin G. Keenan

University of Wisconsin - Milwaukee, Milwaukee, WI, USA  
email: bheintz@uwm.edu

## INTRODUCTION

Many electronic devices require manipulation of touch screens, a hybrid task requiring both well-directed forces and movements. Hybrid force/motion tasks are challenging motor control tasks [1], especially for older adults [2], which may contribute to decreased use of technology and limit benefits associated with its use (e.g., decreased perceived life-stress and increased social support).

In addition to age-associated differences manipulating touch screens, other factors could influence performance. First, low-friction surfaces, such as those found on many touch screens, lead to impaired motor performance [1, 2]. Second, motor performance is dependent on hand use, and left-hand use by right-handed individuals sometimes leads to decreased dexterity [3]. Third, drawing implement (e.g., finger or stylus) has been shown to both improve and impair performance on touch screens [4]. How these factors interact with age to influence use of touch screens is not clear.

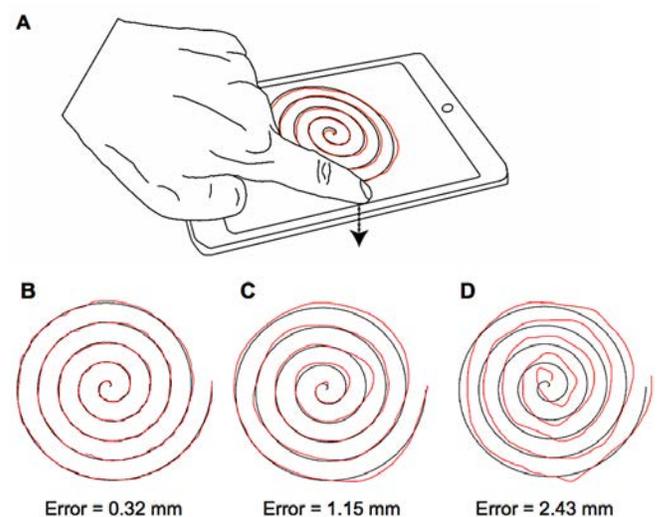

Thus, the purpose of our study was to examine differences between young and older adults tracing an Archimedes spiral on a tablet while swiping against low- and high-friction surfaces using either the finger or stylus with the left or right hand.

## METHODS

26 young (age:  $24.0 \pm 3.8$ ; 15 females) and 24 older (age:  $73.9 \pm 6.4$ ; 14 females) adults volunteered. All participants gave informed consent and were right-handed with no reported neuromuscular problems.

Participants traced an Archimedes spiral displayed on an iPad mini rigidly mounted on a force sensor (Fig. 1A). Spiral tracing was completed using: 1) index finger or a stylus, 2) left or right hand, and 3)

a low- or high-friction touch screen surface [5]. Mean RMS error for each condition was calculated to assess the proximity of the participant's trace to the template [6] (Fig. 1B). Mean downward pressing force and completion time were determined for each condition.

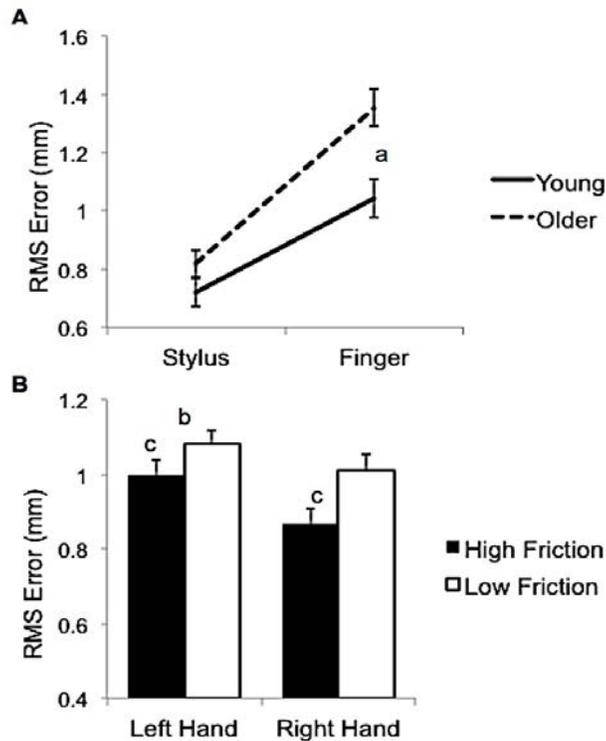

**Figure 1:** (A) Spiral template (black) and subject's trace (red) for the spiral tracing task using the left hand, with normal force aligned with the downward direction (arrow). Representative data for (B) low, (C) medium, and (D) high RMS error.

Additional variables known to change with advancing age were also quantified, as was their relationship to RMS error (e.g., reaction time, fingertip sensory thresholds, and touch screen usage/ownership). Simple reaction time (SRT) and choice reaction time (CRT) tests were completed on a portable laptop. Mean time from stimulus onset to response for 20 trials for each test was determined. Index fingertip sensation was assessed using the standardized von Frey anesthesiometer. A brief survey was given to assess previous touch screen use and ownership.

## RESULTS AND DISCUSSION

Repeated measures ANOVA indicated a significant interaction for RMS error between age and drawing implement (Fig. 2A). In addition, a significant main effect for RMS error was found for hand used and friction condition (Fig. 2B).

**Figure 2:** RMS error during the spiral tracing task. (A) There was a significant age by implement interaction for the spiral tracing task, with greater RMS error for older vs. younger adults using the finger (<sup>a</sup> $p = .003$ ) and no difference using a stylus ( $p = .165$ ). (B) RMS error decreased using the left vs. right hand (<sup>b</sup> $p < .001$ ), and on the low- vs. high-friction surface (<sup>c</sup> $p < .001$ ).

Sensory thresholds and reaction times were significantly different between young and older adults ( $p < .01$ ), however these and additional variables were not related to increased RMS error in older adults when using their index finger (Table 1).

Though these variables did not correlate with the age-related change in performance when older adults performed the tracing task with their finger (Table 1), one possible explanation for this result may be related to altered visual feedback. The larger size of the fingertip relative to the stylus may occlude a greater area of the display and decrease visual feedback [7], which may be more detrimental for older adults who rely on visual feedback to modify hand trajectories during the task [8].

Results provide evidence for improved touch screen manipulation when using a stylus vs. fingertip by older adults. Moreover, implementing a higher friction touch screen and using the preferred hand improved performance. Further work is necessary to determine whether impaired visual feedback may be responsible for increased RMS error in older adults.

## INTRODUCTION

Current U.S. Army head-supported mass (HSM) guidelines, USAARL's Performance Curve (PC) and Acute Injury Risk Curve (AIRC), were developed approximately 20 years ago with a focus on the aviation operating environment. The relationships between mass and vertical and/or longitudinal offset (away from the tragion notch) are critical in assessing risk of performance decrement and acute injury risk. The AIRC was developed with respect to risk of injury during a severe dynamic loading event such as a helicopter crash, and researchers determined change in vertical center of mass (CM) offset to be the best predictor of increased acute injury risk (McEntire, 1998). In comparison, the best predictor of performance decrement was longitudinal CM offset (PC).

The USAARL Curves remain the only established guidelines for U.S. Army HSM, but have limited applicability to individual Soldier movement requirements of the dismounted, ground mounted, and airborne operating environments. Helmet developers and program managers have requested new guidelines be developed for the dismounted, ground mounted, and airborne operating environments that take into consideration currently fielded and proposed HSM configurations. The aim of this project was to measure the mass properties (mass and CM offset) of the currently fielded and proposed HSM configurations and compare them against the existing USAARL Curves.

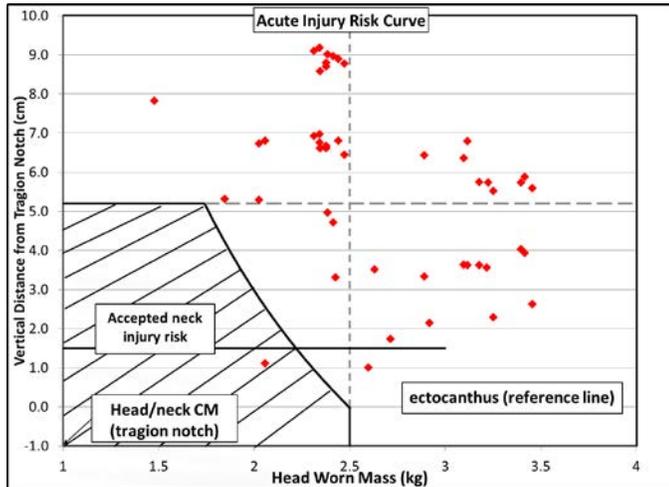

## METHODS

The mass properties of currently fielded and proposed dismounted and ground mounted helmet systems were measured using the USAARL headform on the Mass Property Instrument (KSR 330-60, Space Electronics). The USAARL headform is representative of the U.S. Army Aviation 50th percentile male. Tested helmets included the Advanced Combat Helmet (ACH), Lightweight ACH, Enhanced Combat Helmet (ECH), Combat Vehicle Crewman helmet (CVC), and a developmental helmet. Helmet attachments included two types of night vision goggles (NVGs), protective masks, spectacles, and one pair of protective goggles. Mass and CM offset were compared against the existing PC (longitudinal offset; X-axis) and AIRC (vertical offset; Y-axis) to assess compliance with the existing guidelines. A total of 50 unique helmet and helmet attachment configurations were assessed.

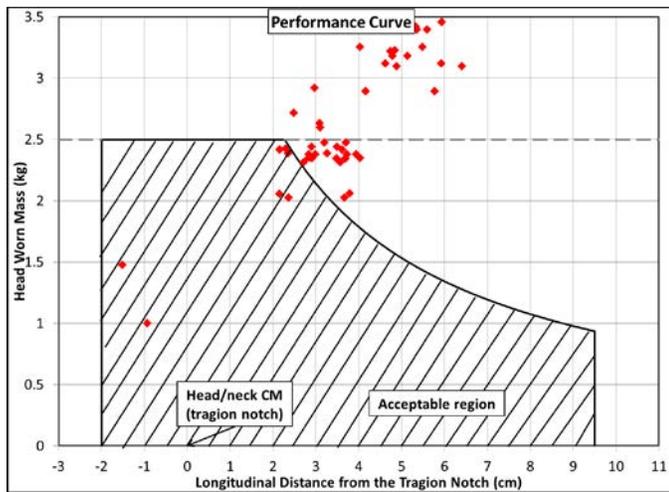

## RESULTS AND DISCUSSION

Based on the current accepted guidelines, less than 5% (2 of 50) of the measured HSM configurations were acceptable on the AIRC (Figure 1), and 14% (7 of 50) were acceptable on the PC (Figure 2). Twenty-four of the tested configurations exceeded the maximum AIRC and PC recommended mass of 2.5kg, 18 of which had masses greater than 3kg.

Twenty-nine configurations exceeded the maximum vertical offset of 5cm on the AIRC, with ten of those exceeding both maximum mass and maximum vertical offset limits. For example, an extreme HSM configuration (helmet, NVGs, and protective mask) had a mass of 3.4kg with 5.5cm vertical offset and 5.5cm longitudinal offset, exceeding mass and CM offset limits on both curves.

**Figure 1:** Acute Injury Risk Curve with Various Helmet and Helmet Configurations

**Figure 2:** Performance Curve with various Helmets and Helmet Configurations

While some individual helmets fell within acceptable limits, the addition of NVGs and protective masks pushed all configurations outside of the recommended guidelines. Frequently used operational configurations, such as the helmet with spectacles and NVGs, exceeded the limits on both AIRC and PC, but were significantly closer to complying with the AIRC and PC curves than less frequently used (worst-case) configurations such as the helmet with NVGs and protective mask.

The current USAARL Curves assess helmets for a small population of the U.S. Army – the Aviator. The ground, dismounted, and airborne Soldier are now exposed to similar helmet loads, but the inertial and moment loading of the cervical spine varies greatly by operating environment.

## CONCLUSIONS

Future curves will need to consider the most likely operating environment, movement techniques, and primary cause of injury. A proposed solution to increased mass and mass offset is to increase or decrease level of protection based on threat. This would allow regulation of the length of time that Soldiers are exposed to extreme HSM configurations. Research should continue to investigate the specific impacts of mass, mass offset, and time of exposure on Soldier health in all operating environments. Guidelines and recommendations developed for the Soldier can be translated to many civilian occupations that use similar, if not identical, HSM configurations such as police SWAT, medical air evacuation pilots and crew, and firefighters.

# EFFECTS OF MILITARY LOAD CARRIAGE SYSTEMS ON SHOOTING PERFORMANCE DURING A SIMULATED TACTICAL ENGAGEMENT

<sup>1</sup>Brian K. Higginson and <sup>2</sup>Patrick R. Lindecker

<sup>1</sup>Gonzaga University, Spokane, WA, USA

<sup>2</sup>University of Montana, Missoula, MT, USA

email: [higginson@gonzaga.edu](mailto:higginson@gonzaga.edu)

## INTRODUCTION

Military load carriage systems have recently been found to compromise not only user mobility [1], but also tactical shooting performance [2] and survivability [3] of soldiers. Load carriage systems (such as backpacks) are typically designed to interface with the user directly. In many military applications, duty requirements often dictate that load carriage systems be worn over body armor. This change in load-user interface often results in a subsequent decrease in load stability. In many military career fields, load instability can result in compromised mission-specific task performance and survivability, particularly during tactical engagements. The two most viable solutions to maximize load stability when an external load is worn over body armor is to develop an integrated armor/load carriage system, or modify the existing load carriage systems to provide a more stable load-user interface. While development of integrated armor/load carriage systems are ongoing, the current study aims to determine the effectiveness of an integrated bolster system to stabilize external loads being worn over body armor.

The purpose of this study was to 1) determine the influence of military load carriage systems on tactical shooting performance measures during dynamic target acquisition and engagement tasks, and 2) determine if external load stabilizers can be effectively used to reduce any potential compromises in tactical shooting performance.

## METHODS

Eleven Special Weapons and Tactics (SWAT) team members (Mean  $\pm$  SD: 41.2 $\pm$ 5.7 yrs, 179.3 $\pm$ 6.0 cm, 92.8 $\pm$ 10.1 kg) participated in a simulated tactical

engagement consisting of three separate targets. The first target was located 10 meters directly in front of the shooter and was acquired starting from the rifle ready (contact/close contact) position. The other two targets were located 60° to the right and left of this forward target, at the same linear distance from the shooter. After engaging the first target, the shooter immediately engaged either the right or left target as fast as possible, finishing with the remaining target. Target engagement order was counterbalanced and dictated to the subject in real time using an external auditory cue, coming from the next target to be engaged, immediately prior to engagement of the first target.

The targets were engaged by the shooter using a fully functional weight-matched airsoft M4 Carbine with inertial properties matching those of an actual M4 in use by the U.S. military. An optical targeting system was mounted to the rifle barrel allowing quantification of all shooting performance measures. Shooting performance measures consisted of accuracy, shot placement, time on target, and engagement times (time between shots). Each shooter engaged the three targets under three different conditions: 1) while wearing body armor with no load, 2) while wearing body armor and a 16 kg assault load contained within a standard assault pack, and 3) while wearing body armor and a 16 kg assault load contained within a standard assault pack equipped with a load stabilizer (bolster system). Previous unpublished data from novice shooters indicates that there may be a direction effect, with shooting performance being dependent on whether the right or left target was engaged immediately after the forward target. For this reason, each loaded condition was performed in each direction in replicate (12 shooting bouts total), and averaged (within direction) for analysis.

Shooting outcome measures were compared across conditions using 2 x 3 (direction x load) repeated measures ANOVA ( $\alpha=.05$ ). Sheffé's post-hoc test was performed for any significant main effect of load.

## RESULTS AND DISCUSSION

As seen with previously unpublished data using novice shooters, there was a small, but significant, increase in engagement times of the second target when it was located to the right vs. left of the forward target ( $1.27\pm 0.08$  vs.  $1.16\pm 0.08$  s, respectively;  $p<.001$ ). This was most likely a function of hand/eye dominance of the shooters. Tactical shooting is typically performed using a "both eyes open" strategy. Since all shooters were right handed, this placed the left target closest to their "free" eye, and the right target closest to their "sight" eye. Unlike direction, load had no effect on engagement times while moving from the first to second targets ( $p=.268$ ). Unlike engagement times for the second target, engagement times for the third target were not affected by the direction of acquisition ( $p=.836$ ), but were found to be significantly longer ( $p=.026$ ) for the bolstered condition ( $1.62\pm 0.11$  s) than the unloaded condition ( $1.44\pm 0.09$  s).

Interestingly, after collapsing engagement times across direction and load, it was found that these times did not double from targets 1-2 to 2-3 as expected. Although there was a significant increase in engagement times from targets 1-2 and 2-3 ( $p<.001$ ), the overall magnitude was relatively small ( $1.21\pm 0.08$  vs.  $1.52\pm 0.09$  s, respectively). Given that the angular displacement was twice as great going from target 2-3 as target 1-2 ( $120^\circ$  vs.  $60^\circ$ , respectively), these results indicate that the shooters had an increased angular velocity while engaging the third target when compared to the second.

The time on target prior to engagement was not influenced by direction or load for either the second target ( $p=.310$  and  $p=.402$ , respectively) or third ( $p=.122$  and  $p=.064$ , respectively). This was not unexpected as this target acquisition and engagement task was so dynamic that very little time (0.32 - 0.44 s) was spent on each target, regardless of condition.

Measures of accuracy were not influenced by direction of target engagement or load condition for either the second target ( $p=.251$  and  $p=.591$ , respectively) or third target ( $p=.668$  and  $p=.828$ , respectively) engaged. Similarly, when comparing accuracy between targets 2 and 3, there was no change in accuracy ( $71.5\pm 7.2$  vs.  $68.3\pm 6.4$  mm, respectively;  $p=.400$ ). As with time on target measures, the dynamic nature of this shooting task may have contributed to the lack of differences seen in accuracy measures between conditions and targets. The dynamic nature of this task resulted in relatively large variability between conditions within each subject.

## CONCLUSIONS

The results of this study indicate that engagement times, time on target, and accuracy are minimally affected by load carriage systems during a tactical target acquisition and engagement task. Likewise, from a functional outcomes perspective, the use of a load stabilizer appeared to have little influence on these measures. The lack of significant findings in the current study may be due in part to the highly dynamic nature of this task resulting in relatively large variability between conditions.

This study primarily focused on functional performance outcomes. It may be possible that the use of other more sensitive measures, such as quantifying pack and rifle motion relative to the shooter, may provide more insight into the relationship between load carriage systems and tactical shooting performance. In addition to incorporating more sensitive measures, future research should consider different loads and load distributions, as well as varying engagement strategies and requirements.

# UPPER EXTREMITY MUSCLE ACTIVATION AND STRENGTH ASSESSMENT IN NATIVE AND NON-NATIVE SIGN LANGUAGE USERS

<sup>1,2</sup>Gretchen Roman, <sup>1</sup>Naoaki Ito, and <sup>1</sup>Meghan E. Vidt

<sup>1</sup>Exercise Science and Health Promotion, Arizona State University, Phoenix, AZ, USA

<sup>2</sup>Physical Therapy, Midwestern University, Glendale, AZ, USA

email: garoman@asu.edu

## INTRODUCTION

Over 30% of sign language interpreters are injured on the job [1]. Job demand for interpreters and translators is anticipated to grow 29% by the year 2024 [2]. Because of this projected growth, an even higher number of sign language interpreters are expected to suffer from musculoskeletal (MSK) pain. Most interpreters are non-native American Sign Language (ASL) users – individuals born to non-signing, hearing parents. Native ASL users – Deaf or hearing individuals who have at least one Deaf parent – are an overlooked demographic within sign language interpreting research [3]. Upper extremity (UE) biomechanical considerations unique to the work style of sign language interpreters have long been identified, but only crudely noted. The proposed biomechanical considerations thought to relate with MSK injury include ballistic signing, insufficient micro rest breaks, excessive deviations from neutral wrist, excursions outside the normal interpreting work envelope, and muscle tension [4]. However, little quantitative information is available describing the influence of these biomechanical contributions on the increased MSK injuries reported by non-native ASL users. The focus of this study is to characterize muscle tension and rest in a cohort of native and non-native ASL users while signing. It is hypothesized that non-native users will have worse outcomes, presenting with shorter rest and greater muscle tension, which will be correlated with increased MSK pain and UE weakness.

## METHODS

Five native (4F/1M; 3 Deaf/2 hearing; all right-hand dominant) and 5 non-native (3F/2M; 5 Deaf; 4 right-/1 left-hand dominant) ASL users (age  $41.8 \pm 15.53$  yrs) were studied. Participants interpreted, at a self-selected pace, 3 trials of a 7min source from a video in sign language with audio and closed captioning.

At least 5min rest was given between trials. The third trial was selected for analysis. For all trials, a Noraxon DTS system (Noraxon, Inc., Scottsdale, AZ) was used to measure surface electromyography (EMG). Measures were acquired bilaterally from upper, middle compartments of trapezius, and anterior, middle compartments of deltoid at 1000 Hz. Prior to data collection, maximal voluntary contractions (MVC) were acquired using postures that elicit maximal activity. Surface EMG was processed with a custom Matlab (MathWorks, Inc., Natick, MA) program. Raw EMG signal was band-pass filtered from 10-490Hz with a 4<sup>th</sup> order Butterworth filter, rectified, and enveloped with a 2<sup>nd</sup> order low-pass Butterworth filter with 3Hz cutoff frequency. Signal was normalized by each muscle's corresponding MVC. Micro rest breaks were quantified from processed EMG signal as temporal delay between sequential signs ( $\geq 0.2565$ sec duration with a level of activation  $< 18\%$  of MVC) [5]. Muscle tension was quantified by mean %MVC activation. %rest and %MVC were evaluated across the entire trial duration.

Isometric joint moment was used to assess strength. Measurements were taken at the shoulder for abduction/adduction, flexion/extension, and internal/external rotation with a Humac Norm (CSMI, Stoughton, MA) isokinetic dynamometer. Three 5sec trials were performed for each direction; 1min rest was given between trials and 2min rest was given between tests to offset fatigue [6]. A custom Matlab program was used to identify the maximum joint moment maintained for at least 0.5sec. The maximum value across the 3 trials was evaluated.

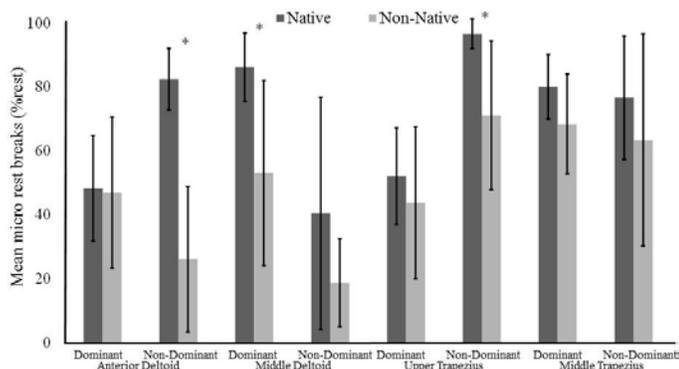

MSK pain was measured using a numeric pain rating scale (NPRS) [7]. Participants were asked to rate whether they experience pain from using sign language on a 0-10 scale (0=no pain; 10=worst imaginable pain). A participant with a rating  $> 0$  was

considered to have pain, while a 0 rating was considered without pain.

Group differences between native and non-native ASL users (independent variables) were evaluated using separate Mann Whitney U tests for rest (%rest), muscle tension (%MVC), and strength for self-reported dominant and non-dominant sides (dependent variables). Group differences between those with and without pain (independent variables) were also evaluated using separate Mann Whitney U tests for the same dependent variables. Associations between significant %rest and %MVC findings in the separate muscle compartments were evaluated with corresponding strength measures using Spearman correlation analyses. All analyses were performed using SPSS, (v.23, IBM Corp., Armonk, NY).

## RESULTS AND DISCUSSION

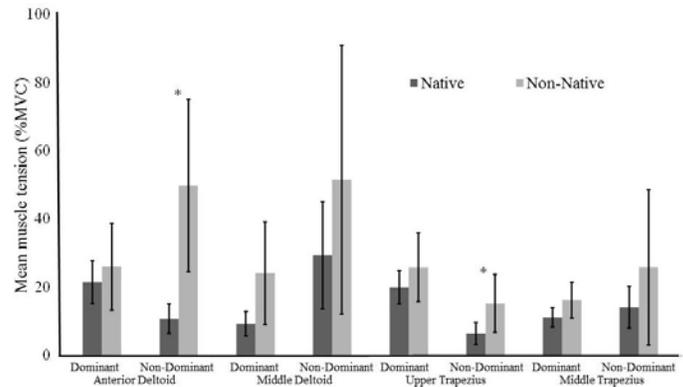

Native ASL users had significantly more %rest compared to non-native in the non-dominant anterior deltoid ( $p=0.009$ ), dominant middle deltoid ( $p=0.047$ ), and non-dominant upper trapezius ( $p=0.047$ ) (Fig. 1). Within the non-native group, there were no differences in the significant %rest measures between those with and without pain (all  $p>0.248$ ). When evaluating the association between significant %rest and corresponding muscle strength, dominant middle deltoid %rest for the non-native group was positively correlated with dominant shoulder abduction ( $r^2=1.0$ ;  $p=0.01$ ).

**Figure 1:** Mean (95% confidence interval) micro rest (%rest) for native and non-native ASL users;  $p$ -value $<0.05^*$ .

Non-native ASL users demonstrated greater %MVC activation for non-dominant anterior deltoid ( $p=0.009$ ) and non-dominant upper trapezius ( $p=0.047$ ) (Fig. 2). Within the non-native group, there were no differences in significant %MVC

between those with and without pain (all  $p=0.564$ ). There was no correlation between significant %MVC and corresponding strength for native and non-native groups. UE strength differences were not significant between native and non-native groups (all  $p>0.076$ ), or between those with and without pain (all  $p>0.221$ ).

**Figure 2:** Mean (95% confidence interval) muscle tension (%MVC) in native and non-native ASL users;  $p$ -value $<0.05^*$ .

## CONCLUSIONS

Non-native ASL users demonstrated lower %rest, and greater %MVC activation for muscle groups at the shoulder compared to native ASL users. MSK pain was not significantly associated with amount of time spent in rest or muscle tension, which were hypothesized to be indicators of cumulative muscle strain. The association between dominant shoulder abduction weakness and fewer micro rest breaks potentially leads to higher short-term fatigue and greater injury risk long-term. A longer source duration or increased number of trials, and a quantitative measure of fatigue may help to foster a better understanding of the role of muscular fatigue in ASL users. Ongoing work continues to identify primary contributors to increased MSK injury risk in ASL users, including assessments of a larger cohort, and the influence of kinematic and kinetic measures.

# ARE HYBRID SIT-STAND POSTURES A GOOD COMPROMISE BETWEEN SITTING AND STANDING?

Mamiko Noguchi, Michal Glinka, Maureen F. Riddell, Graham Mayberry, and Jack P. Callaghan

Department of Kinesiology, University of Waterloo, Waterloo, ON, CAN

email: [mnoguchi@uwaterloo.ca](mailto:mnoguchi@uwaterloo.ca)

## INTRODUCTION

Both standing and sitting postures, when maintained statically for a prolonged period of time, are linked to the development of low back pain and discomfort [1]. The range of hybrid sit-stand postures (i.e. perching) offers potential alternatives between sitting and standing. Sit-stand stools allow users to work near their standing height, while offloading some upper body weight onto the stool to relieve lower limb demands. Compared to sitting, perching reduces anterior-posterior shear force at the low back and encourages users to move more frequently [2]; however, it is also associated with increased lower leg swelling, decreased hip comfort [3], and no difference in low back discomfort [2]. Perching also reduces anterior-posterior shear force at the low back when compared to standing [2]; however, lower limb discomfort may be higher or lower depending on the footrest position [2,3,4], and back extensor activity and co-contraction are higher in perching [2]. As these results show, there are some benefits to the use of sit-stand stools; however, questions remain as to whether perched postures are different enough to be a solution for the negative consequences associated with sitting and standing.

Although perching encompasses a range of postures from sitting to standing, there is limited empirical evidence to suggest how a sit-stand stool should be set up. It has been suggested that the lumbar angle closest to neutral with the thigh muscles in passive equilibrium is 135° of trunk-thigh angle in lateral recumbent position [5]. In addition, reclining the chair backrest to 130° reduced the lumbar load by approximately 60% [6]. However, there has yet to be a quantitative study examining whether this angle is in fact optimal and preferred when upright. Therefore, the primary purpose of this study was to identify where lumbar and pelvic angles deviate from sitting and standing and determine three phases: sitting, perching, and standing. The secondary purpose was to examine the differences between phases for trunk and knee extensor muscle activities and ground reaction forces.

## METHODS

Twenty-four participants, 12 males (age  $25.7 \pm 2.3$  years; height  $177.5 \pm 5.6$  cm; mass  $80.2 \pm 15.3$  kg) and 12 females (age  $24.3 \pm 2.2$  years; height  $167.5 \pm 6.1$  cm; mass  $66.0 \pm 8.6$  kg), were recruited. Each participant completed 19 one-minute trials from sitting (90° trunk-thigh angle) to standing (180° trunk-thigh angle) in 5° trunk-thigh angle increments. Three-dimensional kinematic data were collected from trunk, lumbar, pelvis, thighs, and shanks at 50 Hz (Northern Digital Inc., ON), and Cardan angles (sagittal-frontal-transverse) were calculated using Visual 3D (C-Motion, MD). Both lumbar and pelvic angles were expressed as the deviation from the five-second standing trial that was completed before the study began. To assess whether the transition postures significantly deviated from either standing or sitting postures, a statistical approach employing Dunnett's test was performed (R3.3.0 MULTCOMP) for each gender separately.

Electromyography (EMG) data were collected from thoracic erector spinae (TES), lumbar erector spinae (LES), and vastus medialis oblique (VMO) at 2000 Hz (AMT-8; Bortec Biomedical Inc., Calgary, AB). After removing electrical and heart rate artifacts and normalizing the data (%MVC), an average was calculated for each of the one-minute trials. Ground reaction forces were collected at 400 Hz (OR6-7, AMTI Inc., Watertown, MA) and normalized to the participant's body weight (%BW). Similar to EMG, an average of each trial was calculated for each axis of force. Using the classification from each gender, one-way repeated measures ANOVAs were performed to determine the effect of phases ( $p < 0.05$ ).

## RESULTS AND DISCUSSION

Standing lumbar and pelvic angles were different from all other trunk-thigh angles for both males and females ( $p < 0.0001$ ), suggesting that standing is a distinct posture and is difficult to achieve with the current seat interface (e.g. flat, low friction surface) and within the constraints of this study (e.g. feet

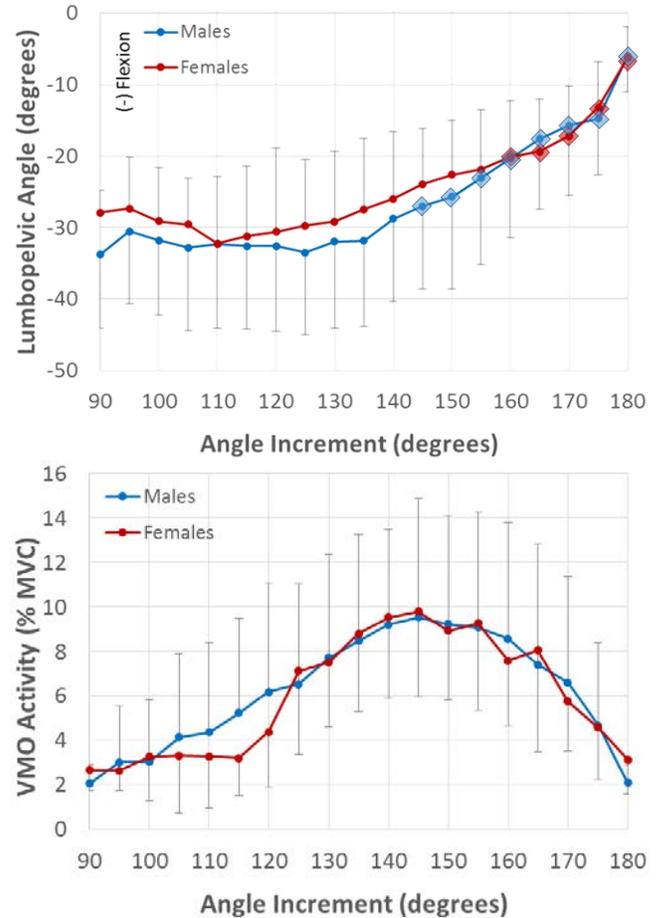

position, shank angles). Lumbar angle deviated from sitting at 145° ( $p = 0.0001$ ) and 160° ( $p < 0.0001$ ) trunk-thigh angles for males and females, respectively (Figure 1 top). Pelvic angle was different from sitting at 180° trunk-thigh angle ( $p = 0.004$ ) for males and at 115° and 180° trunk-thigh angles ( $p = 0.025$ ) for females. This gender difference comes from females tending to maintain a more upright posture (less lumbar flexion and more anterior pelvic tilt) compared to males [7], resulting in a wider range of angles that are similar to sitting. Both lumbar and pelvic angles at 135° trunk-thigh angle, as suggested by Keegan [5], were not different from sitting.

The level of muscle activity was low ( $< 10\%$  MVC) in all muscles throughout the trials (Figure 1 bottom). Males exhibited no difference between phases for both trunk extensors (TES  $p = 0.247$ ; LES  $p = 0.319$ ) while a significantly lower VMO activity was seen in standing compared to perching or sitting ( $p = 0.005$ ). Females showed significant differences in all muscles in which TES was higher in sitting compared to perching or standing ( $p < 0.005$ ), LES was higher in standing compared to perching ( $p = 0.015$ ), and VMO was lower in standing compared to perching or sitting ( $p = 0.003$ ). In terms of ground reaction force, all phases were different from each other in the anterior-posterior direction ( $p < 0.001$ ), where perching required approximately 15% BW to maintain postures. Taking both EMG and force data into consideration, the notable differences between phases were in the level of leg effort required to remain upright, which provides insight into considerations for seat designs.

## CONCLUSIONS

Whenever the pelvis is in contact with a low friction supporting surface, changes in lumbar angle do not occur for a wide range of trunk-thigh angles [8]. While the lumbar angle gradually shifted towards neutral from approximately 110° trunk-thigh angle, VMO activity and anterior-posterior shear force at the feet increased, reaching its maximum at 145° trunk-thigh angle. There is no ‘ideal’ seat position that includes all of the benefits from sitting, perching, and standing; however, it is possible to increase the range of perching with fewer lower limb challenges.

Therefore, future chair designs should be focused on reducing discomfort between 115 and 170° trunk-thigh angles with these two key points in mind: 1) the seat interface focusing on pelvis alignment to improve lumbar angles and to offload some of the lower limb demands and 2) the design of the foot support focusing on redirecting force from shear to compression with respect to the lower limb joints [4] while reducing cumbersomeness when it is in use.

**Figure 1:** Lumbar angle (top) and VMO activity (bottom) from sitting (90° trunk-thigh angle) to standing (180° trunk-thigh angle) postures. The square markers denote significant difference from the sitting posture ( $p < 0.05$ ).

## INTRODUCTION

Dental care practitioners frequently encounter neck, back, and shoulder injuries caused by long durations of time in non-neutral positions. Musculoskeletal pain in the upper body appears early in practitioners' careers and often leads to reduced hours or early exit from clinical practice [1-2]. Impairment caused by musculoskeletal disorders (MSDs) on dental operators' clinical activities has a significant impact on the healthcare delivery system and can become a factor in rising costs of healthcare. Several interventions have been suggested to reduce the risks of MSDs among dental operators. Previous studies have used operator awareness [3] and physical fitness [4] to reduce the risk of MSDs in dental practitioners.

Another intervention is the use of magnification loupes to increase visibility of the mouth, thereby improving dental clinicians' posture. Numerous studies have reported the value of loupes for this purpose, but most have used subjective or qualitative data as justification, such as self-reported pain scales and real-time or video evaluations [5-10]. The emergence of motion capture equipment and analysis provides a quantitative method to analyze body kinematics during practice and therefore evaluate whether interventions lead to ergonomic postures [11-15]. Electromyography is another tool which can be used to quantify the effects of intervention through analysis of muscle activity. The purpose of this study was to investigate the feasibility of using motion analysis and electromyography in quantifying dental operator posture. We hypothesized that the use of magnification loupes would exhibit trends toward improved posture, as quantified by upper extremity kinematics and muscle activity.

## METHODS

Two subjects participated in this study, which was approved by the University of Missouri- Kansas City Institutional Review Board. Subjects were selected based on opposing demographics. There was one male subject and one female subject, one of whom was a recent graduate of a periodontal residency program, and the other was a dental hygienist. Both were of similar height. Each operator received a complimentary set of Through-the-Lens (TTL) and Flip-Up lens (FL) loupes (Orascoptic, Middleton, WI, USA). Each subject also used his or her own basic eyewear (BL), including safety lenses worn by the periodontist, and prescription lenses worn by the dental hygienist. Each operator used a light attached to the loupes, and the overhead dental operatory light when using basic eyewear. A standard dental operatory was equipped with 10 OptiTrack Flex 13 motion capture cameras (NaturalPoint, Inc., Corvallis, OR, USA). Each subject was fitted with a motion capture suit to which reflective motion capture sensors were applied. This system measured and recorded 3D positions of the markers during each procedure. Data were collected using Motive software (NaturalPoint), and analyzed using MATLAB (The MathWorks Inc., Natick, MA, USA). Motion data was collected at 120 Hz. Each operator was also fitted with DELSYS Myomonitor IV electromyography (EMG) sensors bilaterally on the upper trapezius and the lumbar erector spinae. Data was collected using the EMGWorks software (DELSYS) at 2 kHz. The operator sat on a stool equipped with a back rest and wheels. Data was collected while the practitioner collected periodontal depths of the patient using a standard probe. The same live patient was used for all procedures, and the type of lenses worn varied for

each of the 3 data collection sessions to minimize practice effects.

Marker position data were used to calculate head angle time series representing forward and lateral angular deviation of the head away from the body midline. Angular range of motion and standard deviations were extracted for 3 different time series: a fixed 40-second duration ( $T_{40}$ ) in which the operator was actively performing the task, the duration in which the operator's chair was between the 9 and 12 o'clock positions ( $T_{9-12}$ ) relative to the patient, and reach-to-reach ( $T_{Reach}$ ), the duration between reaching movements to pick up and set down the probe. To examine muscle activation, raw EMG data was normalized to maximum EMG amplitude within each trial, and root mean square (RMS) values of the EMG data were calculated for  $T_{40}$  time series only.

## RESULTS AND DISCUSSION

Both operators exhibited reduced forward flexion range of motion when using TTL or FL loupes compared to BL conditions. On average, Subject 1 used 50.1% and 48.9% less forward flexion when using TTL and FL lenses respectively, in comparison to the BL lens. Subject 2 on average used 73.9% and 26.6% less forward flexion when using FL and TTL lenses, respectively, in comparison to the BL lens. Table 1 demonstrates the forward flexion range of motion for each of the 3 time series conditions.

**Table 1:** Forward Flexion ROM, in Degrees

	Subject 1			Subject 2		
	$T_{40}$	$T_{9-12}$	$T_{Reach}$	$T_{40}$	$T_{9-12}$	$T_{Reach}$
BL	22.3	19.6	20.2	16.8	18.2	21.7
TTL	12.3	8.5	10.3	12.7	14.3	14.3
FL	10.0	10.8	10.8	0.4	8.7	6.1

No consistent trends were observed in lateral flexion range of motion. This is likely attributable to relatively high variability of head movements in the frontal plane. Additionally, EMG results did not exhibit any consistent trends across testing conditions. This is likely due to the unconstrained time durations across which RMS values were

calculated. In addition to larger sample sizes, future studies using EMG should report muscle activity over smaller and more accurately-defined sub-tasks comprising the overall procedure.

## CONCLUSIONS

In this study, we observed a consistent trend towards improved posture when using magnification loupes during a routine dental procedure. This preliminary analysis provides some basis for the use of motion capture and electromyography in evaluating the effectiveness of ergonomic interventions for medical care providers. This was a pilot study, and further research with a larger sample size is necessary to fully evaluate the utility of motion and EMG analysis of dental operators. Additionally, the clinicians were evaluated in an authentic dental clinical setting not designed for motion capture research, and the suits worn by the practitioners may have interfered with their posture, comfort, and clinical ability. Furthermore this study was conducted without a set period of time or pre-determined order for mouth probing; implementing procedures for these aspects in future studies may improve consistency.

# BIOMECHANICAL DIFFERENCES IN LIFTING BETWEEN A MANUAL VS. POWER COT

<sup>1</sup> Steven Capehart, <sup>1</sup>Michael Callihan, <sup>1</sup>Amanda Ransom, and <sup>1</sup>Katherine Worcester

<sup>1</sup>The University of Kentucky, Lexington, KY, USA

Email: steven.capehart@uky.edu

## INTRODUCTION

Musculoskeletal injuries consistently account for about half of all injuries to emergency medical service (EMS) providers (1). These injuries result in lost work time, permanent disability, and high worker compensation costs (2). More than half of all EMS injuries happen when lifting patients and the back is the primary body part affected (3).

National Institute for Occupational Safety and Health (NIOSH) has established safe lifting limits for health care providers of 51 pounds but unfortunately for EMS, many routine lifts, far exceed this recommended compression limit (1). As the prevalence of obesity in the general population increases, the risk for injury to EMS workers who handle and transport patients increases (4).

One such lifting scenario where EMS workers may be at risk of injury occurs when lifting ambulance cots, with patients on them, from the ground to standing height. Implementing mechanical lifting equipment in these situations may reduce the risk of musculoskeletal injury by reducing the force required to lift the patient.

Thus, the purpose of this study was to analyze trunk and lower extremity muscle activity and sagittal plane kinematics and kinetics when lifting a patient between two different cots (mechanically operated cot (Power-cot) and manually operated cot (Manual-cot)).

## METHODS

As of this submission, 10 healthy female nursing students (age  $23.6 \pm 3.2$  weight (kg)  $64.5 \pm 9.8$  height (m)  $142.8 \pm 3.2$ ) and 4 male emergency medical service (EMS) providers age  $34.6 \pm 5.3$  weight (kg)  $80.5 \pm 7.9$  height (m)  $1.78 \pm 0.4$ ) were recruited to take part in a larger study analyzing lifting mechanics during various work-related lifts. The nursing students in this study were untrained as

they have never used the Manual or Power cot before. The EMS providers in this study were considered trained as they have had previous experience using both types of cots regularly.

Stryker EMS provided us with Performance-PRO XT cot (Manual) and Power-PRO XT cot (Power) for comparison in this study (Figure 1A, 1B). The Manual cot features a handle grip that requires two lifters (Figure 1A). For the Manual cot condition, the subjects were at the feet of the cot, while the same trained EMS was lifting from the head of the cot. The mechanically operated Power cot features a battery-powered hydraulic system that raises and lowers the cot with the touch of a button only requiring 1 person. Subjects performed 3 trials lifting the cots from the ground to standing height for each cot. To represent the weight of an average patient, a 75-kg mannequin was secured resting on each cot during collection.

**Figure 1:** A) Manual cot handle vs. B) Power cot handle  
Lower extremity kinematic, kinetic and electromyography were collected during each lift.

Retroreflective markers were placed bilaterally on bony landmarks of the trunk, pelvis and lower extremity and were collected using 10 high speed Motion Analysis Cameras (Motion Analysis Corp, Santa Rosa, CA) at a sampling rate of 200 Hz. Kinetic variables were collected using two Bertec force plates (Bertec Corporation, Columbus, OH) to collect ground reaction forces at 1000 Hz. Joint/segment dynamics were calculated in Visual 3D (C-Motion Inc, Germantown, MD). All kinetic data were normalized to the participants' body mass (kg). Muscle activity (EMG) of the gluteus maximus (GM) rectus femoris (RF), biceps femoris (BF), external oblique (EO), rectus abdominus (RA) and erector spinae (ES) was measured through surface EMG and amplified by a Bagnoli™ 16-channel system (Delsys Inc.)

Statistical comparisons were made via paired t-tests comparing manual vs power cot for both the nursing and EMS groups with  $\alpha = 0.05$  using GraphPad Prism version 7.00 for Windows, GraphPad Software, La Jolla California USA.

## RESULTS AND DISCUSSION

Results of this study found that peak muscle activity of all the trunk and lower extremity muscles were significantly lower ( $p < .001$ ) in the Power Cot condition for both the nurse and EMS groups (Table 1). The most dramatic decrease in peak muscle activity was observed in the RF ( $\downarrow 44.2\%$ ) and BF ( $\downarrow 40.2\%$ ) for the nurse group and RF ( $\downarrow 32.3\%$ ) and GMAX ( $\downarrow 31.9\%$ ) for the EMS group. The Rectus Abdominis had the least amount of change for the nurse ( $\downarrow 1.7\%$ ) and EMS ( $\downarrow 1.8\%$ ).

There was no significant difference between the different lifts for peak trunk or pelvic angle in either

group. Peak hip and knee flexion angle were significantly decreased ( $p < 0.001$ ) during the Power cot condition for both the nurse ( $\downarrow 32^\circ$ , &  $\downarrow 38^\circ$ ) and EMS group ( $\downarrow 25^\circ$ , &  $\downarrow 42^\circ$ ). Peak hip and knee extension moments were significantly decreased ( $p < .001$ ) during the Power cot condition for both the nurse ( $\downarrow 1.1$  Nm/kg, &  $\downarrow 0.23$  Nm/kg) and EMS group ( $\downarrow 0.69$  Nm/kg, &  $\downarrow 0.32$ ).

**Table 1:** Results presented as Peak EMG %MVIC mean and standard deviation. \*  $p < 0.001$  v. Manual

	Nurse		EMS	
	Manual	Power	Manual	Power
<b>ES</b>	37.0 ± 39.7	16.0 ± 23.5*	11.7 ± 2.2	7.1 ± 1.3*
<b>RAB</b>	9.0 ± 3.0	7.3 ± 2.1*	8.4 ± 2.8	6.6 ± 1.5*
<b>RF</b>	70.0 ± 45.3	26.8 ± 28.7*	40.8 ± 38.7	8.5 ± 1.4*
<b>BF</b>	56.8 ± 46.3	16.6 ± 9.9*	37.3 ± 28.2	20.5 ± 11.9*
<b>GMAX</b>	34.0 ± 22.6	12.6 ± 12.3*	51.0 ± 30.0	19.1 ± 11.7*

## CONCLUSIONS

The significantly lower peak muscle activity, and peak joint moments in the Power-cot may indicate that using a Power-cot is much less strenuous and may decrease the risk of musculoskeletal injury when lifting patients.

## ACKNOWLEDGEMENTS

Special thanks to Stryker EMS for allowing the use the Power-PRO XT cot and the Performance-PRO XT cot for our study.

# BIOMECHANICALLY-ASSISTIVE GARMENT OFFLOADS LOW BACK DURING LEANING AND LIFTING

Erik P. Lamers, Aaron J. Yang and Karl E. Zelik

Vanderbilt University

email: erik.p.lamers@vanderbilt.edu, web: my.vanderbilt.edu/batlab

## INTRODUCTION

Low back pain is the leading cause of limited physical activity, affecting 80-85% of adults in their lifetime [1]. Development of low back pain can result from elevated, prolonged and/or repetitive forces on the spine, which commonly occur during daily activities such as leaning and lifting. Wearable assistive devices (e.g., exoskeletons) are emerging as a potential means of mitigating low back injury risks and associated pain, by offloading the lumbar spine. The majority of these exoskeletal devices have bulky form-factors (designed for use in industrial settings), but are less practical for daily use at home or in other business, social or clinical settings. An appealing, low-profile alternative may be to adapt clothing by embedding structures that assist movement biomechanics. These structures could be entirely passive (springs), quasi-passive (clutchable springs), or active (actuated); where both quasi-passive and active might be controlled via feedback from wearable sensors. The purpose of this initial study was to investigate the degree to which a biomechanically-assistive garment could passively offload lumbar muscles and discs during leaning and lifting.

## METHODS

We developed a biomechanically-assistive garment prototype that passively assists lumbar extension during leaning and lifting, and is sufficiently low-profile to be worn as (or under) clothing. We then tested 8 healthy subjects (7 male, 1 female,  $74 \pm 8.7$  kg,  $1.8 \pm 0.05$ m,  $23 \pm 3$  yrs.) performing leaning and lifting tasks with vs. without the prototype to assess its effect on lumbar muscle activity, which was used as an indicator of biological tissue loading. The prototype consists of an upper-body interface (shirt), a lower-body interface (shorts), and

elastic bands which run along the back, connecting the upper and lower interfaces (Fig. 1A). As the user leans forward, the elastic bands stretch, providing a lumbar extension moment, which reduces moments required by the muscles. Because the elastic bands act with larger moment arms about the spine (than muscles), they provide equivalent extensor moments with smaller force magnitudes, resulting in reduced compressive forces on the spine. Subjects performed 10 trials: (3 leaning angles + 2 lifting weights) x (2 conditions, i.e., with and without the prototype), while we recorded kinematics, force and electromyography (EMG) data. Each subject gave informed consent prior to participation. Subjects leaned forward to a pre-determined angle ( $30^\circ$ ,  $60^\circ$ ,  $90^\circ$ ) for 30 seconds while holding a 4.5 kg weight to their sternum. Subjects then lifted a weight (12.7 or 24 kg) using a squat posture. Mean EMG was used as the main outcome metric for the leaning and lifting trials. Intersubject means and standard deviations were computed. Paired t-tests were performed to assess significance ( $\alpha = 0.05$ ).

## RESULTS AND DISCUSSION

Wearing the prototype during leaning and lifting tasks reduced erector spinae EMG activity (Fig. 1B). Mean EMG was reduced by  $23\% \pm 13\%$  ( $p=0.01$ ),  $27\% \pm 10\%$  ( $p=0.006$ ) and  $43\% \pm 33\%$  ( $p=0.001$ ) for the  $30^\circ$ ,  $60^\circ$  and  $90^\circ$  leaning tasks, respectively (Fig. 1C). Mean EMG was reduced by  $13\% \pm 8\%$  ( $p=0.006$ ) and  $16\% \pm 7\%$  ( $p=0.001$ ) for the 12.7 and 24 kg lifting tasks, respectively.

These EMG reductions suggest that the prototype reduced lumbar muscle forces. Since these muscle forces constitute the majority of compressive force on the lumbar spine [2], these findings suggest that lumbar disc loading may also be reduced. These

results demonstrate the feasibility of biomechanically-assistive garments to reduce lumbar muscle and disc loading, which may help mitigate overuse and/or overloading risks that can lead to low back injury and pain. Future prototypes will integrate quasi-passive structures and wearable sensors in order to control the magnitude and timing of assistance.

## CONCLUSIONS

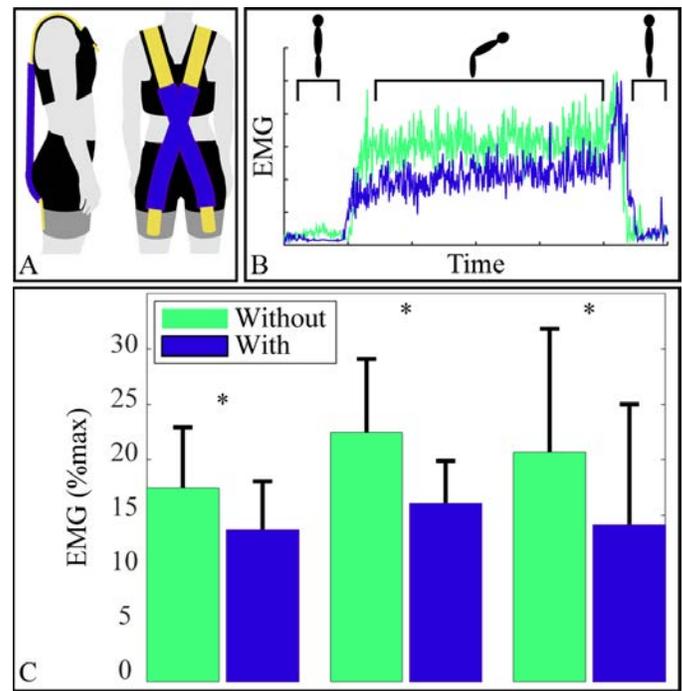

We found that passive, biomechanically-assistive garments are capable of offloading low back muscles during leaning and lifting, which may reduce force-induced injury risks.

# USING ELASTIC ANKLE EXOSKELETONS TO COUNTERACT AGE-RELATED STRUCTURE-FUNCTION DEFICITS

 email: rwnuckol@ncsu.edu

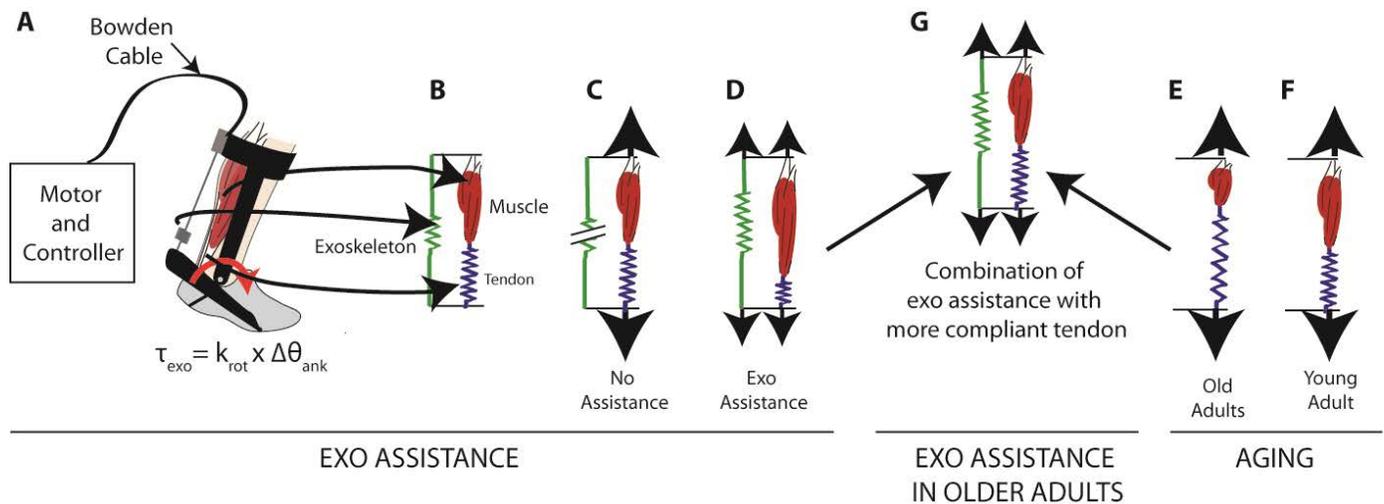

## INTRODUCTION

Elastic exoskeletons have the potential to add structural stiffness about a joint during gait using external springs placed in parallel with biological muscle-tendon units (Fig. 1 A-D). Our previous work has shown that elastic exoskeleton assistance at the ankle leads to decreases in plantarflexor force and activation as well as a decrease in whole body metabolic demand [1]. This is despite evidence for unfavorable changes in fascicle dynamics (*e.g.* longer fascicle lengths) in young adults [2]. Aging on the other hand is associated with a myriad of performance declines. For example, with age comes slower walking speeds and increased metabolic costs [3]. Evidence suggests that the ankle plantarflexors are at the forefront of these performance declines, with age-associated decreases in Achilles tendon (AT) stiffness and muscle force-generating capacity contributing to shorter fascicles and reduced ankle push-off capability in older adults [3,4] (Fig. 1 E-F).

Our aim is to determine whether walking with elastic ankle exoskeletons can augment plantarflexor performance in older adults (Fig. 1). Unlike in young adults, longer fascicle lengths in older adults may lead to improved economy of muscle force production at normal walking speeds [4]. We hypothesized that parallel elastic assistance during walking in older adults would decrease the biological ankle moment, decrease muscle activation, and increase soleus muscle fascicle operating lengths (Fig. 1G).

## METHODS

One elderly subject (female, age: 68) completed the IRB approved protocol. The subject walked for 5 minutes at 1.25 m/s while we applied three exoskeleton assistance levels (stiffness = 0, 100, 150 Nm/rad).

**Figure 1:** Cartoon representation of the expected effect of exoskeleton assistance and aging on the ankle plantarflexors muscle-tendon units (MTU). **A:** Diagram of exoskeleton testbed where plantarflexion assistive torque is applied to the ankle. **B:** Simplified representation of MTU and exoskeleton as parallel force-applying actuators. **C:** Without exoskeleton assistance, the MTU generates the required force for walking. **D:** With exoskeleton assistance, the force is distributed between the parallel elements and force in the MTU decreases leading to a decrease in tendon stretch. **E:** Decrease in tendon stiffness and muscle force-generating capacity associated with aging results in longer tendon length and shorter fascicles compared to **F:** MTU of young adult. **G:** Hypothesized effect of exoskeleton assistance in older individuals. Muscle fascicles return to longer lengths due to decreased tendon stretch as MTU force is offloaded using exoskeleton.

Ankle exoskeleton assistance was delivered to the user through an exoskeleton emulator consisting of bilateral ankle exoskeletons, a benchtop motor and transmission, and a control system (Fig. 1A). A torque-angle relationship was imposed to emulate elastic assistance. We collected a comprehensive kinematic, kinetic, EMG, ultrasound, and metabolic dataset while the subject walked on an instrumented treadmill. Specifically, we recorded kinematics using reflective markers (Vicon), muscle activity in the medial and lateral gastrocnemii and soleus using surface EMG (Biometrics), soleus fascicle lengths using B-mode ultrasound (Telemed), and whole body metabolic power using indirect calorimetry (OxyCon Mobile).

## RESULTS AND DISCUSSION

Compared to the no assistance condition (0 Nm/rad), the stiffest exoskeleton condition (150 Nm/rad) reduced the peak biological plantarflexion moment by 4.8% and the soleus integrated EMG by 12% (Fig. 2A). During stance, average soleus fascicle length increased by 8.5% when high exoskeleton stiffness was applied (Fig. 2C). Assistance also increased the ankle quasi-stiffness (Fig. 2B) and decreased metabolic demand by more than 5%. In this pilot study, the subject obtained the greatest metabolic benefit from the stiffest condition prescribed (150 Nm/rad). Interestingly, this is about twice as stiff as the optimal stiffness in young adults (80 Nm/rad). Due to the structural MTU changes associated with

aging (e.g., reduced AT stiffness), it is unclear whether making the exoskeletons even stiffer could further improve metabolic outcomes.

## CONCLUSIONS

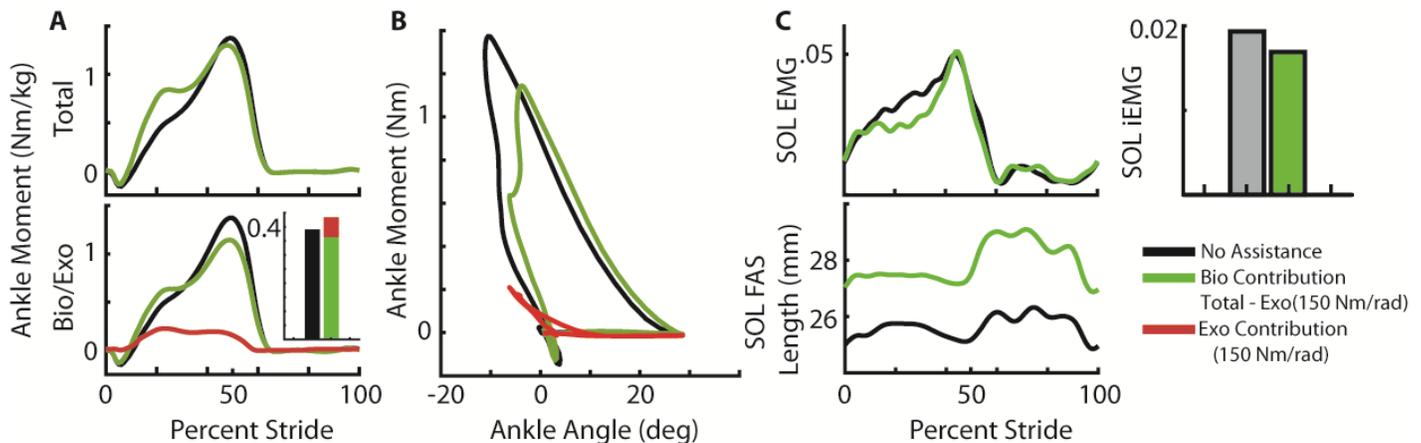

The optimal prescription of elastic ankle exoskeletons has the potential to preserve or restore mobility in our aging population. Ultimately, by personalizing the structural properties of the device to the morphology of an individual user, we may offset unfavorable reductions in tendon stiffness and their metabolic consequences, thereby maximizing independence and quality of life.

## INTRODUCTION

Recent breakthroughs in assistive walking exoskeletons (exos) using a spring-clutch mechanism in parallel with the ankle plantarflexors have been shown to reduce the net metabolic cost of walking by up to 7% [1]. Joint level analysis revealed that this decrease in metabolic cost occurred in a “sweet spot” of stiffness, where walking economy increased and muscle activity decreased. Simple modeling results suggest that plantarflexor muscle mechanics are negatively impacted when working in parallel with an elastic “exo-tendon” [2]. However, the impact of altered ankle kinematics and individual muscle contributions on plantarflexor mechanics and energetics during exo-assisted gait remains unknown. In order to address this knowledge gap, we employed multi-joint models to drive forward simulations with experimental data and investigated the muscle-level impact of exo-assisted walking in the “sweet spot.” We hypothesized that the “sweet spot” occurs when the costs of detuning underlying muscle dynamics to less favorable mechanical conditions and the benefits of reduced muscle force requirements are effectively balanced, resulting in reduced muscle-level metabolic cost.

## METHODS

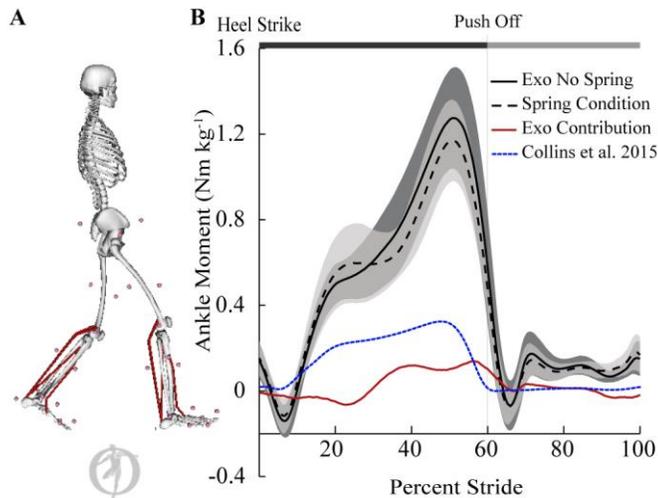

A subset of data collected from a previous study [1] including four healthy adults (2 F, 2 M;  $21.8 \pm 2.5$  yrs.) walking ( $1.25 \text{ m} \cdot \text{s}^{-1}$ ) at three conditions (no exo, exo with no spring, exo with spring stiffness of  $180 \text{ N} \cdot \text{m} \cdot \text{rad}^{-1}$ ) was analyzed. Kinematic data were collected using a motion capture system (Vicon), ground reaction forces from an instrumented treadmill (Bertec) and muscle activity from a wired electromyography (EMG) system (Biometrics Ltd).

All data were processed using OpenSim and Matlab (MathWorks). A lower limb model [3] was modified by removing all muscles except the medial and lateral gastrocnemii (MG and LG), soleus (SOL), and tibialis anterior (TA) and adding a metabolic probe [4, 5]. This base model was then scaled to each subject’s anthropometry using marker data from static trials. These individualized models were used to create forward dynamic simulations driven by the measured EMG of the muscles crossing the ankle with simultaneously constrained kinematics and ground reaction forces; this method has been previously described for simulating hopping with an exo [6]. Raw EMG data were processed for input to the simulations using custom Matlab scripts that rectified, filtered (4th order band pass filter, 20-300 Hz), and enveloped (rolling root mean square, 100 ms window) the signal. Because EMG from maximum voluntary contraction was unavailable, a subject-specific scale factor was applied to the EMG activation envelope; the value was selected such that the muscle-generated ankle moment during no exo walking minimized errors when compared to the net ankle moment from inverse dynamics [6]. Verification of the models and analyses was done by comparing inverse kinematics, moments and powers from the same subjects previously reported [1]. From these simulations, we analyzed the muscle states including fiber force, activation, fiber length and metabolic power.

## RESULTS AND DISCUSSION

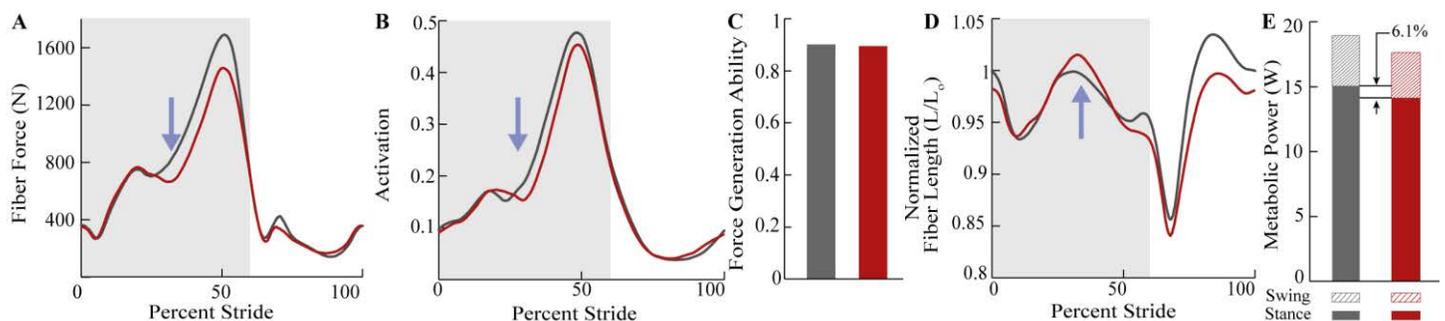

Joint level analyses of kinematics and moments predicted by our simulations are consistent with previously published values [1], and the simulated muscle-generated ankle moments demonstrated similar moment profiles when walking without an

exo and with an exo without a spring. The difference between the biological moment production in the exo no spring and spring conditions was congruent with spring force provided by the exo during stance (0-60% stride); limited differences among all conditions were seen during swing, as expected (Fig. 1).

**Figure 1:** **A:** Simulated model **B:** Average summed muscle moment across subjects for exo no spring (solid) and spring (dashed) conditions. Difference in exo no spring and spring conditions yields exo contribution (red), previous findings in blue (dotted).

Muscle-level mechanics of the plantarflexors are dominated by the uniaxial SOL, which accounts for approximately 60% of the summed physiological cross-sectional area. Decreases in the net ankle moment were reflected by a decrease in SOL fiber forces (10.5%) and reduced activations (7.8%) during stance (Fig. 2A,B). SOL force generation ability during stance was not found to be substantially reduced (0.8%) (Fig. 2C). However, in support of our hypothesis, there was an increase in SOL fiber lengths (Fig. 2D). Metabolic power for the

**Figure 2:** Exo no spring (Grey) vs Spring (Red) for SOL **A:** Fiber Force **B:** Activation **C:** Average Force Generation Ability during stance (force per unit activation) **D:** Fiber Length **E:** Average Metabolic Power

SOL was found to decrease (6.1%) in the spring condition compared to no spring (Fig. 2E).

## CONCLUSIONS

Our simulations show reduced biological force production during stance resulting from passive exo assistance. The SOL force-generating ability remained unchanged despite a shift in muscle dynamics. The metabolic cost reduction found in the SOL demonstrates that at the “sweet spot” the trade-off between reduced force requirements and detuned muscle dynamics is managed. Future work will include *in vivo* ultrasound measurements to confirm and expound upon current knowledge of plantarflexor dynamics during assisted walking.

# AN INSTRUMENTED ANKLE FOOT ORTHOSIS FOR QUANTIFYING THE INFLUENCE OF PLANTARFLEXION RESISTANCE ON JOINT KINEMATICS IN HEALTHY INDIVIDUALS

Nicholas B. Bolus, Caitlin N. Teague, Geza F. Kogler, and Omer T. Inan

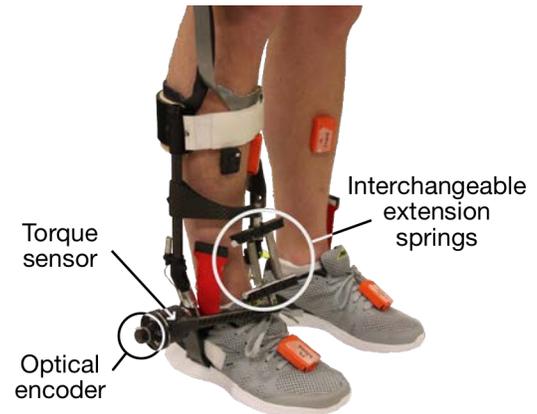

Georgia Institute of Technology, Atlanta, GA, 30332, USA  
emails: {nbolus, c.teague, geza, inan}@gatech.edu

## INTRODUCTION

Ankle-foot orthoses (AFOs) are commonly prescribed for individuals with biomechanical deficits of the lower limbs (e.g., foot drop). Traditionally, selection of AFO stiffness has been subjective, based on a practitioner's (e.g., orthotist's) experience and observations to determine a stiffness that maximizes functional mobility during walking. To provide clinicians with quantitative metrics for orthotic prescription, we developed an instrumented ankle foot orthosis (*i*AFO) with embedded sensors that can be used in the clinical setting (Fig. 1). The *i*AFO is capable of measuring orthosis ankle joint kinematics, electromyography, orthosis ankle torque, shank-foot segment orientation, gait state periods, and orthotic interface pressures. These clinically relevant measures are salient for orthotic prescription formulation—particularly for determining the optimal stiffness parameters of an orthosis to maximize each individual's walking performance. We present data from a healthy-subject pilot study using the *i*AFO to investigate the effect of modulating orthotic plantarflexion (PF) resistance on ankle kinematics during level walking. This study will form the foundation for our follow-on work to characterize these kinematics in a larger population of able-bodied subjects and subjects with foot drop.

## METHODS

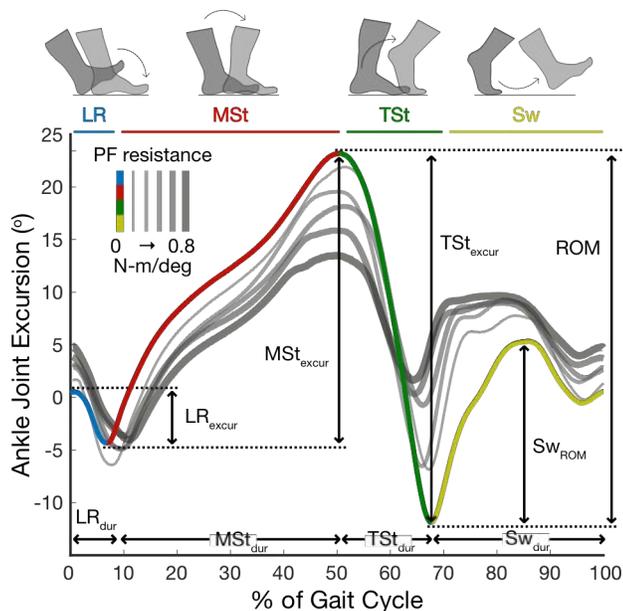

All studies were approved by the Georgia Tech Institutional Review Board and the Army Human Research Protection Office. Three able-bodied adults (two males, one female) were asked to don the *i*AFO and walk on a level treadmill at a speed of 1 m/s for a set of orthotic stiffness conditions ranging from 0 Nm/° (i.e., unloaded/no springs) to 0.8 Nm/° of PF resistance. Data were recorded continuously for 75 s per trial, and the signals were windowed into individual gait cycles and ensemble-averaged prior to extraction of features as defined below (Fig. 2).

**Figure 1.** The instrumented ankle-foot orthosis (*i*AFO) is a modular, custom-designed, articulated AFO equipped with a variety of sensors to monitor gait parameters in response to varying degrees of orthotic ankle constraint.

## RESULTS AND DISCUSSION

A tendency towards general attenuation of orthosis ankle joint motion in response to increasing PF resistance is evident in the ensemble-averaged waveforms of ankle joint trajectory (Fig. 2). More quantitative trends in specific features of that kinematic data are consistent across all subjects (Fig. 3). For instance, features such as overall range of motion (ROM), excursion of the ankle joint during mid-stance and terminal stance ( $MSt_{\text{excursion}}$  and  $TSt_{\text{excursion}}$ , respectively), and range of motion during swing phase ( $SW_{\text{ROM}}$ ) all decreased in response to increases in PF resistance torque. Interestingly, despite the fact that the device ostensibly *assists* dorsiflexion, the maximum dorsiflexion angle achieved was found to decrease, perhaps suggesting a compensatory mechanism of locomotion in these able-bodied subjects that attempts to counteract any perceived perturbation, assistive or otherwise, in an attempt to restore normal gait mechanics or prioritize stability. We also observed an apparent reorganization in the *timing* of the gait phases, specifically a tradeoff

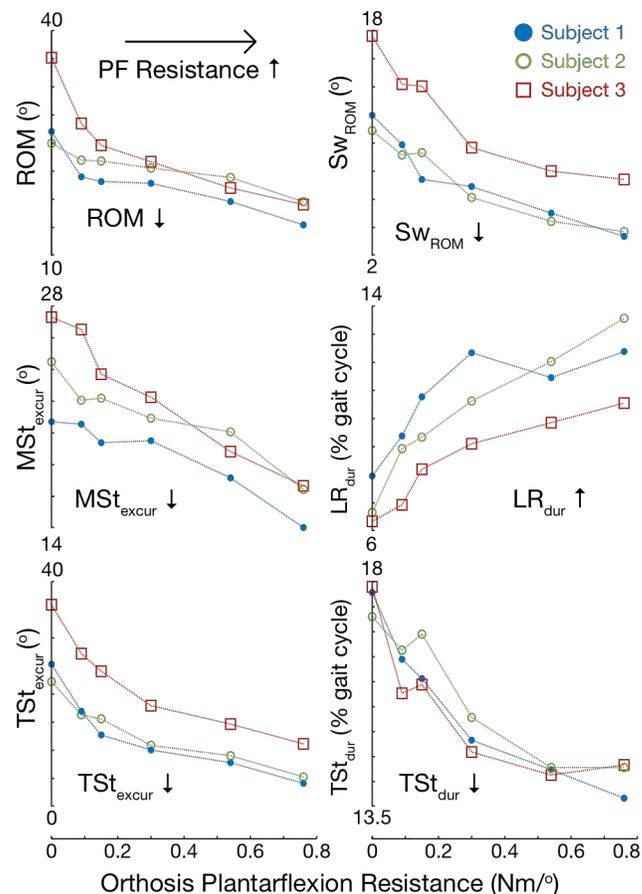

**Figure 2.** Definitions of features of the gait cycle, segmented into four phases—loading response (LR), mid-stance (MSt), terminal stance (TSt), and swing (Sw)—for a representative subject.

between a longer loading response ( $LR_{dur}$ ) and a shorter terminal stance ( $TSt_{dur}$ ). The lengthening of LR is a consequence of the anterior-mounted springs more effectively decelerating the foot after initial contact—an important function of an AFO to prevent “foot slap.” However, as gait velocity was constrained by a constant-speed treadmill, this protraction of LR necessitated a truncation of another phase(s), which we found occurred most prominently in TSt. This siphoning of gait cycle time away from TSt rather than MSt or Sw is likely a matter of walking efficiency: TSt is the phase in which the subject is “fighting against” the imposed orthotic constraint the most, so perhaps the subjects preferentially abbreviated this phase to avoid undue effort, compensating elsewhere along the lower limb, likely at more proximal joints (knee, hip).

## CONCLUSIONS

In this study we found that an increase in orthotic PF resistance led to a general decrease in ankle joint range of motion in healthy individuals, with marked reduction in joint excursion during mid-stance, terminal stance, and swing phase. We also observed a redistribution in the timing of the gait phases: specifically, protraction of loading response and

**Figure 3.** Trends in ankle joint kinematic data over a range of PF stiffness conditions ( $n=3$ ).

truncation of terminal stance. We affirmed that our device, the *i*AFO, was capable of decelerating the foot after initial contact and lifting the foot during swing to maintain toe clearance—two key functions of conventional AFOs. Furthermore, this study served to validate the *i*AFO as a clinical tool for monitoring gait parameters during locomotion, preparing us for further investigations on populations with lower limb motor deficits.

Email: gregory.freisinger@usma.edu

## INTRODUCTION

As exosuit technology develops, it is important to not only quantify the performance gains that they grant wearers, but also begin to attempt to maximize those gains by implementing training. Although research has been done on creating and refining exosuits themselves, few investigations have measured the effects of training. Developers recommend a varied amount of familiarization, however these recommendations are not always supported by quantitative data. Many studies include at least one initial familiarization session before testing [1,2,4,5], however few focus on the effects of repeated use of exosuit systems [3,6].

The primary purpose of this study was to quantify the effects of training with a powered soft exosuit. This work specifically investigated the braking and propulsive impulse between conditions and over multiple sessions. We hypothesized that braking and propulsive impulses would decrease over the course of a single session and between sessions during powered walking, as the wearer becomes better adapted to the exosuit. We also hypothesized that there would be significantly less braking and propulsive impulse during unpowered walking as compared to powered walking.

## METHODS

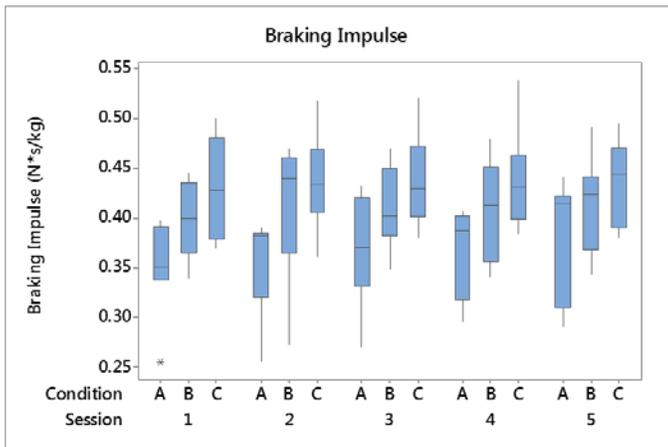

Eight male United States Military Academy cadets (age:  $20.6 \pm 1.2$  yr; height:  $1.80 \pm 0.09$  m; weight:  $78.6 \pm 9.2$  kg) participated in this study after providing IRB approved informed consent. The participants completed five sessions over 20 days, utilizing a backpack mounted soft exosuit, which provides assistance in hip extension during stance phase [7]. The exosuit mass was 5.4 kg and the backpack was loaded with an additional 20.4 kg. Each session consisted of 20 minutes of walking

with the exosuit powered on, followed by 5 minutes of walking with the exosuit powered off. Multiple sessions were separated by at least 48 hours to reduce any impact from fatigue. Ground reaction force data was collected using an instrumented treadmill at 1000 Hz from the first two minutes of powered walking (condition A), the last two minutes of powered walking (condition B), and the last two minutes of walking with the exosuit powered off (condition C). Foot strikes from each two minute period were used in follow on calculations ( $94.6 \pm 26.4$  foot strikes per condition).

Braking and propulsive impulse were normalized by body mass and calculated during the right stance phase. Braking and propulsive impulse were found by taking the area under the posterior and anterior ground reaction force curves, respectively. Four different repeated-measure 2-way ANOVAs were used to identify statistical differences within and across sessions. Powered condition A was compared to powered condition B, for both braking and propulsive impulses separately. Powered condition B was compared to unpowered condition C, for braking and propulsive impulses separately. An alpha = 0.05 was chosen to represent a statistically significant difference between conditions and across sessions.

## RESULTS AND DISCUSSION

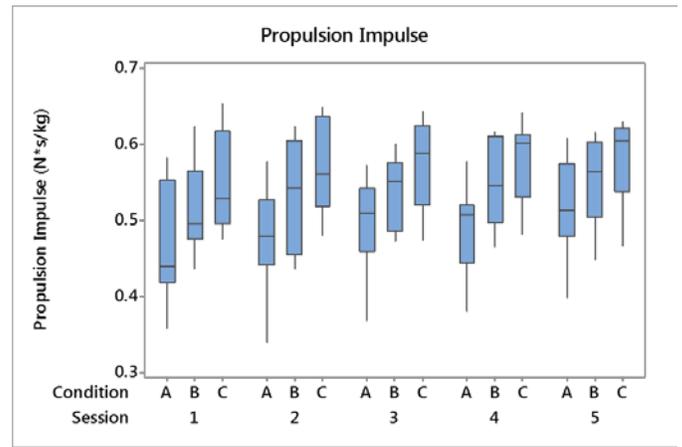

Mean and standard deviation for braking and propulsive impulses across conditions and sessions are shown in Table 1. For braking, across conditions A and B, main effects were found for subject ( $p < 0.001$ ) and condition ( $p < 0.001$ ), but not for session ( $p = 0.416$ ). For propulsion, across conditions A and B, main effects were found for subject ( $p < 0.001$ ), condition ( $p < 0.001$ ), and session ( $p = 0.001$ ).

**Figure 1:** Boxplot of braking impulse for five sessions, conditions A, B, and C for each session.

For braking, across conditions B and C, main effects were found for subject ( $p < 0.001$ ), and condition ( $p < 0.001$ ), but not for session ( $p = 0.773$ ). For propulsion, across conditions B and C, main effects were found for subject ( $p < 0.001$ ), session ( $p = 0.001$ ), and condition ( $p < 0.001$ ).

These results indicate that successive training sessions using the exosuit changed how subjects applied propulsive impulse, but do not have significant effects on how they applied braking impulse. Between conditions A and B, from minutes 0-2 of powered walking to minutes 18-20 of powered walking, braking and propulsive impulse increased in magnitude. The highest magnitude of braking and propulsive impulse were recorded during condition C during minutes 23-25 of unpowered walking.

**Figure 2:** Boxplot of propulsive impulse for five sessions, conditions A, B, and C for each session.

## CONCLUSIONS

We identified a significant difference in braking and propulsive impulses between powered and unpowered conditions. Propulsive impulse also changed significantly between multiple training sessions, while no difference was found in braking impulse across sessions. This data supports the notion that individuals may alter ground kinetics over time while using a powered exosuit. More research is required to identify how much training is necessary before steady state kinetics are obtained, and to identify the influence of fatigue and time on impulse.

email: nussbaum@vt.edu

## INTRODUCTION

Use of assistive devices is emerging as an effective intervention to reduce physical demands imposed on workers. For example, Rashedi et al. [1] recently demonstrated that using an upper extremity exoskeletal vest with a mechanical arm can reduce physical demands involved in overhead work. Though such devices may effectively control exposure to overexertion, they are generally rigid structures; such rigidity and the added mass may constrain the natural motions of the upper body. This may be a particular concern in terms of occupational slip- and trip-related falls, given that: 1) broad evidence supports that external loads on the body can adversely affect gait performance [2-4]; 2) a change in trunk kinematics can affect gait performance such as step width [5]; 3) post-slip or post-trip trunk kinematics are associated with fall recovery ability [6]; and 4) slips, trips, and falls are a major source of occupational injuries and fatalities [7]. However, little effort has been reported regarding the effects of an assistive device on the risks of slip- and trip-related falls.

This study examined how the use of a newly developed Wearable Assistive Device (WADE) – an upper extremity exoskeletal “Vest” (EksoBionics Inc., USA; Fig. 1) – affects gait performance. The WADE involves shoulder torque generating components and a rigid vertical column along the spine, with mass = 6.5 kg. We hypothesized that wearing the WADE will adversely affect gait performance, due to the rigid structure potentially limiting natural motions of the trunk and the added mass on the trunk.

## METHODS

To assess slip and trip risks, 20 participants (10F & 10M) completed gait trials on a linear walking track (1.5 m × 15.5 m) instrumented with two force platforms (AMTI OR6, Watertown, MA), both with and without the WADE (Fig. 1). All participants provided informed consent, following procedures approved by Virginia Tech IRB.

Participants were provided with standard laboratory shoes, and asked to walk across the track several times with and without the WADE for familiarization. During this familiarization phase, a starting foot position was marked on the walking track, so that participants walked across two force platforms, with each foot and without visible adjustments to gait patterns. Participants completed 10 walking trials at their normal walking speed in each of the Vest Intervention conditions (i.e., with vs. without the WADE on), the order of which was alternated between participants.

During walking trials, triaxial ground reaction forces (GRFs) were sampled at 1 kHz from the two force platforms. Gait kinematics were captured at 100 Hz, using a 7-camera optical motion capture system (Vicon MX-T, Los Angeles, CA), from markers placed over selected anatomical landmarks, and subsequently low-pass filtered (20 Hz, 4<sup>th</sup>-order Butterworth, bidirectional).

For each walking trial, minimum toe clearance (MTC) was calculated for each foot over the force platform to assess trip risks. MTC was defined as the minimum vertical distance between the 2<sup>nd</sup> metatarsal head and the ground during the mid-swing phase of gait. To assess slip risks, the maximum required coefficient of friction (RCOF) was computed as the largest instantaneous ratio of the resultant of transverse and longitudinal shear

GRFs to the normal GRF within 50-200 milliseconds after heel contact [10].

Main and interaction effects of gender and Vest Intervention on each outcome measure were examined using separate repeated measures of analyses of variance (ANOVAs). Statistical significance was determined at  $p < 0.05$ .

Figure 1. Example of a walking trial with the WADE on the linear walking track.

## RESULTS AND DISCUSSION

Our results failed to support the hypothesis, in that neither MTC or RCOF were significantly affected by any main or interaction effects of gender and Vest Intervention (all  $p$  values  $> 0.29$ ). The mean (SD) of MTC and RCOF values were 60.0 (7.7) mm and 0.22 (0.03) with the WADE, respectively; and 60.8 (8.4) mm and 0.22 (0.03) without the WADE, respectively.

The mass of the WADE was 6.5 kg, which was on average close to or less than 10% of participants' body mass. Interestingly, earlier studies have reported that carrying a load less than 10% of body mass does not have substantial effects on trip and/or slip risks, although it can affect spatial-temporal gait characteristics [8,9]. The finding here of no significant effects of WADE on either peak RCOF or MTC confirmed the results of those earlier studies.

In the current study, we found that the upper extremity rigid exoskeletal vest examined imposes no obvious increase in the risk of slips or trips.

However, though not statistically significant, wearing the WADE yielded slightly lower MTC values (by  $\sim 0.8$  mm). Given this, and that a rather simple linear walking task was considered here, further research is needed to set the boundary of working conditions within which gait performance is not compromised with the use of a WADE. For example, the added mass on the body (i.e., from wearing a WADE) may result in a higher postural demand when the wearer needs to walk faster, cross an obstacle, and/or perform different ambulatory activities (e.g., turning, sudden stopping while walking). Moreover, trip and slip recovery were not considered in the current study, and the added weight from the vest might reduce trip and slip recovery capacity of a worker. In addition, kinematics and spatial-temporal characteristics of gait were not considered here, which will be addressed in future study.

**Disclaimer:** EksoBionics and The Boeing Co. financially supported this research. While contributing to the study design, they were not involved in data analysis, interpretation, or decision for publication.

# Effects of a Leg Kinetic Energy Harvester on Soldiers' Gait

Jessica Batty, Megan Coyne, Clifford L Hancock, and Karen Gregorczyk  
Natick Soldier Research, Development, and Engineering Center, Natick, MA, USA  
email: jessica.m.batty.civ@mail.mil

## INTRODUCTION

Due to the unique power requirements of soldiers in operational scenarios, the U.S. Army is investigating the use of passive energy harvesting technology. Although energy requirements depend upon the specific mission, on average nine-man squads of infantry soldiers carry a total of 41 kg in batteries during a 72-hour field mission [1]. Wearable energy harvesting systems have the potential to reduce the number of batteries that need to be carried and may enable the development of self-powered wearable devices, such as exoskeletons and prosthetics.

In the present study, a Knee Energy Harvester (KEH) system was evaluated that utilizes the kinetic energy of human movement to produce electrical current. The KEH is composed of two units, one worn on each leg, and the rotation of the thigh and shank segments about the knee joint allows generators within the KEH to convert mechanical work into electrical energy. The electrical energy can then be used to power other devices or to charge batteries. While the KEH allows full range of motion of the knee joint during walking and running, the generators apply a variable resistance torque between 1 and 15 N·m, which could impact gait mechanics. The purpose of this study was to identify the effects of the KEH on gait kinetics and kinematics.

## METHODS

Eight male soldiers (Age, 24±5 yrs; Ht, 176.8±6.5 cm; Wt, 84.1±13.1 kg) performed two 10-min marching trials on a treadmill. The marches were conducted at 1.34 m/s on a 0% treadmill grade, with two different equipment configurations. One configuration included soldier gear and the KEH. The other included the same soldier gear and the KEH was not worn (noKEH). The soldier gear used during all trials weighed 6.34 kg and included combat boots, socks, T-shirt, shorts, a helmet, and a simulated weapon. Additional weight of the KEH

was approximately 0.6 kg. Prior to data collection, subjects familiarized themselves with the KEH during two 2-hr training sessions.

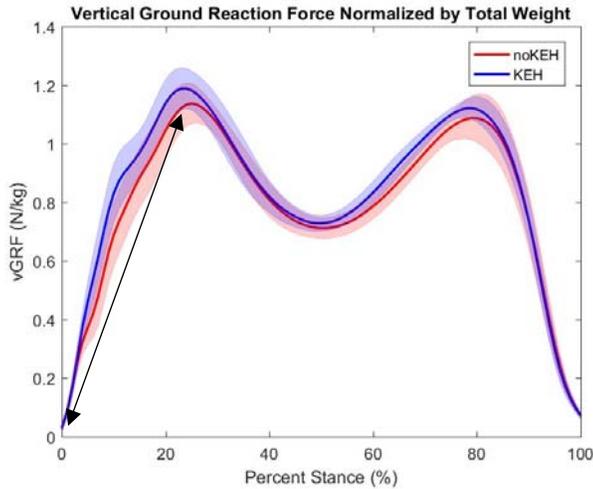

Kinetic and kinematic data were collected using a force plate treadmill (AMTI, Watertown, MA), reflective markers, and an 8-camera (Oqus, Qualysis AB, Gothenburg, Sweden) motion capture system. At 3 min into each trial, force plate and kinematic data were collected over 3-5 right initiated and 3-5 left initiated consecutive strides. Means were evaluated for each leg, and then an overall mean was found for each measure. Ground reaction forces, spatiotemporal measures, and knee joint angles were analyzed. A one-way repeated measures analysis of variance (ANOVA) was used to assess differences between the KEH and the noKEH conditions.

## RESULTS AND DISCUSSION

The ANOVA revealed a significant effect of equipment configuration for impulse ( $p=.014$ ), defined as the integral of the vertical GRF during stance, as well as both average ( $p=.011$ ) and instantaneous peak loading rate ( $p=.016$ ) (Figure 1). The average loading rate was calculated as the slope of the ascending vertical GRF line from heel strike through the first peak vertical GRF, while the instantaneous peak loading rate was the maximum slope achieved along this same line. Compared with the noKEH condition, impulse increased by 2.2%, average loading rate increased by 6.2%, and instantaneous loading rate increased by 14.7% when the KEH was worn.

Analysis of knee joint kinematics indicated that joint movement with the KEH was not the same as movement when the KEH was not used. Knee range of motion (ROM) during the walking task decreased in the KEH condition by 10.5° ( $p=.002$ ). While the maximum knee flexion angle did not statistically differ for the KEH and the noKEH conditions ( $p>.05$ ), wearing the KEH did reduce the maximum

extension angle by  $8.49^\circ$  ( $p=.008$ ). The speed and acceleration of the joint rotation also differed significantly for the KEH and the noKEH conditions. Maximum knee joint angular acceleration decreased by 44.2% ( $p=.003$ ), and maximum knee joint angular extension velocity decreased by 30.0% ( $p=.001$ ) when the KEH was used.

**Figure 1:** Average vertical GRFs for 1.34 m/s walking at 0% grade, normalized by total weight (body weight plus soldier gear and KEH, if applicable). Error bands identify  $\pm 1$  SD. Arrow designates line portion used to calculate loading rates.

Spatiotemporal metrics were also evaluated between the KEH and noKEH conditions (Table 1). Cycle time, step time, and stride length all increased while wearing the KEH ( $p=.001$ , 1.8%;  $p=.001$ , 1.8%; and  $p=.006$ , 1.9%, respectively).

**Table 1:** Example metrics (mean (SD)). All had a significant main effect of equipment configuration ( $p<.05$ ).

Metric	noKEH	KEH
Cycle Time, sec	1.08(.05)	1.10(.04)
Step Time, sec	.54(.02)	.55(.02)
Stride Length, m	2.10(.10)	2.14(.08)
Knee ROM, deg	71.0(4.4)	60.5(2.7)
Max Knee Extension*, deg	5.67(6.3)	-2.82(3.7)

\*Negative extension value indicates flexion, where  $0^\circ$  equals standing calibration knee position.

Considering the overall results of the analyses of the kinetic, kinematic, and spatiotemporal variables, an altered gait pattern emerges that is attributable to use of the KEH. The elevated impulse and loading rates may cause increased strain on the lower extremities, which could increase the likelihood of injury after repeated gait cycles [2].

The reduction of knee joint angular acceleration and velocity was also a key component of the altered gait pattern with the KEH and could be a direct result of the variable resistive torque applied at the knee by the device. Subjects may have compensated for this slower leg motion and limited dynamic ROM by increasing stride length, step time, and cycle time to maintain the overall walking speed of 1.34 m/s.

Given the increased loading rates and impulse demonstrated in the KEH condition as well as the observed kinematic changes at the knee, further analysis of joint kinetics is appropriate to determine if such alterations to normal gait change the manner in which GRFs are transmitted through and absorbed by the body. Additionally, the KEH structure may impact the transfer of GRFs through the connections to the body at the shank and thigh, altering the resultant forces acting on the body. Further characterization of the device’s influence on these forces may mitigate any adverse effects and injury risk indicators.

## CONCLUSIONS

The use of the KEH system resulted in an altered gait pattern for subjects walking at 1.34 m/s on a 0% grade. Altered gait mechanics with the KEH included increased impulse, average and instantaneous peak loading rates, cycle and step times, stride length, as well as decreased knee joint ROM, maximum angular acceleration, and maximum angular extension velocity. While these gait alterations seemingly point to an overall amplified risk of lower-limb injury, further work is required to evaluate the role of the KEH in absorption or transfer of GRFs in order to better understand the cumulative impact of the KEH on gait. Additional investigation to address KEH effects during uphill and downhill walking, as well as jogging conditions is also necessary to evaluate the system as it would be used in the field.

# PERFORMANCE OF A POWERED ANKLE EXOSKELETON USING NEUROMUSCULAR MODEL-BASED CONTROL OVER A RANGE OF WALKING SPEEDS

James V. McCall, Sasha A. Philius, Richard W. Nuckols, and Gregory S. Sawicki  
 Joint Dept. of Biomedical Engineering at UNC Chapel Hill and NC State, Raleigh, NC, USA  
 email: jvmccall@ncsu.edu, web: www.bme.ncsu.edu/labs/hpl

## INTRODUCTION

Powered exoskeletons can improve locomotion performance by providing assistive torques to offset biological moments generated by lower-limb joints. So far, the majority of exoskeleton controllers rely on *a priori* tuning of parameters based on a reduced set of locomotor tasks (*e.g.* level walking at preferred speed). This limits their effectiveness to a small subset of functional conditions. To be useful in the real-world, exoskeleton controllers need to be able to automatically adjust to the user and the environment.

The purpose of this study was to explore whether ankle exoskeleton control based on a neuromuscular model could adapt to the increasing mechanical demands associated with increased walking speed (*i.e.*, increased ankle power).

A neuromuscular model (NMM) based controller simulating a Hill-type muscle-tendon with positive force feedback has previously been implemented in an ankle-foot prosthesis [1]. By emulating physiological neuromuscular mechanics, the prosthesis adapted to variable gait speed by way of modulating net work output at each speed. To date, the performance of NMM based controllers has yet to be explored in lower-limb exoskeletons.

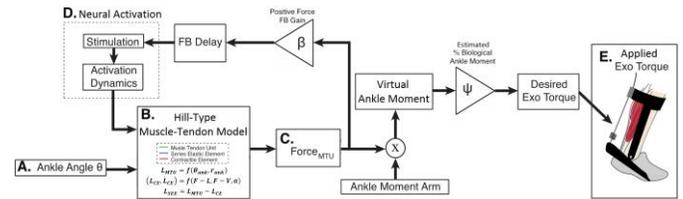

We hypothesize that a powered ankle exoskeleton employing a NMM-based controller would automatically adapt to walking speed by 1) increasing net work at increased speeds and 2) maintain reductions in metabolic cost across speeds.

## METHODS

**Exoskeletons:** We provided bilateral plantarflexion assistance via a tethered ankle exoskeleton device. Off-board motors and Bowden cable transmission delivered torque to the custom carbon fiber exoskeletons.

**Controller:** We designed the NMM based controller in Simulink (MathWorks, USA) and implemented it through a dedicated real-time control system which

also handled signal IO (500 Hz, dSPACE, Germany). We calculated applied exoskeleton torque from a load cell (500 Hz, LCM Systems Ltd, UK) placed in series with the applied assistance, and a goniometer (500 Hz, Biometrics, UK) attached to the exoskeleton joint provided real-time ankle angle.

**Figure 1:** Neuromuscular model controller block diagram. Biological force, as computed by the internal muscle-tendon state, is scaled and applied across a moment arm to calculate desired exoskeleton torque.

The NMM based controller implemented in our system was similar to a reflex-based force feedback controller previously demonstrated [1]. A Hill-type muscle-tendon model was the basis for the emulated muscle-tendon unit (MTU) consisting of a contractile element (CE) with both active and passive properties and a series elastic element (SEE) (Fig.1B). We calculated MTU length from ankle angle and musculoskeletal geometry (1.1) and CE dynamics was subject to force-length, force-velocity and activation (1.2). We calculated SEE length as the difference in length of the CE from the MTU (1.3).

$$L_{MTU} = f(\theta_{ank}, r_{ank}) \quad (1.1)$$

$$(L_{CE}, \dot{L}_{CE}) = f(F-L, F-V, a) \quad (1.2)$$

$$L_{SEE} = L_{MTU} - L_{CE} \quad (1.3)$$

MTU force ( $F_{MTU}$ ) was a function of the model's SEE stiffness and strain. In the reflex pathway, we normalized MTU force to  $F_{max}$  and applied a gain (1.2); a 10ms delay was added to emulate a positive force feedback neural reflex signal (Stim) and CE activation dynamics (ACT) were modeled to close the feedback loop (Fig.1D).

We calculated desired exoskeleton torque as a portion of the estimated biological moment.

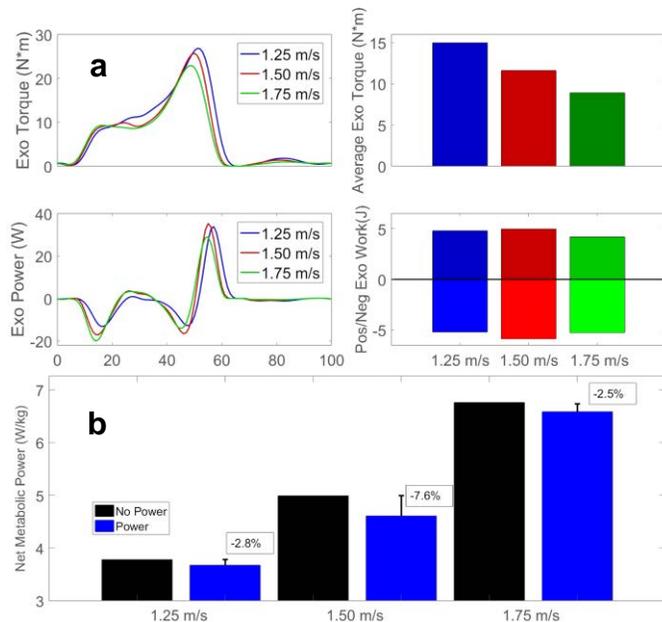

$$\tau_{exo} = F_{MTU} \times r_{ankle} \times \psi \quad (1.4)$$

where  $\psi$  represented a percentage of the estimated biological torque. We calculated and recorded internal model states ( $F_{MTU}$ ,  $L_{MTU}$ ,  $L_{CE}$ ,  $STIM$ ,  $ACT$ ) in dSpace for 5 second periods for offline analysis.

**Testing Protocol:** Two healthy young adults (M/77.4 kg, and F/75.2 kg) completed the IRB approved protocol. Each subject walked in two conditions (with exoskeleton-No Power and with exoskeleton-Power) and at three speeds for each condition (1.25, 1.50, and 1.75 m/s) for a total of six trials presented in random order. Metabolic power was estimated from indirect calorimetry data collected in minute 5 and 6 of each trial (OxyCon Mobile, Carefusion, USA).

## RESULTS AND DISCUSSION

Mechanical performance of the neuromuscular model (NMM) based controller diminished as walking speed increased. Average exoskeleton torque decreased as speed increased from 1.25 to 1.50 to 1.75 m/s (15.0, 11.6, 8.9 Nm) and peak torque followed a similar trend (Fig. 2a). Net work performed per stride remained nearly constant across speed as the exoskeleton dissipated small amounts of energy in each case.

**Figure 2:** Trial results of two subjects walking at different speeds and conditions. **A.** Exoskeleton Torque and Mechanical Power over the stride along with Avg. Torque and Work for each speed. **B.** Net metabolic rate with % reduction displayed for PWR trial compared to NPWR trial at each speed.

Exoskeleton mechanical assistance resulted in reduced metabolic cost across all walking speeds. Compared to the exoskeleton-No Power condition, the reductions in net metabolic rate due to exoskeleton assistance were 2.8%, 7.6%, and 2.5% at 1.25, 1.50 and 1.75 m/s respectively (Fig. 2b).

## CONCLUSIONS

Our initial results indicate that the adaptive properties of NMM-based control seen in prostheses may not generalize to lower-limb exoskeletons. This finding may not be that surprising given that this biologically-inspired control framework is designed to mimic the mechanical performance of biological plantarflexors. In fact, gastrocnemius and soleus muscles exhibit reduced force production at higher walking speeds [2] due to unfavorable force-velocity effects [2,3]. Previous studies on lower-limb prostheses using this control strategy may have avoided this constraint by operating at relatively low walking speeds ( $\leq 1.4$  m/s) [4].

Perhaps an improved class of NMM-based controllers, incorporating a feedforward contribution to neural drive, would lead to improved adaptive performance. For example, adding the user's EMG or some other phase-based signal generator that responds positively to locomotion task demand, on top of reflexive positive force feedback could help counteract the aforementioned performance deficits due to force-velocity effects in the CE component of the NMM.

# ANKLE FOOT ORTHOSIS STIFFNESS AND MARGINS OF STABILITY DURING WALKING

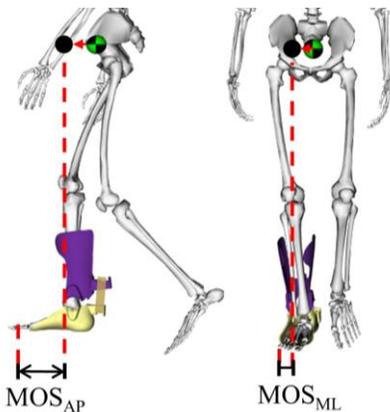

<sup>1</sup> Michael C. Rosenberg, <sup>1</sup> Hwan Choi, <sup>1</sup> Keshia M. Peters, <sup>1</sup> Katherine M. Steele

<sup>1</sup> University of Washington, Seattle, WA, USA

email: mcrosenb@uw.edu, web: <https://depts.washington.edu/uwsteele/>

## INTRODUCTION

Individuals with neurologic impairments often exhibit lower levels of stability during walking than their unimpaired peers. Reduced stability hinders an individual's ability to move safely and autonomously during activities of daily living. Ankle foot orthoses (AFOs) are frequently prescribed to individuals with neurologic impairments to improve gait mechanics and assist walking, but activity-level responses to AFOs are inconsistent. The ankle torques generated by AFOs have been proposed as an efficient way to stabilize the center of mass (COM) during walking [1]. For example, children with cerebral palsy (CP) often have weak ankle plantarflexors, and AFOs may improve stability by enhancing ankle plantarflexor torques. However, studies evaluating AFOs' impacts on gait stability have only compared device types rather than specific AFO mechanical properties [2]. To inform AFO design, a more detailed understanding of how AFO stiffness impacts stability is needed.

**Figure 1:** Margins of stability (MOS) during AFO-stance. The extrapolated center of mass (black circle) position and velocity are used to compute the anterior-posterior (AP) and mediolateral (ML) margins of stability. Elastic bands (on the back of the AFO) were used to modulate AFO stiffness.

The goal of this study was to evaluate whether AFO stiffness impacts margins of stability (MOS) during level walking. MOS is defined as the minimum distance between the base of support (BOS) of the feet and a vertical projection of a combination of the center of mass (COM) position and velocity (Fig. 1) [3]. A larger minimum MOS has been associated with poorer scores on functional assessments of stability [4]. We hypothesized that mediolateral (ML) MOS would be larger during shoe walking compared to walking with an AFO, and that minimum ML MOS would increase with increasing AFO stiffness.

## METHODS

We collected gait kinematic data from five unimpaired adults, two males, three females: age=24.2 ± 5.4 (avg ± SD), mass=62.9 ± 9.3 kg, height=1.7 ± 0.1 m, during treadmill walking at a fixed slow speed, normalized by leg length. Participants walked with and without a unilateral passive AFO. AFO stiffness was varied from zero to 3.7 Nm/deg using elastic polymer bands (Fig. 1).

We calculated COM trajectories over 25 gait cycles per participant using a 33 degree of freedom model in OpenSim. We then computed the maximum anterior-posterior (AP) and minimum ML extrapolated COM (XCOM, Eqn. 1), which are defined as the sums of the COM position,  $x(t)$ , and the COM velocity,  $\dot{x}(t)$ . The AP and ML BOSs were defined as the positions of the stance limb's toe (AP) and fifth metatarsal (ML) markers. The MOS (Eqn. 2) for each participant and AFO condition can then be computed [3]. To compare between participants, the MOS was normalized by COM height,  $h$ .

$$XCOM(t) = x(t) + \dot{x}(t) \sqrt{\frac{g}{h}} \quad (1)$$

$$MOS(t) = BOS(t) - XCOM(t) \quad (2)$$

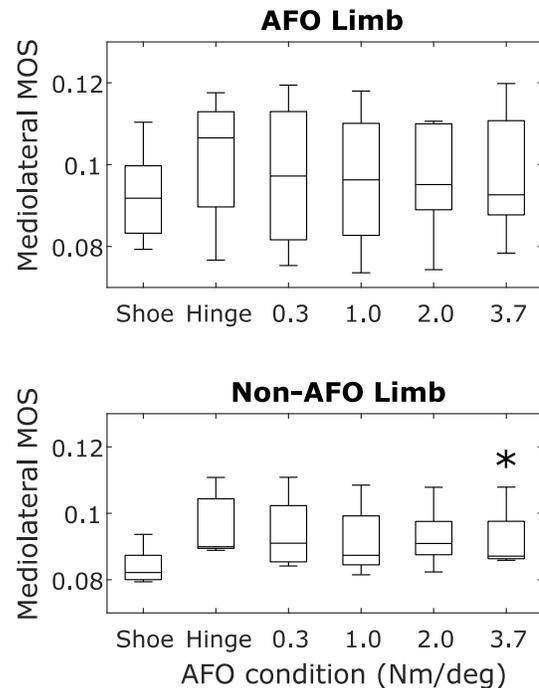

To identify differences in maximum AP and minimum ML MOS between shoe walking and walking with AFOs, we performed t-tests with a Bonferroni correction for multiple comparisons (significance level at  $\alpha=0.01$ ). We also performed linear regression to identify relationships between MOS and AFO stiffness.

## RESULTS AND DISCUSSION

The maximum AP MOS was significantly smaller in only the AFO limb for most AFO conditions ( $p<0.001$ ) and there was a trend towards greater minimum ML MOS when walking with an AFO compared to shoe walking (Fig. 2). The minimum ML MOS increased on average by 0.11 in both limbs for the AFO conditions compared to shoes alone. However, there was greater inter-subject variability in minimum ML MOS ( $p<0.001$ ) for the AFO limb compared to the non-AFO limb for all stiffness conditions.

Neither maximum AP nor minimum ML MOS changed with increasing AFO stiffness ( $r^2<0.35$ , slope $<0.004$ ). Conversely, ML MOS increased with step width in the AFO ( $r^2=0.76$ , slope $=0.41 \text{ deg}^{-1}$ ) and non-AFO ( $r^2=0.78$ , slope $=0.29 \text{ deg}^{-1}$ ) limbs. These trends are consistent with studies showing that the modulation of step width may be used to stabilize the COM, and may increase in the presence of new or uncertain environments, such as walking with AFOs [1, 4]. With further adaptation time, step width may decrease as participants become more comfortable with the AFOs.

The small sample size and slow walking speed in this study may have limited our ability to detect changes in MOS when walking with an AFO. Greater walking speed may be required for changes in AFO stiffness to perturb gait enough to impact MOS among unimpaired individuals. Regardless, these findings are consistent with a study that reported slightly larger inter-subject kinematic variability in the AFO limb when walking with an AFO [5], suggesting that changes in minimum MOS of the AFO limb may be harder to predict than those in the non-AFO limb. Understanding the impact of AFOs on stability in CP and other clinical groups is an important area for future investigation.

**Figure 2:** Minimum ML MOS for the AFO limb (top) and non-AFO limb (bottom). Asterisks denote significant differences compared to shoe walking ( $p<0.001$ ).

## CONCLUSIONS

These findings are an early step towards quantifying the impacts of AFO mechanical properties on dynamic stability of walking. However, to improve the translational impact of such information to AFO use during daily life, this work should be extended to faster walking speeds and longer adaptation periods in unimpaired adults and individuals with neuromuscular impairments. Using stability to inform device design may improve safety and enhance mobility during daily living.

## INTRODUCTION

Ankle fractures represent a significant portion of orthopedic trauma injuries that occur in the United States. Patients who sustain irreversible cartilage damage or joint instability from ankle injuries are likely to develop ankle osteoarthritis (OA). Between 70%-80% of ankle OA cases are associated with a previous traumatic injury, a condition known as the Post-Traumatic Ankle Osteoarthritis (PTOA) [1]. PTOA pain and inflammation can be managed noninvasively using orthotics such as the Ankle-Foot Orthosis (AFO) (i.e., brace). A Patellar Tendon Bearing AFO (PTB) applies compression to the lower leg to transfer some weight from the foot and ankle to the lower leg and patellar tendon. This is important since reduced axial ankle loads have been shown to effectively reduce the pain and discomfort of ankle arthritis [2]. However, current AFO designs do not provide a controlled offloading of the ankle joint and tend to limit ankle motion during gait [3].

A new Dynamic Ankle Orthosis (DAO) was designed to provide the coupled benefits of ankle offloading while supporting the range of ankle motion. The DAO applies a distractive force along the axis of lower leg and through the rotational axis of the device, creating an offloading effect. Further, the arrangement of the device's rotational axis with the anatomical axis of the ankle joint allows for a walking range of dorsiflexion ( $\sim 10^\circ$ ), plantar flexion ( $\sim 15^\circ$ ), and some frontal plane motion. The purpose of this preliminary work was to compare ankle joint kinematics and ground reaction force variables between the newly designed DAO and a standard PTB in healthy individuals during level-walking. A non-brace shoe condition (CON) served as the control group. Greater dorsiflexion and eversion excursions while walking were expected in the DAO compared to the PTB.

## METHODS

Three healthy young women ( $22.3 \pm 0.6$  yrs;  $59.8 \pm 9.2$  kg;  $1.62 \pm 0.07$  m) were recruited to participate in this pilot research study. Two braces, DAO and PTB, were fabricated under the supervision of a licensed orthotist (COPI, Memphis, TN) for all participants. Over-ground walking trials were performed wearing shoes with 1) no brace (CON), 2) DAO and, 3) PTB. The DAO distractive force was set to 75N. Participants first completed five over-ground walking trials to measure their preferred walking speed in each condition using photocells and an electronic timer (Lafayette Instruments Inc., IN, USA). Anatomical markers and tracking marker clusters were then placed on both lower extremities and a standing calibration trial was collected. A 9-camera motion capture system (240Hz, Qualisys AB, Sweden) and a force platform (1200Hz, AMTI, Inc., USA) were used to collect kinematic and GRF data, respectively. Participants then completed five over-ground walking trials at a set speed ( $1.4 \text{ m/s} \pm 5\%$ ).

Visual3D biomechanical software (C-Motion, Germantown, USA) was used to process and analyze all data. Joint kinetic variables were calculated using Newtonian inverse dynamics. The mean of each variable during the five walking trials was used for analysis. Due to the preliminary nature of work and small sample sizes ( $n=3$ ), only Cohen's  $d$  effect sizes were reported to assess effect magnitudes with Hopkins' interpretation (i.e., small:  $d < 0.6$ , moderate:  $0.6 \leq d \leq 1.2$ ; large:  $d > 1.2$ ).

## RESULTS AND DISCUSSION

Preferred walking speed was not different between CON and DAO conditions ( $d=0.25$ ) but was faster in CON ( $d=1.20$ ) and DAO ( $d=1.66$ ) compared to PTB walking; both showing large effect sizes (**Table 1**). These findings suggest that DAO does not restrict preferred walking speed unlike the

standard PTB. Step length was longer with DAO ( $d=0.61$ ) and PTB ( $d=0.71$ ) compared to CON. Peak dorsiflexion was greater in DAO ( $13.2^\circ$ ) compared to CON ( $7.7^\circ$ ,  $d=2.92$ ) and PTB ( $7.5^\circ$ ,  $d=3.13$ ) (**Fig. 1**). Dorsiflexion ROM was larger in DAO ( $22.1^\circ$ ,  $d=0.94$ ) but smaller in PTB ( $14.1^\circ$ ,  $d=2.02$ ) compared to the CON ( $18.9^\circ$ ). Only the PTB and CON difference showed a large effect size. Thus, DAO appears to improve dorsiflexion ROM similar to CON compared to PTB. Peak eversion was similar between DAO ( $-3.9^\circ$ ) and CON ( $-3.8^\circ$ ,  $d=0.05$ ), but smaller with PTB ( $-3.3^\circ$ ) compared to CON ( $d=0.21$ ) and DAO ( $d=0.54$ ), but effect magnitudes were all small. Finally, although eversion ROM in CON ( $4.85^\circ$ ) was larger compared to DAO ( $4.05^\circ$ ,  $d=0.52$ ) and PTB ( $0.19^\circ$ ), large effects were only observed between PTB and CON ( $d=6.31$ ) and DAO ( $d=2.87$ ). The DAO allows for greater frontal plane ankle motion than a standard PTB which is more like a non-braced condition.

Bracing conditions had negligible effects ( $d < 0.6$ ) on peak horizontal GRF variables (**Table 1**). However, vertical loading response and push-off peaks were lower in DAO compared to CON ( $d=1.39$  and  $d=0.30$ ) and PTB ( $d=1.42$  and  $d=0.67$ ). PTB increased the vertical loading response ( $d=0.56$ ) and push-off peaks ( $d=0.49$ ) compared to CON. The DAO reduced vertical loading to the body which may promote better tissue recovery during rehabilitation, but more work is needed to fully assess the ankle offloading benefit of the DAO.

## CONCLUSIONS

Findings from this preliminary work support our hypotheses that DAO allows for greater ankle

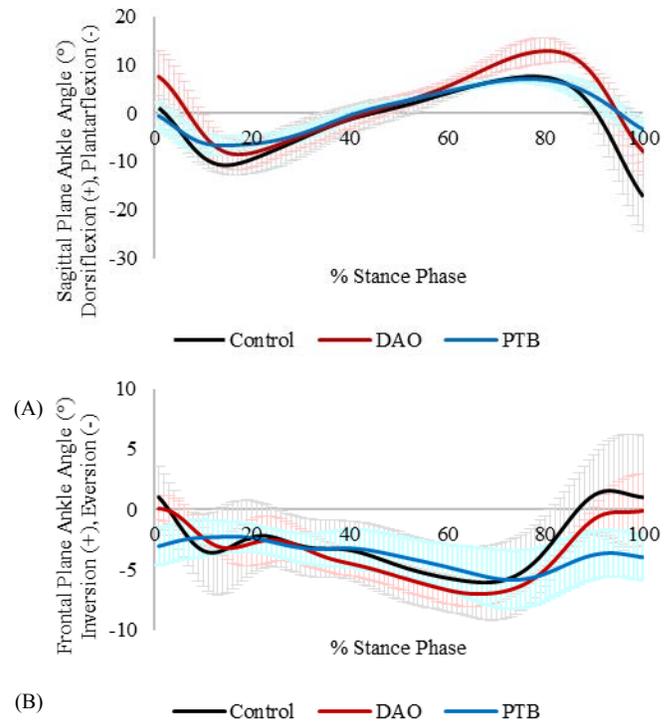

mobility and reduces vertical loading compared to a standard PTB during walking. We are currently

## INTRODUCTION

Ankle-foot orthoses (AFOs) are commonly prescribed assistive devices that aid in correcting pathological gait in a wide range of patient populations, from individuals with cerebral palsy to stroke rehabilitation. AFOs come in a variety of designs and sizes, both off-the-shelf and custom-made, to accommodate the diverse population. The AFO fitting process, however, lacks quantitative metrics, and clinicians are left to rely on experience and visual observation of gait to make AFO selection choices.

This work points to the recent interest in emulator technology, which mimics the behavior of active exoskeletons and prosthetic devices with off-board motors [1], as a solution to bridging the gap towards quantitatively determining optimal, personalized AFO designs for patients. A control framework is presented for emulating the torque-angle curve of passive AFOs using an active exoskeleton device. While patients wear the actuated exoskeleton and walk on a treadmill, the off-board controller and motor setup would allow them to ‘try on’ different AFO devices as a sensor suite evaluates their performance. This work includes the exoskeleton design, sensor suite, and simulated control framework, as well as an experimental setup for quantifying the torque-angle curve of passive AFOs.

## METHODS

Taking inspiration from [2], the exoskeleton (Fig. 1) had a single joint at the ankle and consists of a modified surgical shoe, with a rigid foam base, and adjustable metal stirrups. The exoskeleton can be actuated by controlling an off-board motor to pull on a tether attached through a spring to the bottom footplate inside the shoe sole.

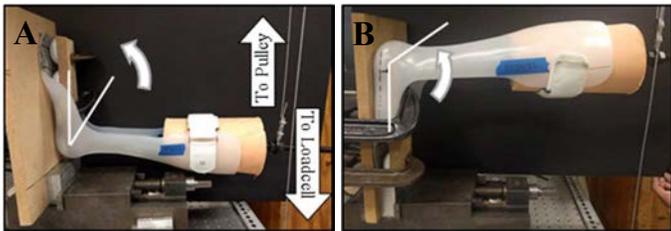

**Figure 1:** The exoskeleton and sensor suite with a diagram of where the spring and tether will connect to deliver torque from an off-board motor.

The exoskeleton was outfitted with a potentiometer to approximate ankle angle and three footswitches (placed underneath the heel (H) and 1<sup>st</sup> and 4<sup>th</sup> metatarsal heads (M1 & M4)) and a gyroscope (posterior to heel) for gait phase detection. An algorithm discussed in [3] is used to identify gait phases. Additionally, the gyroscope is used to identify plantarflexion versus dorsiflexion. The gyro is reset during stance to mitigate drift. The gait phase detection algorithm was tested with a healthy, 26-year old, female subject while walking on a treadmill at 1.5 *mph*.

The control framework was simulated in Simulink and Matlab (Mathworks Inc., Natick, USA). The collected sensor data were stored in Matlab and sampled by the simulation to emulate real-time application. The algorithm first selects an AFO design to emulate. Then, sensor readings are used to determine the gait phase and ankle angle and then command an appropriate exoskeleton torque to the motor driver. Ankle angle and gait phase time histories are collected in a buffer until ten steps are completed. The buffered data is sent to a performance algorithm that calculates a measure of symmetry [4] between the left and right maximum ankle ROM. The process is then repeated for another AFO design selection and a new symmetry metric is

produced. Greater symmetry indicates better patient performance. Once the patient has ‘tried on’ all possible design options, the algorithm chooses the design with the highest symmetry metric as the optimal AFO selection.

The torque-angle curve of a passive AFO was obtained by measuring the displacement of a central rod attached to a wooden pylon fixed inside the AFO (Fig. 2) after a force was applied by tensioning a cable fixed to the rod and to a loadcell. The AFO foot plate was fixed with clamps during the experiment.

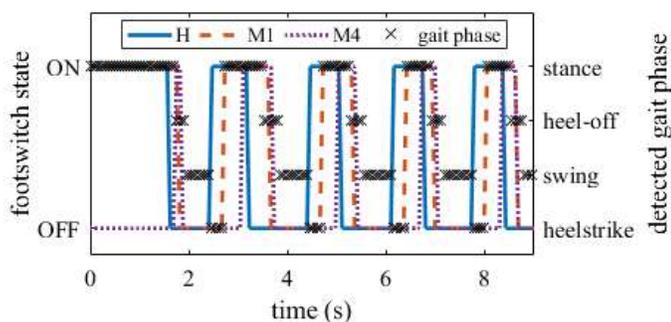

**Figure 2:** Experimental setup to acquire AFO stiffness curves during (A) flexion and (B) extension.

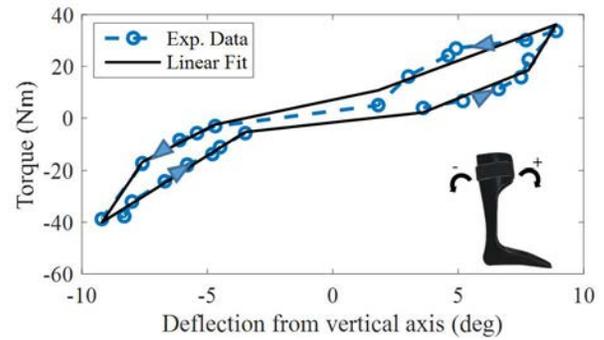

## RESULTS AND DISCUSSION

The gait detection worked well in simulated real-time (Fig. 3) to differentiate steps and gait phases, which were used to prompt the 10-step buffer and calculate the average symmetry metric. The controller used the state and angle to look up the appropriate command torque from the stiffness curves (Fig. 4). In the future, inertial sensing and automation will be added to the stiffness test to capture viscoelastic behaviors.

This framework still needs to be tested on a healthy and pathological patient population. The effectiveness of the emulation will be evaluated by

**Figure 3:** Gait detection code identified 4 gait cycle phases (x) based on footswitches (H, M1 & M4) and gyroscope (not shown).

**Figure 4:** The ankle torque-angle curve of a solid-ankle passive, thermoplastic AFO from a static deflection test. Flexion and extension of the AFO was performed. A piece-wise linear fit is applied.

comparing inertial readings and patient feedback between the real, passive and emulated, active AFO versions. The chosen performance metric allows comparison across AFOs and quantifies increased gait symmetry, which is an outcome clinicians look for during their visual evaluation of patients.

Future work will include closing the control loop by utilizing learning control to find the optimal torque-angle curve that maximizes performance and then matching it to available designs. With advances in manufacturing technology, especially additive manufacturing, greater design versatility could allow the creation of unconventional designs to meet customized torque-angle behaviors.

## INTRODUCTION

The plantar flexors play a critical role in moving the body forward by eccentrically contracting, during mid- to late- stance, to control shank rotation and forward progression [1]. Insufficient control of the shank's rotation due to plantar flexor weakness [2], an impairment seen in individuals post-stroke [1], may result in gait dysfunctions, such as crouch gait [2] and asymmetric step lengths [3]. Ankle-foot orthoses (AFOs) are rehabilitative devices that can be prescribed to individuals post-stroke who have plantar flexor weakness [2], with the goal of improving gait function [4]. Individuals' post-stroke often experience variable outcomes with currently-prescribed AFOs [5], likely because these AFOs are not properly customized for each individual [6]. We have developed a novel AFO design and prescription process that personalizes the passive-dynamic ankle-foot orthoses (PD-AFO) bending stiffness to each individual to assist their weakened plantar flexors. The bending stiffness can potentially replicate function of the plantar flexors by adding to the resistance needed to control shank rotation [2]. Plantar flexor function can be quantified by the peak plantar flexion moment [7]. Thus, we hypothesize that PD-AFO bending stiffness can be customized to add to an individual post-stroke's peak plantar flexion moment, enabling the net (individual + PD-AFO) moment to reach a typical level. The purpose of this study was to evaluate if personalized PD-AFOs bending stiffness improved the gait of individuals post-stroke.

## METHODS

Three individuals with chronic stroke (> six months post-stroke) consented to participate in this study.

Anthropometric measurements, height, and weight of all subjects were recorded. There were three parts to this study: a baseline visit, PD-AFO manufacturing, and an evaluation visit.

At the beginning of the baseline visit, a 10-meter walk test was performed to measure the subject's self-selected walking speed. The subject then underwent an instrumented gait analysis to collect the data needed to drive personalization of the PD-AFO bending stiffness. For the gait analysis, a seven-camera motion capture system (Motion Analysis Corporation, Santa Rosa, CA) was set up around a split-belt instrumented treadmill (Bertec Corp., Columbus, OH). Retro-reflective markers were attached to specific anatomic lower extremity landmarks. The subject walked on the treadmill at his/her self-selected walking speed while wearing his/her currently-prescribed AFO (Original AFO). Kinematic and kinetic data from 10 gait cycles were captured at 240 Hz and 1200 Hz, respectively. Data were exported into Visual 3D (C-Motion Inc., Germantown, MD) for analysis. Specifically, peak plantar flexion moment during stance was calculated and analyzed.

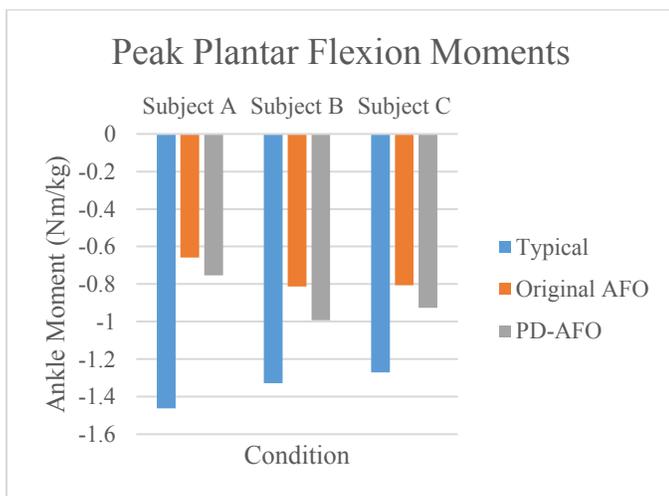

The PD-AFOs were made out of carbon fiber (CF) composite material. Each PD-AFO was custom fit to the subject's shank and foot by digitally capturing their size and shape using a 3D Fusion FaroArm (FARO Technologies Inc., Lake Mary, FL). The bending stiffness of each PD-AFO was personalized as the difference between the subject's peak plantar flexion moment from the healthy, speed-matched, peak plantar flexion moment obtained from the lab's normative database, divided by a typical dorsiflexion range of motion of 12°.

During the evaluation visit, the subject walked under two conditions: while wearing his/her Original AFO and while wearing the personalized PD-AFO. The same instrumented gait analysis procedures from the baseline visit were used. Peak plantar flexion moment and step length were calculated in Visual 3D and compared across conditions to determine if the individual was able to reach the targeted typical peak plantar flexion moment and if the PD-AFO improved step length symmetry.

## RESULTS AND DISCUSSION

Two females and one male participated in this study (Subject A: male, 61 years, 1.92 m, 81.4 kg; Subject B: female, 37 years, 1.66 m, 74.6 kg; Subject C: female, 62 years, 1.672 m, 76.7 kg). Subjects A, B, and C walked at a scaled velocity of 0.6, 0.4, and 0.3 statures/second, respectively.

Results showed that wearing the PD-AFO increases the peak plantar flexion moment when compared to each subject's Original AFO condition (Fig. 1). While these findings show benefits of the personalized PD-AFO, our hypothesis was not fully supported because the peak plantar flexion moment while wearing the personalized AFO did not return to typical levels (the peak plantar flexion moment of speed-matched typical individuals). Step-length ratio also became more symmetrical with the use of the PD-AFO in comparison to Original AFO for two of the three subjects (Table 1).

**Figure 1:** Peak plantar flexion moments of the three subjects while wearing the PD-AFO and Original AFO.

**Table 1:** Step-length ratio of the three subjects while wearing the original AFO and PD-AFO.

Step-Length Ratio	Typical	A	B	C
Original AFO	1	1.355	1.111	1.103
PD-AFO	1	1.361	0.978	0.98

## CONCLUSIONS

The goal of this study was to evaluate if the personalized PD-AFO bending stiffness improves the gait of an individual post-stroke. The results indicated that the PD-AFO improved the peak plantar flexion moment and gait symmetry in comparison to each subject's originally-prescribed AFO. However, the personalized PD-AFO did not return the plantar flexion moment and gait symmetry to typical levels. To reap benefits from the PD-AFO bending stiffness, the individual must load the brace into dorsiflexion during mid- to late-stance. The individuals post-stroke, in this study, often did not immediately adjust their gait pattern to properly use the PD-AFO. While this study focused on immediate effects of the personalized PD-AFO, future research should investigate training the individuals how to use the PD-AFOs to determine if even greater benefits can be gained from the personalized bending stiffness.

## INTRODUCTION

Powered gait-assistive exoskeletons have become increasingly available both in the clinic and in the home. Exoskeletons offer mobility-impaired individuals numerous advantages over wheelchairs, including loading a user's skeleton with external forces. Weight-bearing interventions have been shown to improve bone health in spinal cord injured individuals [1], but little is known regarding the loads imparted by exoskeleton-assisted gait.

Limited data suggests that exoskeleton-assisted gait is relatively slow (0.22 to 0.5 m/s) and that kinematics are affected by walking speed [2]. Joint forces and moments during exoskeleton-assisted gait have yet to be examined extensively. Here we describe a framework for utilizing traditional laboratory motion capture methods to characterize the lower extremity joint forces resulting from and the joint range of motion prescribed by powered exoskeleton-assisted gait. We report data from the first individual who has completed data collection.

## METHODS

*Theoretical Framework:* The underlying theoretical approach to analyzing the biomechanics of exoskeleton-assisted gait described here hinges upon the interaction between the device and the user. Combining these two multi-body systems into a single "lumped" system allows the calculation of lumped net joint moments. Any moments generated by the user's muscles or connective tissues (including any spasticity or contracture) are theoretically represented by the difference between these lumped system joint moments and the torque provided by the device's joint motors, as follows:

$$\text{User-provided moment} = \text{Lumped system moment} - \text{Exoskeleton motor torque}$$

This lumped system approach relies on the assumption that the motor torques reflect all torque provided by the device throughout the gait cycle (i.e. torque is not provided by structural features at end ranges of motion). Additionally, joint angles and reaction forces for the user can be calculated using tracking markers on the user's segments and a measurement or reasonable estimation of the force between the device's footplate and the user's foot. The validity of our estimation of these footplate reaction forces is evaluated and discussed below.

*Case Study:* A 35 year old male ("user") with chronic motor-complete spinal cord injury (ASIA score = A at T4; height: 1.83 m; mass: 65.9 kg) was trained to use the Ekso<sup>TM</sup> powered exoskeleton device (Figure 1) until he was proficient at walking unassisted. The segments of the Ekso were defined with retroreflective markers while the user's segments were defined with marker triads. Anatomical landmarks obscured by the device were located using a marker wand. The user completed four walks across the laboratory while marker positions were collected using a ten camera Vicon system (120 Hz). Ground reaction forces were collected using two force platforms at 1080Hz.

Hip and knee joint angles for the Ekso in the sagittal plane were determined with a six-degree-of-freedom approach, while user joint angles were resolved into joint coordinate systems. User joint reaction forces were calculated using a footplate reaction force estimated from the ground reaction force signal.

**Figure 1.**  
Ekso<sup>TM</sup> powered  
exoskeleton device

Joint moments for the combined user-Ekso system were calculated from the ground reaction force and combined kinematic terms. These combined user-Ekso system joint moments in the sagittal plane were compared to the torque provided by the Ekso joint motors. Strides were defined from Ekso heelstrike to subsequent ipsilateral heelstrike, and left and right stride data averaged together under the assumption of bilateral symmetry.

## RESULTS AND DISCUSSION

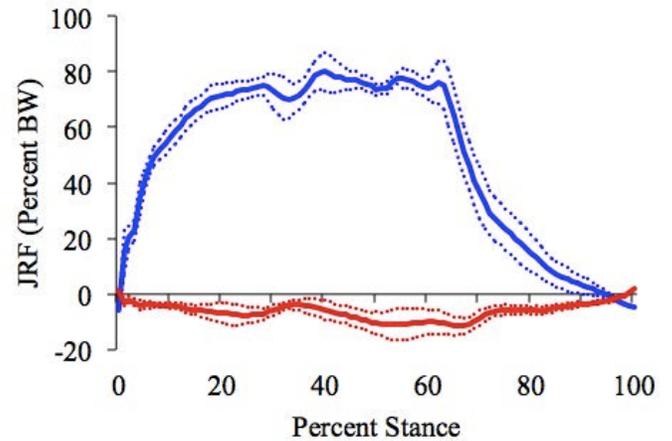

The accuracy of our method for estimating footplate reaction forces was deemed acceptable, with RMS differences in acceleration profiles of matched user-Ekso segments of 0.15 - 0.36 m/s<sup>2</sup> throughout the gait cycle. The user achieved an average walking speed of 0.18 m/s. Compared to reported kinematics during assisted gait using a ReWalk exoskeleton [2], the knee and hip ranges of motion, and likely the joint angular velocities, were greater despite a slower walking speed (Table 1).

**Table 1.** User hip and knee ROM and angular velocities.

	Hip	Knee
<b>Range of motion (deg)</b>	38.3	56.1
<b>Max flexion velocity (deg/s)</b>	101.1	121.9
<b>Max extension velocity (deg/s)</b>	49.8	129.3

Knee joint reaction forces, expressed in the tibia anatomical coordinate system, reached a peak value of 0.83 body weight along the longitudinal axis and 0.13 body weight along the anterior-posterior axis, directed inferiorly and anteriorly into the proximal tibia (Figure 2).

Magnitudes of the joint reaction forces experienced by the exoskeleton user never surpassed one body weight. Compared to standing frames, which would be expected to apply a static load of approximately 0.5 body weight per limb, exoskeleton-assisted walking imparts larger and more dynamic forces. These mechanical loading characteristics have been linked to increased bone adaptation [3]. Spasticity or contracture in lower extremity muscles would provide additional bone forces not accounted for in an inverse dynamics solution.

**Figure 2.** Axial (blue) and AP (red) tibia joint reaction forces during stance phase.

Patterns of torque provided by the Ekso joint motors agreed in a general sense with joint moments calculated for the lumped user-Ekso system, but the magnitude and timing of local peaks did not agree well. It was not possible to hardware-synchronize the Ekso and motion capture systems, so visual matching of events was used here but may explain some of the discrepancy. It is also possible that torque is provided passively by joints at terminal ranges of motion (i.e. knees locked), although the measured actuator knee torques do not support this idea. Clarifying these issues would allow future investigations to better quantify the resistive torque between the user and the exoskeleton due to spasticity or contracture, or any assisting torque due to conscious muscle activation in individuals with residual efferent control.

## CONCLUSION

We developed inverse dynamics methods to calculate user joint kinematics and kinetics during exoskeleton-assisted walking. For a case-study individual with SCI, knee ROM was 56.1 degrees, and JRF was 0.83 body weight.

## INTRODUCTION

Powered exoskeletons are beginning to break new ground in enhancing locomotion performance for both able-bodied users [1] and individuals with pathologies such as stroke [2]. A major factor in determining exoskeleton performance is the control architecture that is used to generate the commands to motors that apply torques to the lower-limb joints. Approaches to torque control include using preset stiffness and damping values set as a function of joint angle or stride percentage (*i.e.*, impedance control) [1], or using muscle activity of the user (*i.e.*, myoelectric control) [2] to generate a reference signal for the exoskeleton actuators to follow.

Model-based control is another option that may lead to more robust behavior in response to changes in the state of the user or the environment. For example, previous research on a powered ankle-foot prosthesis demonstrated that, with optimized parameter settings, a neuromuscular model (NMM) based on the biological plantarflexors can normalize mechanics and energetics for amputees across a range of walking speeds [3]. It remains to be seen, whether a similar approach can be effective on a powered ankle exoskeleton system.

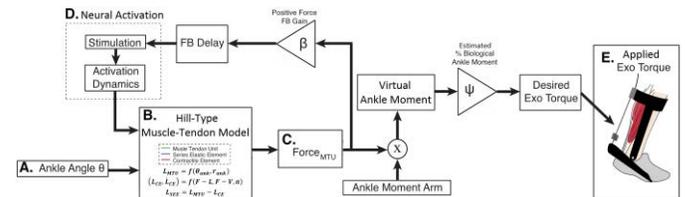

The purpose of this study was to test the effect of varying the reflex feedback parameters within a NMM-based controller designed to emulate the human ankle plantarflexors on a powered ankle exoskeleton. We hypothesized that increasing reflex feedback gain while minimizing the feedback delay would maximize net exoskeleton work and produce the largest reductions in users' metabolic cost.

## METHODS

**Exoskeletons:** We provided bilateral plantarflexion assistance via a tethered ankle exoskeleton device. Off-board motors and Bowden cable transmission delivered torque to the custom carbon fiber exoskeletons.

**Controller:** We designed the NMM based controller in Simulink (MathWorks, USA) and implemented it

through a dedicated real-time control system which also handled signal IO (500 Hz, dSPACE, Germany). We calculated applied exoskeleton torque from a load cell (500 Hz, LCM Systems Ltd, UK) placed in series with the applied assistance, and a goniometer (500 Hz, Biometrics, UK) attached to the exoskeleton joint provided real-time ankle angle.

**Figure 1:** Neuromuscular model controller block diagram. Biological force, as computed by the internal muscle-tendon state, is scaled and applied across a moment arm to calculate desired exoskeleton torque.

The NMM based controller implemented in our system was similar to a reflex-based force feedback controller previously demonstrated [3]. A Hill-type muscle-tendon model was the basis for the emulated muscle-tendon unit (MTU) consisting of a contractile element (CE) with both active and passive properties and a series elastic element (SEE) (Fig.1B). We calculated MTU length from ankle angle and musculoskeletal geometry (1.1) and CE dynamics was subject to force-length, force-velocity and activation (1.2). We calculated SEE length as the difference in length of the CE from the MTU (1.3).

$$L_{MTU} = f(\theta_{ank}, r_{ank}) \quad (1.1)$$

$$(L_{CE}, \dot{L}_{CE}) = f(F-L, F-V, a) \quad (1.2)$$

$$L_{SEE} = L_{MTU} - L_{CE} \quad (1.3)$$

MTU force ( $F_{MTU}$ ) was a function of the model's SEE stiffness and strain. In the reflex pathway, we normalized MTU force to  $F_{max}$  and multiplied by a feedback gain. A delay was added to emulate a positive force feedback neural reflex signal (Stim) and CE activation dynamics (ACT) were modeled to close the feedback loop (Fig.1D). We calculated desired exoskeleton torque as a portion of the estimated biological moment.

$$\tau_{exo} = F_{MTU} \times r_{ankle} \times \psi \quad (1.4)$$

where  $\psi$  represented a percentage of the estimated biological torque. We calculated and recorded

internal model states ( $F_{MTU}$ ,  $L_{MTU}$ ,  $L_{CE}$ ,  $STIM$ ,  $ACT$ ) in dSpace for 5 second periods for offline analysis.

**Testing Protocol:** Three healthy-young adults (1 male; average mass  $72.2 \pm 6.1$  kg) completed the IRB approved protocol. Each subject walked at 1.25 m/s with the exoskeletons unpowered, and then powered with four different gains (0.8-2.0 gain sweep) at a set delay (10ms) and four different delays (10-40ms delay sweep) at a set gain (1.2). Metabolic power was estimated from indirect calorimetry data collected in last two minutes of each trial (Carefusion, USA).

## RESULTS

Increases in the NMM controller gain resulted in systematic increases in exoskeleton torque and power output (Fig. 2A, C-D green). The exoskeleton produced net negative work at low gain and net positive work at high gain (Fig.2B, green). In contrast, increasing NMM controller delay generated a decrease in exoskeleton net work (Fig. 2B, blue) and increased torque output to a point of diminishing returns (Fig.2D, blue). Users' metabolic energy consumption was reduced by 4% from the unpowered condition with a 1.2 feedback gain and 10ms delay. All other NMM controller settings increased metabolic demand – 6% in the worst case (Fig. 3).

## DISCUSSION AND CONCLUSIONS

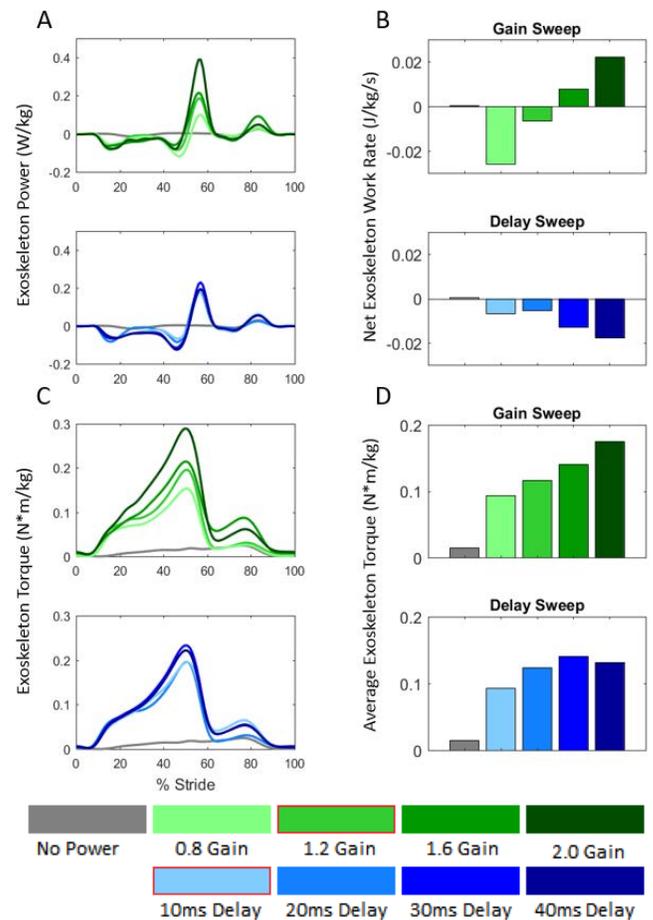

From a mechanical standpoint, the NMM controller functioned as expected with the highest gain and smallest delay providing the most assistance. Surprisingly, this condition did not result in the largest metabolic reduction. Net work delivered by an exoskeleton may not be the only determinant of metabolic benefit to the user. More data and further analysis to examine changes in joint mechanics at the knee and hip, as well as muscle activation patterns may reveal underlying mechanisms driving these observations.

**Figure 2:** In the gain sweep, exoskeleton power (A) and net work rate (B) increased across conditions by increasing the torque profile (C) and average torque (D). In the delay sweep, average torque peaked, before decreasing and net work rate was entirely negative. Darker colors indicate higher values. Red outline indicates base parameters (Gain: 1.2, Delay: 10ms). Curves are study average trajectories.

**Figure 3:** Average change in metabolic rate across gain (A) and (B) delay sweeps. Metabolic rate decreased at base (Gain: 1.2, Delay: 10ms) condition, but increased with all other parameter values.

# PREDICTIVE SIMULATION FRAMEWORK FOR COMBINED DEVICE AND HUMAN MECHANICS

Mohammadhossein Saadatzi and Ozkan Celik

Department of Mechanical Engineering, Colorado School of Mines, Golden, CO, USA  
email: msaadatz@mymail.mines.edu, web: brl.mines.edu

## INTRODUCTION

A primary challenge in design of wearable robots and their controllers is the difficulty in device performance prediction due to human adaptation to device dynamics and control. Combined predictive simulations of device and human musculoskeletal mechanics carry the promise to address this challenge and significantly accelerate design, testing and implementation of wearable robots. In this abstract, we present a predictive simulation framework for combined human-robot mechanics of bipedal walking.

## METHODS

The computational framework makes use of OpenSim API in C++ [1]. It employs forward dynamic simulations that are iteratively optimized via Covariance Matrix Adaptation (CMA) [2] to minimize metabolic cost of walking while satisfying a reference walking speed. Employing this single shooting method allows straightforward implementation of a variety of cost functions.

We use a simplified version of the musculoskeletal model “Gait2392-Simbody” available with OpenSim [1], which is commonly used for simulation of bipedal walking. The simplified model has 9 sagittal degrees of freedom and 9 muscle groups on each leg: Soleus, Vasti, Gastrocnemius, Tibialis anterior, Bicep femoris short head, Hamstring, Rectus femoris, Gluteus maximus, and Iliopsoas.

Uniquely, our framework generates bipedal walking through optimization of muscle actuation profiles, eliminating the need for manually-tuned reflex control laws, which were considered in [3,4]. Use of muscle actuation profiles rather than reflex control

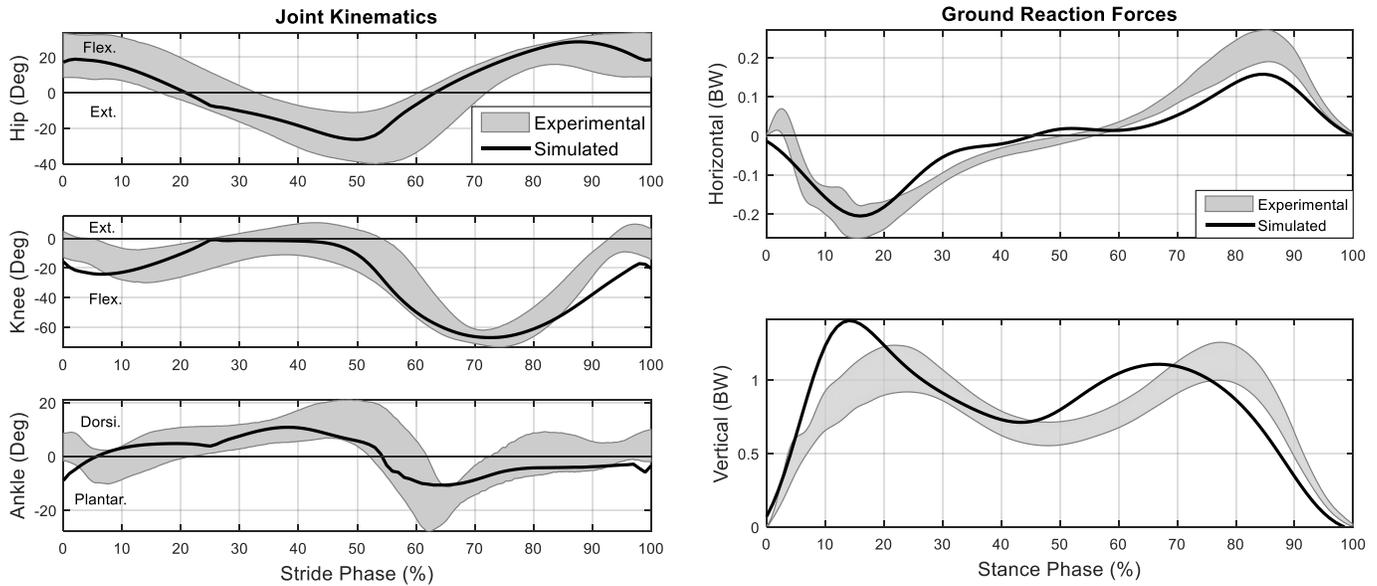

laws improves the exploration ability of the optimization and facilitates consideration of different human musculoskeletal models. Additional states can be easily incorporated in our framework to generate bipedal walking for models with different number of muscles.

For the control of locomotion, two controller states are considered, corresponding to support and swing phases, which are detected based on heel strike of the swing leg. Actuations in each state for one leg are mirrored to the other leg. This selection reduces the number of optimization parameters.

Actuation profile of each muscle is defined as a piecewise linear function with 10 parameters (6 parameters for stance phase, and 4 parameters for swing phase). Hence, there are 90 optimization parameters to be determined. To speed up the optimization, routines have been written to terminate the forward dynamic simulation in case of irrelevant solutions.

Complementary to the increased freedom in optimization, we use the computed muscle control (CMC) method to generate favorable initial optimization parameters, which reduce convergence time and probability of getting stuck in local minima. We use Open Science Grid [5], an open source high-throughput computing (HTC) resource, to run multiple simultaneous optimizations so as to identify the solutions that are as close as possible to the global minimum.

A credible simulation of bipedal walking must closely follow experimental human gait data. To validate our simulation, we compare our results with experimental data presented by Dorn et al. in [4].

**Figure 1:** Sagittal plane joint kinematics and ground reaction forces for normal (level ground, unloaded) walking at 1.5 m/s. Experimental data for walking are represented by the shaded region ( $\pm 1$  SD) and is from [4]. The solid line represents equivalent simulation results obtained by our predictive simulation framework.

## RESULTS AND DISCUSSION

We successfully used our framework for planar simulation of muscle-driven bipedal walking at 1.5 m/s (Figure 1). Joint angles predicted by our simulations are mostly in agreement with normal human walking. Specifically, joint angles during 88.6 percent of the gait cycle (hip 100%, knee 76.95%, ankle 88.92%) are within 1 standard deviation of experimental data. Also, the ground reaction forces (GRF) of simulated walking reproduce the main features of experimental GRF.

The convergence of the optimization with 90 parameters takes approximately 12 hours on a desktop computer with an eight-core processor. The computational efficiency of our framework and its ability to consider additional parameters for more complex / finer resolution force profiles compatible with human motor control, or external devices, is highly promising.

The framework proposed in this study can be used for design of various types of exoskeletons, including both passive and active, as well as exoskeletons with feedback controllers or optimal actuation profiles. So far, we have used our

framework to perform combined simulation and optimization of passive and active ankle exoskeletons with successful results, which fall beyond the scope of this abstract. Extending our work to simulation of bipedal walking in three-dimensional space and running gait constitutes our future direction.

## CONCLUSIONS

Simultaneous predictive simulation of human and device mechanics has significant potential for facilitating design and control of human augmenting devices. In this work, we presented initial results from the framework we have developed for this purpose.

# DESIGN AND CONTROL OF A MODULAR LOWER-LIMB EXOSKELETON EMULATOR FOR ACCELERATED DESIGN AND EVALUATION OF ASSISTIVE GAIT EXOSKELETON PARAMETERS

Kyle Heer, Jason Lee, Nick Collins, Megan Auger, & Ozkan Celik  
Department of Mechanical Engineering, Colorado School of Mines, Golden, CO USA  
email: kheer@mymail.mines.edu, web: [brl.mines.edu](http://brl.mines.edu)

## INTRODUCTION

Recent advances in robotic technology and control have made robotic exoskeletons and prostheses increasingly viable for a number of applications, including gait assistance [1]. However, difficulty in computational prediction of human adaptation to such devices constrains evaluation of potential device parameters to experimental studies, requiring physical devices that can be worn by a person [2]. For this reason, the use of emulators (testbeds capable of displaying wide ranges of physical parameters to their users) has emerged as an efficient approach to exoskeleton and prosthesis design [2-5]. This abstract describes the implementation of such a device intended for investigation into lower-limb exoskeleton parameters and control strategies.

## METHODS

The emulator (Figure 1) is a modular haptic device capable of closed-loop torque control and real-time angular sensing in up to four simultaneous sagittal-plane lower-limb joints. It comprises five braces to interface with a human user and an actuation cart to house the motors and data acquisition hardware. Table 1 presents a summary of emulator parameters.

Braces for human interface were designed to have sufficient adjustability to accommodate a wide range of user body types and sizes, based on 5<sup>th</sup> and 95<sup>th</sup> percentile values of various anthropometric measurements [6, 7]. In order to minimize mass while maintaining rigidity, all structural components were manufactured from 2024 aluminum. Three human attachment mechanisms are utilized: thin-wall PVC lined with medical foam (leg cuffs), aluminum brackets lined with 1" memory foam (torso brackets), and modified athletic sandals (foot attachment). 10 total functional joint axes provide rotational degrees of freedom (DOF) to the braces.

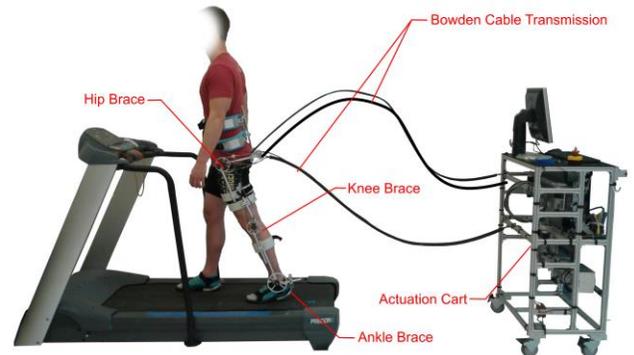

Figure 1: Lower-limb exoskeleton emulator

Four remotely-housed 200 Watt brushless DC motors (Maxon 16-275-EN) are used to independently actuate joints in the exoskeleton braces via Bowden cable transmission – pulleys on the motor output shafts convert torques to tensile forces, which are conducted by a lightweight synthetic fiber (Vectran™) to pulleys at the exoskeleton joint axes. Joint torques and angles are monitored in real time with miniature load cells (FUTEK LSB200) and rotary encoders (US DIGITAL E2-1250) at a frequency of 10 kHz.

Torques applied to the brace joints are controlled with a position feedback controller utilizing a least-squares second order regression model defining the desired motor position as a function of brace joint angle and desired brace torque (Equation 1).

$$\theta_m = A \theta_b + B \tau_{des}^2 + C \tau_{des} + D \quad (1)$$

Where  $\theta_m$  is the desired motor position,  $\theta_b$  is the current brace position, and  $\tau_{des}$  is the desired torque at the brace. Calibration trials conducted over the entire range of continuous torque generation and brace ROM were used to determine coefficients  $A$ ,  $B$ ,  $C$ , and  $D$  in order to account for cable compliance and friction within the Bowden sheath.

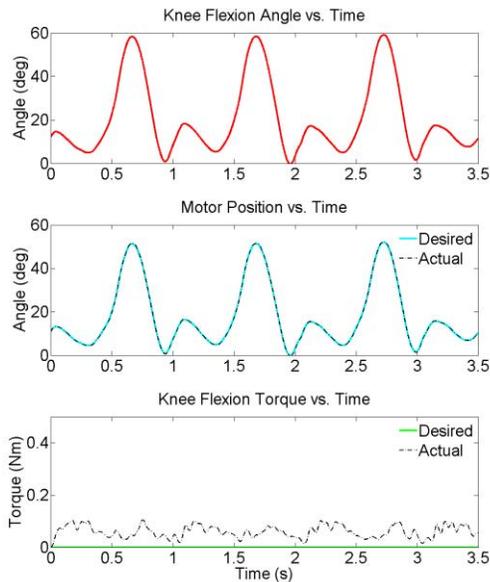

**Table 1:** Exoskeleton Emulator Parameters (asterisks denote powered DOF)

	Peak Torque (Nm)	Max Steady-State Torque (Nm)	Mass (kg)	Range of Motion (deg)
Hip	15.6	10.4	2.30	135 F/E*, 70 A/A
Knee	15.6	10.4	0.54	135 F/E*
Ankle	22.8	15.1	1.05	70 D/P*, 35 I/E

To evaluate the performance of the controller, two walking trials were conducted at 1.2 m/s. During the first trial, desired torque was held at zero, so that the motor would let out and take in slack to maintain a constant cable length (transparent mode). In the second trial, desired torque patterns were generated as a function of knee flexion angle to emulate a clutched torsional spring ( $k = 3.18 \text{ Nm/rad}$ ) to resist knee extension during swing. Brace angle, motor position, and resulting tensile forces at the brace were recorded and converted to torque.

## RESULTS AND DISCUSSION

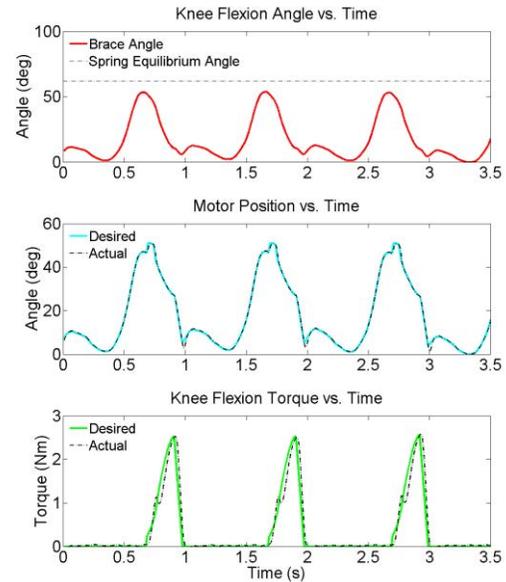

Position controller results for both operation modes are presented in Figures 2 and 3 for three representative gait cycles.

**Figure 2:** Knee flexion angle, desired vs. actual motor position, and desired vs. actual joint torque during treadmill gait with emulator in transparent operation mode

In transparent mode, motor position closely tracked its desired trajectory, and interaction torques remained at or below 0.1 Nm for the entire trial. Motor position tracking was also consistent during spring emulation mode, resulting in torque profiles closely matching their desired trajectories with

minimal delay.

**Figure 3:** Knee flexion angle, desired vs. actual motor position, and desired vs. actual joint torque during treadmill gait with an emulated torsional spring resisting knee extension during swing

## CONCLUSIONS

We have developed, integrated, and characterized a modular lower-limb exoskeleton emulator system with offloaded actuation: an experimental platform to accelerate the identification and testing of exoskeleton design and control parameters. Future work will utilize the emulator to answer research questions related to feasibility of multi-joint spring/clutch driven gait exoskeletons and human joint impedance identification, and to validate results from predictive computational simulations using combined human and device mechanics.

# MID-FLIGHT TRUNK MOTION INCREASED UNILATERAL LOADING DURING LANDING: A CENTER OF MASS ANALYSIS

Taylor Hinshaw, Daniel Davis, Jacob Layer, and Boyi Dai

University of Wyoming, Laramie, WY, USA  
email: thinshal@uwyo.edu, web: <http://www.uwyo.edu/kandh/>

## INTRODUCTION

Anterior cruciate ligament (ACL) injuries frequently occur in jump-landing tasks. Individuals commonly demonstrate low knee flexion angles, increased knee valgus/varus angles, and increased trunk motion near the time of ACL injury [1]. While the effects of knee biomechanics on ACL loading have been well established, the mechanism between increased trunk motion and ACL injury risk remains unclear. Newton's first law indicates that an individual's total body center of mass (COM) will demonstrate a parabola shaped trajectory while in the air. Because total body COM is composed of multiple segments, movement of specific segments in a particular direction relative to total body COM will result in counter-movements in the opposite direction. Trunk motion in the air is likely to result in motion of the legs simultaneously, and affect landing mechanics.

The purpose of this study was to quantify the effect of mid-flight medial-lateral trunk motion on COM distribution and subsequently landing mechanics. It was hypothesized that medial-lateral trunk motion would cause leg movements in the opposite direction, subsequently resulting in increased impact vertical ground reaction force (VGRF) to the leg that was closer to the total body COM.

## METHODS

Eighteen males and 23 female recreational athletes (age:  $22.0 \pm 3.0$  years; height:  $1.74 \pm 0.10$  m; mass:  $71.0 \pm 13.9$  kg) participated. Forty-four markers were used to establish a full-body model. Kinematic and kinetic data were collected using eight Vicon cameras (160 Hz) and two Bertec force plates (1600 Hz). Participants completed three trials of a jump-landing task in three conditions: reaching left, reaching right, and up. Starting with one foot on each force plate, subjects jumped for maximum height and

land back with one foot on each force plate. In the reaching left condition (Figure 1), participants laterally bended their trunk and reached both hands to the left as far as possible after they reached the maximum height. In the reaching right condition (Figure 2), participants laterally bended their trunk and reached both hands to the right as far as possible after they reached the maximum height. In the up condition (Figure 3), participants reached both hands as high as possible when they reached the maximum height. This task was designed to simulate basketball rebounding and volleyball blocking.

The total body was modeled as four components: the upper body including all segments above the pelvis, the pelvis, the ipsilateral leg of the reaching side, and the contralateral leg of the reaching side [2]. For the up condition, the right side was used as the ipsilateral leg, and the left side was used as the contralateral leg. Time events of initial contact were identified for the ipsilateral and contralateral legs. Time differences were quantified with the initial landing of the ipsilateral leg prior to the contralateral leg defined as positive. At the first foot initial contact, the COM locations of the four body components relative to the total body COM were determined with the direction of the reaching side defined as positive. The peak VGRF during the first 100 ms after initial contact was quantified for each leg.

## RESULTS AND DISCUSSION

The ipsilateral legs landed earlier for the two reaching conditions compared with the up condition (Table 1). At first initial contact, the upper body moved towards the reaching direction while the pelvis and both legs moved in the opposite direction for the two reaching conditions compared with the up condition. The ipsilateral leg experienced the greatest VGRF for the two reaching conditions.

When individuals laterally bend their trunk in mid-flight, the pelvis and two legs moved in the opposite direction. As a consequence, the ipsilateral leg moved closer to the total body COM, and the contralateral leg moved further away from the total body COM, resulting in an asymmetric posture between the left and right leg for landing. First, the ipsilateral leg is likely to land earlier, and the leg landing earlier may experience greater VGRF. Second, utilizing the leg that is closer to the total body COM will result in decreased moment arms from the body weight vector to lower extremity joints, which may decrease joint torques and increase postural stability. These two factors together predispose the ipsilateral leg to experience greater impact VGRF compared with the contralateral leg.

The findings provide insight into understanding increased trunk motion during ACL injuries, and can help explain the prevalence of ACL injury for certain sports. Most jump-landing related ACL injuries in volleyball and badminton are on the knee opposite of the spiking arm or racket arm (dominant arm) [3, 4]. A ball or shuttlecock on a player's dominant side can be reached by extending the dominant shoulder and arm; however, a ball on the non-dominant side may also require lateral trunk bend. The greater mass of the trunk compared with the mass of an arm will induce greater perturbation to the whole body and increase the asymmetries in landing. The increased likelihood of lateral trunk bending towards the non-dominant-arm direction is likely associated with the higher injury rates of the knee opposite to the dominant arm.

While medial-lateral trunk movements may not be avoidable for achieving sports performance, several strategies may be adapted to decrease its impact on landing mechanics. First, after completing the reaching task in the air, participants should try to bend the trunk back to the natural position and establish a symmetric landing posture. Second, individuals may increase the knee and hip flexion in air, which will increase the time for adjusting posture and preparing for a soft landing. Third, when medial-lateral trunk motion is excessive and the contralateral leg is too far away from the total body COM, individuals may land softly on the ipsilateral leg and adopt effective falling strategies.

## CONCLUSIONS

Medial-lateral trunk movements in mid-flight resulted in pelvis and leg movements in the opposite direction, which imposed an asymmetric posture for landing and increased the loading of the ipsilateral leg. The findings provide information for understanding ACL injury mechanism and developing ACL injury prevention strategies.

# PERFORMANCE CONSTRAINTS DO NOT ALTER LANDING IN REACTIVE JUMPS

Mitchell L Stephenson and Jason C Gillette

Iowa State University, Ames, IA, USA  
email: mitch.stephenson@gmail.com, web: www.kin.hs.iastate.edu

## INTRODUCTION

Non-contact anterior cruciate ligament (ACL) injuries continue to pose a common problem to the athletic community. Recent research [1] has identified the role of reaction time in reactive landing strategies that indicates delayed decision-making for movement direction the instant before lower extremity loading changes movement patterns and decreases performance. It was suggested that a tradeoff between performance and “safe” landing biomechanics may exist, and the previous estimations of lower extremity loading in reactive jump landings may be conservative. An independent investigation partially confirmed this tradeoff in a non-reactive protocol [2].

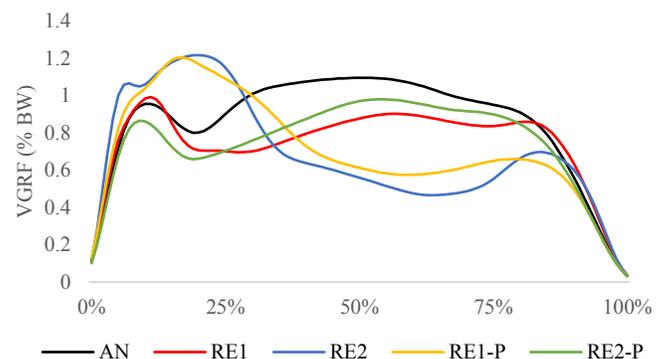

The current investigation was performed to determine if this tradeoff between performance and loading also exists in a reactive jump landing test. Participants were asked to maintain the movement speed they performed in an anticipated setting during their reactive performances as well. Based on previous results [2], it was expected that the maintenance of the faster movement speed would result in decreased range of motion at the knee and increased vertical ground reaction forces (VGRF).

## METHODS

Nine physically-active, right-foot dominant, uninjured recreational athletes (6 females and 3 males;  $20.8 \pm 1.2$  years;  $1.70 \pm 0.10$  m tall;  $70.7 \pm 11.3$  kg) have volunteered for the ongoing study. Participants provided informed consent, executed a warm-up protocol, and then performed a series of successful practice trials for familiarization.

Participants jumped forward 50% of their height from a 30cm tall block, landed bilaterally on two force platforms (1600 Hz, Advanced Mechanical

Technology Inc., Watertown, MA), and then quickly and fluidly jumped to the left or right  $60^\circ$  from anterior for maximum speed and distance. The jump direction was indicated by one of two lights mounted at eye level in front of the participant. These indicators were lit before the participant began the trial such that the direction was anticipated (AN), or two conditions where the participant had to react to the indicator during the performance: The instant the participant left the 30cm box (RE1), or at the instant they landed on the force platforms (RE2). Participants performed three trials in each direction in each timing condition.

**Figure 1:** Mean VGRF across percentage stance time for each timing condition while jumping right.

The stance time on the force platforms between the two jumps in the AN condition was extracted and averaged. Participants then performed three more trials in each direction for the reactive conditions (RE1-P and RE2-P), but were constrained to maintain the stance time (ST) from the AN conditions. If ST was not fast enough for a trial, it was repeated randomly later until the target ST was reached, or a total of 9 repeats were performed. In the latter situation, the fastest 3 performances were subsequently analyzed.

The jump direction and timing condition were block-randomized and the participant was blinded to these variables. Kinematics of 19 retroreflective markers placed on the right lower extremity, pelvis, and torso were recorded via 8 Vicon cameras at 160Hz through Vicon Nexus 1.8.2 (Vicon Corp, Oxford, UK).

Peak knee valgus and flexion angles as well as the peak unilateral VGRF was extracted during the first 100ms of contact with the force plates. A repeated-measures analysis of variance was performed to compare the effect of the timing condition and performance preservation on knee kinematics and landing VGRF for each jump direction.

## RESULTS AND DISCUSSION

A significant ( $p < 0.001$ ) interaction between the jump direction and timing condition was identified. Significant main effects were identified for knee flexion, VGRF, and ST ( $p < 0.0001$ ). Pairwise comparison results maintaining a false discovery rate (FDR) of 0.05 are presented in Table 1.

As previously reported [1], ST increased from AN to RE1 to RE2. Participants were generally able to reduce ST in the RE-P conditions, but only obtained similarity to the AN condition for RE1-P left jumps; otherwise ST was longer than the AN conditions.

Also similar to previous analyses [1], dependent variables were characteristically unique to jump direction. Knee flexion only changed significantly

for right jumps, remaining shallower in RE2 conditions independent of performance constraints. VGRF changed for both directions, reducing for the left jumps and increasing in the right jumps for the RE2 conditions independent of performance constraints. For right jumps, RE2-P demonstrated slightly less VGRF than the RE2 condition.

Participants were able to consciously reduce their stance times in the constrained conditions, which could have training implications. However, results were otherwise not as expected. Performance constraints did not appear to significantly modify knee kinematics in the first 100ms of landing. Only VGRF for right jumps were affected by the performance constraints in the first 100ms, but this resulted in a *reduction* of VGRF compared to the unconstrained performance.

While it is possible that kinematic and kinetic changes took place beyond the first 100ms of landing (Fig 1), these changes likely do not affect ACL loading [3]. As such, it is likely not necessary to control ST in further reactive jump landing test paradigms. Furthermore it is not likely that previous reactive jump landing investigations underestimated changes in ACL load due to a lack of ST control.

email: bdai@uwyo.edu, web: <http://www.uwyo.edu/kandh/>

## INTRODUCTION

Investigators have examined the effects of landing height and technique on performers' motion, impact forces, and their associated risk of injury [1]. Strategies to decrease injury risk during landing include increasing lower extremity joint range of motion and lengthening landing time [1]. Parkour is a form of acrobatic street gymnastics. One important skill in Parkour is to land safely from a high height. Parkour practitioners use their arms and roll their body during landing [2]. Investigators have quantified landing forces for Parkour landings from a drop height of 0.75 m [2]. How Parkour practitioners effectively execute landings from a high height remains unclear.

The purpose of this study was to compare the center of mass (COM) velocities and accelerations among a traditional squat landing, a Parkour precision landing, and a Parkour roll landing when Parkour practitioners landed from a drop height of 2.7 m.

## METHODS

Seventeen male Parkour practitioners (age:  $23.9 \pm 4.7$  years; height:  $1.78 \pm 0.06$  m; mass:  $67.6 \pm 8.5$  kg; experience in Parkour training:  $7.0 \pm 2.3$  years) participated. All participants were confident and had no anxiety about landing from a drop height of 3 m utilizing each of three landing techniques.

Three video camcorders (60 Hz) were used to record participants' landing motion. The cameras were calibrated for the direct linear transformation procedure using a 32-point calibration frame [3]. Participants performed one trial using each of three landings: squat landing, Parkour precision landing, and Parkour roll landing from a drop height of 2.7 m in a random order. For the squat landing,

participants landed softly with only feet contacting the ground (Figure 1). For the precision landing, participants landed softly with both feet and both hands contacting the ground (Figure 2). For the roll landing, participants landed softly with a rolling motion from both feet to the back (Figure 3).

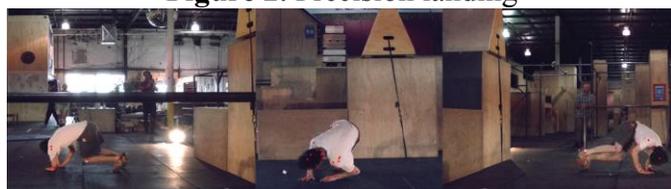

Twenty-one body landmarks [3] were manually digitized from initial foot contact to the end of the landing, defined as the first frame that the vertical velocity of the COM became positive or one of the feet left the ground, whichever occurred earlier. Three dimensional coordinates of body landmarks were obtained from synchronized two dimensional coordinates and calibration parameters, and filtered at a low-pass frequency of 7.14 Hz [3]. COM of the whole body was calculated [3]. Landing time, COM horizontal and vertical velocities, and accelerations were compared using repeated measures analyses of variance, followed by paired t-tests ( $\alpha=0.05$ ).

**Figure 1. Squat landing**

**Figure 2. Precision landing**

**Figure 3. Roll landing**

## RESULTS AND DISCUSSION

The roll landing resulted in the longest landing time, greatest anterior horizontal velocities at both initial contact and the end of landing, greatest downward vertical velocity at the end of landing, and lowest peak posterior horizontal acceleration during landing compared with the squat and precision landings. The precision landing demonstrated greater anterior horizontal velocities at the end of landing compared with the squat landing (Table 1).

Inappropriate landing techniques can cause excessive impact forces and loading to the lower extremities, resulting in musculoskeletal injuries [1, 3]. In the current study, Parkour practitioners landed from a height of 2.7 m, and no injuries occurred. This evidence suggests that a great initial landing velocity does not necessarily result in injury if appropriate landing techniques are utilized.

Although the roll landing started with the greatest initial anterior horizontal velocity, it also resulted in the lowest peak posterior horizontal acceleration during landing. Most initial horizontal velocity was maintained throughout the landing phase until the downward vertical velocity was largely decreased. The decreased peak posterior acceleration during the roll landing is likely to result in decreased posterior ground reaction forces, which are associated decreased knee extension moments and anterior cruciate ligament loading [3].

A drop landing was studied in the current study, but we speculate that the roll landing will be even more effective when individuals have to jump over a horizontal distance between the drop height and landing height, which will impose a greater

horizontal velocity at initial contact. The rolling motion allows individuals to emphasize decreasing the vertical and horizontal velocities during different time periods. When the vertical velocity is largely attenuated during the landing phase, the horizontal velocity can be subsequently decreased at the end of landing. Dissipating vertical and horizontal velocities separately is likely to decrease the peak loading imposed on the lower extremities.

## CONCLUSIONS

The Parkour roll landing resulted in the least horizontal acceleration during landing and allowed individuals to decrease the vertical and horizontal velocity over a longer period of time, which is likely to decrease the peak loading imposed on the lower extremities. The findings may provide information for developing landing training strategies for decreasing musculoskeletal injuries in high-risk populations such as athletes and military personnel.

# LANDING MECHANICS IN CONTROLLED SCREENING TASKS AND SIMULATED GAMES IN VOLLEYBALL

Bradley Beardt, Myranda McCollum, Taylor Hinshaw, Jacob Layer, and Boyi Dai

University of Wyoming, Laramie, WY, USA  
email: bbeardt1@uwyo.edu, web: <http://www.uwyo.edu/kandh/>

## INTRODUCTION

Injuries to the anterior cruciate ligament (ACL) are common during jump-landing tasks. Most ACL injuries are non-contact in nature, and ACL injury rates may be decreased through neuromuscular training. Screening and training athletes that are at high risk for ACL injury will increase the efficiency of ACL injury programs.

A controlled jump-landing task has been utilized for screening movement patterns associated with increased ACL loading. Contradicting results have been found for utilizing controlled jump-landing tasks to predict future ACL injuries [1, 2]. One potential reason of a lack of strong predictive value is the discrepancy between the controlled jump-landing task and actual sports environment. It is unknown whether the risky movement patterns identified in a controlled task will remain when athletes compete in game situations. The purpose of this study was to evaluate the differences and correlations in landing mechanics and performance among a controlled jump-landing task, a volleyball-specific jump-landing task, and a jump-landing task performed in a simulated volleyball game.

## METHODS

Thirteen female club volleyball players (age:  $20 \pm 1.7$  years, height:  $167.8 \pm 7.1$  cm, mass:  $66.5 \pm 10.2$  kg) participated. Participants performed five trials each of three jump-landing tasks. The first was a controlled jump-landing task [1] (Figure 1). The second was a jump-landing for spiking a volleyball set to the outside, which only involved a setter and an outside hitter (Figure 2). The third was a jump-landing task for spiking a volleyball set to outside in a simulated game situation, which involved a team on both sides (Figure 3). Jump-landing trials were

recorded simultaneously by three cameras at a sample frequency of 60 Hz. The cameras were calibrated for a direct linear transformation procedure using a 32-point calibration frame [3].

Participants' bilateral shoulders, greater trochanters, knees, and ankles were manually digitized. Three dimensional coordinates of body landmarks were obtained from synchronized two dimensional coordinates and calibration parameters [3]. Participants' stance time, jump height, knee flexion angle at initial contact and peak knee flexion during landing for both left and right legs, and knee-ankle distance ratio at the lowest height were extracted for analysis. Paired t-tests and Spearman's rank correlation tests were performed between two jump-landing conditions for each variable ( $\alpha=0.05$ ).

Figure 1: Controlled jump-landing task

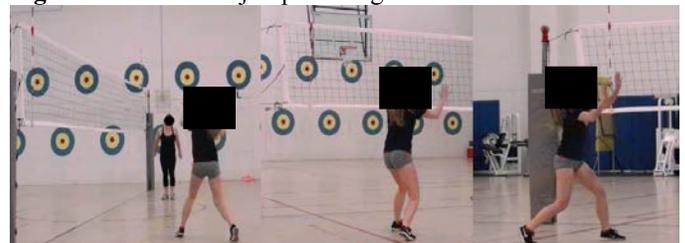

Figure 2: Volleyball specific jump-landing

Figure 3: Jump-landing in a simulate game

## RESULTS AND DISCUSSION

The results of the paired t-tests showed significant differences between the controlled jump-landing and both the volleyball-specific jump-landing and jump-landing in a simulated game for all variables. The Spearman's rank correlation test showed significant correlations for both the volleyball-specific jump-landing and jump-landing in a simulated game for most variables (Table 1).

ACL injuries commonly occur during jump-landing tasks. A controlled drop-jump has been developed to screen movements associated with increased ACL loading to predict ACL injuries with inconsistent findings [1, 2]. The findings of the current study suggest that the landing patterns during a controlled jump-landing task are different and do not correlated well with the landing patterns in a simulated game in female volleyball players. As most ACL injuries occur during actual sports environment, the findings raise concern regarding the testing specificity of utilizing a controlled jump-landing task to screen for risky movement patterns. Screening athletes during actual sports environment is likely to increase the predictive value of using landing biomechanics for future ACL injuries and warrant future investigations.

While screening athletes during sports environment is desirable, requirements of the direct linear transformation procedure such as clear views from cameras, accurate calibration, limited calibration volume, and manual digitizing may compromise its practical application. Other equipment such as inertia sensors and portable goniometers that can be

worn by players without affecting their normal movements may overcome these obstacles.

Meanwhile, the similar and strongly correlated landing patterns between the volleyball-specific landing and landing in a simulated game suggest that a sports-specific task without a simulated game environment could be used as a surrogate when data collection in game situations is not feasible. A volleyball-specific task may be implemented in a lab setting by hanging a ball from a ceiling without involvement of extra players.

## CONCLUSIONS

Landing patterns in a controlled jump-landing task may not represent landing patterns in game situations in female volleyball players. Screening athletes' movement patterns in a sports environment is likely to improve the predictive value of landing biomechanics for ACL injuries. The similarity and correlation between the volleyball-specific landing and landing in a simulated game indicate that it could be possible to utilize a sports-specific landing task in a non-game setting to screen for poor landing mechanics.

# Implications of Added Body Mass on Lower Limb Joint Kinetics During Vertical Jumping

Hailey N. James, Lindsey E. Allison, Douglas W. Powell, Lawrence W. Weiss, Max R. Paquette

email: [mrpquette@memphis.edu](mailto:mrpquette@memphis.edu); web: <http://www.memphis.edu/shs/research/mal.php>

## Introduction

Vertical jump (VJ) ability is considered to be a good predictor of athletic performance and physical capabilities (1). Vertical jump ability is applicable to sports involving high power generation and vertical displacement. For example, basketball players need high power production for rebounds, blocks, and shots. Due to the importance of VJ ability, the maximal vertical jump has been used as a test to monitor improvements in jumping ability following a strength and conditioning program (3). Therefore, it is essential to understand factors that affect lower limb joint powers during jumping. One of these factors is body mass. Following off-season rest periods, athletes may return to training with slightly more body mass due to inactivity or reduced training intensity. In running, added body mass to the trunk (i.e., abdominal area) increases peak knee flexion and extensor moment as a result of increased forward trunk lean (2). Added trunk mass may also alter joint kinetics during vertical jumping which may impact the power contribution of each lower limb joints.

The purpose of this study was to assess the acute effects of added mass equivalent to a 5% increase in body fat on countermovement vertical jump (CVJ) performance and lower limb joint kinetics. We expected a decrease in CVJ performance and a proximal shift in lower limb joint power generation with the added mass.

## Methods

Seventeen recreationally trained young adults (8 women and 9 men) participated in this study (22±2yrs; 70.8±15.2kg; 1.72±0.11m; 15.1±8.1 % body fat). Participants attended one testing session to perform maximal vertical jumping wearing their own footwear. All participants were instructed to refrain from exercise the day before the testing session.

Testing involved measurement of anthropometric variables, a general warm-up on a cycle ergometer, a dynamic warmup including 10 bodyweight squats and 5 jump squats, three maximal unloaded countermovement vertical jumps (**Normal**), and three maximal loaded (**Weighted**) CVJ. During the Weighted CVJ a weight vest with added mass equivalent to a 5% increase in body fat was worn by all participants. Rest periods of at least 75s were provided between maximal jumps. Maximal vertical jump height was standardized to standing reach height. During jumping trials, a 9-camera motion capture system (240Hz, Qualisys AB, Sweden) and a force platform (1200HZ, AMTI, Inc.) were used to collect kinematic and ground reaction force data, respectively.

Visual 3D software (C-Motion, Germantown, MD) was used to process and analyze both kinematic and kinetic data. Newtonian inverse dynamics were used to compute internal joint moments (Nm). Angular joint powers (W) were computed as the product of joint moments and joint angular velocities. The average of all biomechanical variables from each jumping trial during the concentric phase of jumping was used in statistical analyses. Repeated measures ANOVA were used to compare mean from within-subject comparisons (Normal vs Weighted) ( $p<0.05$ ). Cohen's  $d$  effect sizes were also computed to compare the effect magnitude of mean differences.

## Results and Discussion

As hypothesized, vertical jump performance was *greater* during the Normal (41.4±11.1cm) compared to the Weighted condition (39.7±10.6cm;  $p=0.003$ ;  $d=0.16$ ). However, the small effect size suggests that the meaningfulness of this difference is questionable.

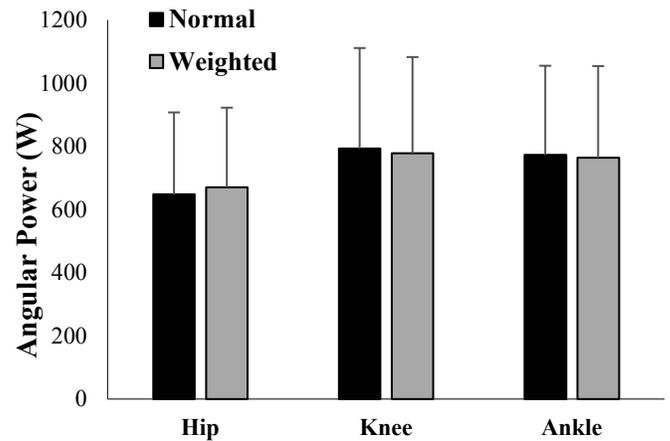

Peak plantarflexor, knee extensor and hip extensor moments were greater during the Weighted

compared to Normal jumping condition (**Table 1**). This is not surprising considering the joint moments were not normalized to body mass. The small effect sizes (i.e.,  $d < 0.22$ ) for joint moments suggests that these moment differences have minimal importance. Increased body mass, as simulated by a weighted vest, increases peak knee flexion angle and knee extension moment during running (2). In vertical jumping, the deeper countermovement position would increase ankle and knee ROM, which increases joint lever arms and as a result, increases peak internal moments (**Table 1**). In addition, the deeper countermovement leads to increased forward trunk inclination, and therefore, greater hip flexion. This greater hip flexion with added mass would result in an increased hip extension ROM from the bottom of the countermovement to take-off and a greater lever arm at the hip, which would explain the increased hip extension moment (**Table 1**).

As expected peak lower limb joint powers were redistributed proximally during Weighted compared to Normal jumping (**Figure 1**). However, statistically, condition means were not different at the hip ( $p=0.14$ ;  $d=0.09$ ), knee ( $p=0.30$ ;  $d=0.03$ ), and ankle ( $p=0.15$ ;  $d=0.05$ ) joints. During maximal vertical jumping, the power generated at the knee joint is suggested to be limited due to this forward trunk inclination (4). Although not significant, our findings are similar, such that during the Weighted condition, peak knee power was slightly lower. The observed power redistribution from ankle and knee to the hip during Weighted jumping may be the result of increased angular hip extension velocity. Hip extension velocity may be increased to displace the trunk through the larger angular displacement in an effort to match the timing of joint angular positions at take-off with added trunk mass.

## Conclusions

The findings from this study suggest that added trunk mass to simulate a 5% increase in body fat does not significantly change peak lower limb joint powers during vertical jumping. However, we observed a redistribution in lower limb joint powers from the knee and ankle to the hip joint when mass is added to the trunk. This may suggest that any body mass gained by athletes during the off-season may impact the lower limb joint strategy to produce power during jumping.

## INTRODUCTION

Appropriate landing is important for minimizing the risk of injuries during human locomotion such as running, walking, and landing from jump. Incorrect landing techniques may lead to anterior cruciate ligament (ACL) and ankle injuries. There are about 200,000 ACL injuries occurring every year during sport activities. ACL injuries occur during quick deceleration or landing maneuvers in non-contact situations.

A previous study indicated that increased ground reaction forces (GRF) during landing are associated with increased ACL loading [1]. Commonly used GRF variables are calculated from time domain analysis, including peak force, loading rate, and time to peak force. From frequency domain analysis, previous studies identified high and low frequency components during the landing phases from running and walking activities [2-3]. Different frequency content may be related to different landing strategies. However, there is a paucity of study focusing on frequency domain analysis of landing from jumps. Thus, the current study used frequency domain analysis to classify landing performance from counter movement jump (CMJ).

## METHODS

Forty four Division I football players (body mass  $101 \pm 18.96$  kg, age  $21 \pm 2$  years old) participated in the study. All athletes wore training shoes and thirty of them wore the same type of training shoes. The testing included three trials of a countermovement jump. Jumping and landing kinetic variables from dominant and non-dominant legs were measured from two force platforms (AMTI) at a frequency of 1000 Hz. Trials were considered to be valid only when both jump and

landing were on the force platforms. Informed consent was obtained from each athlete in accordance with the protocol approved by the Institutional Review Board.

Jump height (JH) was calculated based on flight time. GRF was normalized to body weight. Direct current component was eliminated from the signal. Frequency components of the vertical force during the landing phase were identified by the Fourier transformation. 99% of the signal power was reconstructed from the inverse Fourier transform of the first several significant components to verify the validity of the Fourier transform.

## RESULTS AND DISCUSSION

The reconstructed signals from components lower than 80 Hz (Figure 1) matched well with the original signals ( $RE < 1\%$ ). Athletes demonstrated different spectra of frequency for left and right legs (Figure 2). Starting from the lowest frequencies, components were added up to a percentage of the total signal power. The result showed that the frequency components of some athletes were below 10 Hz while of some others were always higher than 15 Hz. When athletes were classified into three groups based on spectral ranges at 85 percentage of the total signal power: A: 4-10 Hz, B: 12-27 Hz, and C: 30-44 Hz. There were 11 athletes in group A (JH  $55.9 \pm 5.4$  cm), 29 athletes in group B (JH  $54.7 \pm 10.9$  cm), and 4 athletes in group C (JH  $47.1 \pm 9.0$  cm). Paired T-tests indicated that the JH differences were not statistically significant among these 3 groups ( $p > .05$ ); however, frequency spectra among the 3 groups were significantly different. Therefore, different landing techniques rather than jump height were more likely to affect the frequency components of the landing forces.

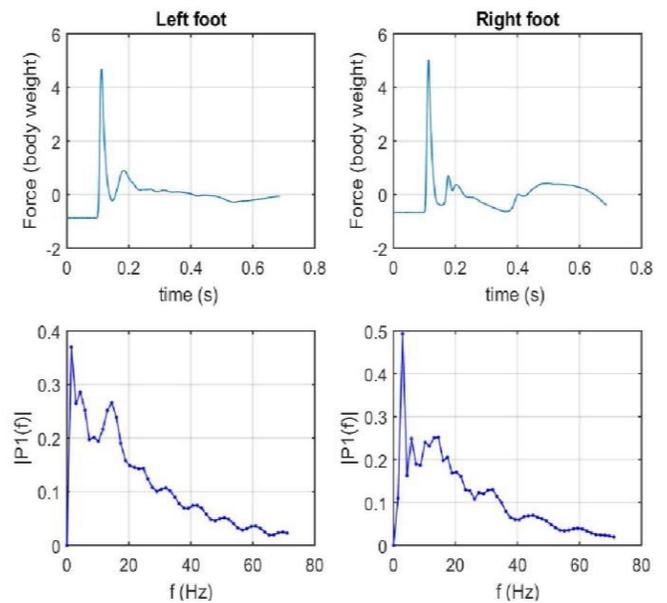

Different landings may also relate with different mechanisms of impact attenuation. Previous studies [3,4] demonstrated impact attenuation is a combination of active and passive mechanisms. Active mechanisms involve muscle pre-activation, contraction, and segment configuration. A previous study [1] indicated changing body segments configuration, such as trunk, hip, knee flexion angles and type of foot landing would affect landing time, magnitude and direction of impact force. That may explain the three groups of athletes that had different distributions of frequency components from the current study. Passive mechanisms include bone, articular cartilage, and shoes. Bone and articular cartilage may respond to high and low impact frequencies differently [4]. How this relates with risk of injury still needs to be studied.

## CONCLUSIONS

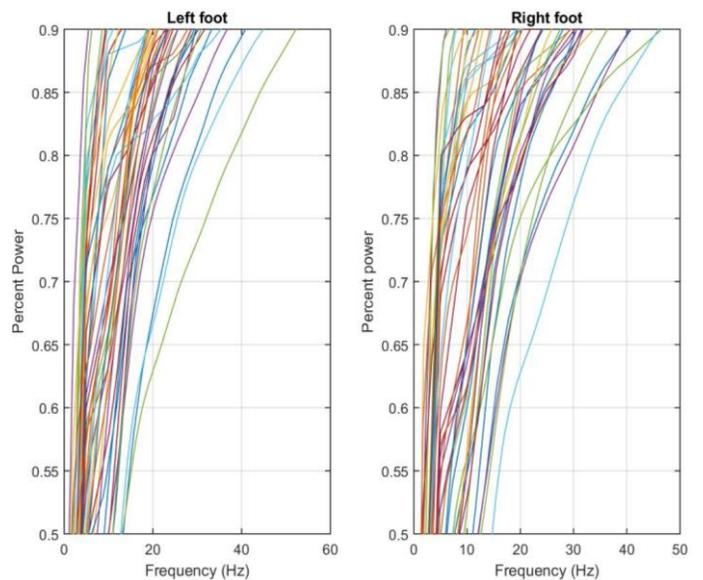

By applying frequency domain analyses, we have quantified the frequency components of landing forces from CMJ. For athletes with similar jump height, different frequency components distribution were observed. Frequency domain analysis provides another method to classify landing performance. Frequency analysis provides another method to classify landing performance. Future studies may include kinematic information to explore the mechanism of changes in frequency components and whether frequency components are related to potential injury risk factors.

# ALTERED LOWER EXTREMITY KINEMATICS AND GROUND REACTION FORCES IN DISTRACTED VS. FOCUSED LANDING

Patrick Rider, Hannah Ellis, Caroline Yeomans, Alison Ratti, and Nicholas Murray

East Carolina University, Greenville, NC, USA  
email: riderp@ecu.edu

## INTRODUCTION

Soccer is the most popular sport in the world with rapidly growing numbers of female participants. Soccer also has one of the highest injury rates of any sport, especially among female athletes. Most of these injuries occur to the lower extremity. As a result, significant research has been conducted to quantify injury mechanisms in female soccer players and to evaluate training programs that help correct mechanical problems that might place an athlete at a higher risk of injury. For example, athletes who land with more extended knees or with larger vertical ground reaction forces have shown a higher incidence of non-contact ACL tears<sup>1</sup>. Many of these risk factors are modifiable through training and many training protocols have shown promise in reducing injury rates.

The most effective training programs involve incorporating muscle strengthening and plyometric drills, as well as biomechanical feedback from a coach to alter landing kinematics. Athletes are given feedback about body position and are instructed to focus on their landing technique<sup>2</sup>. While this is important for proper instruction and training purposes, it is less clear if these mechanical changes translate to the field where the athlete's focus will be on an external task, such as heading a ball or moving into position to defend in response to an opposing player. The purpose of this study, was to investigate landing mechanics between distracted and focused landing in female collegiate soccer players. We hypothesize that when distracted with an external task, participants will land with more joint extension and greater peak vertical ground reaction forces.

## METHODS

Twelve female Division 1 soccer players completed the study protocol (BMI  $24.7 \pm 2.58$ ). Each participant was cleared by the team athletic training staff prior to protocol implementation. All participants provided university approved informed consent and completed a short questionnaire to obtain information about position (4 defenders, 5 midfielders, and 3 forwards) and weekly training/playing time ( $1050 \pm 228.2$  total minutes per week). Each athlete had on average  $13.5 \pm 2.4$  years of playing experience. Goal keepers were excluded from this study.

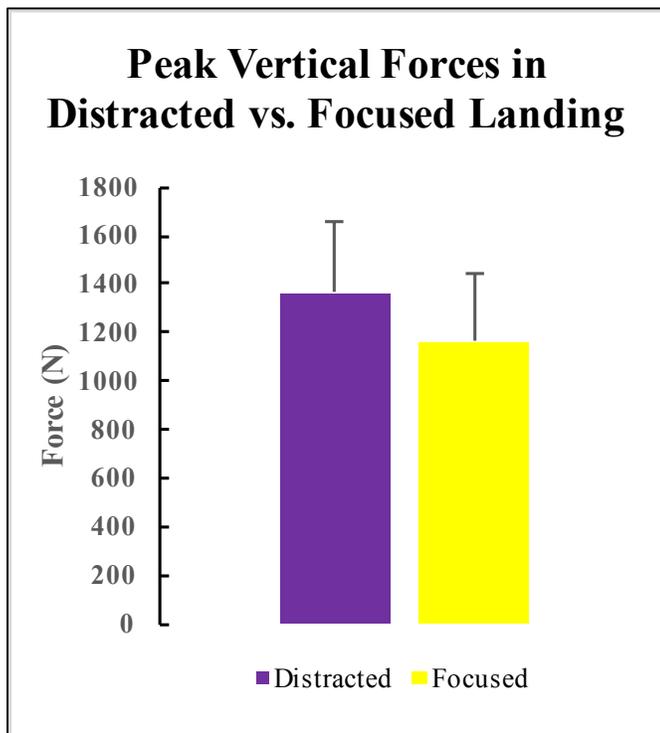

Participants were prepped for trunk and bilateral lower extremity 3D motion capture utilizing two force platforms. They were asked to perform 3 successful trials of 2 separate jump landing tasks. The distracted landing task involved an externally focused task which required the participant to tap their forehead a suspended soccer ball. The ball was suspended on a tether from the ceiling and placed approximately .15 meters anteriorly and .20 meters vertically from the participant's starting position. During the focused landing condition, the participant was instructed to jump and focus their attention on their landing. Peak jump height was not different between the two conditions (Distracted:  $0.27\text{m} \pm 0.6\text{m}$  vs. Focused:  $0.27\text{m} \pm 0.7\text{m}$ ). Condition order was randomized between participants.

## RESULTS AND DISCUSSION

The distracted landing condition showed significant differences in sagittal plane joint kinematics for the hip, knee and ankle at contact compared to the

focused condition (Table 1). Participants in the distracted condition landed significantly more extended at all lower extremity joints.

There was also a large increase in peak vertical ground reaction forces in the distracted landing condition. Results are presented in the following figure.

These results indicate that an athlete’s focus has a significant impact on their mechanical performance of a task and training protocols might benefit from incorporating external focus elements into their design. This finding is supported in the motor control literature as well, in that external focus is

more critical to performance in experienced athletes, while internal focus is more useful when learning a task<sup>3</sup>.

### CONCLUSIONS

The results of this study supported our hypothesis that distracted landing produces more extended joint positions at contact and increases in external ground reaction forces. Additionally, the results support the predictions of the constrained action hypothesis.<sup>4</sup> Jump landing training protocols could potentially be more effective by utilizing externally focused tasks during implementation because this may allow the motor system to more naturally adapt an individual’s landing mechanics. Future studies should investigate whether the incorporation of this type of methodology during jump training provides a better transfer of correct mechanics to in-game situations.

## INTRODUCTION

Anterior cruciate ligament (ACL) injuries are common in the United States with an annual incidence rate estimated of 250,000 [1]. High vertical ground reaction forces (vGRF) and knee valgus in jump landings are thought to contribute to these injuries. With young females experiencing a risk of ACL injury 2-6 times greater than males [2], they may benefit from focused training interventions on landing strategies.

Performance feedback can be used clinically to assist individuals in developing motor control patterns that decrease vGRF and minimize knee valgus in jump landings [3]. However, there has been disagreement on whether feedback is effective in modifying performance over the long term [4]. It is possible that this effect is mediated by the nature of the deficits displayed in landing performance prior to receiving training.

The aim of this study was to identify whether visual feedback is effective in improving landing kinetics in females presenting initially with high or low vGRF. We also evaluated whether these effects would persist at an immediate post-test and following a 1-week retention.

## METHODS

Forty-nine college-aged females (Age:  $21.2 \pm 1.6$  years, Height:  $169.6 \pm 7.0$  cm, Mass:  $67.7 \pm 9.7$  kg) participated on two days of testing. Each performed a total of 30 drop landings from a hang bar with mid-foot positioned 50 cm above the ground. Kinematic data were collected using a 15 camera motion capture system (Motion Analysis

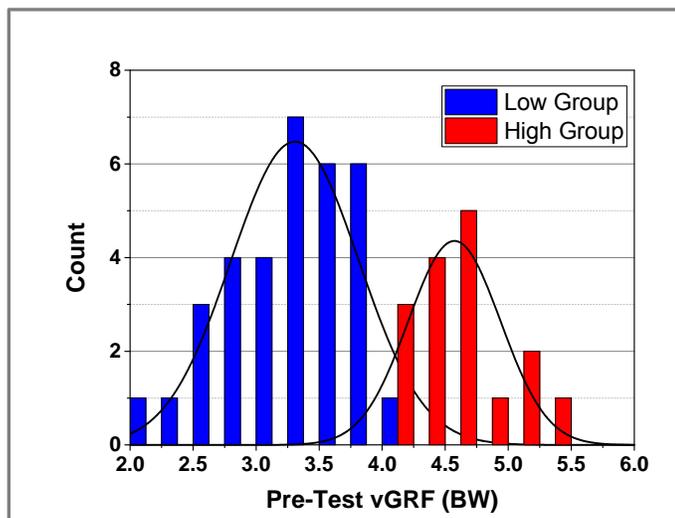

Corporation, Santa Rosa, CA, USA) sampled at 180 Hz. Bilateral kinetic data of vGRF were collected by two force platforms (Model 4080, Bertec Corporation, Columbus, OH, USA) sampled at 1800 Hz.

Participants performed 6 baseline landing trials (Pre-Test) where they were instructed to land as softly as possible without specific instructions on how to alter their performance. Following a 1-minute rest period, 12 training trials were completed. Post-trial feedback of peak vGRF was given immediately after landing and displayed for 10 seconds. Feedback was provided as a numeric representation in multiples of body weight (BW) on a projector in front of the participant. After the set of training trials, feedback was removed and participants completed 6 Post-Test trials. Participants returned 1 week later for a follow up session of 6 trials without feedback (Retention). They were not provided any instruction on how to lower peak vGRF values to avoid bias.

Means for peak vGRF (BW) were calculated for the Pre-Test, Post-Test, and Retention trial blocks. A hierarchical cluster analysis (HCA) using Ward's method with squared Euclidean distances was performed to yield two different sub-groups based on peak vGRF from the Pre-Test (High Group vs. Low Group). A repeated measures mixed model ANOVA (alpha set to 0.05) was performed on peak vGRF to analyze Group by Time effects. Effect sizes (Cohen's *d*) were calculated between post-hoc comparisons. Statistical tests were completed using SPSS, version 24 (IBM Corporation, Armonk, NY, USA).

## RESULTS AND DISCUSSION

The HCA produced two sub-groups from Pre-Test values: High Group ( $n = 16$ ); Low Group ( $n = 33$ ) (Fig. 1). The ANOVA produced a Group by Time interaction ( $F(2,46) = 13.0, p < 0.001$ ). The High Group with a large initial vGRF ( $4.57 \pm 0.37$  BW) demonstrated a reduction in Post-Test and Retention peak vGRF values from Pre-Test ( $-9.0\%$ ,  $4.16 \pm 0.64$  BW,  $p < 0.001, d = -0.79$ ;  $-12.0\%$ ,  $4.02 \pm 0.43$  BW,  $p < 0.001, d = -1.37$ ). The Low Group with a smaller initial peak vGRF ( $3.31 \pm 0.51$  BW) was not different between Post-Test and Retention values ( $-0.25\%$ ,  $3.30 \pm 0.52$  BW,  $p > 0.05, d = -0.02$ ;  $+4.3\%$ ,  $3.45 \pm 0.53$  BW,  $p > 0.05, d = +0.27$ ) compared to the Pre-Test.

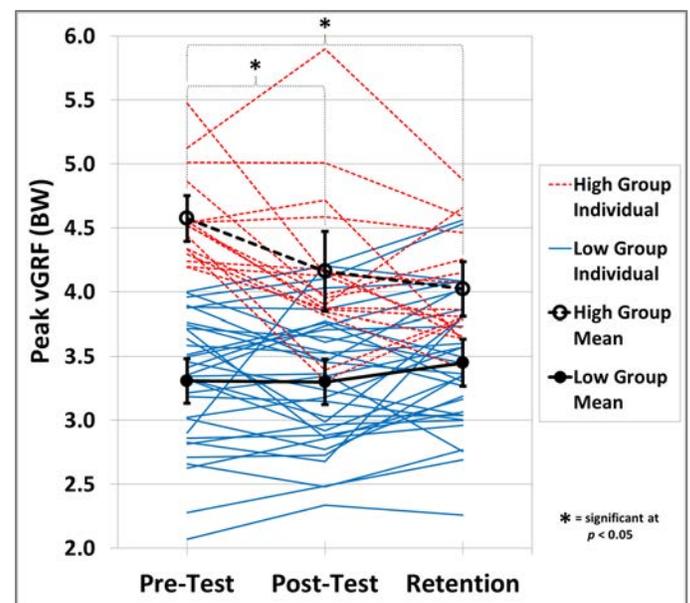

**Figure 1:** Distributions of Pre-Test vGRF values by Group resulting from hierarchical cluster analysis.

The results suggest that participants starting with a high initial vGRF are able to integrate visual feedback of peak vGRF to make meaningful improvements (Cohen's  $d$ : 0.8-1.3) in landing kinetics within-session and at 1-week retention. However, this feedback did not cause a change in vGRF in individuals presenting with a low initial vGRF (Fig. 2). This may represent a floor effect in this performance variable where this group may be already at a reduced risk of ACL injury and the lack of room for improvement would yield negligible gains [3]. Rather than being hindered by an unnecessary form of feedback, these individuals

may instead benefit from feedback of kinematic and other performance variables to lower injury risk factors other than peak vGRF.

## CONCLUSIONS

Visual feedback was shown to be effective for individuals presenting with a high vGRF. This suggests that feedback may need to be matched to an individual's unique needs determined through pre-test screening of landing performance analyzing variables such as peak vGRF. Future efforts will focus on using HCA to classify individuals based on pre-test kinematic performance variables.

**Figure 2:** Performance curves of peak vGRF by Time condition for all individuals. Group means are shown with  $\pm 95\%$  confidence intervals.

## INTRODUCTION

Increased forces between the femur and acetabulum are commonly accepted as a mechanism for damage in traditional hip osteoarthritis, and a proposed factor in femoroacetabular impingement [1]. Males have been reported to land with a hip dominant landing strategy that is associated with a reduced risk of knee injury [2]. The resulting hip loading associated with this landing strategy is not fully understood.

Unfortunately, hip joint forces cannot be directly measured via non-invasive methodologies. These forces can, however, be estimated through musculoskeletal modeling using measured kinematics and kinetics [3,4]. A comprehensive understanding of hip joint loading during landing in a healthy population will provide a foundation for comparison to symptomatic pathological hips.

The purpose of this study was to understand if there is an interaction between gender and limb side on hip mechanics during unilateral drop landings. Females have been associated with significantly higher vertical ground reaction forces during landings [5,6]. As such, we hypothesized females would exhibit a concurrent increase in maximum hip joint force (HJF) compared to males.

## METHODS

Forty-two healthy, physically active participants between the ages of 18 and 30 (21 females, 60.37±9.27kg, 1.65±0.07m; 21 males, 80.37±16.26kg, 1.79±0.09m) volunteered to complete single leg drop landings (height = 40cm). Five trials on each landing leg were collected and order was counterbalanced. Ground reaction forces (GRF) and three-dimensional (3D) marker coordinate data were collected synchronously using a Bertec flush mounted force plates (2000Hz) and an

eight-camera Vicon motion capture system (200Hz). Raw 3D marker coordinate and GRF data were low-pass filtered using a 4th-order, Butterworth filter with a cutoff frequency of 10 Hz.

In OpenSim [3], a 19-dof, eight segment generic musculoskeletal model (Gait2392) with doubled strength and activation, was scaled for each subject using individual anthropometric data from a calibration trial. The inverse kinematics problem was solved at each frame to compute model joint angles using a least squares approach while accounting for constraint weights [7]. Inverse dynamics were addressed using calculated joint angles and measured GRF data to identify net joint reaction forces and moments necessary to maintain equilibrium. Muscle forces were estimated using static optimization at each time step with inverse dynamics outputs, external load data, a scaled model and the sum of muscle stress squared as the optimization criteria. The JointReaction analysis algorithm within OpenSim was used to calculate hip joint forces (HJF). Resulting hip torques were verified as null.

The landing phase was defined from initial contact to maximum knee flexion of the landing limb. Resultant HJF and GRF were calculated from force components and normalized by body weight. HJF is expressed as the pelvis on the femur in the femoral reference frame. Timing of peak force represents time from initial contact. Variables of interest were maxHJF, time of maxHJF, maxGRF, 3D hip, knee, and ankle range of motion (ROM), and 3D hip, knee, and ankle angles at initial contact (IC). All variables were evaluated for normality and homogeneity. Separate 2x2 ANOVAs were used to assess differences between each variable with respect to gender and limb side ( $p < 0.05$ ).

## RESULTS AND DISCUSSION

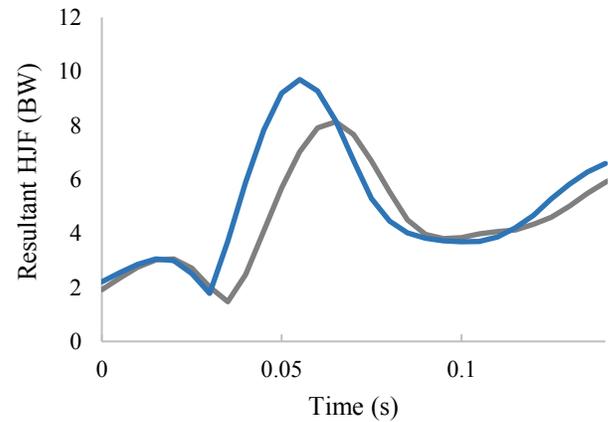

Significant main effects of gender were identified for maxHJF, maxGRF, time of MaxGRF, HipFlexionIC, and HipRotationIC ( $p < 0.05$ ). No other significant main effects were reported for gender. Across all variables examined, there were no significant findings pertaining to main effect for limb nor any interaction effects between gender and limb.

As hypothesized, females performed landings with greater peak resultant GRF and HJF. The HJFs reported in this study are higher than those measured from instrumented prosthesis [4], however, they are comparable to modeling estimates in a young, healthy population [8]. The increased peak forces were present despite a lack of gender differences in lower extremity ROM during the landing phase. PeakGRF occurred earlier in the landing phase in females than males, while MaxHJF timing did not indicate a significant gender effect. This suggests both genders experience MaxHJFs at similar timing between initial contact and maximum knee flexion. Previous research has suggested males absorb more force at the hip during landing while females rely more heavily on the knee [2].

Studies utilizing single leg landings have yielded less consistent findings when compared to those with double leg landings. In the current study, males demonstrated less hip flexion and more internal rotation than females at initial contact. The large standard deviations observed across all variables may indicate that a variety of landing techniques are being employed by participants. Yet, overall, bilateral differences were not identified for any of the kinetic, timing, and angular measures. Similar findings have been reported in studies using healthy populations [5].

## CONCLUSIONS

Bilateral differences were not indicated for unilateral landings with a sample of young, healthy, and recreationally active participants. Females experienced greater GRF and HJF peaks, yet only the GRF timing was different. Examining the muscle kinematics and energetics may help disentangle gender differences in hip loading.

**Figure 1:** Sample male and female HJF for one right leg trial with similar times from initial contact to maximum knee flexion. Grey represents male and blue represents female.

## INTRODUCTION

Altered neuromuscular activation patterns following a musculoskeletal injury may inhibit the control of the lower extremity during dynamic movements. [1] Physically active individuals often perform complex dynamic movements that require both shock absorption and postural stabilization. Postural stability has been linked to ankle and knee injuries [2] and examining factors associated with stabilization may provide insight as to how musculoskeletal injuries may influence stability and joint loading during dynamic movements.

The purpose of this study is to determine if physically active individuals with a self-reported knee injury occurring within the last year have decreased knee extension strength, altered landing mechanics, or altered stabilization strategies during a forward jump single-leg landing task. We hypothesized that those with a history of knee injury will have decreased knee extension strength, land with a stiffened knee strategy, and with less stability compared to controls.

## METHODS

Knee strength and lower extremity kinematics were collected on 31 physically active males, 16 with a previous self-reported knee injury (age  $26.9 \pm 3.9$  yrs; height  $180.48 \pm 6.31$  cm; mass  $83.69 \pm 7.68$  kg), and 15 control subjects without a history of lower extremity injuries (age  $25.2 \pm 2.7$  yrs; height  $179.32 \pm 5.36$  cm; mass  $82.27 \pm 8.02$  kg). All subjects performed a self-reported injury history questionnaire guided by a licensed clinician. Injuries were defined as a musculoskeletal injury event that occurred within the last year from the date of the questionnaire and resulted in altering physical training for at least one day. Healthy control subjects reported no history of lower extremity injuries. Individuals reporting bilateral injuries, neurological conditions, and musculoskeletal injuries affecting other lower

extremity joints were excluded from this analysis. Knee extension strength (KES) was collected using an isokinetic dynamometer (Biodex Medical Systems Inc., Shirley, NY) and normalized to body mass for group comparisons. Lower extremity kinematics, peak vertical ground reaction forces (pkVGRF), and dynamic postural stability index (DPSI), a composite of the anterior-posterior, medial-lateral, and vertical ground reaction forces were collected during a Forward Jump Single-Leg Landing task (FJSL). Subjects were instructed to jump forward, clearing a hurdle approximately 31 cm in height, landing on a single limb, stabilizing rapidly and maintaining postural control following the landing.

Subjects were outfitted with reflective markers and lower extremity kinematics were collected using an 8-camera 3D motion capture system (Vicon Motion Systems Ltd, Centennial, CO) and vertical ground reaction forces were collected by two force plates at 1200 Hz (Kistler Instrument Corp., Amherst, NY). Data were processed with Vicon Nexus software using a Plug-in-Gait model. Marker trajectories were filtered using a Woltering filter with a predicted mean square error at 10mm. Hip, knee and ankle flexion and adduction angles at initial contact (@IC) and peak flexion angles (pkFlex) were recorded from the kinematic analysis.

Independent samples t-tests were used to examine differences in KES, kinematics, and DPSI between those who experienced a knee injury within the last year (INJ) and those with no history of lower extremity injuries (CON). Paired samples t-tests were used to evaluate lower extremity asymmetries between the injured and uninjured limbs within the INJ group using the same measures as the group comparison. Pearson correlation coefficients examined the relationships between KES, landing kinematics, pkVGRF, and DPSI. All data were

analyzed using SPSS (SPSS 22 IBM Corp, Armonk, NY). Significance level was set at  $\alpha = 0.05$ .

## RESULTS AND DISCUSSION

There were no significant differences in KES, pkVGRF, or DSPI between groups ( $p > 0.05$ , respectively). The INJ group had significantly lower KES in the injured limb compared to that of the uninjured limb ( $p = 0.006$ ) and these KES asymmetries were not observed in the CON group ( $p = 0.331$ ), Figure 1). There were no significant differences between the injured and uninjured limb within the INJ group for any of the kinematic measures, pkVGRF or DSPI ( $p > 0.05$ , respectively). Within the INJ group increased KES significantly correlated to a decreased pkVGRF and an improved DSPI (Table 1) but only when landing on the uninjured limb. When landing on the injured limb, KES did not correlate to pkVGRF, DSPI or any kinematic measure ( $p > 0.05$ , respectively). HipFlex@IC correlated to pkVGRF during the FJSL task for both the injured and uninjured limb (Table 1) while AnkleFlex@IC correlated with pkVGRF for the injured limb only (Table 1). Though there were no significant differences between the INJ and CON groups, we found between limb KES asymmetries within the INJ group that were not observed in the CON group. Furthermore, the asymmetrical KES observed in the INJ group may influence pkVGRF and DSPI differently between limbs.

Individuals reporting a knee injury within the last year may experience decreased KES for a significant period of time following the injury. Though asymmetrical KES within the INJ group did not lead to asymmetrical pkVGRF, or DSPI it may have

altered the strategies used between the different limbs to achieve similar shock absorption and stabilization. Based on the lack of correlations between KES and the biomechanical outcomes on the injured side, individuals may attempt to compensate for the decreased KES by relying more on the ankle during landing. Due to the limited sample size, complexity of the task, and the differing severities of the knee injuries further research is needed to determine if specific compensation strategies are utilized for shock absorption and stabilization and examine if these strategies translate to other dynamic movements.

## CONCLUSIONS

Individuals who reported having a knee injury demonstrated KES asymmetries within one year following their injury. Further research is needed to investigate how decreased muscle function, including KES and neuromuscular function following a knee injury influence joint specific loading and dynamic joint stability during both bilateral and unilateral dynamic movements.

# DYNAMIC VALGUS DURING DROP LANDING RESULTS IN DECREASED LATERAL PLANTAR PRESSURE

<sup>1</sup> Christopher Ferrigno, <sup>1</sup> Jade He, <sup>1</sup> Philip Malloy, <sup>1</sup> Markus A. Wimmer

<sup>1</sup> Rush University Medical Center, Chicago, IL, USA  
email: christopher\_ferrigno@rush.edu, web: <http://asb2017.org/>

## INTRODUCTION

Anterior cruciate ligament (ACL) injuries are highly debilitating and commonly occur in sporting activities involving sudden stops and change of direction. Following ACL reconstruction (ACL-R), re-injury rates to the ipsilateral or contralateral knee are as high as 31% [1]. Movement asymmetries such as increased dynamic valgus at the knee during sport-specific tasks such as the box drop vertical jump test (DVJ) are associated with ACL rupture and persist following ACL-R. These aberrant movement patterns place high demands on the ACL, increasing the likelihood of re-injury three-fold [2]. Such patterns are modifiable [3]; therefore, detecting asymmetries during sport-specific tasks is crucial for determining at-risk individuals.

Clinically, identifying lower limb movement anomalies using semi-quantitative two dimensional (2D) video recording or 3D analysis is time consuming and impractical for most settings. Detecting plantar pressure is quick and affordable, making it clinically feasible. Faulty kinematic responses during the DVJ have a large frontal-plane component; therefore, similar medial-lateral pressure shifts likely occur during dynamic valgus.

The purpose of this proof-of-concept pilot study was to explore the plantar pressure response to three different landing strategies during the DVJ. We hypothesized that healthy subjects demonstrate higher lateral plantar pressures during hip abducted landing, while demonstrating lower lateral pressures during hip adducted landing.

## METHODS

Eight healthy participants were enrolled in this institutional review board approved study at Rush University Medical Center (29.9±4.6yrs, 2 women,

BMI=25.3±2.9). All subjects were healthy with a self-reported absence of knee pathology, surgery to the lower extremities, or current pain in their lower extremities.

All subjects wore a standardized shoe (Dr. Comfort, FlexOA, Mequon, WI, USA) containing a pair of fully-integrated pressure-detecting shoe insoles (OpenGo, Moticon GmbH, Munich, Germany) with built-in 13 capacitive sensors (Figure 1).

**Figure 1.** The Moticon OpenGo Insole.

Subjects completed a total of 6 DVJs from a box (31cm high) (Figure 2). For all jumps, subjects were instructed to drop forward off the box and immediately perform a sub-maximum vertical jump. During the first set of 3 jumps, subjects performed their jumps according to previous work [3] with their feet initially positioned 35 cm apart on the box. To increase the dynamic valgus for the final set of 3 jumps, a foam block was placed between the distal thighs. Subjects were instructed to perform the DVJs without releasing the foam block from between their knees.

**Figure 2.** The DVJ. The subject preparing to drop from the box (left) and landing with a self-selected technique (center) or with dynamic valgus (right).

Plantar pressure data was wirelessly downloaded and processed with OpenGo Software (Moticon GmbH, Munich, Germany). The maximum pressure from each of the 26 total sensors was recorded from each during the first half of the initial landing following the drop from the box. The three trials for each DVJ condition were averaged. To examine whether imparting a dynamic valgus resulted in a change in medial or lateral foot pressure, select sensors were grouped to represent the entire lateral foot, medial foot, or different regions of interest during landing (Figure 3). For the medial foot, sensors 0, 2, and 6 were selected since they are likely to contact the floor during the first half of stance (far left). For the lateral foot, sensors 5 and 9 were selected and grouped to capture the plantar loading on the lateral surface for the 5<sup>th</sup> metatarsal heads (sensor 5) and heel (sensor 9) during the first half of stance (far right). Comparisons were made for these specific pressure sensor groupings.

Statistical analyses were performed using SPSS 23 (IBM, Armonk, NY). Paired t-tests were used to compare the plantar pressures of sensor groupings.

## RESULTS AND DISCUSSION

Paired t-tests revealed that jumping with knees directed medially using a foam block resulted in a considerable decrease in plantar pressures in the sensor group representing the entire lateral foot (sensors 5,7,9,11) and select sensors (sensors 5,9) (Table 1). No significant changes were measured in the sensor groupings of the entire medial insole ( $p > 0.152$ ) or selected sensors 0, 2, and 6 ( $p > 0.071$ ).

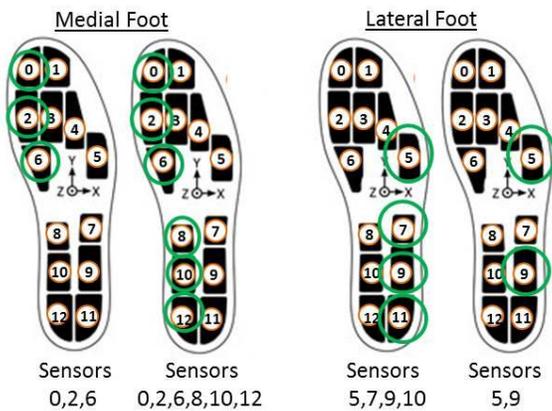

In this proof-of-concept study, lateral plantar pressure reduced bilaterally during the induced dynamic valgus landings. A larger study to further explore the changes in plantar pressure, as well as the potential for using plantar pressure-based as a feedback training tool, are warranted.

## CONCLUSIONS

This pilot study suggests that plantar pressures decrease in the lateral foot during a landing position which places the athletes at risk for ACL injury or re-injury during sport.

## INTRODUCTION

The lower extremity, especially at ankle and knee joints, is more vulnerable to injuries during movements that involve repetitive landings. Adjustments in landing posture control can be beneficial for mediating the magnitudes of the impact forces, joint loading, and energy absorption [1]. These altered landing strategies, however, will be negatively affected when neuromuscular fatigue has been developed by prolonged exercise [2, 3]. It is noteworthy that a majority of these studies on fatigue effects have demonstrated different responses in both mechanical characteristics and lower extremity control strategies. However, there is limited evidence that indicates whether the biomechanical changes of the lower extremity are related to the type, site, or severity of fatigue.

The aim of this study was to determine the effect of two typical fatigue protocols on sagittal plane joint mechanics, stiffness, and energy absorption during drop landings.

## METHODS

Fifteen collegiate male players (age:  $20.9 \pm 0.8$  yrs; height:  $175.5 \pm 4.2$  cm; weight:  $68.9 \pm 5.5$  kg) with an average of 4.2 years of experience in jumping events were recruited to participate in the study. They were asked to be in the laboratory and to complete landing tasks within one of the two fatigue-induced protocols on two separate days. A period of 1 week rest was required between visits to ensure that fatigue was eliminated and the two protocols would not affect each other.

The participants were asked to complete the bipedal drop landing (DL) tasks from a height of 60 cm.

The DL technique required the participants to step off from a landing platform without losing balance, and as naturally as possible with a toe-heel landing. 5 successful trials were acquired for analysis. The DL tests were performed before and after conducting each of the fatigue-induced protocols.

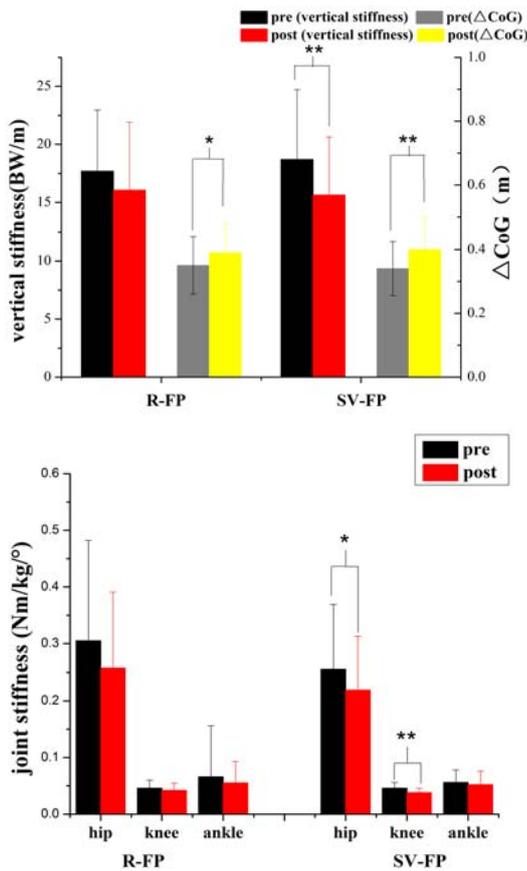

Constant-speed running fatigue protocol (R-FP) and shuttle sprint + vertical jump fatigue protocol (SV-FP) were used in the study [2, 3]. R-FP required participants to run at 4.0 m/s on a treadmill until they felt fatigue maximally and could not continue running. The participants were considered to have reached a fatigued condition when the HR of the participant reached 90% of his age-based maximum HR. SV-FP consisted of five consecutive vertical jumps followed by a set of 6×10 m shuttle sprints. The participants were required to repeat the above sequence at least five times until they could not reach 70% of the maximal vertical jump height for all five jumps.

During the procedure of either fatigue-induced intervention, the highest HR was recorded. Meanwhile, the rating of perceived exertion (RPE) for each participant was acquired immediately after the intervention was completed. 3D kinematics (Vicon, 240 Hz) and ground reaction force (Kistler, 1200 Hz) were measured simultaneously. The variables included joint moment, stiffness, and energy absorption. The first, second, and third peaks of the hip ( $M_{H1}$ ,  $M_{H2}$ ), knee ( $M_{K1}$ ,  $M_{K2}$ ,  $M_{K3}$ ), and ankle joint movement ( $M_{A1}$ ,  $M_{A2}$ ) were selected [1]. Two-way ANOVAs and paired sample t-tests were used to determine the influence of independent variable (fatigue × protocol) on the dependent variables (kinetics, energy absorption, and stiffness) using SPSS 21.0. The significance level was set at  $\alpha=0.05$ .

## RESULTS AND DISCUSSION

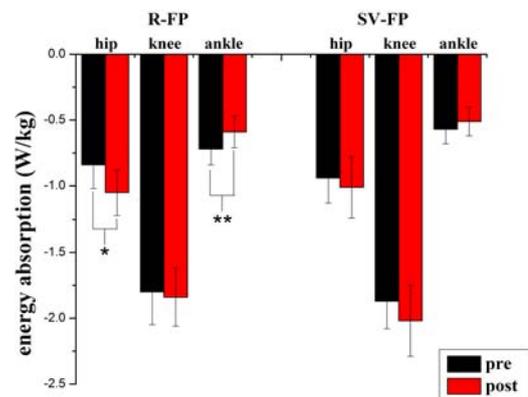

A significant increase in the center of gravity (CoG) displacement (Figure 1) as well as each joint of range of motion was found after fatigue both in R-FP and SV-FP. A significant increase in the  $M_{K1}$  was showed in post-fatigue compared to pre-fatigue using SV-FP, which suggested that knee extensor moment might increase to resist GRF to prevent corruption of lower extremity.

The reduced vertical stiffness in SV-FP might be a protective landing control strategy during the impact phase. The joint stiffness results showed that the contribution in hip and knee were larger than ankle. However, no differences were observed in the stiffness using R-FP which may be explained by the lower-limb biomechanical adaptation for different protocols (Figure 1).

**Figure 1:** Effects of two fatigue protocols on vertical stiffness, center of gravity displacement (CoG, upper), and joint stiffness (lower).

Both fatigue protocols induced similar overall joint energy absorption. Specifically, the knee joint extensors accounting for about 55% of the total energy absorption were the major contributors to energy absorption, then the hip joint extensors group for further absorption during impact. Furthermore, our results revealed that a greater eccentric work was observed at hip joint (+25.1%) in R-FP with a less eccentric work done by ankle muscles (-19.1%). However, no changes were found in joint work for SV-FP which might due to different muscle fatigue induced by different protocols (Figure 2).

**Figure 2:** Effects of two fatigue protocols on energy absorption of lower extremity during landings.

## CONCLUSION

The control strategies of lower limb in a fatigued condition vs. non-fatigue were varying from different fatigue protocols in terms of kinetics, stiffness, and energy absorption of joints during landings. Specifically, changes in energy absorption were mainly observed in R-FP; while altered joint moments and stiffness were occurred in SV-FP.

# PERTURBATION OF SYSTEMS CONTRIBUTING TO NEUROMOTOR CONTROL OF POSTURE IN PERSONS WITH RECURRENT LOW BACK PAIN

<sup>1</sup> K. Michael Rowley and <sup>1</sup> Kornelia Kulig

<sup>1</sup> University of Southern California, Los Angeles, CA, USA  
email: krowley@usc.edu, web: pt.usc.edu/krowley

## INTRODUCTION

Non-specific low back pain (LBP) is an incredibly large problem for industrialized nations, with up to 80% of adults experiencing an episode at least once in their lifetime [1] and about a third suffering from recurrent or chronic symptoms [2]. Motor control changes during symptom remission have been identified in patients with recurrent symptoms including delayed and reduced activation of deep trunk muscles [3] and changes in trunk stiffness [4]. Treatment interventions designed from these findings and tested in randomized control trials, however, have not shown greater benefit over usual care [5]. In addition, while many researchers have promoted subgrouping of patients based on psychometrics and movement impairments, little work has been done investigating the interaction between these measures. The purpose of this study was to investigate the effects of dual-task interference on trunk control during a dynamic unstable postural task in participants with and without recurrent LBP. Associations between these effects and psychometric measures were also tested.

## METHODS

Six pain-free control participants (4 Females, 2 Males; Age:  $30 \pm 4$  yrs; Height:  $174 \pm 5$  cm; Weight:  $73 \pm 12$  kg) and four participants with recurrent LBP (3 Females, 1 Male; Age:  $25 \pm 1$  yrs; Height:  $169 \pm 7$  cm; Weight:  $72 \pm 9$  kg) were recruited to participate in the study and signed informed consent per Institutional Review Board guidelines. Control participants had no history of low back pain or any current musculoskeletal or neurological complaints. Participants with non-specific recurrent LBP have had at least two episodes per year for at least one year, but were in symptom remission at the time of testing.

Participants completed three 3 trials of a balance-dexterity task (Fig. 1), adapted from combining a lower-extremity-dexterity test [6] and single-limb balance. They then completed another three trials with a concurrent cognitive dual-task recalling a list of five numbers and performing mental arithmetic on those numbers. Two measures of trunk coordination were calculated: (1) correlation coefficients between motion of the thorax and pelvis in the frontal plane (trunk coupling) and (2) ratio of deep-to-superficial paraspinal muscle activity. Change in trunk coupling was calculated by subtracting trunk coupling R value during the dual-task from trunk coupling R value during the single-task. Participants also completed the validated Movement-Specific Reinvestment Scale (MSRS) [7,8] to provide a quantitative measure of attentional resources they typically devote to their movement. A higher score indicates greater tendency to invest conscious attention in movement. Means were compared between single- and dual-task conditions using dependent t-tests, and correlations were tested using Pearson's test. Statistical significance set at  $\alpha=0.05$ .

## RESULTS AND DISCUSSION

For the six control participants, the change in trunk coupling from single- to dual-task conditions (a positive value indicating an increase in coupling when the dual-task was added) trended toward negative association with MSRS score ( $R= -0.70$ ,  $p= 0.12$ ) (Fig. 2). A subset of three participants underwent EMG instrumentation of the paraspinals. These data indicated that pain-free participants who scored high on the MSRS (and therefore decreased their trunk coupling under dual-task interference) also increased the ratio of deep (multifidus) to superficial (erector spinae) muscle activation ( $R=0.87$ ,  $p=0.33$ ) (Fig. 3). This supports the

hypothesis that a control strategy utilizing increased superficial musculature and decreased deep musculature is not robust to attentional interference as we see the opposite occur in conditions of dual-task interference. The four participants with recurrent LBP showed an association between the change in trunk coupling from single- to dual-task conditions and MSRS score trending in the same direction ( $R = -0.89$ ,  $p = 0.11$ ) (Fig. 2). While the direction was the same as the controls, the data were shifted upward such that all participants increased trunk coupling when the dual-task was added. The deep-to-superficial muscle activation data did not reach significance ( $R = 0.51$ ,  $p = 0.49$ ) (Fig. 3).

These findings indicate that, in pain-free participants, there is no uniform change in trunk coupling during this dynamic task when a cognitive dual-task is added. Importantly, however, the change in dynamic trunk stiffness measured in each individual may be related to his or her score on the MSRS. In persons with recurrent LBP in symptom remission, however, all participants increased trunk coupling when the cognitive task was added, regardless of score on the MSRS. This is quite an

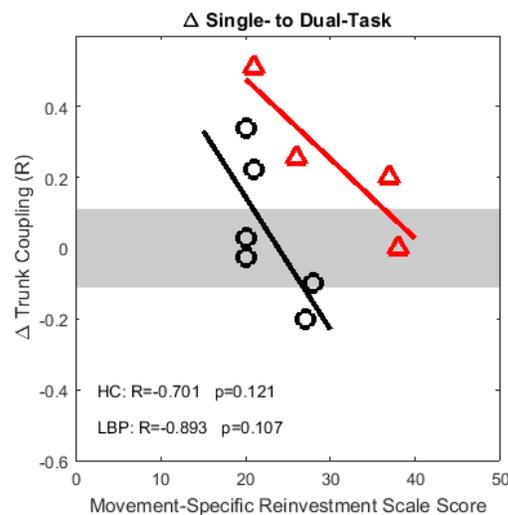

important finding which informs rehabilitation given that dual-tasking is often prescribed during rehab to practice real-life situations. These findings indicate that dual-tasking should be prescribed with caution as it may increase trunk coupling in this patient group. Findings from continued work on this study will help us learn more about interactions between attention, psychometric measures, and motor control measures in patients with recurrent LBP. Understanding these interactions will enhance multi-modal treatments, which up until now have been marginally successful.

## INTRODUCTION

Neck pain is one of the most commonly reported symptoms in primary care settings, and a major contributor to increasing healthcare costs[1]. Cervical manipulation is a common and clinically effective intervention for neck pain. However, the biological mechanisms underlying spinal manipulation remain unknown.

Chiropractic spinal manipulations are mechanical events that produce mechanical effects at the treatment site. These mechanical effects may initiate neurologic responses, leading to positive clinical outcome. However, little is known about the biomechanics of spinal manipulation. This lack of knowledge is due, in part, to the inability to accurately measure the intervertebral kinematics of the spine during manipulation.

Considering that previous research has documented pre- to post-manipulation changes in facet gapping[2], and that the cracking sound that is elicited during high-velocity low-amplitude manipulation (HVLA) is believed to be cavitation of the spinal facet joints, it is reasonable to hypothesize that facet kinematics are the (or one of the) primary kinematic mechanisms behind manipulation. Therefore, the purpose of this pilot study was to measure, for the first time, *in vivo* facet joint gapping during cervical spine manipulation.

## METHODS

Ten participants with acute mechanical neck pain were enrolled in this IRB-approved study. Cervical manipulation was performed by a licensed chiropractor within a biplane radiography system (Figure 1). The manipulation was performed using the thumb cervical extension technique. With the patient lying supine, the head rotated 90° away from the clinician, and the target segment on the upside,

the clinician delivered a thrust straight across the articular pillar with the thumb.

**Figure 1:** The biplane imaging system configured to collect dynamic biplane radiographs during HVLA manipulation. The X-ray sources are to the right, and image intensifiers and high-speed cameras to the left, providing sagittal-oblique views of the spine without occlusion from the clinician.

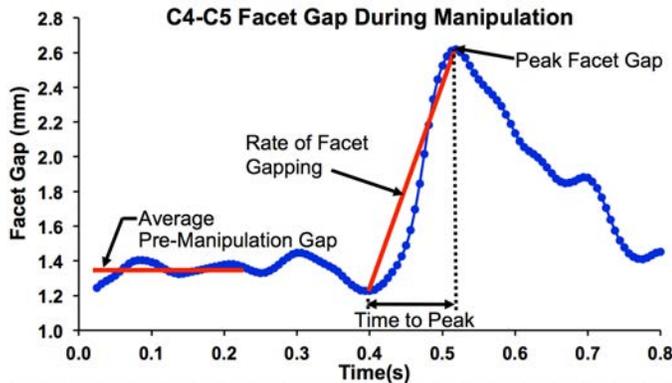

Synchronized, 2.0 ms duration pulsed biplane radiographs were collected at 160 images per second for 0.8 seconds during the manipulation. High resolution CT scans (0.29 x 0.29 x 1.25 mm) of C1-C7 were collected from each participant after the manipulation. A validated volumetric model-based tracking process was used to track bone motion during manipulation with sub-millimeter accuracy[3]. Bone kinematics were filtered using a 4<sup>th</sup>-order Butterworth filter with the filter frequency (10 Hz) determined by residual analysis[4]. Facet joint gapping was calculated as the average distance between adjacent articular facet surfaces.

Outcome parameters included the change in facet joint gap during manipulation (pre-manipulation to peak gap), the rate of facet gapping, and the time to peak facet gap (Figure 2).

## RESULTS AND DISCUSSION

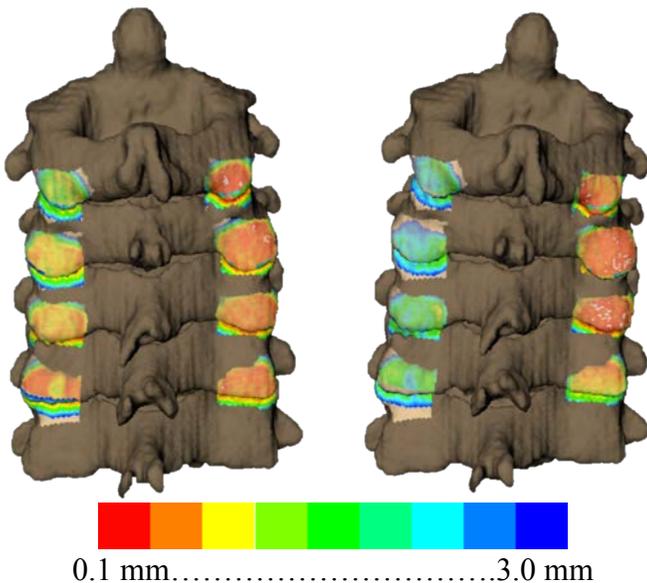

The upper cervical spine was occluded, either by the chiropractor's hands or the patient's mandible, for 3 of the 10 participants. Audible cavitation did not occur for one participant, and the timing between

the manipulation and radiographic imaging was not synchronized for 1 participant, leaving data from 5 participants available for the final analysis (2 M, 3 F; average age: 38±15 yrs.). Motion of 3 to 5 vertebrae from C2 to C6 was tracked during manipulation for each participant.

**Figure 2:** Facet gapping during manipulation and measured outcome parameters for one representative subject. Each blue data point represents one frame of tracked motion during the manipulation.

Facet joint gapping consistently occurred across all tracked vertebrae (Figure 3). This result demonstrates that manual manipulation affects the targeted and adjacent motion segments.

**Figure 3:** A posterior view of the cervical spine pre-manipulation (left) and during manipulation (right). Gapping of the left facet joints is demonstrated by the color-coded facet joint surfaces.

The maximum increase in facet gap from pre-manipulation to peak facet gap averaged 0.98±0.30 mm across the 5 participants, while the average increase in facet gap over all tracked motion segments was 0.78±0.32 mm. This maximum increase in facet gap during manipulation was more than double the peak facet joint distraction that occurs during full ROM flexion/extension in healthy individuals[5]. This finding confirms that manipulation induces facet joint motion beyond the normal physiologic range.

The average time to peak facet gap was 129±55 ms, slightly longer than the previously reported thrust duration during cervical manipulation (90 to 120 ms)[6]. The average rate of facet gapping over all motion segments was 7.4±2.9 mm/s. A strong relationship was observed between the rate of facet gapping and the increase in facet gap during manipulation ( $R^2 = 0.57$ ).

**CONCLUSIONS**

This study is the first to measure facet gapping during cervical manipulation on live humans. These preliminary results improve our understanding of the basic *in vivo* biomechanics of spinal manipulation. Continuing this line of research will allow clinicians and researchers to design better interventions that reliably and sufficiently impact the key mechanisms behind manipulation.

## INTRODUCTION

Lower back injuries are a major burden on society [1]. To reduce these injuries, potentially harmful tasks need to be identified, assessed, and modified. L5S1 resultant joint moments calculated from inverse dynamic modeling (IDM) are a powerful means of comparing the lower back demands of lifting tasks [2]. The accuracy of IDM moments depends on both the approach used and the veracity of any applied assumptions.

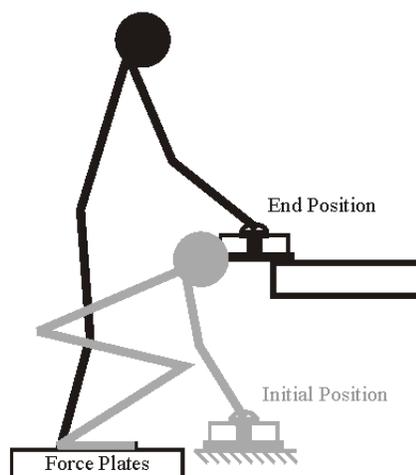

The two fundamental approaches for calculating L5S1 joint moments are characterized as top-down (TD) and bottom-up (BU) [3]. The BU approach requires lower limb segment motion, inertial characteristics and measured foot/ground forces [4]. In contrast, the TD approach uses upper body segments and hand/external load information. Less soft tissue and, thus, greater rigidity of the lower limb segments favors the application of the BU approach when foot/ground forces can be measured. In the absence of measured external forces and moments, or in more natural environments, assumptions of the load must be made. The impact of these assumptions on TD L5S1 resultant joint moments during lifting has not been established.

In this study, we compare the L5S1 resultant joint moment during a sagittal manual materials handling task, calculated from four IDM models: 1) BU with measured foot/ground forces; 2) TD model using a lifting box instrumented with force sensors measuring hand forces (TD\_FS); 3) TD without measured hand forces, but accounting for all known box inertial and kinematic characteristics (TD\_I $\alpha$ ); and 4) TD similar to TD\_I $\alpha$  but simplified by assuming no knowledge of the box's rotational kinematics (TD\_I0).

## METHODS

18 healthy young ( $\leq 35$  years) and fit (BMI $\leq 30$ ) male participants ( $25\pm 5$  years;  $178\pm 6$  cm;  $80\pm 10$  kg) agreed to an institutional informed consent prior to participation in this study.

A custom-built robotic lifting shelf was designed to repeatedly return a box (34 x 56 x 16 cm) to an initial position following each lift. The box handles were instrumented with six-axis force sensors (AMTI, Watertown, MA). The lifting motion was recorded at 100Hz with 8 near infrared cameras and 12.5mm passive reflective markers on the box and participants' body segments (Motion Analysis Corporation, Santa Rosa, CA). Force plates (Kistler Instruments Corporation, Amherst, NY) positioned under each foot recorded ground reaction forces during a 9.1kg lifting task from the floor to a knuckle high shelf (Fig. 1), performed at 4 lifts/minute.

**Figure 1:** Lifting task setup.

A 3D Newtonian-based IDM was coded in Matlab (Mathworks, Natick, MA). Body segment characteristics were defined by de Leva [5] and

Hanavan [6]. The L5S1 joint centers were projected 34% anterior from L5S1 spinous process [7]. Box inertial properties were modeled as a uniform rectangular prism. External sagittal L5S1 moments were reported relative to the pelvis' coordinate system. Lift durations were defined by the interval when the hand force exceeded 5N. For the TD\_I $\alpha$  and TD\_I0 approaches in which the hand force was not directly measured, the period of definable box movement was identified. To minimize effects due solely to modeling upper versus lower body segments, the average difference between the TD moments and a BU L5S1 moment during quiet standing was added to all of the TD moments.

Root mean square (RMS) and peak moments were computed from all L5S1 joint moment curves. Three lifts from each participant were used in repeated measure ANOVAs for both RMS and peak moments to compare the four approaches, with post hoc Tukey testing of model means ( $p < 0.05$ ).

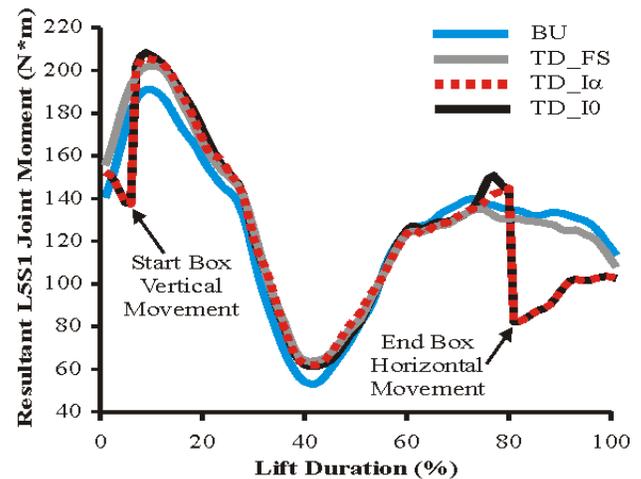

## RESULTS AND DISCUSSION

Table 1 shows that L5S1 moments were influenced by the choice of approach. All TD approaches resulted in significantly greater peaks and RMS than the BU approach. Within the three TD models, peak moments were equivalent (TD\_FS = TD\_I $\alpha$  = TD\_I0), but the RMS moments were higher with the use of the measured hand forces (TD\_FS > TD\_I $\alpha$  = TD\_I0).

As illustrated in Figure 2, load assumptions have the greatest impact on L5S1 moments in the initial and final portions of lifting. This highlights the importance of accurately defining when the load being lifted is in contact with a support surface. Without measured forces, the gradual loading and unloading which occurs as the load transitions from and onto the support surface cannot be assessed accurately.

**Table 1:** Mean  $\pm$  standard deviation peak and RMS values for the four models. Superscripts indicate model significance for peak [ $a \neq b$ ] and RMS [ $x \neq y \neq z$ ] moments ( $p < 0.05$ ). See text for abbreviation definitions.

L5S1 Moment (N*m)	BU	TD_FS	TD_I $\alpha$	TD_I0
Peak	195.2 $\pm$ 22.1 <sup>a</sup>	214.2 $\pm$ 27.4 <sup>b</sup>	219.0 $\pm$ 27.9 <sup>b</sup>	218.9 $\pm$ 28.6 <sup>b</sup>
RMS	144.7 $\pm$ 18.6 <sup>x</sup>	155.7 $\pm$ 23.3 <sup>z</sup>	150.3 $\pm$ 23.2 <sup>y</sup>	150.5 $\pm$ 23.3 <sup>y</sup>

**Figure 2:** Typical resultant L5S1 sagittal joint moment curves.

All TD approaches generated a  $\sim 10\%$  offset in L5S1 moments when compared to the BU approach. This offset is due to varied effects of rigid body segment assumptions, as the massive trunk segment in the TD models is far less rigid and its center of mass less predictable than any lower extremity segment. This discrepancy between average peak L5S1 moment(s) matches previous reports during a similar task [3].

Limitations of this study include: 1) analysis of a single planar task; 2) use of a single lifting speed; and 3) evaluation of only the L5S1 joint moment. It is hypothesized that examination of these limitations would further highlight the differences between the different IDM approaches.

# ESTIMATION OF MECHANICAL DEMANDS OF A LOWERING AND LIFTING TASK ON THE LOWER BACK IN PATIENTS WITH ACUTE LOW BACK PAIN

Iman Shojaei, Elizabeth G Salt, Quenten Hooker, and Babak Bazrgari  
University of Kentucky, Lexington, KY, USA  
Email: shojaei.iman@uky.edu

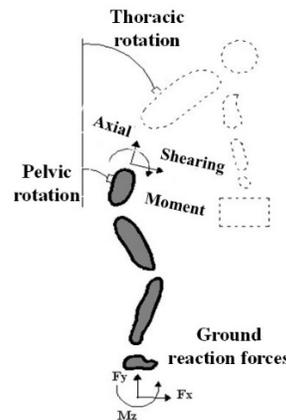

## INTRODUCTION

Mechanical loads experienced in the lower back during daily activities have been reported to be different between patients with chronic low back pain (LBP) and asymptomatic individuals. Whether such differences in mechanical loads have a causal role in transition from acute to chronic LBP is unclear. As the first step toward addressing such a research gap, the objective of this study was set to investigate differences in mechanical demands of a lowering and lifting task in the sagittal plane on the lower back between patients with acute LBP and asymptomatic individuals. Under free forward trunk bending and return, we have recently observed that patients with acute LBP adopt larger pelvic rotation and smaller trunk angular acceleration compared to asymptomatic controls [1]. Considering the impact of such kinematics difference on mechanical demands of task on the lower back [2], we hypothesized that the shearing and moment demands of the lowering and lifting task on the lower back to be, respectively, larger and smaller in patients with acute LBP versus controls.

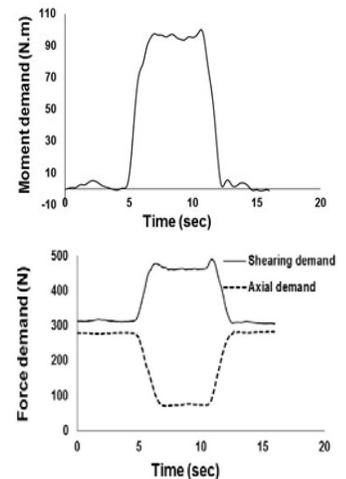

## METHODS

Nineteen females with health-care provider diagnosed acute LBP and nineteen matched asymptomatic controls were included in this study. Prior to data collection, all participants completed an informed consent procedure approved by the University of Kentucky's Medical Institutional Review Board. Participants were instructed to complete one symmetric lowering (a 4.5 kg load) and lifting task at their preferred cadence while standing on the center of a force platform (AMTI, Watertown, MA). Wireless Inertial Measurement Units (Xsens Technologies, Enschede, Netherlands) superficial to the thorax, pelvis, right thigh, and right shank were used to track the motion of these body parts, as rigid bodies. The kinematics and kinetics data were sampled at the respective rates of 50 and 1000 Hz.

A linked-segment model of the lower extremities and pelvis, developed in MATLAB (The MathWork Inc., Natick, MA, USA, version 8.6) [2], was used to estimate the mechanical demands of task on the lower back. The model included rigid bodies of seven segments (bilateral feet, shanks, and thighs as well as the pelvis) that were connected using frictionless point-contact joints (Fig. 1). A “bottom-up” inverse dynamics approach was used to estimate reaction forces and moments at the lower back which was considered to be the superior level of the pelvis. Projections of the lower back reaction forces perpendicular (axial) and parallel (shearing) to the L5-S1 intervertebral discs were calculated to represent the contribution of task demand to the total axial and shearing forces [2] (Fig. 1).

**Figure 1:** The linked-segment model used to estimate the mechanical demands of a lowering and lifting task.

**Figure 2:** A typical example of moment, axial, and shearing components of task demand on the lower back

The axial, shearing, and the moment components of task demand (Fig. 2) at the time of peak moment component (TPMC) as well as the peak pelvic and thoracic rotations along with the corresponding values of lumbar flexion were used as dependent measures for statistical analyses. Univariate analysis

of variance (ANOVA) tests were conducted on the task demand and the kinematics variables.

## RESULTS AND DISCUSSION

The moment component of task demand between patients with acute LBP and asymptomatic controls was not different. However, the shearing and axial components at TPMC were, respectively, larger and smaller in patients (Table 1). Moreover, the patient group completed the task with a smaller thoracic rotation and a smaller lumbar flexion (Table 1).

Our hypothesis on the smaller moment demand of task in patients was driven by our findings of similar peak thorax rotation but smaller peak angular acceleration during free trunk forward bending and return in patients vs. controls [1]. However, the patients adopted a different trunk motion under lowering and lifting task compared to free forward bending and return. Specifically, the thoracic rotation ( $F=0.14$ ,  $p=0.709$ ) and angular acceleration ( $F=0.35$ ,  $p=0.562$ ) at TPMC were not different between patients and controls under lowering and lifting task.

No differences in the moment demand of the task on the lower back between the groups, though an indication of comparable total internal tissue responses to the task demand, doesn't suggest comparable active muscle response. Specifically, the observed smaller lumbar flexion in patients (Table 1) suggests a smaller passive contribution of lower back tissues in offsetting the moment demand of task,

hence an indication of larger active muscle contribution.

Our hypothesis on the larger shearing demand of task in patients with acute LBP versus controls was based on our earlier observation of larger pelvic rotation in patients vs. controls during free forward trunk bending and return [1]. In contrast to free motion, peak pelvic rotation was found to be comparable between the groups (Table 1) during lowering and lifting task. Nevertheless, our hypothesis was approved as pelvic rotation at TPMC, where the statistical analyses for the task demands were performed, was larger ( $F=8.44$ ,  $p=0.006$ ) in patients.

## CONCLUSIONS

In summary, we found patients with acute LBP vs. controls adopt distinct trunk kinematics to perform lowering and lifting task which leads to larger shearing and smaller axial demands of the task on the lower back. Although the potential role of abnormal mechanics of lower back in transition of an acute LBP case to chronic and/or recurrent LBP should be investigated using longitudinal studies, our observation of differences in the lower back mechanics, both kinematics and kinetics aspects, between patients with acute LBP and asymptomatic individuals support such a role.

## INTRODUCTION

Cervical spondylotic myelopathy (CSM) is a neurologic condition resulting from cervical stenosis and spinal cord compression due to degenerative changes within the cervical spine.[1] These changes can include disc herniations, disc osteophyte complexes, ligamentum flavum hypertrophy, spondylolisthesis, or cervical kyphosis.[2] CSM is most common after the age of 50 years, but the age of onset is variable depending on the degree of congenital spinal canal narrowing and other factors.[1] Gait imbalance is a frequent symptom of CSM, and has been reported to be improved by surgical intervention.[3] Clinical studies have determined that individuals with CSM have a slower gait speed, prolonged double support duration, and reduced cadence compared to healthy controls.[4] In fact, difficulty with gait and balance are the most common manifestations of CSM.

**Figure 1.** Preoperative and postoperative MRI of a myelopathic patient

While there may be some debate as to when patients with radiographic cervical stenosis should undergo decompressive surgery, most surgeons will agree on

surgery for patients with moderate or severe myelopathy.[5] The purpose of this study was to evaluate the effect of cervical decompression surgery on the biomechanics and neuromuscular control of the lower extremities and spine during gait in patients with CSM before and after surgical intervention and to compare these parameters to a healthy control group.

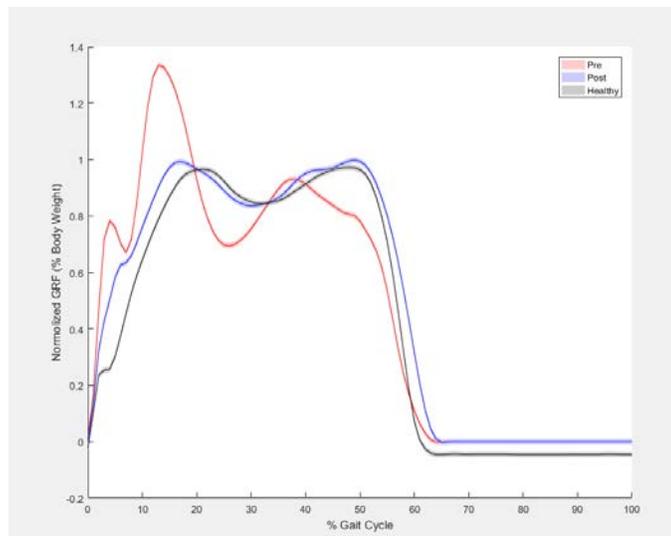

## METHODS

Ten subjects with CSM who have been deemed appropriate surgical candidates performed gait analysis one week before (Pre) and 3 months after surgery (Post3). Twenty healthy volunteers served as a control group. Fifty-one reflective markers (9.5 mm diameter) were utilized to collect full body three-dimensional kinematics using 10 cameras (VICON, Denver, CO) at a sampling rate of 100 Hz. Ground reaction forces (GRFs) were measured using three sequential force plates (AMTI, Watertown, MA). Trunk and lower extremity muscle activity was measured using surface EMG electrodes (Delsys, Inc, Natick, MA). For the test, the patient walked barefoot at his/her self-selected speed along a 10 meter walkway. Spine and lower extremity neuromuscular control, spatiotemporal and vertical GRFs were measured and recorded. A 2 factors repeated measures ANOVA was used to determine differences in gait patterns in adult CSM patients before and after their surgery and compared to the healthy controls.

## RESULTS AND DISCUSSION

After cervical decompression surgery, CSM patients had significantly faster walking speed (Pre: 0.82 vs Post3: 1.03 m/s,  $p=0.050$ ), longer step (Pre: 0.48 vs Post3: 0.60 m,  $p=0.013$ ) and stride length (Pre: 0.98 vs Post3: 1.14 m,  $p=0.050$ ). The delay in rectus

femoris onset was significantly improved (Pre: -0.13 vs -0.08 sec,  $p=0.037$ ) after cervical decompression surgery. The duration of semitendinosus and rectus femoris muscle activity decreased (ST: Pre: 53.2 vs 42.9 % of gait cycle,  $p=0.018$ ; RF: 48.8 vs 41.4 % of gait cycle,  $p=0.044$ ) after cervical decompression surgery and approached that of normal controls. The first peak of the vertical GRF was also found to occur earlier (Pre: 21.05 vs Post: 17.90 % of gait cycle,  $p=0.050$ ) after cervical decompression surgery (Figure 2).

**Figure 2.** Vertical ground reaction forces during gait from a representative patient with cervical myelopathy pre- and post-surgery and healthy adults.

In comparison to the control group, CSM patients preoperatively presented with a significantly slower gait speed (0.24 m/sec;  $p=0.037$ ), decreased step length (0.11 m;  $p=0.014$ ), stride length (0.20 m;  $p=0.019$ ), and increased step width (0.05 m;  $p=0.001$ ). Cadence, stride and stance times, swing-stance ratio, and single support time were not found to be statistically different. Control group muscle onsets were later (Multifidus: 0.69 sec,  $p=0.024$ ; Rectus femoris: 0.51 sec,  $p=0.036$ ; Semitendinosus: 0.38 sec,  $p=0.032$ ; Tibialis Anterior: 0.29 sec,  $p=0.044$ ) in comparison to preoperative CSM patients. Furthermore, control group muscle durations were significantly shorter (Multifidus: 8%

of gait cycle,  $p=0.035$ ; Rectus femoris: 9 % of gait cycle,  $p=0.021$ ; Semitendinosus: 11 % of gait cycle,  $p=0.018$ ; Medial Gastrocnemius: 6 % of gait cycle,  $p=0.049$ ) in comparison to preoperative CSM patients. Moreover, preoperative CSM patients presented with a lower vertical GRF 2nd peak (0.09% of BW;  $p=0.050$ ), later 1st peak (3% of gait cycle;  $p=0.048$ ) and valley (3% of gait cycle;  $p=0.049$ ) in comparison to the healthy group (Figure 2). After surgical decompression, CSM patients had normalization of their gait with only minor differences when compared to the control group.

## CONCLUSIONS

Cervical decompression surgery improved the gait pattern in patients with cervical spondylotic myelopathy. Based on our preliminary results, CSM patients walk slower and with reduced trunk and lower extremity function and efficiency in comparison to a healthy control group. However, surgical decompression resulted in faster walking speeds with longer steps and an increase in spine and lower extremity function and efficiency. These post-operative CSM patients actually had similar walking patterns in comparison to controls. Spine care providers should use gait analysis as part of their clinical evaluation to better understand the effects of the disease and its treatment on their patients' gait, function, and, ultimately, quality of life.

# EFFECT OF TRUNK POSITION AND ANGLE OF PULL ON SPINAL LOADING DURING A ROW EXERCISE

Lyndsay Stutzenberger and Michael Pavol

Oregon State University, Corvallis, OR, USA

email: [stutzenl@oregonstate.edu](mailto:stutzenl@oregonstate.edu)

## INTRODUCTION

Osteoporotic vertebral fractures are common in older age, particularly in women, and can have profound effects on quality of life [1]. Promisingly though, resistance-training programs that include rowing exercises have been shown to improve lumbar bone density [2]. Rowers also have increased lumbar bone density, arguably due to the loads that rows apply to the spine [3]. However, little is known regarding effects of variations in technique on spinal loading during a row exercise. Such knowledge may serve to improve exercise programs against osteoporosis. This study thus determined the effects of trunk position and angle of pull on spinal loading during row exercises.

## METHODS

Five healthy, premenopausal women (mean  $\pm$  SD age:  $43 \pm 3$  years, mass:  $60 \pm 6$  kg, height:  $165 \pm 3$  cm) with recent experience in upper-body strength-training exercises participated in this study after providing informed consent. After a task-specific warm-up, 32 reflective markers were placed on each participant's trunk and lower and upper limbs. Participants performed sets of standing rows against resistance from elastic tubing (Black Mountain Products, Lakemoor, IL). Rows were performed in each of two trunk positions: erect and flexed  $30^\circ$  from vertical, for each of three angles of pull: vertical, angled  $45^\circ$  from horizontal, and horizontal. For vertical and angled rows, the tubing looped through an anchor on the ground ahead of the participant. For horizontal rows, a researcher held the midpoint of the tubing still at the participant's chest height, ahead of her. Tubing used was selected based on calibration equations and measured body dimensions. To perform a row, participants either stood erect or squatted down until one hand reached

a marked position on the thigh at which the trunk would be flexed  $30^\circ$ , as established initially using an inclinometer. Beginning with arms outstretched towards the tubing's anchor point, participants smoothly pulled the tubing's handles to their chest in about 1 s, and with minimal pause, returned to their starting position. Sets of 3-4 repetitions of each row exercise were performed against an aimed-at peak resistance of 111 N. Kinematic data were recorded at 60 Hz with nine motion-capture cameras (Vicon, Los Angeles, CA) and ground reaction forces under the feet were recorded at 360 Hz by side-by-side force plates (Bertec, Columbus, OH). Body dimensions and weight were also measured.

Motion capture and force plate data were filtered at 7 Hz and 14 Hz, respectively. Marker positions relative to body segments and joint centers were then calculated (BodyBuilder, Vicon). Finally, the AnyBody Modeling System (Aalborg, Denmark) was used, with the lumbar spine model from the AnyBody Managed Model Repository (v1.2) and custom models of the lower limbs, to calculate compressive and anteroposterior shear forces at the L5/S1 spinal segment, as well as tubing length, from the collected data. The model was scaled to each participant, and inverse dynamics solutions were found to minimize the sum of the cubed muscle fascicle activations in each frame of data.

Peak spinal forces, normalized to body weight, were averaged across trials for each set, excluding trials with calculated peak tubing forces outside of 89-134 N. Mixed-model multiple linear regression was used to determine the effects of trunk position and angle of pull on peak compressive and anterior shear forces on L5 from S1 and their ratio. Fixed main and interaction effects, as well as random effects of participant, were modeled using dummy-variable or effects coding.  $p < .05$  was used for significance.

## RESULTS AND DISCUSSION

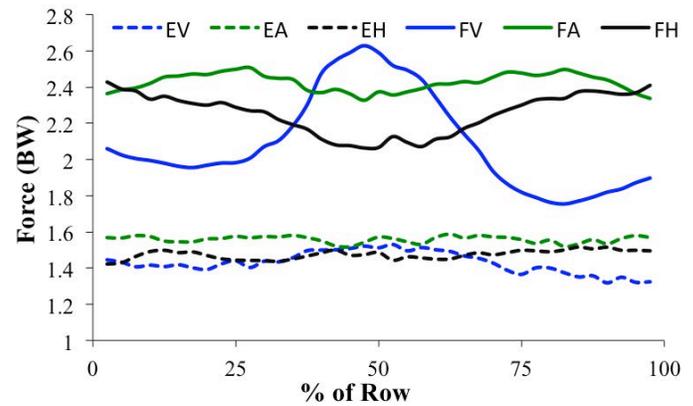

Independent of angle of pull ( $p > .36$  for interaction effect), the peak compressive and anterior shear forces on L5 from S1 during the rows were greater in the trunk-flexed than in the trunk-erect position ( $p < .001$ ; Figure 1, Table 1). This is consistent with the larger moment arms of the head-arms-torso weight and, for vertical and angled rows, of the tubing resistance force with the trunk flexed. The resulting larger external moment would require greater force from the lumbar extensors to offset.

Surprisingly, angle of pull had no effect on the peak compressive and anterior shear forces on L5 from S1 during the rows ( $p > .42$ ; Table 1). Qualitatively, the patterns of loading appeared to differ between angles of pull though, with peak forces typically occurring near the midpoint of vertical rows but near the start or end of horizontal rows (Figure 1). Changes in loading at L5/S1 during the rows reflect changes in both the tubing resistance force and the moment created by the upper limbs' weight. The resistance force is greatest at the row midpoint, but during horizontal rows, the moment created by the limbs' weight is greatest at the start and end. These offsetting influences can explain the present results.

As was true for the peak forces, angle of pull also had no effect on the ratio of peak compression to shear force at L5/S1 in either trunk position (Table 1). This suggests that no angle of pull is optimal for maximizing bone loading while minimizing loading of soft tissue. For peak tubing resistances near 111 N, standing rows at any angle of pull from vertical to horizontal may be equally appropriate for creating a potentially osteogenic stimulus at L5/S1. However, peak resistances larger than 111 N may be needed to produce an osteogenic response [3].

**Table 1:** Mean  $\pm$  SD values of the peak compressive force and peak anterior shear force on L5 from S1, in body weights, and the compression to anterior shear peak force ratio for each row exercise. \*  $p < .001$  vs. Erect.

Trunk Position	Angle of Pull	Compressive	Anterior Shear	Compression:Shear
Erect	Vertical	1.44 $\pm$ 0.19	0.15 $\pm$ 0.02	10.1 $\pm$ 2.0
Erect	Angled	1.85 $\pm$ 0.38	0.27 $\pm$ 0.09	7.2 $\pm$ 1.5
Erect	Horizontal	1.77 $\pm$ 0.32	0.26 $\pm$ 0.11	7.6 $\pm$ 2.4
Flexed	Vertical	2.73 $\pm$ 0.95*	0.45 $\pm$ 0.13*	6.0 $\pm$ 0.6*
Flexed	Angled	2.64 $\pm$ 0.53*	0.53 $\pm$ 0.09*	5.0 $\pm$ 0.4*
Flexed	Horizontal	2.69 $\pm$ 0.67*	0.52 $\pm$ 0.19*	5.4 $\pm$ 0.8*

**Figure 1:** Ensemble averages of compressive force at L5/S1 across the row. Timing is in terms of the tubing length, where 50% corresponds to maximal length. Type of row: E=erect, F=flexed, V=vertical, A=angled, H=horizontal. BW=body weight.

## CONCLUSIONS

The present results support the inclusion of row exercises performed in a trunk-flexed position with elastic tubing in exercise programs against spinal osteoporosis, as these produce greater spinal loading than similar rows performed with the trunk erect.

# THE EFFECT OF TWIST ON THE MECHANICAL PROPERTIES OF THE INTERVERTEBRAL DISC

Maxine Harvey-Burgess, Diane Gregory

Wilfrid Laurier University, ON, CAN

email: [harv8610@mylaurier.ca](mailto:harv8610@mylaurier.ca)

## INTRODUCTION

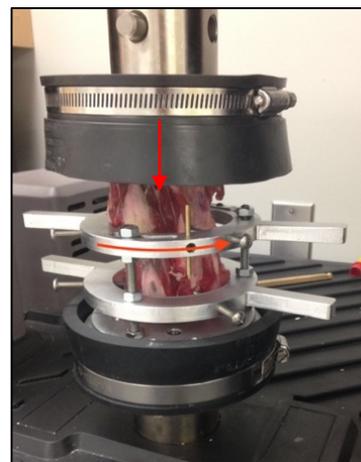

Herniation is a common injury to the intervertebral disc (IVD) and contributes to low back pain. The IVD contains the nucleus pulposus (NP) surrounded by the multi-layered annulus fibrosus (AF). Within the AF there are two structures which both have important adhesive properties: the interlamellar matrix and the intralamellar matrix. The interlamellar matrix is the area between adjacent AF layers and the intralamellar matrix is the area between collagen fibres of a single layer of the AF. IVD herniation occurs when the NP breaks through the layers of the AF through both the inter- and intralamellar matrices [1].

When combined with flexion, twist has been shown to contribute to low back pain [2]. In vitro, twist combined with flexion has been shown to increase the risk of IVD herniation and damage to the AF [3]. Therefore, it is plausible that twisting of the IVD may damage the inter- and intralamellar matrices due to the tensile and shear forces twist places on the AF. However, it remains unclear how twist affects the mechanical properties of the AF. The purpose of this study was to examine the effect of twist on the mechanical properties of the inter- and intralamellar matrices of bovine IVDs.

## METHODS

This study used 18 bovine IVDs from the caudal region. Dissected functional spine units (FSU) were loaded in a custom twisting jig and a mechanical testing system (MTS, Eden Prairie, MN) (Figure 1). Each FSU was subjected to one of four loading protocols for two hours: (1) 0N of compression and 0° of twist, (2) 1000N of compression and 0° of twist, (3) 0N of compression and 12° of twist, or (4)

1000N of compression and 12° of twist. All FSUs were preloaded with 125N of compression and 0° of twist for 15 minutes prior to the two hour loading protocol.

**Figure 1.** An FSU in twist and mounted in the mechanical testing system.

Following mechanical loading, three samples were dissected from each IVD. One sample, containing at least two adjacent layers of the AF, was used for a peel test. During the peel test, the sample was mechanically delaminated to measure interlamellar matrix strength. The variable of interest from the peel test was peel strength.

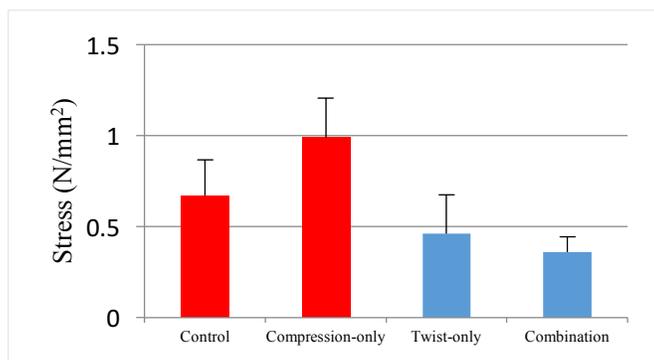

The other two samples were dissected down to single layers of the AF, which were subsequently mechanically tested in tension until failure. Care was taken to ensure that the collagen fibres of dissected single layers were oriented in the direction of twist. During the single layer tests, tension was applied perpendicular to the orientation of the collagen fibres in order to measure intralamellar matrix strength. The variables of interest from the

single layer testing included toe region stress/strain, stiffness, and yield point.

## RESULTS

Average yield point of the single layer samples exposed to 12° of twist, regardless of the magnitude of compression (0N or 1000N of compression), was 0.42 N/mm<sup>2</sup> (±0.27) while the average yield point of the single layer samples that were not exposed to twist (0N or 1000N of compression) was 0.81 N/mm<sup>2</sup> (±0.48) (p=0.025) (Figure 2).

Additionally, the average yield point of the single layer samples exposed to combination loading (twist and compression) was 0.36 N/mm<sup>2</sup> (±0.13) and the average yield point of the single layer samples exposed to compression-only loading was 0.98 N/mm<sup>2</sup> (±0.45) (p=0.019).

**Figure 2.** Average yield point from the single layer tensile test. The red bars indicate FSUs exposed to 0° twist while the blue bars indicate 12° twist.

Average peel strength of the samples exposed to 12° of twist (0N or 1000N of compression) was 2.10 N/mm (±0.61) and the average peel strength of the samples that were not exposed to twist (0N or 1000N of compression) was 3.46 (±1.83) (p=0.116) (Figure 3).

## DISCUSSION

The single layer samples exposed to twist (0N and 1000N of compression) had significantly lower yield points than the single layer samples that were not exposed to twist (0N and 1000N of compression). This suggests that twist, regardless of compression exposure, negatively affects the strength of the intralamellar matrix. Given that part of herniation progression is migration through clefts in the intralamellar matrix [1], this may explain why risk of herniation is higher when the IVD is twisted.

Though the difference between the peel strength of IVDs exposed to twist compared to those not exposed to twist was not found to be significant (p=0.116), there appears to be a trend of decreasing strength in twisted samples. Therefore, it is possible that twist may be negatively affecting the AF's ability to resist delamination, which would contribute to increased risk of herniation. Further examination is needed to confirm this.

## CONCLUSIONS

The lower yield points observed in the twisted single layer samples compared to those that were not twisted indicated that twist reduced the strength of the intralamellar matrix. Previous research has indicated that twist in combined loading scenarios increases the risk of IVD herniation [3]. According to the results of the current study, this increased risk could be due to twist causing damage to the AF, allowing herniation to occur more easily. Further research should explore the mechanical effects on the AF as a result of combination loading with flexion; a well-established risk factor for herniation.

# LUMBOPELVIC POSTURAL CONTROL SYSTEM ORGANIZATION IS ALTERED IN INDIVIDUALS WITH LOW BACK PAIN

<sup>1</sup>Courtney M. Butowicz, PhD, CSCS and <sup>1</sup>Sheri P. Silfies, PT, PhD

<sup>1</sup>Drexel University, Philadelphia, PA, USA  
email: silfies@drexel.edu

## INTRODUCTION

Movement impairments associated with low back pain (LBP) may result from alterations in the mechanisms by which the central nervous system processes sensory information in the presence of painful and non-painful stimuli. Current evidence proposes that patients with recurrent and chronic LBP exhibit altered sensorimotor integration that is coupled with a reorganization of the somatosensory and motor cortices [1-4]. Biomechanical studies assessing trunk postural control consistently demonstrate degradation in performance (increased center of pressure (COP) movement) in individuals with LBP, but analysis approaches have provided limited insight into the interaction of sensorimotor components of the system [5]. Non-linear analysis of system complexity (sample entropy) may provide information regarding the interaction of components within the neuromuscular control system and allow improved insight into system organizational changes in individuals with LBP.

The purpose of this study was to characterize differences in postural system organization between individuals with and without LBP when lumbopelvic control is challenged during unstable sitting.

## METHODS

Ten individuals with subacute LBP (5 males; age:  $26.1 \pm 12.1$  yrs; stature:  $168.6 \pm 8.7$  cm; mass:  $69.9 \pm 11.0$ kg) and 10 healthy controls [CTR] (5 males; age:  $30.5 \pm 8.5$  yrs; stature:  $169.7 \pm 8.8$  cm; mass:  $75.8 \pm 17.0$  kg) completed a biomechanical test of trunk neuromuscular control. Participants provided written informed consent and all procedures were approved by the local IRB. Trunk neuromuscular control was assessed using a custom apparatus

consisting of an unstable chair situated on an elevated force plate (Kistler, Inc. Fig. 1). Extremity constraints (e.g., arms across chest, feet supported, legs strapped together) required isolated trunk neuromuscular control to maintain upright sitting. Participants performed three-60s trials in an eyes open (EO) and eyes closed (EC) condition with a 60s break between trials [5].

**Figure 1:** Trunk neuromuscular control testing apparatus. Hemisphere under seat creates instability in the sagittal and frontal planes requiring trunk movement to maintain balance.

Force data were collected at 240 Hz (down sampled -120Hz) and COP variables derived to quantify mediolateral (frontal) plane control. Time series data were filtered (2nd-order low pass Butterworth filter at 10 Hz) to eliminate low amplitude measurement noise. A custom Matlab program (Mathworks, Inc.; Natick, MA) was used to calculate sample entropy (SEn; parameters  $r = 0.2$ ,  $m = 3$ ). SEn quantifies the structure of variability over time allowing for continuous assessment of changes in postural organization. SEn examines the logarithmic probability that a time series of data points a set distance apart will demonstrate comparable characteristics on the next comparison segment within the state space [6]. SEn values typically range between 0-2. Lower values represent increased regularity, which was interpreted as a more constrained system with fewer degrees of freedom and less organization of the control system components [7]. Between trial test-retest reliability of SEn was calculated (trial 1 to 3) using an intra-

class correlation coefficient (ICC<sub>2,1</sub>). A two-way ANOVA compared performance differences between groups and conditions (EO, EC) (P<.05) with partial eta squared presented as an index of size of the differences.

## RESULTS AND DISCUSSION

Test-retest reliability was good to excellent (Table). There was a significant main effect of group ( $F_{(1,18)}= 12.87, p= 0.002, \eta_p^2= 0.42$  and a significant interaction effect ( $F_{(1,18)}= 52.97, p< 0.001, \eta_p^2= 0.75$ ). Lumbopelvic system organization within the groups was similar during the EO condition. However, when visual feedback was removed the groups presented a significantly different organizational strategy (Fig. 2). The CTR group's organization became more flexible (higher SEN), while those with LBP became more constrained (lower SEN).

Table. Between Trial Reliability and Standard Error of Measurement

Group	Eyes Open		Eyes Closed	
	ICC	SEM	ICC	SEM
CTR	.77	.05	.88	.10
LBP	.81	.05	.67	.08

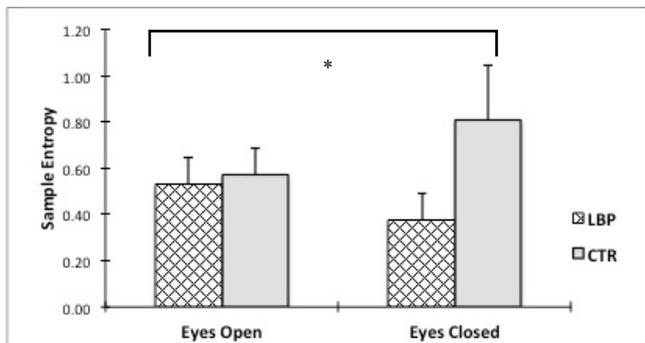

Figure 2: Group means and standard deviations for sample entropy during tests of isolated trunk neuromuscular control in eyes open and eyes closed conditions. CTR- control; LBP - low back pain; \* P<.05

Improved understanding of potential impairments in the interaction of components of underlying control mechanisms (visual, proprioceptive, vestibular, neuromotor) in patients with LBP may assist in therapeutic intervention choices. The significant interaction effect suggests that when a component of the control system (visual input) was removed, the control system's adaption was different between groups. The LBP group became less organized (more constrained), reducing the adaptive capability

of the lumbopelvic postural control system. The CTR group however, became more organized (less constrained), increasing the adaptive capability of the system. As sensory information was removed, the CTR group was better able to reorganize and increase interconnections between proprioceptive, vestibular and neuromotor system components in order to adapt to the challenge of unstable sitting. The response of individuals with LBP to removal of visual input suggests that vision may be a more dominant aspect of their control mechanism. This finding also suggests an inability to adequately reorganize or re-weight system sensory input [8] and may be reflective of impairments within or between the control system components. A similar response was reported following experimental impairment of trunk muscles (fatigue protocol) in which individuals without LBP adapted by increasing organization of the system, while those with LBP demonstrated less system organization during lumbopelvic movements. [9]

## CONCLUSIONS

Individuals with LBP demonstrate altered trunk postural control system organization compared to healthy controls particularly when challenged to adapt or reorganize the system following a perturbation of a system component.

## INTRODUCTION

Axial lumbar twist is a significant factor in low back pain development and cause of injuries [1]. The accurate measurement of spinal twisting is important in evaluating its biomechanical properties, yet our ability to measure this movement *in vivo* remains difficult due to skin movement artifacts and technological constraints [2]. Magnetic resonance imaging (MRI), computerized topography, and x-ray instruments have formerly been used as a gold standard for measuring and tracking axial twist of the spine [3,4]. While these results are important, the positions and postures that can be studied are very limited.

The use of ultrasonography (US) to measure tissues below the surface of the skin and lumbosacral motion has been used in previous studies with great success [5,6]. While MRI does represent a gold standard in internal measurements, it is often too costly, inaccessible, or unreasonable for certain postures or environments. The use of US to measure lumbar axial twist of the spine may provide a viable alternative, given its low cost, portability, and availability. The purpose of this study was therefore to validate the use of US to measure axial twist of the lumbar spine by comparing results obtained from MRI technology.

## METHODS

Twenty (10 males, 10 females) healthy participants were recruited for this study with no history of low back pain over the past 12 months who successfully passed the MRI screening process. A Siemens MAGNETOM 3T Trio MRI scanner was used to acquire 3D MRI scans, using a T1-weighted VIBE sequence, while a Sonosite M-Turbo medical

ultrasound imaging system, with a 3-5 MHz linear transducer was used to acquire US images.

Participants were secured to an MRI-safe spine board that had been customized to allow for both US and MR imaging. After manual palpation, a vitamin-E capsule was affixed to the skin so to ensure that the same vertebral levels were being compared. During the imaging session, the participant was imaged using US in either a neutral or an axially twisted (where a 30° padded wedge was locked to the spine board beneath the pelvis) position. The participant was then transferred to the MRI bed by four researchers while the participant remained motionless in order to maintain their position on the spine board. The lumbar spine was then imaged using MRI, followed by the reverse order such that each participant was imaged in both the neutral and twisted positions using both MRI and US.

Intervertebral axial twist was measured using OsiriX (© Pixmeo Sarl, V 5.0.1) and Matlab (9.1, The MathWorks Inc.) for MRI and US data, respectively. External surface markers were adhered to the thorax, pelvis, and US probe in order to determine vertebral body location relative to both the thorax and pelvis. Intervertebral rotation was calculated using spinous processes for all subjects, while a subset of images were used where both spinous process (SP) and transverse process (TP) could be identified. Welch two sample t-tests were used in both the full (measure using spinous process) and subset (spinous and transverse process) of data to compare MRI and US measures, where the motion was calculated relative to the thorax (USThor) and pelvis (USPel). A Bland-Altman plot analyzing agreement between the MRI and both the USThor and USPel measurement techniques was also performed.

## RESULTS AND DISCUSSION

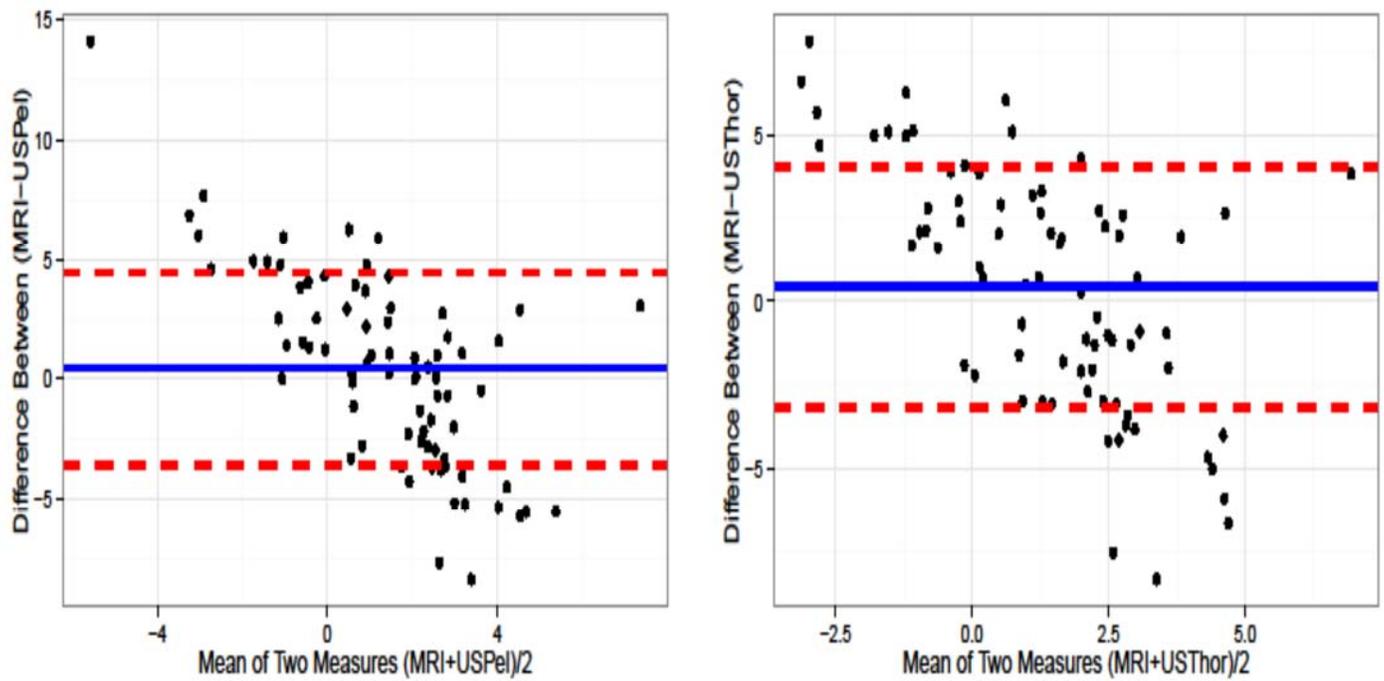

Figure 1: Bland-Altman Plots comparing MRI and US measurements of lumbar axial twist relative to the pelvis (USPel) and thorax (USThor).

T-test results are displayed in Table 1, demonstrating that there were no significant differences between MRI and US measures of axial twist, regardless of landmarks (SP or SP+TP) used. The Bland-Altman plots reveal that lumbar rotation measured using US and MRI are very similar (Figure 1).

The results of this study suggest that US can be a valid tool for measuring axial twist in the lumbar spine. Whether using the SP alone or a combination of SP and TP, it appears that the technique developed to measure rotation using a combination of surface markers and US does not solely depend on the ability to see the entire vertebral structure, leading the authors to believe that imaging of the thoracic spine in this manner would also be valid. Furthermore, we determined that there was no difference in intervertebral angles when calculating angles relative to the pelvis or thorax rigid body surface markers.

## CONCLUSIONS

This validation study has demonstrated that axial twist of the lumbar spine can be measured using the coordinated ultrasound and motion capture approach demonstrated in this study. The ability to use US to accurately measure spinal rotation vastly improves our understanding of how specific tasks and body positions affect the internal structures, thus providing researchers and clinicians an opportunity to better predict spinal motion patterns that result in injury.

# LOW VELOCITY COLLISION CHARACTERISTICS ASSOCIATED WITH CLAIMED LOW BACK PAIN

Kayla M. Fewster<sup>1</sup>, Robert J. Parkinson<sup>1,2</sup>, Jack P. Callaghan<sup>1</sup>

<sup>1</sup>Department of Kinesiology, University of Waterloo, Waterloo, ON

<sup>2</sup>-30- Forensic Engineering., Toronto, ON, Canada

email: kfewster@uwaterloo.ca

## INTRODUCTION

Up to fifty percent of individuals involved in low velocity collisions report low back pain (LBP) [1]. Epidemiological studies suggest there is an association between developing a whiplash neck injury from a motor vehicle collision and reporting low back pain, with the reported incidence of low back pain with a whiplash injury ranging between 40 to 60% of all whiplash cases [2,3].

Despite the statistical relationship, there is a lack of knowledge regarding injury mechanisms associated with LBP reporting. Frequently, lumbar injury (pain) is reported after low velocity collisions, even with little vehicle damage, a lack of objective evidence upon medical examination and negative radiographic evidence. As a result, assessments of injury remain solely reliant on symptom reporting, despite the psychosocial issues known to be present in litigated claims.

To assess causation of low back injuries claimed after collisions, forensic engineering firms are engaged to determine the likelihood that an injury was sustained. As a result, they have unique access to details from the collision to allow for an understanding of the detailed collision characteristics such as vehicle velocity changes and vehicle orientations. In addition, hospital reports and medical records are reviewed to assess the injuries claimed and any associated preexisting medical conditions. This unique source of data provides the rare opportunity to match reported collision circumstances with reported low back injury outcomes, circumventing the need for assessors and researchers to solely rely on occupant recall and reporting in understanding causation.

However, this data is rarely analyzed to understand 'population' trends and relationships. In order to

identify potential low back injury mechanisms resulting from low velocity collisions it is necessary to characterize and identify the physical dynamics of low velocity collisions that result in LBP claims and establish links between collision circumstances and injury outcomes. Therefore, the primary objective of this investigation was to characterize the physical circumstances of low velocity motor vehicle collisions that resulted in claims of low back injury.

## METHODS

This investigation involved the secondary analysis of a data set obtained from a forensic engineering firm based in Toronto, Ontario, Canada. Each analyzed case was obtained from a search of the firm's internal electronic database. The database was searchable by a number of different fields including: start/finish date of the claim, project description and case number.

The searchable database encompassed 15 years of cases (2000-2014), and was searched using specific key words. All cases that were returned based on the search criteria were documented using the case number to keep personal information confidential. Only cases that included a biomechanical evaluation of the injuries sustained in a collision with a collision severity of 25 km/hour or less were included in the analysis. Each identified case was reviewed for specific collision characteristics, injuries claimed and pre-existing medical conditions (Table 1).

Descriptive statistics (mean, SD and ranges) along with proportions across low back injury claims were computed for documented variables. In order to protect the privacy of any involved individuals, all data presented was deidentified and grouped to ensure it was not possible to identify an individual

person or case. This approach was reviewed and approved by the University of Waterloo Office of Research Ethics.

**Table 1:** The documented variables for each case meeting the search criteria

Characteristics Specific to Collision	Occupant Specific Characteristics
Collision Severity	Age
Direction of Collision Forces	Gender
Vehicle Repair Cost	Seating Position
Event Data Present	Claimed Injuries
Tow Away vs. Self Reported	Pre-Existing Medical Complaints
Vehicle Type	Seatbelt Worn
Number of Occupants in Vehicle	Disc Degeneration Present & Level
	Prior Accidents

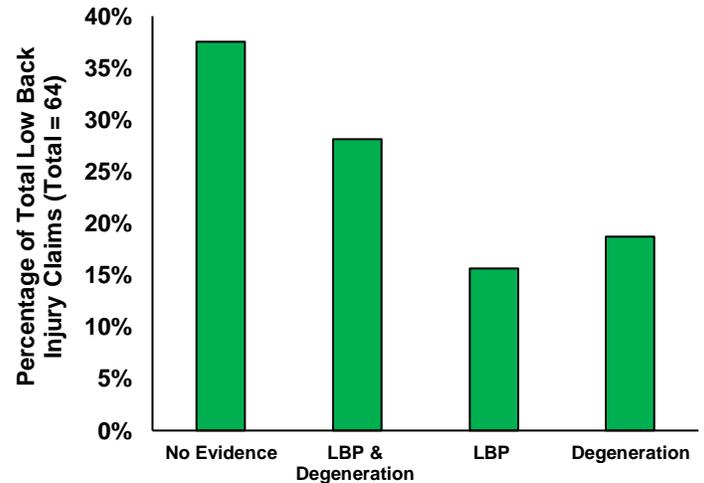

## RESULTS AND DISCUSSION

In total, 83 cases met the inclusion criteria. The automotive collisions assessed occurred between the years of 2002 and 2014. The mean (SD) age across all claimants was 41.2 (10.6) years, with a range of 15 to 65 years of age. Males and Females were relatively equally distributed across all claims; 45.8 percent of all claimants were male and 54.2 percent of all claimants were female.

Out the 83 cases reviewed, 77% involved a claim of low back injury. Specific to those who claimed low back injury, the mean age was 41.5(10.2), 78% of claimants were the driver of the vehicle and 100% of claimants were wearing their seat belt. The most common pre-existing medical conditions were pre-existing LBP or evidence of lumbar disc degeneration with 63% of claimants either having had a history of LBP or displayed evidence of lumbar disc degeneration, or both (**Figure 1**). Of all low back injury claims, 97% were accompanied by a whiplash and/or whiplash associated disorder claim.

For low back injury claims, a rear-end impact was the most common configuration (70% of all low back injury claims involved a rear-end collision).

The majority of all low back injury claimants experienced a change in velocity of 13 km/hour or less (69%), with 42% of all low back injury claims falling between collision severities of 10 – 12 km/hour. Sedans and minivans were the most common types of vehicles, accounting for 72% and 19% of all vehicles respectively.

**Figure 1:** Low back injury claims as a function of pre-existing low back medical conditions.

## CONCLUSIONS

Results indicate that rear-end collision severities of 10 – 12 km/hour appear to be particularly common with respect to low back injury reporting; more severe collisions were not associated with greater low back injury reporting. This result contrasts with previously published neck injury risk data which demonstrated the risk of neck injury symptom reporting increases with collision severity [4].

The results of this investigation provide knowledge of collision characteristics that can be employed in future studies on the mechanisms of low back injury in low speed motor vehicle accidents.

# THE INFLUENCE OF WALKING BREAKS WHILE STANDING ON GLUTEUS MEDIUS ACTIVITY AND LOW BACK PAIN

Bryce Daniels, Marcus Payne, Aaron Caldwell, Matthew Ganio, and Kaitlin Gallagher  
University of Arkansas, Fayetteville, AR, USA  
email: kmg014@uark.edu

## INTRODUCTION

In an attempt to reduce diseases related to sedentary activity, the transition to standing and sit-stand desks in the office workplace has led to more people being exposed to bouts of prolonged standing[1]. Unfortunately, as many as 71% of people will experience low back pain (LBP) during 2-hour bout of prolonged standing[2]. Previously, it has been shown that there is an increased gluteus medius co-contraction in prolonged standing induced LBP developers[2]. Walking could be a practical general back exercise since it increases trunk muscles activation as opposed to standing[3]. To date, there has been no research on how prolonged standing induced LBP developers would be affected by a walking break. The purpose of this study is to compare LBP reports and gluteus medius muscle activity during prolonged standing and prolonged standing with walking breaks. This work can lead to new insight on the potential causes for prolonged standing induced LBP development and the potential for walking breaks as an intervention.

## METHODS

A total of 11 participants, six males ( $22.3 \pm 3.78$  years;  $1.84 \pm 0.08$  m,  $82.9 \pm 8.31$  kg) and five females ( $21.6 \pm 1.82$  years;  $1.62 \pm 0.09$  m;  $56.0 \text{ kg} \pm 7.78$  kg) were recruited for this study. Exclusion criteria included previous low back surgery or injury, an allergy to rubbing alcohol, an implanted pacemaker, or any history of fainting/dizziness. Participants wore running shoes and clothes they would be comfortable standing or walking in for two hours. Participants signed an informed consent prior to beginning the study.

Surface electromyography (EMG) sensors (Delsys, Natick, MA) were used to measure bilateral gluteus medius muscle activity. A disposable razor was used to remove any hair and dead skin cells from the area, then it was cleaned with isopropyl alcohol. Maximum voluntary contractions were measured using bilateral side-lying clamshells. For each muscle, the baseline signal was removed, full-wave

rectified, low pass filtered at 2.5 Hz, and then normalized to its maximum voluntary contraction.

Pain scores for the low back region were collected using a 100 mm Visual Analogue Scale (VAS). Participants were asked to mark their current level of pain on the scale with anchors of “no pain” on the left and “worst pain imaginable” on the right. One scale was filled out immediately upon arrival to the lab to serve as the baseline value. Scales were then filled out at the start of the trial and every 15 minutes for the full two hours. The VAS from the start of the trial was subtracted from all subsequent scores. An increase of 10 mm from baseline categorized a participant as a pain developer (PD)[2].

Participants completed two 2-hour experimental trials separated by at least one week. Participants stood on a treadmill and watched a documentary for either two hours or had a walking break (2 mph) every 25 minutes (100 minutes of standing and 25 minutes of walking). The order of the experimental trials was randomized between participants.

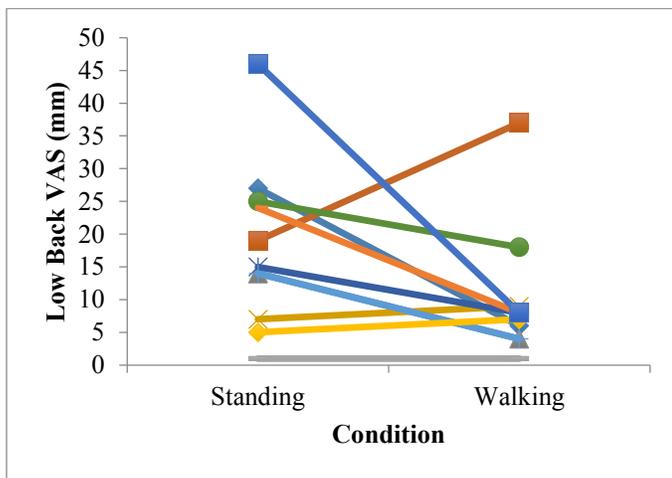

Muscle activation analyzed were taken at three instances (1) for the standing-only trial, (2) the standing portion of the walking break day and (3) walking breaks. An amplitude probability distribution function (APDF) was used to determine the median and range of gluteus medius contraction. Cross-correlation analyses were used to quantify the phase characteristics of the right and left gluteus medius signals[4]. A phase shift of  $\pm 250$  ms was used. The analysis was run on 1-minute blocks of data then averaged over the entire section. A positive cross-correlation coefficient between two muscles indicates that they are acting together, and a negative value indicates they are firing reciprocally.

Due to the lack of non-PDs at this time, the analysis compared variables between conditions. A one-way repeated measures ANOVA with a within factor of condition (standing only, standing on walking break

day, and walking) was run on the median, range, and cross-correlation coefficient. A Tukey HSD post hoc test was run a significant main effect. Significance was set at  $\alpha=0.05$ .

## RESULTS AND DISCUSSION

Out of the 11 participants, eight participants were classified as PDs during the standing visit while only three were classified as PDs during the standing with walking breaks visit. Seven participants reported a lower low back region VAS score on the walking breaks day (Figure 1). None of the participants who were nonPDs in standing were PDs on the walking breaks day.

**Figure 1:** Maximum low back region pain scores for the standing-only and standing with walking break trials.

There was a significant main effect of condition for the muscle activation range of the right and left gluteus medius muscles and the cross-correlation coefficient ( $p<0.0001$ ) (Table 1). There was no significant difference for the median %MVC for either muscle. Outcome variables for standing were not significantly different across days. Due to

**Table 1:** APDF median and ranges, and cross correlation coefficients across conditions. Different letters denote significant difference between conditions for that outcome measure.

Measures	Conditions		
	Stand	Stand-Walk	Walking
Median Right Gluteus Medius (%MVC)	4.1 ± 2.2	4.3 ± 4.0	6.2 ± 3.7
Range Right Gluteus Medius (%MVC)	4.7 ± 4.8 <sup>a</sup>	3.3 ± 5.3 <sup>a</sup>	15.9 ± 8.9 <sup>b</sup>
Median Left Gluteus Medius (%MVC)	5.7 ± 5.3	4.5 ± 2.3	6.0 ± 2.2
Range Left Gluteus Medius (%MVC)	5.3 ± 9.4 <sup>a</sup>	4.7 ± 5.3 <sup>a</sup>	19.3 ± 7.3 <sup>b</sup>
Gluteus Medius Cross-correlation Coefficient	0.008 ± 0.18 <sup>a</sup>	0.043 ± 0.18 <sup>a</sup>	-0.571 ± 0.14 <sup>b</sup>

single leg support phase during walking and swing phase of the contralateral leg, it was expected that the range of muscle activity would be higher for walking and demonstrate a more reciprocal firing of the right and left gluteus medius muscles compared to standing.

While we did not assess the difference between PDs and non-PDs as of yet, the increased range of firing and the reciprocal pattern of firing may point to a potential intervention to promote less co-activation of the hip abductor muscles in standing. With more PDs in our current sample, it demonstrates that even those who have been shown to have greater levels of co-activation in prolonged standing have cyclic gluteus medius recruitment in walking.

With the collection of more participants, future work will assess the difference in magnitudes of these correlations to determine if PDs are still co-activating at higher levels than non-PDs during walking. Studies should also assess the impact of walking speed on muscle co-activation.

## INTRODUCTION

Traditional methods of kinematic measurement offer limited ability to determine precise intersegmental motion of the spine. Recently, dynamic biplane fluoroscopic imaging has proven to be an accurate, effective, and non-invasive method of quantifying three-dimensional kinematic motion of the spine and other joints [1-3]. Previous studies have utilized 3D bone models reconstructed from computed tomography (CT) and shaped-matched to biplanar dynamic radiographs to determine underlying kinematics [1]. This approach has been validated previously in the spine by comparison to the standard measure of dynamic radiostereometric analysis (RSA) using implantable tantalum beads [1,2].

The purpose of this study was to validate our dynamic biplane fluoroscopy system's accuracy in the assessment of cervical spine flexion motion through CT-based registration and RSA comparison using a cadaver. Validation is an essential step to complete for each individual fluoroscopy system to ensure accurate and precise results prior to initiating human subject collection. The validation procedure should also closely mirror that of actual human subject collection; for this reason, dynamic activities were simulated using a cadaveric specimen with intact surrounding musculature and soft tissue.

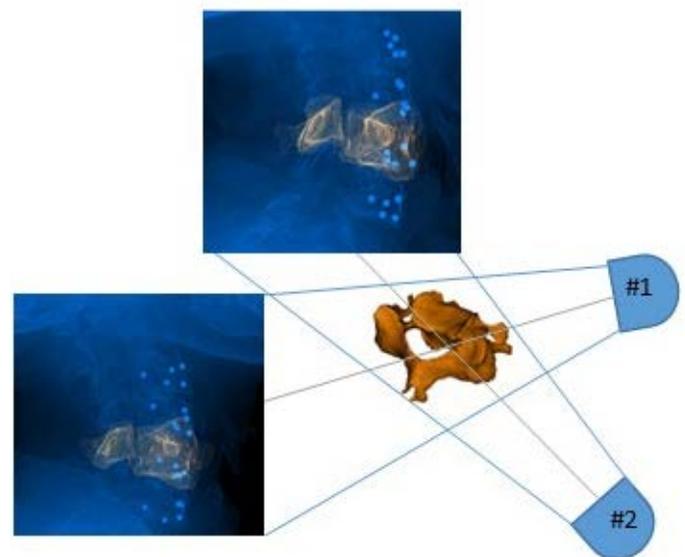

## METHODS

### *Data Acquisition*

Tantalum beads (1.6mm) were inserted into the anterior aspect of the cervical spine vertebral bodies (four in C4; five in C5) of a fresh-frozen cadaveric specimen (male, age 62) to facilitate RSA tracking. CT images were obtained (Siemens Somatom Sensation 64; Forchheim, Germany; kVp: 120;

voxel size: 0.34x0.34x0.6) to generate 3D bone models and establish bead location.

Dynamic radiographic imaging was acquired on a custom biplanar imaging system (Imaging Systems and Services, Inc.; St. Painesville, OH, USA) equipped with 16" image intensifiers and high speed cameras (Xcitex ProCapture). A 55-degree interbeam angle was used with each system parallel to the horizontal and source to detector distance of 152cm (Figure 1). A wedge style radiographic filter (Ferlic Filter Co., LLC, White Bear Lake, MN, USA) was implemented with the following fluoroscopic parameters: 70kv, 250mA, 3.5ms, 60Hz. Cervical flexion was passively simulated from an extended position was obtained with a custom-made apparatus.

**Figure 1:** Biplanar fluoroscopic set-up with 55° interbeam angle. C5 bone model reconstruction inset.

### *Image Processing*

CT images were reconstructed manually to create 3D bone models of levels C4 and C5 and a local anatomical coordinate system (Figure 2) was assigned (Mimics; Materialise, Plymouth, MI,

USA). Bone model bead positions were masked (ImageJ/Fiji, US NIH, Bethesda, MD, USA) to prevent bead-bias while shape-matching. The masked-models were manually shape-matched utilizing digitally reconstructed radiograph (DRR) projections (Autoscooper, Brown University, RI, USA). Ten equally spaced frames from the dynamic trial (full extension to full flexion) were extracted for analysis. RSA was performed (XMA Lab, Brown University, RI, USA) to determine the 3D location of each bead during flexion. The rotational and translational components were then transformed to a local coordinate system and the values from CT-reconstruction were directly compared to RSA values using a Matlab script (Matlab, R2016B, The Mathworks, Inc., Natick, MD, USA). RMS error, bias, and precision were calculated to examine tracking of individual vertebral segments and relative intersegmental kinematic accuracy.

## RESULTS AND DISCUSSION

Summary statistics are displayed in Table 1.

Tracking of individual vertebral segments resulted in an average RMS error of 1.04° and 0.48mm, average precision of 0.88° and 0.33mm, and average bias ranged from -0.65 to 0.53° and -0.33 to 0.40mm for rotations and translations, respectively.

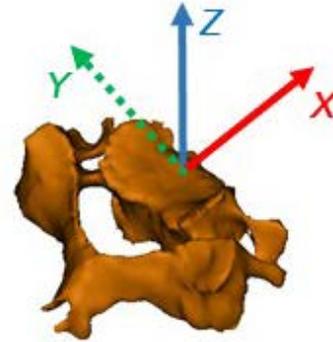

The relative intersegmental kinematic agreement resulted in an average RMS error of 1.48° and 0.61mm, average precision of 1.31 and 0.61, and average bias ranged from -0.96 to 0.77° and -0.22 to -0.03mm for rotations and translations, respectively.

Flexion/Extension rotations indicated the highest degree of error, despite being nearest to in-plane motion (flexion). However; all error was found to be below two degrees (rotation) and one mm

**Table 1:** Accuracy of dynamic biplane fluoroscopy via CT-based registration vs. RSA for cervical spine flexion. Flexion-Extension (FE), Lateral Bending (LB), Axial Rotation (AR), Anterior-Posterior (AP), Medial-Lateral (ML), Superior-Inferior (SI).

	FE (deg)	LB (deg)	AR (deg)	AP (mm)	ML (mm)	SI (mm)
<b>Individual Segment Registration Accuracy</b>						
RMS Error	1.27	0.88	0.97	0.37	0.54	0.53
Bias	-0.34	0.53	-0.65	0.27	-0.33	0.40
Precision	1.24	0.66	0.74	0.19	0.44	0.36
<b>Relative Intersegmental Kinematic Accuracy</b>						
RMS Error	1.98	1.56	0.91	0.63	0.71	0.50
Bias	0.77	-0.96	0.18	-0.22	-0.03	-0.05
Precision	1.97	1.02	0.95	0.58	0.74	0.51

(translation) for both registration and kinematic comparisons, which is comparable to other validation studies of the spine [1,2].

**Figure 2:** Anatomic local coordinate system overlaid on a C5 3D bone model reconstruction (Landmarks: anterior/superior vertebral body, left and right most lateral inferior vertebral notch).

## CONCLUSIONS

The results affirm that our biplane fluoroscopy system is capable of capturing highly accurate bone tracking and kinematic motion of the cervical spine. This validation assessment will serve as the groundwork to proceed on into human subject collection.

## INTRODUCTION

Low back pain (LBP) is a common and costly condition that is one of the leading causes of disability worldwide, yet contributing factors are currently not well understood. Prolonged standing protocols have been extensively used to investigate predisposing biomechanical factors for LBP development in asymptomatic individuals [1]. One identified factor is an altered flexion relaxation response (FRR) in those developing pain in standing (PD) compared with those who remain painfree (NPD). Healthy individuals are expected to demonstrate a 'typical' FRR with myoelectrical silence of the trunk extensors and increased activity of the hip extensors during standing lumbar flexion [2]. Previous work has shown PDs demonstrate a maladaptive pattern of increased gluteal muscle relaxation during standing trunk flexion compared to NPDs [1].

PDs have been shown to be at increased risk for future clinical LBP compared to NPDs [3]. However, PDs have also demonstrated a favorable response to stabilization exercise approaches commonly used in physical therapy intervention [4]. This has led to the hypothesis that PDs may share similar characteristics to individuals with clinical LBP (CLBP) that respond favorably to similar intervention protocols. Relationships between PDs and patients with CLBP subclassified into a LBP subgroup of Stabilization (ie; expected to respond to stabilization based exercise) have not been investigated previously. The purpose of this study was to investigate FRR differences between individuals categorized as NPD, PD and CLBP, with consideration for potential sex differences. Both PD and CLBP groups were expected to demonstrate decreased gluteal and increased spinal extensor activity during standing flexion, and NPDs

expected to demonstrate the opposite pattern, indicating a typical response for healthy individuals.

## METHODS

Data for this submission are a subset of a larger study. Nineteen individuals (9 male,  $25.4 \pm 5$  yrs old) with no prior history of LBP performed a standing protocol of up to 2 hrs while reporting LBP every 15 min on a 100 mm visual analog scale (VAS). Participants were classified as PD if they reported  $\geq 10$ mm increase in LBP during standing. Eleven individuals (4 male,  $35.8 \pm 11.5$  yrs old) with a recent history (prior 12 months) of CLBP and meeting Treatment Based Classification criteria for Stabilization subgroup [5] were also recruited.

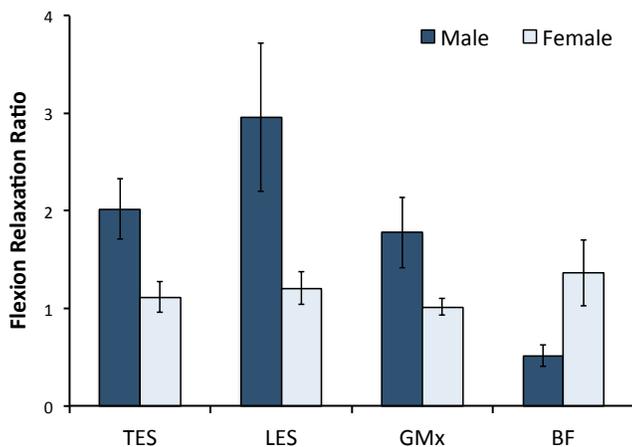

Electromyography data were recorded from 4 bilateral muscle groups (Thoracic Erector Spinae = TES, Lumbar Erector Spinae = LES, Gluteus Maximus = GMx, Biceps Femoris = BF) at 2000 Hz (Bortec, AMT-8, Calgary, AB). Submaximal reference contractions were used for normalization purposes. Participants performed self-paced standing trunk flexion, with a hold in full flexion for approximately 5 seconds. After bias removal, data were full wave rectified and low pass filtered (dual-pass 4<sup>th</sup> order Butterworth,  $f_c=2.5$  Hz). EMG data were plotted for each participant and visually inspected to identify stable windows for upright standing and full flexion. Average activation was calculated across upright and flexion windows for each muscle. FRR was then calculated as the ratio of average upright activation to flexed activation for each muscle [1]. Using this approach, an  $FRR > 1.0$  indicates relaxation during flexion and  $FRR < 1.0$  indicates increased muscle activity during flexion.

To determine if symmetry could be assumed for a data reduction measure, left and right side FRRs for

each muscle were entered into paired t-tests, with non-significant probabilities indicating left/right symmetry. When symmetry could be assumed, left and right sides were averaged to yield a single measure. FRRs were entered into a 3x2 ANOVA (Pain Group x Sex) with alpha = .05.

## RESULTS AND DISCUSSION

Ten of nineteen participants (4 male) were classified as PD with average VAS =  $16 \pm 4.1$  mm (compared with  $2 \pm 2.5$  mm for NPD). No significant differences were found in left/right FRR comparisons, therefore symmetry was assumed for all muscle groups. All muscle groups had a significant main effect of sex, with males having greater relaxation than females of TES, LES and GMx, and females having greater relaxation of BF than males (Figure 1). There was also a significant Pain Group x Sex interaction for TES, with males having higher FRR ( $2.67 \pm 1.44$ ) than females ( $0.72 \pm 0.57$ ) for the NPD group only. There was a main effect of Pain Group on FRR for LES only, with NPD having higher FRR ( $2.97 \pm 2.76$ ) than CLBP ( $1.31 \pm 1.02$ ), neither being significantly different from PD ( $1.79 \pm 1.99$ ).

**Figure 1:** Significant ( $p < .05$ ) sex differences were found for muscle relaxation during standing flexion in all muscle groups. Males increased activation of biceps femoris (BF) during flexion, with marked relaxation in the other extensor groups.

Our hypotheses were partially supported, with PD and CLBP groups demonstrating similar patterns of decreased LES relaxation during standing flexion.

Although differences between NPD and PD groups in this measure were not significant, the NPD group did show the expected increased relaxation for healthy individuals, and were significantly different from the CLBP group.

Findings relative to sex differences, independent of pain group were interesting, and consistent across muscle groups. Males in this study appeared to rely on hamstring musculature for standing flexion (increased BF activation at full flexion) with commensurate relaxation of GMx. Females did not show significant relaxation in any of the muscle groups, with average FRRs close to 1.0, indicating relatively equal activation between upright and flexed postures. Compared to males, females utilized a gluteal dominant strategy at the hip.

## CONCLUSIONS

These findings show some differences in flexion relaxation response between individuals who do not experience standing-induced LBP and those with clinical LBP, specifically for the lumbar portion of the erector spinae. It is possible that between group differences were not detected in this study due to small sample sizes. A post hoc power analysis revealed power ranging from 8-49% for detecting between group differences. Males and females showed markedly different responses during the flexion task. Previous work has indicated potential sex differences in hip musculature response to exercise interventions for standing induced LBP [4]. Implications of the current findings related to LBP risk, movement strategy retraining, and therapeutic exercise interventions should be explored further.

# A COMPARISON OF MUSCLE ACTIVITY DURING SPINE EXTENSION IN PEOPLE WITH AND WITHOUT STANDING-INDUCED BACK PAIN, AND THOSE WITH CHRONIC LOW BACK PAIN

<sup>1</sup>Daniel Viggiani, <sup>2</sup>Bradley S. Davidson, <sup>1</sup>Jack P. Callaghan, and <sup>3</sup>Erika Nelson-Wong

<sup>1</sup>Department of Kinesiology, University of Waterloo, Waterloo, ON, Canada; <sup>2</sup>Department of Materials and Mechanical Engineering, University of Denver, Denver, CO, USA; <sup>3</sup>School of Physical Therapy, Regis University, Denver, CO, USA; email: dviggian@uwaterloo.ca

## INTRODUCTION

Transient low back pain (LBP) development during prolonged standing may predict future LBP. People developing LBP from standing (pain developer = PD) are distinguished from non-pain developers (NPD) by increased trunk and hip co-activity [1], and altered vertebral kinematics in lumbar spine extension [2]. However, there have been no direct comparisons of PDs to people with chronic LBP in supported or unsupported spine extension. This study's purpose was to compare muscle co-activity strategies between NPDs, PDs and a chronic LBP group in two lumbar spine extension variants.

## METHODS

Nineteen participants (9 male; 21-40 yrs old) with no history of LBP and 11 participants (4 male; 20-52 yrs old) satisfying the Stabilization subgroup of the Treatment-based Classification [3] (CLBP) were recruited. A previously used standing protocol was used to separate the 19 participants with no prior LBP history into PD (n=10, 4 male; 22-35 yrs old) and NPD (n=9, 5 male; 21-40 yrs old). Participants were classified as PD if they reported  $\geq 10$  mm increase in LBP on a 100 mm visual analog scale during the standing protocol [1,2]. Following instrumentation for EMG and kinematics, participants performed spine extension in two different postures in a randomized order: standing and prone. In standing, participants were instructed to lean backwards (look overhead as far as possible) without translating hips/pelvis, hold in full extension for 3-4 seconds, and return to neutral standing. While prone, participants were instructed to relax on an examination table with their arms supporting their upper body in lumbar extension (pelvis on table) and hold for 30 seconds.

Kinematics of the trunk and pelvis were measured using active marker clusters (Optotrak 3D

Investigator, NDI, Waterloo, ON), and collected at 50 Hz to identify lean, hold and return phases of standing extension based on the trunk-pelvis sagittal angles. Surface electromyography of six muscles bilaterally (T9 Erector Spinae (TES), L3 Erector Spinae (LES), Gluteus Maximus (GMX), Biceps Femoris (BCF), External Oblique (EXO) and Internal Oblique (INO)) were collected at 2000 Hz during both tasks (AMT-8, Bortec, Calgary, ON). Bias-removed EMG signals were rectified, dual-pass filtered (Butterworth, 2.5 Hz cutoff), and expressed as a percent of reference voluntary contractions to represent muscle activations. Muscle co-activity among sets of two to eight muscles (defined in Table 1) were computed based on commonality (the overlap between muscles of a set) and activity level (the mean activity of muscles in a set) [4]. Measures for each set were averaged over phase of standing extension and over the full prone extension period.

**Table 1:** Muscle Set Definitions (BL = Bilateral)

Set Name	Muscles in Set
<i>Trunk8</i>	BL TES, LES, EXO, INO
<i>ATrunk4</i>	BL EXO, INO
<i>PTrunk4</i>	BL TES, LES
<i>LTrunk4</i>	Left TES, LES, EXO, INO
<i>RTrunk4</i>	Right TES, LES, EXO, INO
<i>Hip4</i>	BL GMX, BCF
<i>BL-TES etc.</i>	BL Muscle Pairs

Mixed model ANOVAs with a between factor of Group (NPD/PD/CLBP), and a within factor of Phase (lean/hold/return) or Posture (standing/prone) were used when appropriate. Tukey's test was used for post-hoc investigations of significant findings.

## RESULTS AND DISCUSSION

There was a main effect of Group where PDs had higher commonalities than NPDs in the Hip4 ( $p =$

0.049) and BL-GMX muscle sets ( $p = 0.043$ ), and higher commonalities than CLBPs in the PTrunk4 set ( $p = 0.035$ ) (Fig. 1). There were no Group effects of activity levels ( $p > 0.371$ ), and no Group\*Pain or Group\*Posture interactions on either measure ( $p > 0.076$ ). There were main effects of Posture where holding prone extension produced higher commonalities ( $p < 0.002$  for ATrunk4, PTrunk4, Hip4, and all Bilateral pairs) and lower activity levels ( $p < 0.038$  for Trunk8, ATrunk4, LTrunk4, RTrunk4, BL-LES, BL-EXO and BL-INO) than holding standing extension. The Trunk8, LTrunk4 and RTrunk4 sets had the highest commonalities in the Return phase ( $p < 0.001$ ). Main effects of Phase on activity levels in standing extension were muscle set-dependent. The Hold phase of standing extension had the highest activity levels ( $p < 0.043$ ) within the Trunk8, ATrunk4, LTrunk4, RTrunk4, BL-EXO and BL-INO muscles sets. The Return phase of standing extension had the highest activity levels ( $p < 0.044$ ) in the Hip4, BL-LES, BL-BCF and BL-INO muscle sets.

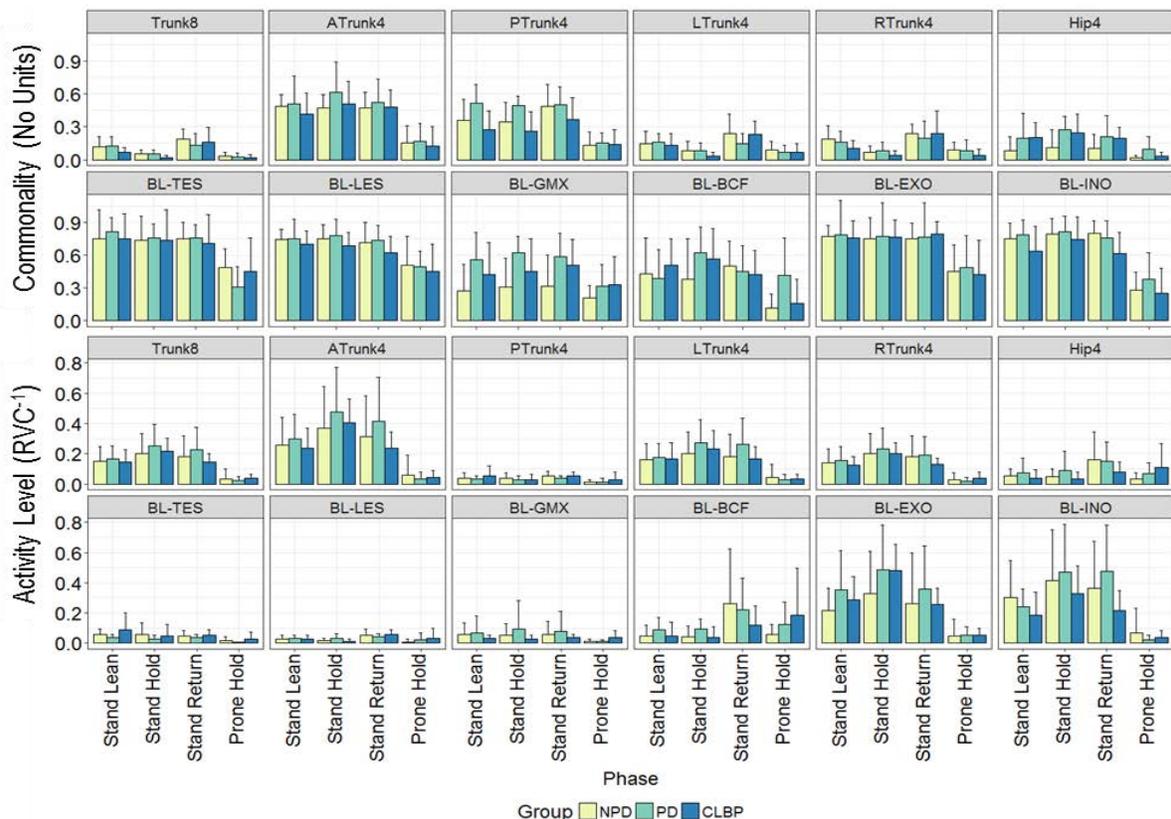

## CONCLUSIONS

The CLBP group was always similar to the NPD group, with PDs exhibiting higher co-activity in

posterior musculature during standing and prone extension. These findings suggest that PDs activate a greater number of muscles during these extension tasks rather than increasing amplitudes compared to NPD and CLBP counterparts. The current CLBP sample was chosen to reflect a subgroup that was intended to be most similar to PDs in terms of LBP reduction following treatment [1,3]. However, this study demonstrates that people with LBP benefitting from stabilization exercises do not exhibit different amounts of “stabilizing” co-activity than low-risk, asymptomatic controls (NPDs) during standing and prone extension tasks. Co-activity during lumbar spine extension was more dependent on movement phase and posture than pain group status. Further comparisons between PDs and subgroups of people with LBP can further our understanding of how transient LBP develops into chronic LBP.

## INTRODUCTION

The rib cage is often assumed to add stability or share loads with the thoracic spine. However, the effects of the rib cage on thoracic spine loading are not well studied, in part due to the difficulty in measuring spinal loading within an intact spine-rib cage construct. Intervertebral disc pressures provide a surrogate measure of loading and may be measured in cadaveric spine tests to provide insight into spinal loading. We have previously reported that the rib cage appears to have a limited effect on thoracic intervertebral disc pressures under static compressive follower loads [1]. However, applied pure moments increase intradiscal pressures in lumbar spine specimens [2], but such measurements are lacking in the thoracic region. Thus, our objective was to examine thoracic intradiscal pressures with applied dynamic moments, and to determine the effect of the rib cage on these pressures.

## METHODS

Eight fresh-frozen human cadaveric thoracic spines (T1-T12) with the rib cage intact were obtained (4 female, 4 male, age range 61-71). Specimens were positioned upright in a testing machine (Applied Test Systems, Butler, PA) with a compressive follower load of 400 N applied by means of cables running lateral to the spine, connected to the spine by a rod inserted through each vertebral body with an eye nut at each end. Dynamic pure moments (0 to  $\pm 5$  N·m) were applied in displacement control at 1°/s in three modes of bending: axial rotation (AR), flexion - extension (FE), and lateral bending (LB). Trials were performed first with the rib cage intact, and again after the rib cage was removed by cutting the ribs about 2 cm lateral to the costo-transverse

joints (Figure 1). Disc pressures were measured at T4-T5 and T8-T9 using needle-mounted pressure transducers (Gaeltec, Isle of Skye, Scotland). Pressure measurements were normalized to pressure at 0 N·m, then the slopes of pressure vs. moment magnitude were calculated via linear regressions. The effect of rib cage on pressure-moment slopes were examined with mixed effects models by spinal level and direction of applied moment, adjusting for specimen as a random variable. Analyses were performed with Stata/IC 13.1 (StataCorp LP, College Station, TX).

**Figure 1:** Testing was performed with rib cage intact (left) and rib cage removed (right). In both cases, pressure transducers (arrows) were inserted in the in the T4-T5 and T8-T9 intervertebral discs.

## RESULTS AND DISCUSSION

Pressure increased with applied moment (whether positive or negative) in all modes of bending (Figure 2). Flexion (positive) and Extension (negative) pressure-moment slopes differed ( $p < 0.05$ ), so these were analyzed separately; directions were combined for axial rotation and lateral bending analyses. Slopes were significant and positive in AR and LB, in Flexion at T4-T5, and in Flexion at T8-T9 with no rib cage ( $p < 0.05$ , Table 1). The pressure-moment slope was higher with no rib cage

at T4-T5 for all loading directions and at T8-T9 for AR only ( $p < 0.05$ , Table 1).

Removal of the rib cage had the largest impact in AR, increasing the slope about three-fold. Slopes were not significant in Extension, perhaps due to a shift of loading from the disc to the posterior elements as the spine moves into extension [3]. Our previous analysis of the same specimens under static compressive follower loads found unclear and likely minimal effects of the ribcage on disc pressure [1]. Thus, it appears that the rib cage contributes to thoracic spine stability or load sharing more so under applied moments or angular motion more than under compressive loading.

### CONCLUSIONS

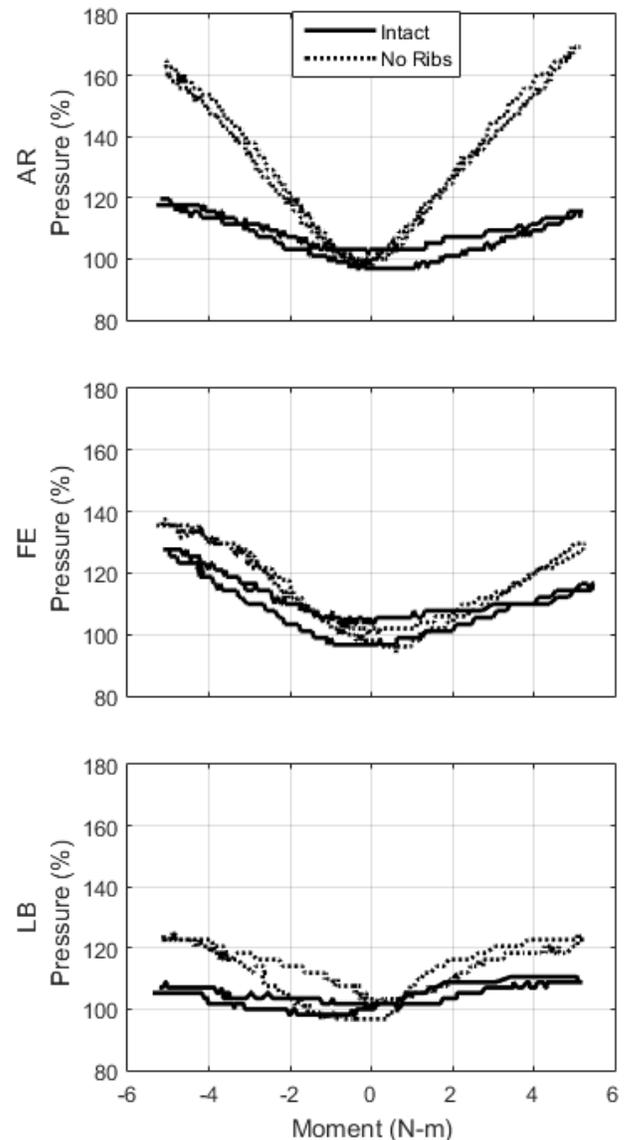

Overall, removing the rib cage increased the pressure-moment slope in most conditions, indicating that the rib cage plays an important role in thoracic spine loading. This unique information will be helpful in future studies and modeling efforts to evaluate spinal loading *in vivo*.

## INTRODUCTION

Chronic low back pain (LBP) affects approximately 28% of adults in the U.S. [1], whereas up to 71% of people with a lower limb amputation (LLA) suffer from LBP [2]. Understanding the reasons for this increased prevalence could help to mitigate LBP in people with or without an amputation. People with LLA have altered low back biomechanics during a variety of movements [3,4], and greater low back loading during walking [4], but low back loading in people with a transtibial amputation (TTA) during the sit-to-stand motion (STS) is not well-characterized. Peak L4-L5 loading is greater during STS compared to walking or running [5], and people with a transtibial amputation (TTA) engage in STS approximately 50 times every day [6]. Thus, the purpose of this study was to determine differences in peak L4-L5 compressive loads, and trunk kinematics between people with and without TTA during STS. We hypothesized that, compared to people without an amputation, people with TTA would have greater loading at more extreme trunk angles and a greater range of trunk motion.

## METHODS

Four people without an amputation (Control, 1M/3F, 23.3±2.9 yrs, 1.66±0.06 m, 65.9±9.3 kg) and four people with a unilateral transtibial amputation (TTA, 4M, 45.5±14.8 yrs, 1.84±0.02 m, 99.4±15.3 kg) participated in this study. No participant had more than minimal LBP as indicated by the Modified Oswestry Low Back Pain Questionnaire [7].

All participants performed five self-paced STS trials, beginning seated with hips, knees, and ankles at 90° of flexion and feet hip-width apart on separate force plates recording at 1200 Hz.

Kinematics were collected at 120 Hz with a 20-camera motion capture system and a full-body marker set including markers placed at C7, T8, xyphoid process, and bilaterally at the acromion, PSIS, ASIS, iliac crest, and greater trochanter.

Kinematics and GRFs were low-pass filtered with a 4<sup>th</sup>-order Butterworth filter with cutoff frequencies of 6 Hz and 10 Hz, respectively. An eight-segment model was used to determine the inverse kinematics solution in Visual3D, which was used as input to an OpenSim 3.3 musculoskeletal model of the trunk, lumbar spine, and lower body with 292 Hill-type musculotendon actuators. A static optimization algorithm solved the muscle recruitment problem at each time step by minimizing an objective function of the sum of muscle activations squared. Once muscle forces were estimated, joint contact loads were calculated at L4-L5 throughout the STS motion. Differences between groups in peak load, trunk range of motion (ROM, relative to the lab frame), and trunk angle at the instant of peak load were compared with t-tests ( $\alpha=0.05$ ).

## RESULTS AND DISCUSSION

Compared to control participants, TTA participants had larger peak L4-L5 compressive loads (Table 1), and greater trunk flexion throughout STS (Figure 1). Peak loads occurred shortly after liftoff and prior to peak trunk flexion for all participants. At the instant of peak loading, TTA participants were in postures with significantly greater trunk flexion and lateral bending (Table 1). Previously, the moment of liftoff has been identified as the period of least GRF asymmetry for control participants, and the period of greatest GRF asymmetry for people with TTA [8]. This asymmetry, along with greater ranges of trunk motion, has been suggested as a reason for

greater low back loading in people with an amputation during STS [3].

Both groups had similar ranges of trunk flexion, but TTA participants had larger ranges of motion in lateral bending and axial rotation that approached significance (Table 1,  $p < 0.10$ ). Greater 3D trunk ROM during STS has been seen previously in people with a transfemoral amputation [3], and in people with LBP [9].

**Table 1:** Mean (SD) trunk kinematics (flexion, lateral bending towards the right/intact leg, and axial rotation towards the prosthetic/left leg are positive) and L4-L5 compression (normalized to body weight (BW)) for each group. Significant  $p$ -values for comparisons between groups are in bold.

	Control	TTA	$p$	
Angle at Peak	Flexion	-41.8° (5.1°)	-49.8° (3.2°)	<b>&lt;0.01</b>
	Lateral Bending	-0.5° (1.8°)	3.8° (4.4°)	<b>&lt;0.01</b>
	Axial Rotation	-1.86° (3.3°)	1.5° (4.8°)	<b>0.01</b>
ROM	Flexion	36.1° (18)	38.3° (19°)	0.64
	Lateral Bending	6.6° (3°)	8.1° (2°)	0.09
	Axial Rotation	4.8° (2°)	6.2° (3°)	0.08
Peak L4-L5 Load (BW)	3.46 (0.4)	3.73 (0.4)	0.05	

## CONCLUSIONS

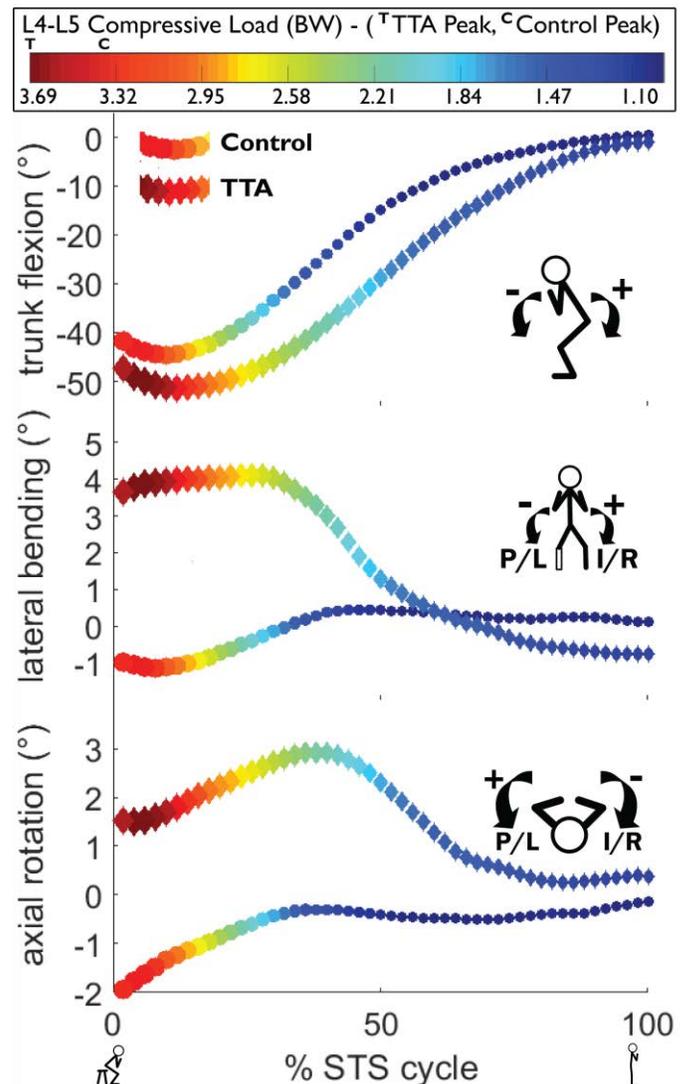

The instant immediately after liftoff has been identified as an important consideration in understanding risks for LBP development. At this instant, people with TTA had greater L4-L5 compressive loading, greater trunk flexion, and greater lateral bending. More extreme trunk postures increase lumbar spine loading [5] and strain on intervertebral discs [10], which suggests a potential pathway to LBP development. Future work will include more participants and identify L4-L5 joint kinematics.

# THE INFLUENCE OF WALKING BREAKS ON LUMBAR SPINE KINEMATICS DURING PROLONGED STANDING

Marcus Payne, Bryce Daniels, Aaron Caldwell, Matthew Ganio, Kaitlin M. Gallagher  
University of Arkansas, Fayetteville, AR, USA  
email: mcpayne@email.uark.edu

## INTRODUCTION

As many as 71% of people experience low back pain (LBP) development during prolonged standing [1]. Both movement and posture based interventions are used to help alleviate low back pain development [2]. Increased lumbar lordosis, or extension, has been found in those who develop pain during prolonged standing [3]. It is possible that movement interventions, such as walking breaks, can alter the posture of the lumbar spine and pelvis, reducing LBP reports; however this has not been assessed. Using indwelling bone pins and motion capture, intersegmental lumbar spine flexion and axial rotation was found to be less than 4 degrees, with the most motion in the frontal plane [4]. The purpose of this study is to investigate how lumbar spine kinematics differ between prolonged standing and walking breaks, and determine the impact on LBP during prolonged standing. We hypothesize that walking will increase lumbar spine movement and LBP reports would be less when walking breaks interrupted standing.

## METHODS

A total of 12 participants (7 males: 18-28 years,  $1.83 \pm 0.08$  m,  $80 \pm 11.4$  kg; 5 females: 19-24 years,  $1.63 \pm 0.05$  m,  $56 \pm 7.7$  kg) have been collected for the study. Exclusion criteria included any previous low back surgery or injury, any allergy to rubbing alcohol, an implanted pacemaker, or any history of dizziness or fainting. Participants were asked to come to the lab on two separate days, separated by at least a week. During one visit, they completed a two hour bout of prolonged standing. During the other visit, they again stood for two hours, but had a 5-minute walking break (2 mph) every 25 minutes (100 minutes standing, 20 minutes walking). The order of the walking and standing trials was randomized. Both trials were completed while standing on a treadmill facing a desk to the side, which facilitated a smooth transition to the walking breaks during the walking trial.

Subjective pain scores for the low back region were collected using a 100mm visual analogue scale (VAS). Participants were asked to mark their current level of pain using a vertical tick on a line anchored with “no pain at all” on the left and “worst pain imaginable” on the right. Scores were collected at the start and every 15 minutes for the duration of the trial. The score at the start of the trial was subtracted from all other scores so each person started with a baseline score of 0. If the participant’s normalized VAS score exceeded 10 mm, they were categorized as a pain developer (PD). Classification into pain groups based on VAS scores has shown to be a repeatable and functional measure [5].

A motion capture system (Qualysis AB, Gotenburg, Sweden) was used to track two rigid bodies throughout the trial. The first rigid body was placed on L1/L2 and the second on the sacrum. Calibration markers were placed bilaterally on the iliac crests and rib cage, and anterior superior and posterior superior iliac spines to create a lumbar region and pelvis segment, respectively. Three-dimensional angles were calculated in Visual3D (C-Motion, Germantown, MD). An amplitude probability function (APDF) was used to calculate the median angle and range between the 10<sup>th</sup> and 90<sup>th</sup> percentiles. The APDF was run on the standing trial, the standing portion of the walking breaks trial, and the walking breaks separately.

Due to lack of non-pain developers at this stage of collection, a one-way repeated measures ANOVA with factor condition (standing only, standing portion of walking trial, and walking breaks). A Tukey post-hoc test was used to test significant main effects. Significance level was set at  $\alpha=0.05$ .

## RESULTS AND DISCUSSION

Seventy five percent of participants were categorized as PDs during the standing-only trial, but only 17% were categorized as PDs during the walking trial (Figure 1). These results demonstrate

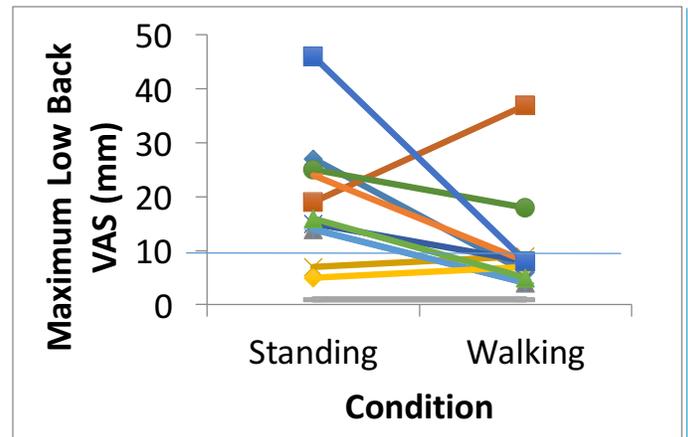

that walking breaks during a bout of prolonged standing may be beneficial for reducing prolonged standing induced LBP.

There was a significant main effect for median flexion/extension angle ( $p=0.0021$ ), but not for lateral bend ( $p=0.35$ ) or axial twist ( $p=0.99$ ) (Table 1). The lumbar spine was more flexed during walking compared to the standing trial on the same day, but not across experimental days. While it did not differ from the first day, this is an interesting find as lumbar lordosis angle has been shown to be more flexed in non-PDs compared to PDs [3].

There was a main effect for flexion/extension ( $p=0.0034$ ) and axial twist range ( $p=0.03$ ) (Table 1). Less range of motion was found in walking compared to the standing on the same experimental day. While this may seem counterintuitive, participants were unconstrained in standing, meaning they could move around and did not maintain fixed position. As a result, participants could have had larger excursions in flexion-extension due to voluntary movements in standing, compared to the much more controlled walking condition. The same may be the reason why there was no difference in the lateral bend range of motion, as shifting weight between left and right foot during standing may have resulted in changes in the lateral bend angle. Axial twist range of motion, which increased with walking, is the only movement that could be difficult to perform without voluntary twisting motions.

A limitation to this study is that it is difficult to measure the exact movement at the intervertebral joint level using surface motion capture. As a result, our measurements represent regional differences between the upper lumbar spine and pelvis. This study also did not address different walking speeds and their influence on pain development. Slower

walking speeds may not elicit the same amount of lumbar spine movement, potentially resulting in similar pain scores between slow walking and standing. Future assessments will split participants into pain groups to determine if movement patterns differ between the groups.

**Figure 1:** Maximum pain scores for the low back region during standing and walking trials.

# The Relationship Between Family History, Biopsychosocial Factors and Seated Posture on LBP Development in Prolonged Sitting

Matthew Barrett, John Charles Snow, and Diana De Carvalho  
Faculty of Medicine, Memorial University of Newfoundland, St. John's, NL, Canada  
email: [mhb726@mun.ca](mailto:mhb726@mun.ca)

## INTRODUCTION

Low Back Pain (LBP) is one of the major health care issues facing society today<sup>1</sup>. LBP has been linked to occupational postures such as prolonged sitting<sup>2</sup>. However, it appears that some individuals are more likely to develop pain from exposures to sitting than others<sup>3</sup>. Prior work has identified groups of transient pain developers (PD) and non-pain developers (NPD) within study populations<sup>3</sup>. Currently it is not known what factors drive this differential pain response. The purpose of this study is to investigate the relationship between seated spine posture, family history of LBP and biopsychosocial factors between participants that do and do not develop transient pain in response to prolonged sitting.

## METHODS

32 participants (4 females, 28 males, average age 23.5 years  $\pm$  6.9 (SD), height 179.4 cm  $\pm$  7.79 (SD) and mass 77.4 kg  $\pm$  11.1 (SD) were recruited from the local community. Exclusion criteria included a history of tumor, infection, fracture, inflammatory arthropathy and/or previous surgery of the spine. A health screening form including questions on family history of LBP, the Tampa Scale of Kinesiophobia (TSK), and the Back Pain Attitudes Questionnaire (BPAQ) were all completed prior to data collection. Two tri-axial accelerometers (ADXL335, Analog Devices, Norwood, MA, USA) were fixed to the skin in the +y down, +z anterior orientation using double-sided tape overlying the L1 and S2 spinous processes. Accelerometer signals were collected at a rate of 1500 Hz using a 16-bit A/D board (Noraxon DTS, Noraxon Inc, Scottsdale, AZ, USA). Following instrumentation four 5s posture calibration trials were collected: upright standing, maximum extension, maximum flexion (standing) and maximum flexion (seated). Participants were then seated at a computer workstation that consisted of an adjustable height table, desktop computer,

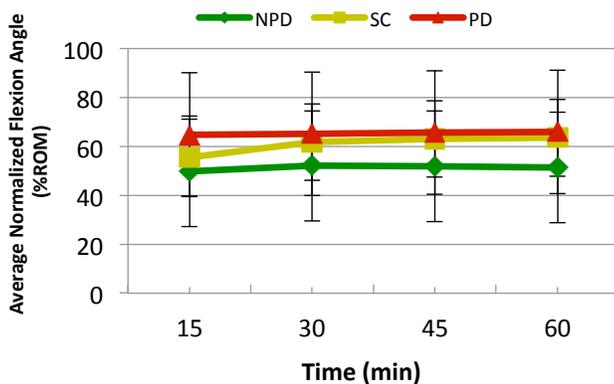

standard keyboard, and the seat pan of a standard office chair. The workstation was individually adjusted to each participant according to ergonomic standards prior to the start of the protocol. Throughout the sitting trial participants completed a standardized typing task that aimed to simulate typical office report writing. Immediately prior to the sitting trial, participants completed a baseline rating of perceived low back pain using a 100 mm visual analog scale (VAS) with anchors of 0 mm (No Pain) and 100 mm (Worst Pain Ever). This rating was then repeated every 7.5 minutes throughout the trial. Accelerometer data were collected continuously throughout the sitting trial in four 15-minute blocks. Accelerometer data were processed using a custom written program (Matlab R2015b The Mathworks Inc., Natick, Massachusetts, USA). This includes calibrating the axes with respect to gravity, converting voltages to accelerations, calculating absolute inclinations from accelerations, smoothing the data using a dual-pass 2<sup>nd</sup> order Butterworth filter with a cut-off frequency of 1Hz and then adjusting the accelerometer inclination according to quadrant (based on the sign combination of the y and z axes). The inclinations of each sensor are then used to calculate the relative lumbar flexion angle and then the normalized lumbar flexion angle, expressed as a percent range of motion. To focus only on changes in perceived pain response, baseline pain ratings were subtracted from each subsequent rating throughout the trial. These baseline-removed ratings of pain were then used to classify participants into three groups based on clinically relevant levels of pain<sup>4</sup>: Pain developers (PD) reported > 20 mm of perceived low back pain, while sub-clinical pain developers (SC) reported > 10 mm but < 20 mm, and non-pain developers (NPD) reported < 10 mm of perceived pain throughout the typing trial. A one-way ANOVA was conducted with a Tukey's post-hoc test to compare the normalized flexion, peak pain rating, and questionnaire scores between pain

groups (SPSS, Version 22.0, IBM, Armonk, NY, USA). Self-reported family history of back pain was correlated to pain group status using Pearson's correlation coefficient. Significance was accepted at the  $p=0.05$  level.

## RESULTS AND DISCUSSION

8/32 (25%) of the study population were identified as PD, 8/32 (25%) as SC, and 16/32 as NPD. Average Peak Pain Ratings for the left and right low back respectively were 2.7(+/-2.83) mm, 2.0(+/-2.62), mm (NPD), 12.7(+/-4.84) mm, 15.2(+/-3.14) mm (SC), and 38.2(+/-19.56) mm, 38.1(+/-20.20) mm (PD). These peak pain ratings were statistically significant between pain groups ( $p=0.0001$ ).

The average normalized lumbar flexion angles adopted by participants throughout the trial were 51.2 (% ROM) +/- 22.57, 60.9 (%ROM) +/- 15.67 and 65.3 (%ROM) +/- 25.29 (Figure 1) for NPD, SC, and PD respectively. Flexion angles were not statistically different between groups ( $p=0.402$ ).

**Figure 1:** Average normalized lumbar flexion angles (%ROM) for all pain groups throughout the typing trial.

With respect to family history of LBP the results suggest no relationship exists with pain group status ( $r^2 = -0.50$ ,  $p=0.799$ ). The TSK and BPAQ show no statistically significant difference between pain groups ( $p=0.303$  and  $p=0.103$  respectively).

Results from this study are similar to previous research by Gallagher et al. (2011) where distinct pain groups emerged in response to prolonged standing. In this investigation a SC group was

identified to be statistically different from both the PD and NPD groups. It is possible that SC individuals did not have enough time to develop into PD since our study only examined a 1-hour exposure, suggesting there are possible differences in response rate between individuals. With respect to seated posture during sitting as indicated by the normalized lumbar flexion angles, it appears that the PD and SC groups adopted more spine flexion for the duration of the hour protocol. This is consistent with previous research where it is hypothesized that flexed postures lead to LBP through mechanisms such as increased disc pressure<sup>5</sup> and/or viscoelastic creep<sup>6</sup>.

## CONCLUSIONS

This investigation found three distinct groups of individuals emerge in respect to perceived pain development during sitting. The identification of the subclinical group suggests that some individuals may develop pain quicker than others. The data from this study showed no relationship between family history, kinesiphobia or negative attitudes towards LBP and pain group. Trends in the data indicate that adopted spine flexion angle may be playing a role. Future work should further investigate the role of spine posture as well as explore the responses in a clinical population.

# Active End-Range Spine Flexion Changes in Response to Prolonged Sitting

<sup>1</sup>John Charles Snow, Matthew Barrett and Diana De Carvalho

Faculty of Medicine, Memorial University of Newfoundland, St. John's, NL, Canada

email: jcs505@mun.ca

## INTRODUCTION

Research has identified that most workers are seated for the majority of the workday in developed countries.<sup>3</sup> Sitting often involves non-neutral postures of the spine, at times inducing near end ranges of spinal flexion.<sup>1</sup> Sustaining extreme ranges of flexion for as little as 20 minutes has been shown to alter spine flexibility.<sup>2</sup> However, the effect of near-end ranges, such as those observed in office chairs<sup>1</sup>, has yet to be studied. The purpose of this study was to examine the effect prolonged office chair sitting has on the active maximum spine flexion angle.

## METHODS

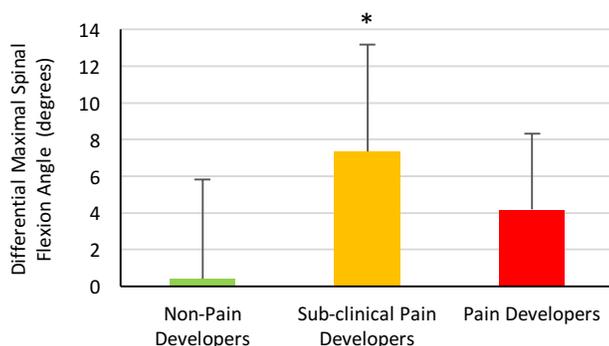

26 participants (4 females, 22 males), average age 24.1 years  $\pm$  7.7 (SD), height 179 cm  $\pm$  8.6 (SD) and mass 78.7 kg  $\pm$  10.7 (SD) were recruited from the local population. Exclusion criteria included a history of tumor, infection, fracture, inflammatory arthropathy and/or previous surgery of the spine. Two tri-axial accelerometers (ADXL335, Analog Devices, Norwood, MA, USA) were fixed to the skin in the +y down +x left, +z anterior orientation using double-sided tape overlying the L1 and S2 spinous processes. Accelerometer signals were collected at a sample rate of 1500 Hz using a 16-bit A/D board (Noraxon, Scottsdale, AZ, USA). Following instrumentation, four 10 s posture calibration trials were collected: upright standing, maximum extension, maximum flexion (standing) and maximum flexion (seated). Participants were then seated at a computer workstation that consisted of an adjustable height table, desktop computer, standard keyboard and the seat pan of a standard office chair. The workstation was adjusted to each participant individually prior to the start of the data collection. Throughout the sitting trial participants completed a standardized typing task that involved mimicked report writing. Immediately prior to starting the sitting trial, participants completed a baseline rating of perceived low back pain using a

100 mm visual analog scale (VAS) with the anchors of 0 mm/"No Pain" and 100 mm/"Worst Pain Ever". This rating was then repeated every 7.5 minutes throughout the trial. Accelerometer data were collected continuously throughout the sitting trial in four 15-minute blocks. Following the sitting trial the maximum flexion (standing) trial (10 s) was repeated. Accelerometer data were processed using a custom written program (Matlab R2015b, The Mathworks, Natick, MA, USA) to extract the lumbar angles from the raw accelerometer data as follows: calibrating the sensors with respect to gravity, converting voltages to accelerations, calculating absolute inclinations, smoothing the data using a dual-pass 2<sup>nd</sup> order Butterworth filter (cut-off frequency 1 Hz) and calculating the relative spine angle from the absolute inclinations of the top and bottom sensor. A normalized flexion angle was calculated using the functional range of motion trials and representing the flexion angle as a percentage of maximum flexion range. Normalized flexion angles were averaged over the sitting trial. To represent changes in spine flexibility, a differential lumbar spine angle was calculated by subtracting the pre-sitting trial maximum spine flexion value from the post- maximum flexion value. To focus only on changes in perceived pain ratings in response to sitting, the baseline pain rating was subtracted from each subsequent rating throughout the trial. Baseline-removed ratings of perceived pain were then used to classify participants into three groups according to the peak value rated at any point in the trial: "Pain developers" (PD) > 20 mm of perceived low back pain, "sub-clinical pain developers" (SC) reported >10 mm but < 20 mm, and "non-pain developers" (NPD) reported <10 mm of perceived pain.<sup>3</sup> A one-way ANOVA with a between factor of pain group was conducted for the outcome measures of maximal spinal flexion angle differential, average lumbar spine angle during sitting and peak perceived pain rating (SPSS, Statistics 23, IBM Software, Armonk New York). Tukey's test was

conducted post hoc. For all tests significance was accepted at the  $p=0.05$  level.

## RESULTS AND DISCUSSION

Of the total study population, 23% were identified as PD, 31% as SC and 46% as NPD (Table 1). The average peak pain ratings were  $31.5 \pm 11.4$ ,  $15.2 \pm 3.1$  and  $2.9 \pm 2.8$  for PD, SC and NPD respectively. The peak pain ratings were statistically significant between pain groups ( $p = 0.011$ ). The differential maximum flexion angle increased for all pain groups ( $4.2^\circ \pm 4.2$ ,  $7.3^\circ \pm 5.8$ , and  $0.4^\circ \pm 5.9$  for PD, SC and NPD respectively, Figure 1). These differences were found to be significantly greater in the SC pain group ( $p = 0.023$ ). The average normalized lumbar spine angles adopted by participants throughout the trial were: 64.6 % ROM  $\pm 24.9$  and 53.9 % ROM  $\pm 23.4$ , 51.0 % ROM  $\pm 21.8$ , for PD, SC and NPD respectively. There were no significant differences between pain groups for average normalized lumbar angle adopted throughout the sitting trial ( $p=0.392$ ).

**Figure 1:** The differential angle (representing the difference between pre- and post- sitting trial measures). The SC group exhibited a significant increase in maximum angle (\*).

Similar to the findings of end-range flexion induced flexibility changes<sup>2</sup>, a one-hour exposure to office chair sitting appears to increase the active maximum spine flexion angle. By analyzing this response in the context of perceived pain, our results show that these flexibility changes appear to differ by pain groups. Considering all pain groups sat with similar spine posture throughout the prolonged sitting trial, the mechanism behind this differential pain development remains unknown. It is interesting that significant differences were found in the SC group but not PD group. Perhaps these flexibility changes begin to reverse as pain increases and reactive stiffness sets in. Future work will need to explore this phenomenon in greater detail.

## CONCLUSIONS

This study shows statistically different pain response groups with a 1-hour exposure to sitting. Further, while all groups showed increasing spine flexibility this difference was only significant for the SC group. Such flexibility changes are of clinical importance as they could result in altered spine stability and potential low back injury. Further research needs to be done to determine if this response is dose dependent and/or affects muscle reflex activations.

## INTRODUCTION

Low back pain (LBP) is a prevalent (18 %), costly (\$15 to \$50 billion per year in the USA), and often disabling musculoskeletal disorder affecting the general population [1]. Among working-age adults, LBP is quite common among sedentary workers next to workers performing heavy lifting. Sedentary work characteristics may explain such prevalence. No substantial association, however, has been reported between perceived low back discomfort (due to prolonged sitting), and objective measures on postures, muscle activity, and blood oxygenation of the lumbar spine [2]. Hence, the causal relationship between occupational sitting and LBP is still unclear.

While identifying a specific cause of LBP development remains challenging, spinal instability has been considered as an important casual mechanism [1]. Stabilization capacity of the trunk can be quantitatively described using trunk intrinsic stiffness and apparent mass that can be obtained based on a displacement-controlled perturbation paradigm to assess the mechanical behaviors of trunk active and passive tissues. In this study, we test the hypothesis that prolonged sitting to perform a computer-based task would be associated with reductions in trunk intrinsic stiffness and apparent mass, given that performing such task in a sitting position likely involves maintaining the trunk in flexed lumbar postures for a long time, and this would in turn alter mechanical stability of the spine.

## METHODS

Five young adults with no self-reported history of low back pain in the previous 12 months completed the study, after completing informed consent procedures approved by the Virginia Tech Institutional Review Board. Their mean (SD) age, height, and weight were 24.8 (2.6) years, 169.7 (12.9) cm, and 70.8 (10.2) kg, respectively. Each participant

performed a total of 3 hours of computer-based tasks in continuous sitting. Prior to the sitting period, and immediately following the sitting period, participants were asked to rate the pain in the low back region using a visual-analog scale (verbally anchored at 0% for no pain and 100% for worst pain imaginable), and trunk mechanical behaviors were assessed using a sudden perturbation paradigm [3].

For trunk perturbation, participants stood up in a rigid metal frame and wore a shoulder harness that was connected by a rigid rod at the T8 level to a servomotor. Then, a pseudorandom sequence of twelve anterior-posterior perturbations ( $\pm 5\text{mm}$ ) were generated by the servomotor and transferred to the trunk via a rigid rod-harness. During the perturbations, trunk motion was measured using signals from the motor encoder and laser sensor, while applied forces were measured by a load-cell sensor which was placed in-line with the rigid rod (Fig. 1). Participants maintained a constant baseline extensor effort which was set as 10% of maximum voluntary RMS (root-mean-square) EMG in the lumbar erector spinae at the L3 level.

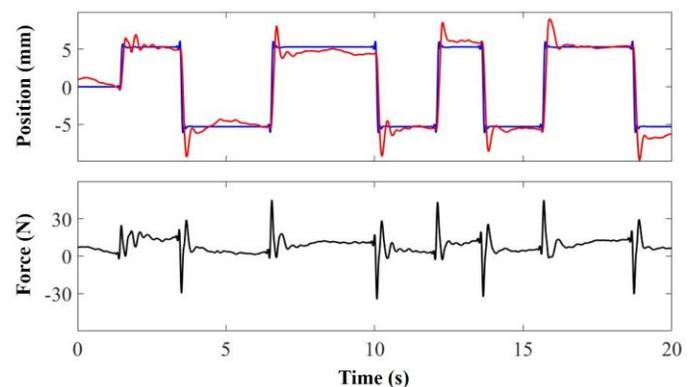

Figure 1: Representative data obtained during a sequence of perturbations [Top: trunk positions measured by the motor encoder (blue line) and measured displacement of T8 level from the laser sensor (red line); Bottom: driving force measured from the load-cell sensor]

Trunk dynamic properties were estimated during a latent period of 60 ms following each perturbation, using a system identification approach relating the measured trunk kinematics to kinetics. A two degree-of-freedom spring–mass–damper system [3] was used to model the trunk (1) and harness-rigid rod assembly (2):

$$F(u, t) = \begin{Bmatrix} F_1 \\ F_2 \end{Bmatrix} = \begin{bmatrix} 2.7 & 0 \\ 0 & m_2 \end{bmatrix} \begin{Bmatrix} \ddot{u}_1 \\ \ddot{u}_2 \end{Bmatrix} + \begin{bmatrix} c_1 & -c_1 \\ -c_1 & c_1 + -c_2 \end{bmatrix} \begin{Bmatrix} \dot{u}_1 \\ \dot{u}_2 \end{Bmatrix} + \begin{bmatrix} k_1 & -k_1 \\ -k_1 & k_1 + -k_2 \end{bmatrix} \begin{Bmatrix} u_1 \\ u_2 \end{Bmatrix}$$

where  $F$  (external force) and  $u$  (displacement) were measured variables,  $m$  (mass),  $c$  (damping), and  $k$  (stiffness) were estimated using a least-squares curve fit procedure. Anteriorly directed perturbations yielding high correlation ( $> 0.99$ ) and low mean square error ( $< 0.005$  N) between measured and model-predicted driving force were selected for further analysis. Intrinsic trunk stiffness and apparent mass for all selected perturbations were averaged to yield one value for each parameter for each subject, prior to sitting and following 3 hours of sitting.

## RESULTS AND DISCUSSION

Table 1 shows the results of the study. Three participants (P2, P4, and P5) showed an average of ~32% increase in low-back discomfort with sitting for 3 hours. This corresponded to ~60% decrease in trunk stiffness and to ~25% decrease in mass. These are in agreement with our hypothesis and aligned with expectations from previous research [3]. However, P1 and P3 presented contrary results: self-reported discomfort was increased by about half as much as the other group (~16%), and trunk stiffness and mass were increased by ~120% and by ~27% after sitting, respectively. These inconsistent results in our limited sub-sample could be due to several

reasons. We speculate that since the reversal in trunk mechanical properties from our expectation was associated with much less discomfort at the end of sitting in 2 participants, there may be some individualized coping strategies associated with prolonged sitting. This may either be that those individuals were not using consistently flexed lumbar postures while sitting or that they may have been sitting in a less “static” manner by employing variable postural/muscle activation strategies. We have recorded the muscle activities from multiple thoracic/lumbar muscles as well as postures during the sitting task. In addition to testing more subjects to improve statistical power, future research will also examine trunk stiffness-related changes of muscle activation and kinematics during the sitting task.

In conclusion, quantifying spinal stability via changes in trunk intrinsic stiffness and apparent mass may be a promising approach to objectively evaluate acute changes in spinal mechanical behaviors as a result of prolonged sitting. This in turn may improve an etiological understanding of why prolonged sitting causes low-back pain, and help inform and set targets for interventions addressing this problem.

## INTRODUCTION

New miniature accelerometers are based on piezoresistive MEMS (Micro-Electro-Mechanical Systems) elements. These smaller sensors can be easily coupled to the low-back/lower-lumbar spine of a human subject. Studies with larger devices have also been conducted with sensors attached to the low back of human subjects [1]. Based on the literature, no studies have compared every-day activities for lumbar-spine acceleration profiles and their frequency content measured simultaneously with MEMS wireless and wired accelerometers. Research has been conducted on lumbar-spine acceleration profiles and their frequency content during ejection seat tests or other severe lumbar accelerations with live human subjects and/or with Anthropomorphic Test Devices, but not during every-day activities[2],[3].

The purpose of this research was to study the lumbar-spine acceleration profiles and their frequency content of a group of human subjects while they carried out every-day activities. This study also compared the performance of a wireless versus a wired device simultaneously coupled to the lumbar spine of each subject.

## METHODS

Fifteen activities and one roller coaster ride event that humans may experience on any given day were performed by seven healthy subjects (Table 1). The subjects were: three females (21-51 y/o; wt: 61-78 kg; ht: 1.52-1.65 m) and four males (35-50 y/o; wt: 72-88 kg; ht: 1.65-1.86 m). Two types of MEMS accelerometers were fastened to a mount molded to fit the lower lumbar area of each subject. One device was a low-cost, wireless triaxial accelerometer (X16-2, GCDC, Inc.) while the other device was a high-cost triaxial accelerometer wired

to an external data acquisition system (53A, MSI, Inc./TDAS-PRO, DTS, Inc.). The sensors measured three orthogonal translational accelerations near the subjects' L5 [lumbar] vertebrae: Front-to-back acceleration was the x-axis component (forward:+), side-to-side was the y-axis (left:+) and up-down was the z-axis (up:+). The wireless sensor sampling rate was set to its maximum, 400 Hz. The wired system sampling rate was set to its minimum, 500 Hz. Both accelerometers detected steady-state and transient accelerations.

Matlab algorithms compared the lumbar accelerations from both devices as follows: (1) the signals from the wireless sensor were up-sampled to 500Hz to synchronize with those from the wired sensor. (2) The Power Spectral Density (PSD) estimates of each raw signal were computed using Welch's Periodogram to study their frequency content. (3) Based on the PSD estimates, the signals were Low-Pass-Filtered (LPF) at various upper cutoff frequencies. (4) The PSD's were also used to characterize the signal-to-noise-ratios (SNR). (5) The correlation coefficients between the signals from each device were computed for the data from each activity. (6) The root-mean-square-deviations (RMSD) between the signals from each device were also computed. (7) The predominant acceleration components and resultant acceleration magnitudes were determined and their profiles were analyzed.

## RESULTS AND DISCUSSION

The acceleration profiles were examined in terms of their peak accelerations and pulse durations. For a comparison of the pulse *durations*, the accelerations were numerically integrated to obtain *velocities*. Table 1 shows the peak velocities and accelerations for selected subjects in the predominant directions for each every-day activity. The average peak values

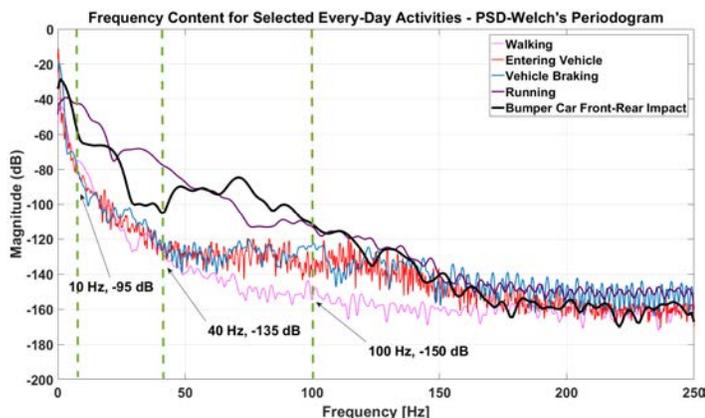

are reported for cyclic events such as hopping, walking, etc.

The frequency content of the accelerations in terms of signal power showed three salient frequency ranges: Long-duration events such as vehicle braking had the most significant signal power at approximately 10-Hz or below.

**Table 1:** Summary of Results (BC=Bumper Car).

Activity, LPF Upper Cutoff (Hz)	Peak Velocities, m/s	Peak Accelerations, g's	Correlation Coefficient
Vehicle Braking (10)	(x) 9.1; (z) -1.3	(x) -0.94 ; (z) 1.12	(x) 1.0 ; (z) 0.99
Speed Bumps (50)	(x) -0.4 ; (z) 0.5	(x) 0.47 ; (z) 2.09	(x) 0.98 ; (z) 0.96
Chair Plops (40)	(x) 1.7 ; (z) -1.8	(x) 1.18 ; (z) 3.93	(x) 0.98 ; (z) 0.86
BC Front Impact (100)	(x) -1.9; (z) 0.6	(x) -1.42 ; (z) 1.93	(x) 0.97 ; (z) 0.87
BC Rear Impact (100)	(x) 1.6 ; (z) -1.0	(x) -0.34 ; (z) 2.78	(x) 0.98 ; (z) 0.94
BC Side Impact (100)	(y) 2.1 ; (z) -0.4	(y) 1.76 ; (z) -0.05	(y) 0.91 ; (z) 0.86
Walking (100)	(x) 1.2 ; (z) 0.1	(x) -0.19 ; (z) 1.33	(x) 0.97 ; (z) 0.98
Upstairs Slow (100)	(x) 0.3 ; (z) 0.8	(x) -0.32 ; (z) 1.56	(x) 0.98 ; (z) 1.0
Downstairs Slow (100)	(x) -0.1 ; (z) 0.0	(x) -0.66 ; (z) 1.97	(x) 0.98 ; (z) 0.98
Upstairs Fast (100)	(x) 0.9 ; (z) 1.6	(x) -0.88 ; (z) 2.90	(x) 0.84 ; (z) 0.91
Downstairs Fast (100)	(x) 1.1 ; (z) -0.4	(x) -0.96 ; (z) 3.48	(x) 0.86 ; (z) 0.99
Running (100)	(x) -0.5 ; (z) 1.5	(x) -0.39 ; (z) 4.69	(x) 0.89 ; (z) 0.99
Heel Strikes (100)	(x) 0.1 ; (z) 0.3	(x) 1.23 ; (z) 6.69	(x) 0.93 ; (z) 0.98
Hopping (100)	(x) 0.5 ; (z) 2.2	(x) -4.24 ; (z) 8.15	(x) 0.97 ; (z) 0.96

The signal power of events such as entering/exiting a vehicle, chair plops and traveling over speed bumps extended into frequencies of 40-50 Hz; short-duration events such as heel strikes, running, hopping and climbing stairs tended to have more signal power of up to 100-Hz. Fig. 1 provides an overview of these frequency ranges. Fig. 2 shows examples of acceleration profiles for selected everyday activities and the braking event from a roller coaster ride.

**Fig. 1:** Accelerations frequency content.

The mean percent difference in the calculated peak resultant accelerations differed at most 9.55% between the low cost and the high-end sensor.

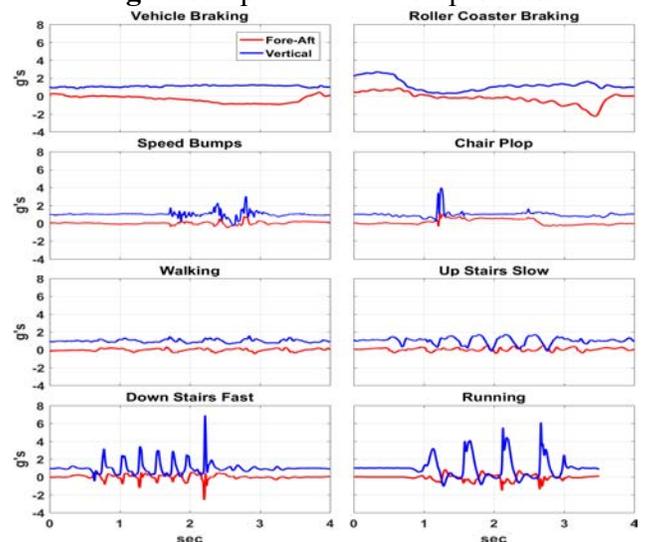

## CONCLUSIONS

The lumbar-spine acceleration profiles and their frequency content were studied for fifteen everyday activities and one roller coaster ride event. Measurements from a wireless (low-cost) and a wired (high-cost) accelerometer were compared. The overall signals of both of these sensors exhibited good correlation (Avg. 95.4%) and low root-mean-square deviations (Avg. 0.103). It was evident that the sampling rates used were limited for some activities. The low-cost device recorded relatively noisier signals than the high-cost device.

# DIFFERENCES IN PRINCIPAL COMPONENTS IN SIT-TO-STAND IN PARTICIPANTS WITH AND WITHOUT LOWER BACK PAIN

Mauricio Nunez Jr, Young-Hoo Kwon  
Biomechanics Laboratory, Texas Woman's University, Denton, TX, USA  
Email: mnunez3@twu.edu

## INTRODUCTION

According to the National Institute of Neurologic Disorders around 80% of adults are affected by lower back pain at some point in their lives. The pain can stem from sprains, strains, herniation, rupture, stenosis, or injury. The etiology of back pain is limitless and ranges from chronic debilitating ailments to acute issues. The problem with back pain is that the symptoms are treated but the root cause is not rectified.

Having imbalances causes some muscle groups to become tightened and others stretched and weakened. The way that these muscle groups are affected can be seen in movement patterns (Nadler et. Al 2000) This study will attempt to identify different movement patterns between self-reported lumbar pain and a control no pain group. The resulting movement strategies, or principle components, will be compared between the two groups.

The purpose of this study was to investigate the kinematic and kinetic differences in non-pain versus self-reported lower back pain and analyze the movement using Principle Component Analysis. The null hypothesis is that there exists no difference in the components of movement between participants with back pain and no back pain.

## METHODS

69 participants ranging from ages 18-35 were selected from the local university student population using emails and flyers. The participants self-reported no lumbar pain versus lumbar pain using a Wong-Baker scale to rate and locate the area of pain. The participants were then divided into a pain and no-pain group; 40 in the control (no-pain) and 29 in the lumbar pain group.

The 10-camera Vicon motion capture system and four AMTI force plates were used for data capture at 100 Hz. The participant was prepped and instructed to stand and sit slowly on a platform 60 cm high and stand back up to complete one stand-sit-stand motion. The task was chosen from normal activities that are repeated various times through a normal day.

Once the data collection for the 3 trials were completed, the 3 trials per participant were averaged. The data was then normalized to only include starting from sitting position to a stand position. The different Principle Components of the marker coordinates were calculated for each participant's average trial. The Eigenvalues, Eigenvectors, and a visual representation of the data was calculated. The results were based on a method previously implemented in a study that analyzed the principle components of alpine skiers (Federolf et. Al 2012). The data used for this study represented the first 10 PCA's that contributed to the overall movement strategy. Each component represented a movement strategy and the results indicated the percent of the strategy used by the participant; if a participant had PC1 of .84, that resulted in the participant using PC 1 as 84% of the overall movement. The resultant components are a method to quantify the different parts of an overall movement. The results were then analyzed using SPSS to evaluate if there were significant differences between participants with lower back pain and the control in the resulting movement strategies.

## RESULTS AND DISCUSSION

Using the results from different components allowed us to analyze the utilization of different movement patterns that muscle groups performed

(Zago et. Al 2016). Since there was 1 dependent variable with 10 levels and 1 independent variable, an independent sample t-test was run and the results demonstrated statistically significant differences in components 4,5,6 and 8 as shown in table 1.

The components that were significant were then analyzed by reconstructing the movement pattern using the PC results to subjectively find a movement strategy for that component. For Example, figures 1 and 2 showed the beginning and end sections of component 8 which was determined to be a knee bending strategy. The video representation demonstrated that the component was an extension and a posterior shift of the knee joint; bringing the knees behind the toes as standing occurred. Component 4 was determined to be a hip strategy in which the hips were posteriorly shifted during the stand. Component 5 was an overall straightening of the body. Component 6 was an adduction of the arms.

## CONCLUSIONS

There were significant differences in certain principle components (4,5,6,8) in a standing test between participants with lower back pain and participants with no lower back pain. We reject the null hypothesis and accept that there is a significant difference between the 2 groups. Further investigation of the timing and velocities of the components will be done in the future to attempt to discover how and why the use of different components is employed by the different groups. Also, kinetic and kinematic data of the involved segments and joints will be further analyzed.

# THE EFFECTS OF BREAST SIZE AND BODY IMAGE ON POSTURE, MUSCLE ACTIVATION AND BACK PAIN DURING 2 HOURS OF PROLONGED STANDING

Susari Wanninayake and Janessa Drake

York University, Toronto, ON, Canada  
email: jdrake@yorku.ca

## INTRODUCTION

Women with large breasts often experience various symptoms such as back pain, neck pain and shoulder grooving from brassier straps [1]. Research has shown that women with large breast sizes can cause greater thoracic kyphosis and lumbar lordosis [1]. These angles improve after women undergo breast reduction surgery [1]. Further, trunk muscle activation has shown to be greater in women with larger breasts compared to women with smaller breasts in some cases [2]. However, it is unclear how women of various breast sizes cope during prolonged exposures. Two hour prolonged standing protocols have been shown to be an effective approach to evaluate spine motion [3].

Additionally, women's breasts can often influence their body image and self-esteem. However, it is unclear whether body image and/or self-esteem influence posture. If other psychological factors such as depression can influence posture, then it is possible that body image and/or self-esteem may also influence posture [4].

The primary objective of this study was to observe how posture in women with various breast sizes respond to prolonged standing. The secondary objective was to determine if there was a possible relationship between body image and posture.

## METHODS

Twenty-one healthy, university aged females (Table 1) were recruited for this study. Each participant measured their two breast circumferences that were used to calculate breast size. The first measurement was taken at the widest point of the breasts (OBCC) and the second measurement was taken under the breast at the mammary fold (UBCC) [5]. Typically,

a 2.54cm (1 in) difference would represent an A cup, 5.08cm (2 in) is a B cup, 7.62cm (3 in) is a C cup, etc. [5]. A ratio of OBCC/UBCC was used to divide participants in breast size groups to factor in different body sizes. Prior to the collection participants completed the Rosenberg Self-esteem Scale (RSES) and the Body Shape Questionnaire (BSQ) to evaluate body image.

**Table 1:** Mean (SD) anthropometrics by comparison groups: small breast size group (SG) and large breast size group (LG).

	SG (n=11)	LG (n=10)
Age (years)	23.36 ±2.58	20.10 ±1.66
Mass (kg)	60.66 ±11.39	61.90 ±7.25
BMI	21.78 ±2.39	22.21 ±2.56
OBCC-UBCC (cm)	7.39 ±2.11	13.97 ±1.80
Avg. Cup Size	~ B-C	~ D-E

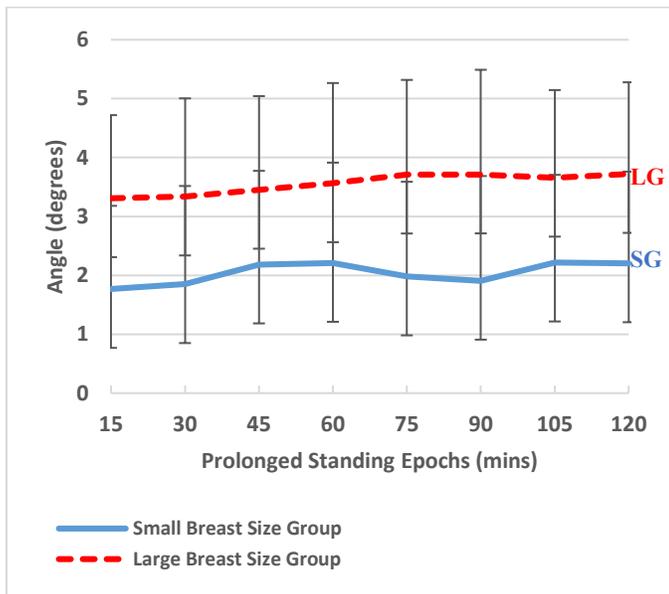

Eight muscles bilaterally were recorded by surface electromyography (EMG) electrodes on the abdominal, back and gluteus medius muscles. Maximal voluntary contractions (MVCs) were collected for each muscle group of interest. Using an optoelectronic system, the motion was tracked for: upper thoracic (C7-T4), mid thoracic (T4-T9), lower thoracic (T9-T12) and lumbar (L1-S2) segments.

Participants stood at a table for 2 hours. During this time, they completed 4 quiet tasks (30 min each) in random order. The Visual Analog Scale (VAS) was used to record perceived pain. The participants rated their upper back (C7-T6), mid back (T6-T12), and low back (lumbar) pain every 15 minutes. Maximum change in VAS was calculated. A change equal to or greater than 10mm was considered to be clinically significant [3].

All statistical analyses were performed in SAS 9.4 (SAS Institute Inc., NC, USA). Three way repeated measures mixed model ANOVAs were performed compare sample groups with dependent variables.

## RESULTS AND DISCUSSION

Throughout prolonged standing, segment flexion angular responses over time were similar between breast size groups (Figure 1). But breast size was a significant main effect in upper thoracic and lumbar segments ( $p < 0.032$ ). But, there is a main effect of breast size on segment flexion angles. LG had more flexed upper thoracic and greater extended lumbar angles, but no difference in the mid thoracic angles relative to SG at each time epoch.

**Figure 1:** Mean upper thoracic segment responses during 2-hr prolonged standing between LG and SG. The initial upright bias was subtracted out.

Four of the 16 muscles showed a significant difference between breast size groups (mean) right rectus abdominis (RRA), left gluteus medius, left external oblique and right thoracic erector spinae at the T4 level, ( $p < 0.031$ ). In general, SG had either greater muscle activation or were no different from LG. This would suggest that the LG group could be relying more on passive tissue. Also, in general SG showed greater variable mean muscle activation than

in LG. It is suspected that this variability in the SG group muscle activation could explain why overall, the LG group had a greater number of pain developers than SG (Table 2).

**Table 2:** Percentage of non-pain developers and pain developers from upper, mid and low VAS scores between SG (n=11) and LG (n=12).

	Upper (%)		Mid (%)		Low (%)	
	NPD	PD	NPD	PD	NPD	PD
SG	45.5	54.5	54.5	45.5	27.3	72.7
LG	10	90	30	70	20	80

There is a possible relationship between self-esteem (RSES) and as well as body image (BSQ) and breast size. The LG group had lower self-esteem and greater body image dissatisfaction than the SG group. These relationships have potential to impact spine angles. However, further research is needed to identify the impact between the psychosocial measures and posture.

## CONCLUSIONS

The more flexed thoracic and more extended lumbar spine angles, differences in EMG and increased pain responses in LG may suggest that women with larger breasts are an important subgroup to be identified in future prolonged standing research. Especially given the potential impact of body image and self-esteem on these responses in LG. Additional participants spanning the A to G+ cup sizes are needed to fully elucidate these relationships.

## INTRODUCTION

Following external forces applied to the head-and-neck (HN) complex, restraint moments are generated by muscles and the viscoelastic soft tissues of the cervical spine, predominantly ligaments and joint capsules, as well as contact forces at the facet joints and intervertebral discs [1]. Quantification of contact forces in response to applied external forces to the head is necessary to characterize the biomechanical response of the HN in general, and to differentiate injury mechanisms at the craniocervical segment. However, due to the complex osteoligamentous morphology of the craniocervical segment, quantification of the contact force in different directions is difficult to anticipate as they will be dynamically shaped by the active response of soft tissues. In this study, we used finite element modeling to investigate the direction and magnitudes of contact forces at the craniocervical segment under application of external anterior-posterior forces to the head.

## METHODS

Predictions were based on simulations of our validated HN 3D nonlinear complex FE model [2]. For the simulation, neck efforts were assumed to be produced under static conditions to maintain HN stability under an antero-posterior force application. An anterior and posterior forces up to 100N and 350N were applied to the occipital and to the frontal bone of the head, respectively, under the presence of a constant 40N HW applied to its center of mass. The first thoracic vertebra was fixed while the head and cervical vertebrae were free to translate but not to rotate. These boundary conditions reflect the rotation restriction applied by the muscles to each bony

structure of the HN to keep the complex in its neutral posture. The computed reaction moments at the center of mass of each bony structure represent the net muscles moments required to counterbalance the applied force and to maintain static stability of the segment. The contact force between the occipital condyles and the superior articular facets of C1 (C0-C1), the transverse ligament (TL) and the dens at C2 (TL-dens) and at the facet joints between adjacent vertebrae (C1-C3) were also predicted. Finally, the relative translation of the occipital condyles on C1 and between each adjacent vertebra of the cervical spine segment was computed along the three anatomical directions. The static nonlinear FE analyses were performed using Abaqus 6.11.

**Figure 1:** Finite Element Model of the head and neck; the location and direction of the externally applied load is shown.

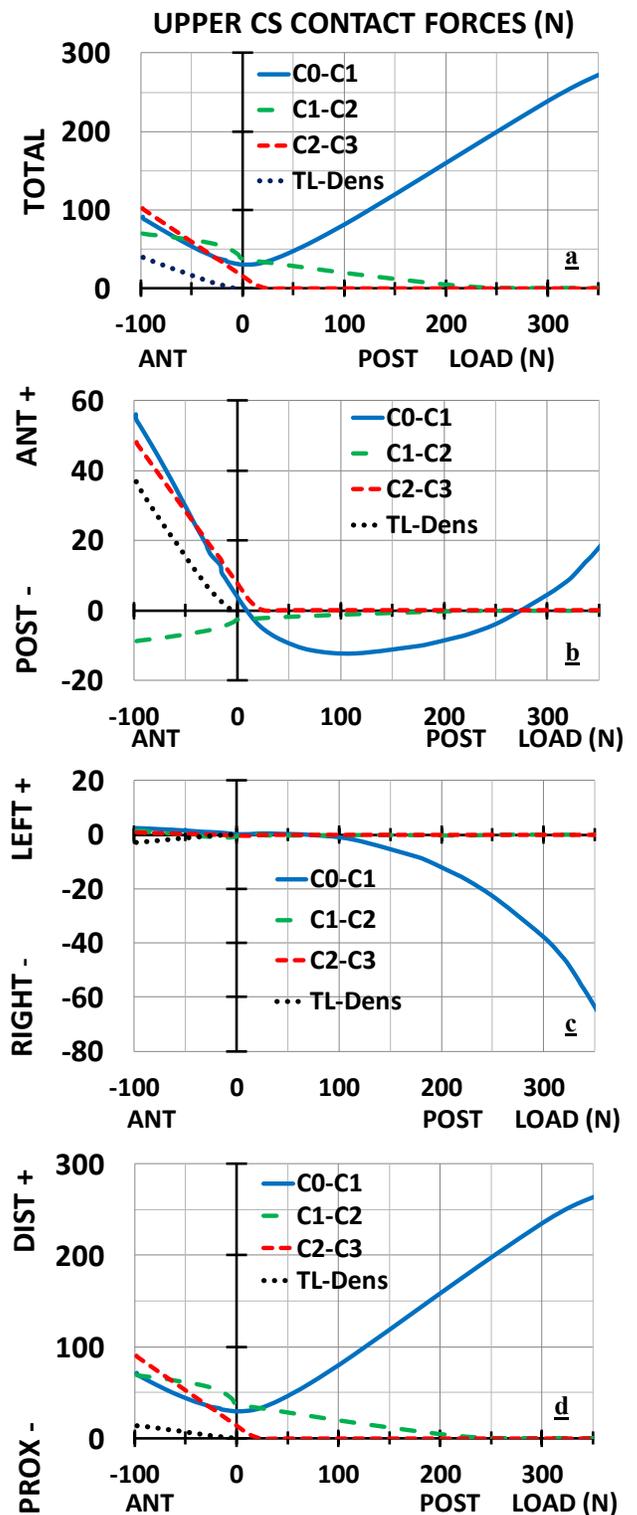

## RESULTS AND DISCUSSION

The CFs at the facets joints of the upper (C0-C3) cervical segments as well as the CF between the transverse ligament (TL) and the Dens of C2 vertebra are shown in Fig 2a-d. The 40N HW produced a total

CF of 29.8N at C0-C1 and 37.1N at C1-C2 oriented mainly to the distal direction (Figs 2b-d). With the application of an antero-posterior load, the contact forces at C0-C1 increased quasi-linearly as a function of the magnitude of the applied force, reaching a maximum of 266N, with a posterior force of 350N, and 84N, with an anterior force of 100N (Figure 2a). At segmental levels below C1, the profile of CFs varied for applied posterior and anterior forces. For anterior forces, the CF on the facet joints and at TL-Dens increased quasi-linearly as a function of increasing magnitude of the applied force (Figures 2a). The predominant CF component of the facets joints segment of C0-C3 was found in the distal direction and pursued by the anterior direction for C0-C1 and C2-C3 and by a posterior force for C1-C2 (Figs 2b, d). In fact, an anterior CF inflects to the HN complex an extra moment applied at the levels of the facets joints requiring an additional net muscles moment to counterbalance the effect of the anterior CFs which is confirmed by a net moment of the whole muscles greater than the maximum moment of the external forces in the HN complex calculated at T1 vertebra. However, for posterior forces, the CF was present mainly at C0-C1 level in the whole directions followed by C1-C2 in the distal direction up to 200N posterior force. The CF at C0-C1 was increased substantially to the right direction after a posterior force of 100N reaching 66N at 350N (Fig. 2c) but remains under 20N in the antero-posterior direction (Fig. 2b) while the force is in the posterior direction.

## CONCLUSIONS

The response of the CFs is mainly related to the shape of the surfaces in contact and the contact response influences directly the muscles response and translations of the vertebra in the joint leading to the development of a coupling phenomenon in which the application of a pure force in the antero-posterior direction, generating external moments in the sagittal plane, leads to a response of the joint in the frontal and transverse planes. This finding may elucidate the understanding of the muscles activities response while a loading is applied in a specific direction and to understand the mechanism of injuries in the cervical spine.

**Figure 2:** Contact forces of the upper cervical joints at the various anatomical directions. The CF are shown over the range of applied anterior and posterior external forces in presence of 40N HW.

# EFFECTS OF LUMBOPELVIC-HIP COMPLEX INSTABILITY ON THROWING MECHANICS AMONGST FEMALE HANDBALL ATHLETES

Gabrielle Gilmer, Sarah Gascon, Gretchen Oliver

Auburn University, Auburn, AL, USA

email: ggg0005@tigermail.auburn.edu, web: www.sportsmedicineandmovement.com

## INTRODUCTION

Throwing is a kinetic chain activity that requires coordinated energy transfer from the proximal segments (pelvis and torso) to the most distal segments (arm and hand) [1]. It has been documented that inadequate strength throughout the kinetic chain may contribute to inefficient force production and decrease optimal energy transfer for throwing performance [2]. The sport of team handball (THB) is unique in that it stresses both the lower extremity (LE) in the side-to-side cutting as well as the upper extremity (UE) in the volume of overhand throwing. Additionally, THB requires segmental stability throughout the kinetic chain for efficient dynamic movement. The ability to transfer energy and perform an accurate shot on goal is dependent on the synchronization, stabilization, and strength of the UE and LE.

The lumbopelvic-hip complex (LPHC) is the key component in connecting the UE and LE [2]. Previous research has shown that proper stabilization of the LPHC leads to higher rotational velocities across all segments [3]. Thus, interruptions in this energy transfer may lead to decreased performance and injury susceptibility [2].

Literature has shown injuries of the shoulder and knee in THB account for 44.0% and 26.7% of all injuries, respectively [4]. Even though the injury rates and the importance of energy transfer throughout the kinetic chain are known, there has yet to be a comparison examining LE segments and their contribution to the UE segments in THB athletes. Therefore, the purpose of this study was to examine the relationship between LPHC stability and segmental sequencing during a jump shot. It was hypothesized that LPHC instability would

affect segmental velocity sequencing of the pelvis (PV), torso (TV), humerus (HV), and forearm (FV).

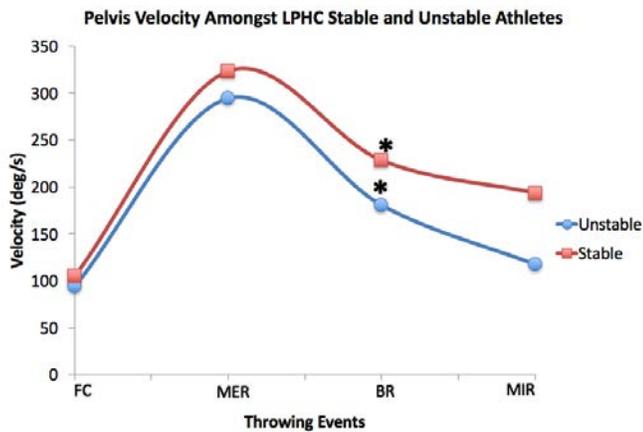

## METHODS

Twenty female THB athletes (26.5±4.7 years; 174.6±4.2 cm; 74.4±6.4 kg) participated. An electromagnetic tracking system was used to collect kinematic data (100Hz) while participants performed three 9-meter jump shots. Data were analyzed across four events: foot contact (FC), maximum shoulder external rotation (MER), ball release (BR), and maximum shoulder internal rotation (MIR).

It is known that dynamic knee valgus indicates LPHC instability, however there are sparse quantitative data indicating what degree of instability is of concern as well as how LPHC instability effects throwing mechanics [5]. The current study utilized FC as the event to classify LPHC instability. This event was chosen because it is early in the throwing motion, and an interruption at this point ultimately cumulates to issues throughout the throw. LPHC instability was classified as 17° or greater knee valgus at FC [6].

## RESULTS AND DISCUSSION

Mann-Whitney U-test was used for analysis. Results revealed statistically significant differences between groups amongst PV at BR ( $p = 0.015$ ). Figure 1 shows the PVs change over the course of the throw. Table 1 shows the TV, HV, and FV medians over the course of the throw. The results from this study reject the hypothesis.

**Figure 1:** Median pelvis velocity values are shown over the course of the throw. Significance was found between groups at BR.

Thus, the authors speculate that LPHC instability could possibly decrease the efficiency of energy transfer through the LPHC and to the upper extremity in these selected athletes. In addition it should be noted that these selected athletes were currently training in the USA Women’s National Team Handball residency program, and it is possible that due to their heavy training regimen, they were still able to stabilize the body even though instability is present.

These finding may also suggest that knee valgus at FC is not a consistent indicator of LPHC instability. It is widely accepted that dynamic valgus is an

indicator for LPHC instability [1], but it remains unclear for what part of the throw and how much valgus deems an individual unstable.

## CONCLUSIONS

The main findings of this study reveal that LPHC instability, as classified at FC, resulted in significant differences between groups in PV at BR. However, it is unknown whether compensations are being made or if FC is a poor indicator of LPHC instability. Therefore, it is recommended that future studies include muscle activation, and further research investigate the best way to classify LPHC instability within a throw among THB athletes.

<b>Forearm</b>	Unstable	444.02	998.22	1684.74	737.04
	Stable	413.61	979.11	1878.06	701.23

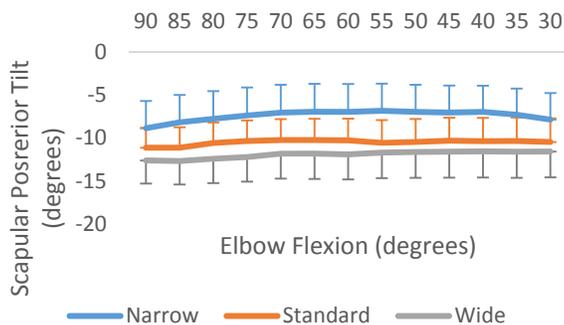

## RESULTS AND DISCUSSION

There was no significant interaction between elbow flexion and hand position for upward rotation (UR) ( $p = .938$ ). There was no main effect of elbow flexion for UR ( $p = .232$ ). However there was a main effect of hand position on UR ( $p < .001$ ). Pairwise comparisons indicated that standard and narrow conditions showed greater UR than wide ( $p = .001$  and  $p = .002$ , respectively). However no significant difference was seen between standard and narrow conditions ( $p = .091$ ) (Figure 2).

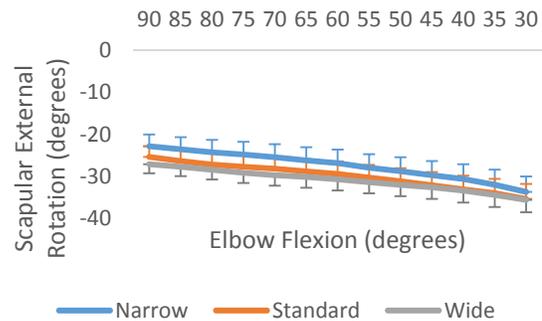

**Figure 2:** Scapular upward rotation (mean  $\pm$  SEM) across elbow flexion angle for each hand position.

There was no significant interaction between elbow flexion and hand position for posterior tilt (PT) ( $p = .821$ ). PT was affected by hand position ( $p = .001$ ), with greater PT in Narrow than in wide conditions ( $p = .004$ ). There was no significant main effect of elbow angle ( $p = .218$ ) (Figure 3).

**Figure 3:** Scapular posterior tilt (mean  $\pm$  SEM) across elbow flexion angle for each hand position.

There was no interaction between elbow flexion and hand position on external rotation (ER) ( $p = .073$ ). There were main effects of both hand position ( $p = .021$ ) and elbow flexion ( $p < .001$ ) on ER. ER decreased linearly with elbow extension ( $p < .001$ ) (Figure 4).

**Figure 4:** Scapular external rotation (mean  $\pm$  SEM) across elbow flexion angle for each hand position.

## CONCLUSIONS

The current data indicates that a narrow hand position shows the greatest amount of UR, ER, and PT during the concentric phase. Furthermore a wide hand position shows the least amount of UR, ER, and PT when compared to standard and narrow. This indicates that a narrow hand position may be more applicable for a rehabilitation setting, as it promotes healthy scapular motion, whereas a wide hand position may put the scapula in a position that is at risk for subacromial impingement.

# NEURAL NETWORK PREDICTION OF JOINT TORQUES IN OLYMPIC WEIGHTLIFTING

Kristof Kipp, Matthew Giordanelli, and Christopher Geiser

Marquette University, Milwaukee, WI, USA  
email: kristof.kipp@marquette.edu

## INTRODUCTION

Biomechanists often analyze joint kinetics because they provide useful information about the neuromuscular and motor control mechanisms during human movement [4]. The problem that sports biomechanists and coaches face is that in order to calculate joint kinetics, they need to collect whole-body kinematic data, ground reaction force data, and anthropometric data.

Neural networks (NN) may provide a viable alternative because they can be used to analyse complex relationships between biomechanical inputs and outputs [1,3]. For example, Liu et al. [3] used a NN to predict lower extremity joint torques during vertical jumps from ground reaction force data (GRF). Further, Hahn and O'Keefe [2] used NN to predict joint torques from kinematic data.

The purpose of this study was to develop and train NN to predict hip, knee, and ankle joint torques from vertical and horizontal motions and mass of a barbell during an Olympic weightlifting exercise.

## METHODS

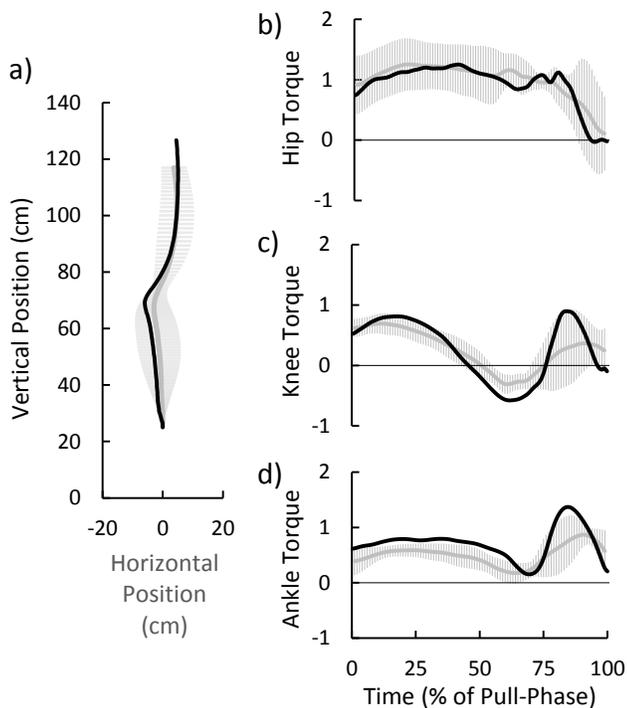

Seven weightlifters (body-mass:  $106.0 \pm 13.2$  kg; max clean lift-mass:  $126.4 \pm 22.9$  kg) were recruited for this study. After a brief warm-up with several repetitions and sets at lighter loads, each lifter performed two repetitions at 85% of their estimated 1-Repetition Maximum (RM) of the clean exercise.

Sixteen reflective markers were attached to various anatomical landmarks of each lifter's feet, shanks, thighs, and pelvis [2]. In addition, a strip of reflective tape was wrapped around the long axis of the barbell at its mid-point. The three-dimensional position of these markers were recorded with a 6-camera motion capture system at 250 Hz. GRF were collected at

1,250 Hz from two force plates that were built into a 2.4 m x 2.4 m weightlifting platform.

The kinematic and kinetic data were filtered at 6 Hz and 25 Hz, respectively. Lower extremity biomechanics were calculated from a rigid-link model that included a foot, shank, thigh, and pelvis segment. An inverse dynamics procedure, which combined kinematic and GRF data with basic anthropometric data, was used to calculate the net internal joint torques of the hip, knee, and ankle joints [4]. Torques were normalized to each lifter's body-mass and height (i.e.,  $\text{N} \cdot \text{m} \cdot \text{kg}^{-1} \cdot \text{m}^{-1}$ ). Time-series data from the right leg were then extracted and time-normalized to 100% of the pull phase, which was defined as period from when the barbell left the platform to when the GRF fell below 10 Newton's. The horizontal and vertical positions of the barbell were also extracted during the pull phase.

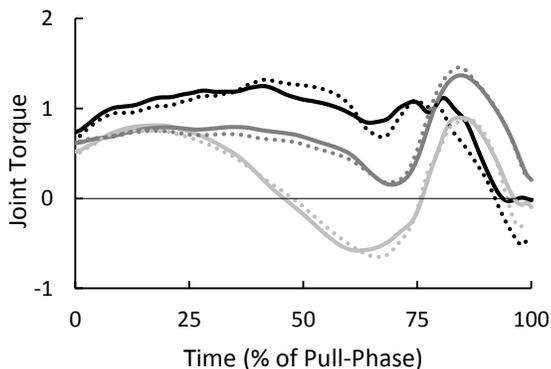

The horizontal and vertical positions as well as the mass of the mass of the barbell served as inputs to a NN to predict the joint torque time-series. The NN consisted of a nonlinear autoregressive network with exogenous inputs, and had a 3-layer input level, a 10-layer hidden level, and a 3-layer output level. The NN was trained with Levenberg-Marquardt back-propagated error correction and had a feedback-delay of 1:2. The NN was developed and trained on data from six of the seven weightlifters, and then tested with data from the one remaining weightlifter (Figure 1) [3]. The performance of the NN was evaluated based on its mean square error (MSE) and inspection of the predicted data output in relation to the actual input data. In addition, the percent difference between actual and predicted peak hip, knee, and ankle joint torques were calculated to provide a pragmatic interpretation of the NN performance [3].

**Figure 1:** Ensemble average (Mean±SD) of training cases (grey line and error bars) and the single test case (black) for a) barbell position and b) hip, c) knee, and d) ankle joint torque data.

## RESULTS AND DISCUSSION

A low MSE ( $4.70e^{-5}$ ) obtained from the training of the NN indicated that the NN effectively captures the relationship between joint kinetic data and barbell mass and kinematic data during the clean.

**Figure 2:** Actual (solid line) and predicted (dotted line) hip (black), knee (dark grey), and ankle (light grey) joint torque data.

Further, application of the trained NN to the test case showed that it was possible to predict joint torques from the barbell kinematic data and mass with a low error (MSE = 0.0119) (Figure 2).

**Table 1:** Percent difference (%Diff) between actual and predicted joint torques with NN.

Joint	Actual	Predicted	%Diff
Hip	1.25	1.31	5%
Knee	0.90	0.88	-2%
Ankle	1.36	1.45	6%

The prediction errors (MSE) for the individual joint torques were 0.0266 for the hip, 0.0092 for the knee, and 0.0096 for the Ankle joint. With respect to the peak joint torques, the results of the current study indicate that the vertical and horizontal barbell motions as well as lift mass could predict the joint torques to within 6% (Table 1).

## CONCLUSIONS

This study highlighted the ability of a NN to predict joint kinetic data from barbell mass and kinematic data. Given that the horizontal and vertical motions of the barbell can be easily recorded and processed with low-cost motion analysis solutions, the results of the current study suggest that sports biomechanists and coaches could use NN to readily analyze joint torque data of weightlifters during either practice or competition without expensive equipment or obtrusive instrumentation of athletes.

# MUSCLE SYNERGIES IN FEMALE ATHLETES WITH GENERALIZED JOINT HYPERMOBILITY

Christopher F. Geiser, Matthew Giordanelli, Lydia Legler, Courtney Kost, Philip Malloy, and Kristof Kipp

Marquette University, Milwaukee, WI, USA  
email: Christopher.geiser@marquette.edu

## INTRODUCTION

Individuals are characterized as having Generalized Joint Hypermobility (GJH) when they have a greater than normal range-of-motion (ROM) at multiple joints throughout their body, and are often referred to in the common vernacular as “double-jointed”<sup>1</sup>. GJH is more common in females and younger ages<sup>2</sup>. Individuals with GJH who participate in athletic activities are more at-risk for knee injury<sup>3</sup>, injury in general<sup>4</sup>, and they sustain more severe injuries than non-GJH counterparts<sup>4</sup>.

Previous studies have examined whether individuals with GJH attempt to control their joint laxity by altering muscle activation patterns. Subjects with GJH were found to have greater co-activation levels of erector spinae muscle groups and of hamstring and quadriceps muscles, all key joint stabilizing muscle groups, during a balance task<sup>5</sup>. GJH subjects also exhibit greater hamstring and quadriceps co-contraction during gait<sup>6</sup> and during isometric knee flexion<sup>7</sup>, presumably to stabilize their more mobile knee joints. However to date, no analysis of motor control or muscle activation patterns have been done in high level athletes during demanding athletic movement tasks.

Non-negative matrix factorization (NNMF) is becoming a popular tool to evaluate muscle synergies and activation patterns, because it offers unique insight into motor control strategies. NNMF has been used to evaluate clinical differences in motor control strategies between children with cerebral palsy and controls during gait<sup>8</sup>. The goal of the current investigation was to use this technique in the evaluation of control strategies of GJH individuals across multiple stabilizing muscle groups during a complex athletic task, testing the hypothesis that high level female athletes with GJH demonstrate muscle synergies similarly to non-GJH control

subjects from the same team and training background.

## METHODS

Thirty eight athletes from a women’s Lacrosse team were screened for GJH using the Beighton and Horan Joint Mobility Index (BHJMI)<sup>9</sup>. Individuals with a score of 5 or greater were assigned to the GJH group<sup>10</sup>. Individuals with scores of 0 or 1 were used as controls, and those with scores of 2 to 4 were excluded from the study.

Eight wireless surface EMG sensors were placed on each players’ dominant side Gluteus Maximus and Medius, Rectus Femoris, Vastus Lateralis and Medialis, Biceps Femoris, Medial Gastrocnemius and Anterior Tibialis of each subject. Leg dominance was determined by asking which leg they prefer to kick a ball with (right leg in all subjects). The skin was prepared by cleaning with an alcohol wipe and allowed to dry prior to electrode placement, no subjects needed shaving. Sensors were applied with manufacturer adhesives strips and reinforced with flexible adhesive tape.

Subjects performed a single-leg land-and-cut (CUT) task in the lab while EMG and force plate data were collected. The CUT task involved standing on a box, jumping forward and landing on the dominant leg, and cutting immediately 90 degrees away from the land leg. The height of the box was set equal to each subject’s max vertical jump height, as measured from the displacement of a pelvis marker during a maximum countermovement jump. The box was set back from the force plate a distance equal to each participant’s maximum single leg stride distance. This task was chosen because it was a challenging single-leg, athletic-like task that still allowed expedient data collection in a controlled lab setting. To avoid biasing subjects, the same instructions to

“land and quickly cut to the left” were given to each subject. Participants were allowed to practice the task until comfortable, and then performed 3 successful trials. Trials were deemed unsuccessful if the subject could not complete the task, or if they turned and faced the CUT direction instead of facing forward.

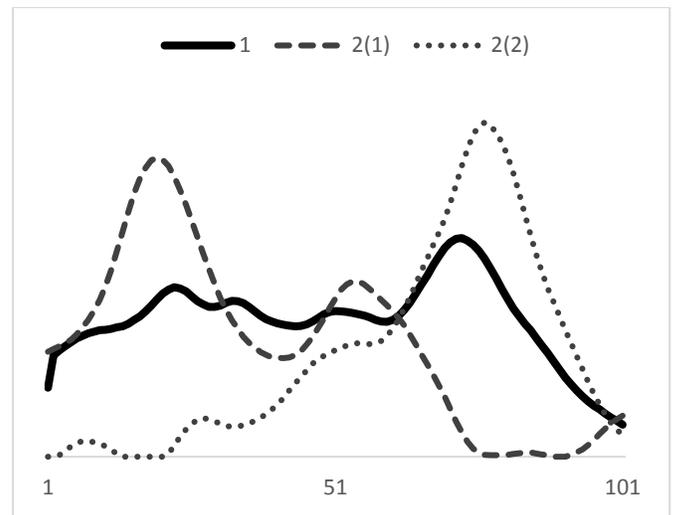

EMG and GRF data were collected at 960 Hz. Data were exported for analysis with custom Matlab software. Data were filtered in Matlab using a Bandpass filter with cutoff frequencies of 10Hz to 400Hz. GRF data were used to determine the stance phase of cutting. The stance-phase EMG data for all muscles were time normalized, and ensemble averages were calculated for each of the 8 muscles. The time-normalized ensemble averages for each subject were used as inputs to an NNMF procedure<sup>8,11</sup>. The NNMF algorithms were looped to continue until the variance accounted for (VAF) in the overall muscle activation profiles reached a threshold of 95% using a sum-of-squares approach. The number of activation synergies needed to reach 95% VAF, and the %VAF by the first synergy were used for statistical analysis. The group differences in means for these two variables were analyzed in SPSS with a one-way ANOVA, with significance level set at  $\alpha = 0.05$ . Simple effects sizes were calculated with Cohen’s  $d$ .

## RESULTS AND DISCUSSION

Seven women had a score of 5 or more on the BHJMI (GJH group:  $19.4 \pm 1.0$  years,  $66.0 \pm 6.1$  kg,  $167.3 \pm 3.3$  cm). Eight controls from that same team had a score of 0 or 1 on the BHJMI (CTRL group:  $19.9 \pm 1.2$  years,  $62.1 \pm 7.1$  kg,  $165.3 \pm 7.3$  cm).

The GJH group exhibited fewer muscle synergies than the CTRL group ( $1.67 \pm 0.43$  vs.  $2.25 \pm 0.43$ ;  $p = 0.02$ ,  $d = 1.38$ ), which points to a less complex muscular control strategy during the stance phase in people with GJH.

Although the VAF of the first muscle synergy did not differ significantly between groups (GJH:  $94.4 \pm 1.2\%$ ; CTRL:  $92.0 \pm 2.8\%$ ;  $p = 0.053$ ,  $d = 0.87$ ), the large effect size indicates that there may be clinically meaningful group differences.

**Figure 1:** Example of synergy activation coefficients for an individual subject with one synergy (1) and a subject with 2 synergies [2(1) and 2(2)] to account for >95% variance in muscle activation patterns.

## CONCLUSIONS

Together, these results provide support for the hypothesis that individuals with GJH use a simpler muscle activation strategy during the execution of an athletic task. The simpler strategy may reflect greater co-contracting of lower extremity muscle groups, which may be a means to better stabilize the lower extremity joints in the face of hypermobility. Given that people with GJH are at greater risk of injury, it would be of interest to further study the association between muscle synergies and risk of injury, as well as the effects of targeted training on muscle synergies in relation to injury risk.

## INTRODUCTION

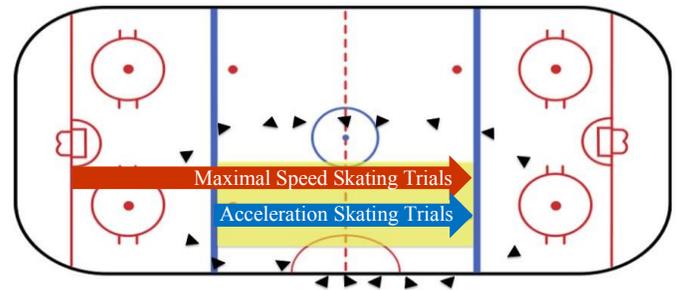

Ice hockey is a popular winter sport in North America. Many factors determine strategic gameplay advantage: one fundamental attribute is an athlete's "power skating"; more specifically, one's ability to achieve rapid skating start acceleration up to maximal speed. Coaches emphasize this in training drills based on total time per distance covered; however, discrete trajectory measures of skaters' position over time are required to understand skating technique mechanics to optimize performance. For instance, in sprint running, centre of mass (COM) acceleration profiles can detect key phase transition points that correspond to changes in body segment angles [1]. Similar analyses in ice hockey would allow a comprehensive understanding of the mechanics involved in acceleration to maximal skating speed.

This is the first study to quantify the COM forward velocity-time trajectories of elite ice hockey skaters from start to maximal speed, and to compare the trajectories of male and female athletes.

## METHODS

Nine male (22±1 years) and ten female (21±1 years) elite ice hockey players participated in this study. A single leg jump test evaluated lower limb power. Each participant was instrumented with a full-body marker set, including instrumented skates and a stick. Data was collected on an ice surface at 240 Hz with an 18-camera Motion Capture system (Vicon®, Oxford, UK) (fig 1). The skating acceleration phase (0-15m) and maximal skating phase (19-34m) were

captured independently. For the acceleration phase, the athletes skated between the blue lines, and the first 7 accelerative steps were captured. For the maximal skating trials, the athletes skated from the red goal line to the far blue line, and 4 steps of maximal skating were captured between blue lines.

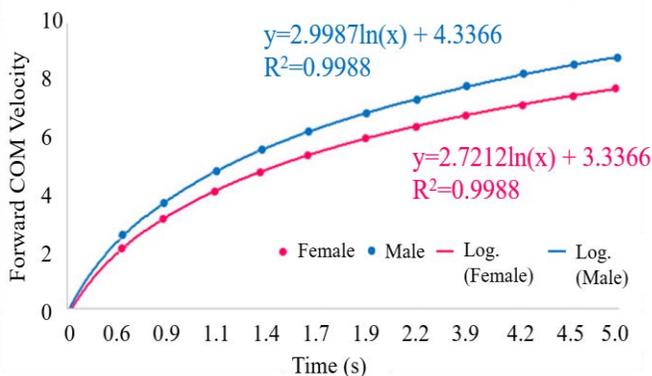

**Figure 1:** On-ice camera set-up (black triangles) and calibrated capture area (yellow shaded area).

The complete skating velocity-time trajectory was generated using logarithmic projection of the accelerative steps' forward velocities. The maximal speed phase steps were plotted on the logarithmic line of best fit according to the respective time (frame) distance between phases for each participant. Data was processed using Vicon Nexus 2.1.1 (Vicon®, Oxford, UK), and Visual 3D software (Ver 5.01.23, C-Motion, Germantown, MD, USA). Data was analyzed using custom MATLAB (Mathworks, Natick, MA, USA) scripts. SPSS Statistic Software (IBM Corporations, Somers, USA, Version 23.0) was used for statistical analysis. Mixed-ANOVAs were used to test for interactions between skater sex and step number on COM measures. A Pearson's  $r$  correlation determined the strength of the relationship between leg power and peak speed. Significance level was set at  $p < 0.05$  for all tests.

## RESULTS AND DISCUSSION

The single leg jump test showed significant differences between females and males on both the right ( $p=0.015$ ) and left ( $p<0.001$ ) sides, with male skaters jumping further in both cases. There was a strong correlation between peak leg power and peak speed ( $R^2=0.81$ ).

Logarithmic COM forward velocity-time profiles from start to maximal speed were similar between male and female skaters, though progressive male velocity gains superseded those of the females, where males were faster ( $p<0.001$ ) at any given distance (fig 2). Males achieved greater peak accelerations in the first 1.25 seconds ( $7.7$  vs  $6.2$   $m/s^2$  for males and females on average over the first four stance phases), but the male vs. female acceleration magnitudes were similar after the first 1.5 seconds of skating. Hence, the leg power output in the first four steps (1.25 seconds) was critical in the skate start performance, so it will be important for coaches to focus on these first four steps, as well as increasing lower body power, to maximize performance.

**Figure 2:** The velocity-time progression for males and females from standing start to maximum speed, including logarithmic equations and  $R^2$  values.

After 34 m from the start, body COM forward velocity was still increasing by 0.4 to 0.5 m/s per stride due to the overall positive net forward propulsion. In theory, skaters would reach their ultimate maximal skating velocity once they reach their anaerobic threshold [2]. It is unlikely that an ice hockey athlete would perform an all-out sprint to

exhaustion, especially in a game setting, so these athletes may never actually achieve their ultimate maximal speed. Hence, the maximal speed variables determined in this study are arguably representative of an in-game context.

The maximum acceleration during the first stance phase was  $7.8 \pm 1.6$   $m/s^2$  for females, and  $9.6 \pm 2.0$   $m/s^2$  for males. There was a significant difference of forward acceleration between sexes during the start phase ( $p=0.015$ ), but not during the maximal speed phase. The maximal speed phase within-stride accelerations oscillated between approximately 2 and  $-2$   $m/s^2$ , and the positive acceleration phase exhibited a bimodal pattern. Overall, a transition point between accelerative and maximal skating may be identified at the point at which negative acceleration intervals occur within the trajectory.

## CONCLUSIONS

Using a 3D motion capture system and a whole-body marker set, this study was successful in tracking skater's body COM movement patterns in an open ice surface setting. To the authors' knowledge, this is the first study to quantify the discrete velocity progression of elite ice hockey athletes from start to maximal skating. Overall, elite male and female ice hockey athletes showed similar COM trajectories, though males achieved a faster peak velocity than females, largely due to males' greater acceleration during the initial first four steps after the start. Hence, all things being equal, lower extremity power and starting step techniques are crucial to achieve maximal speed over a 30 m distance.

Future research on ice hockey skating should include kinematic analyses in conjunction with kinetic and/or physiological measures, in order to fully understand the implications of these sex-specific skating patterns on performance.

# Ball Contact Initiates Forearm Deceleration in a Volleyball Spike

<sup>1</sup> Glen C. Thompson, <sup>1</sup> Dylan G. Schmitz, <sup>1,2</sup> Kayt E. Frisch PhD

<sup>1</sup> Dordt College, Sioux Center, IA, USA

<sup>2</sup> email: [Kayt.Frisch@dordt.edu](mailto:Kayt.Frisch@dordt.edu)

## INTRODUCTION

A previous study has calculated kinetic and kinematic parameters for every arm swing phase prior to ball contact during a volleyball spike [1]. In baseball, a sport with a similar overhand motion, the deceleration phase during pitching has been associated with tensile loads strong enough to peel the biceps and superior labrum complex away from their humeral attachments [2]. Therefore, neglecting to analyze the contact and deceleration phases of the volleyball spike swing may lead to poor estimations of forces in the shoulder.

Minimal research has noted the importance of analyzing the deceleration phase in volleyball. Escamilla et al. presented the idea that contacting the ball produces an equal and opposite direction that acts as the main deceleration of the arm during a spike [3]. This study tests that hypothesis by measuring arm acceleration throughout the course of a volleyball spike to determine when the arm decelerates.

## METHODS

This study evaluated arm motion of five right-handed intercollegiate women's volleyball players. None of the athletes reported current shoulder and/or elbow pain. This study followed a protocol approved by IRB.

Each participant followed standard warm-up procedures prior to data collection. 25 reflective markers were placed on the trunk and upper body and tracked using a 12-camera motion capture system (1280 x 1024 pixels, 240fps, OptiTrack, Beaverton, OR).

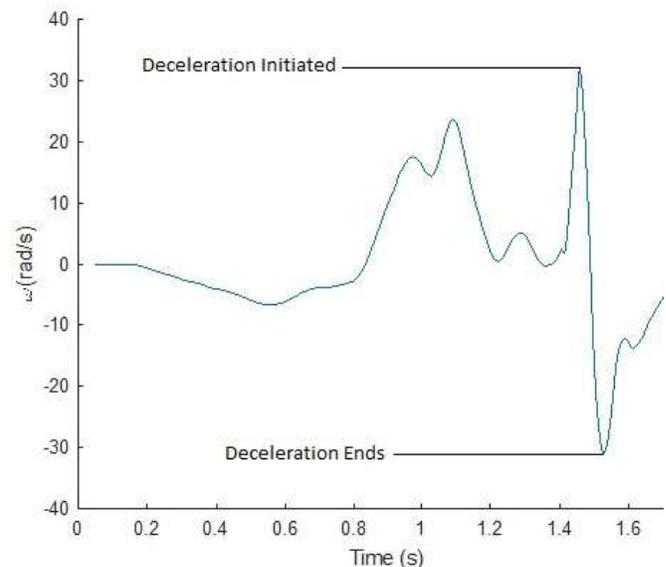

Each athlete was asked to spike the volleyball with a live set five times. Small gaps in the marker data were filled using the built-in interpolator, then

exported as .csv files to be analyzed with a previously created MATLAB program (MathWorks, Natick, MA).

Using the marker position data, the angular position, velocity, and acceleration of the forearm with respect to the global coordinate system's x-axis were calculated. These plots were used to assess the rate and temporal location of deceleration of the forearm during a volleyball spike.

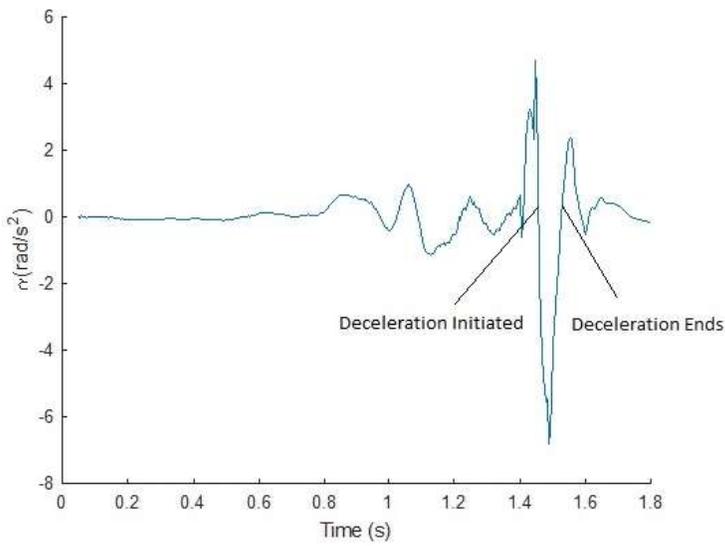

## RESULTS AND DISCUSSION

Consistently across multiple trials, for multiple subjects, the deceleration of the arm begins at the point of maximum angular velocity, which corresponds to a point of inflection in the angular acceleration plot. The deceleration phase finishes when the angular velocity reaches its global minimum, which also relates to another point of inflection in the angular acceleration plot. The trends in angular velocity for an experimental spike can be observed in Figure 1:

**Figure 1:** Forearm Angular Velocity for a Volleyball Spike

Similarly, the trends in angular acceleration for this spike can be seen in Figure 2:

**Figure 2:** Forearm Angular Acceleration for a Volleyball Spike

It was approximated that in this spike, deceleration initiated at 1.45 seconds and finished at 1.55 seconds. This means that the muscles producing the force to spike the volleyball were eccentrically loaded in approximately 0.1 seconds. It is unclear how variation in the rate of eccentric loading affects overall muscle functionality. However, it is possible that variations in loading time affect the muscle's ability to contract repeatedly.

This variance can be caused by many in-game factors. For a volleyball spike, the location of the set can have a large impact on swing mechanics. For example, during a match, the set may be closer to the net than the athlete initially anticipated, causing her to have to adjust her swing. This causes a more rapid

deceleration of the arm after the spike, because the attacker must avoid the net. This rapid deceleration may create a larger load on the rotator cuff, especially the supraspinatus and infraspinatus muscles. Further study is needed to elucidate these possible connections.

## CONCLUSIONS

The results indicate that ball contact initiates a large deceleration during a volleyball spike. This supports the hypothesis that the ball contact initiates deceleration [3]. This emphasizes the need for more information about the contact forces during a volleyball spike. The contact forces during a spike would provide the best estimate for the relatively large deceleration loading on the arm, and help determine if volleyball athletes are subject to the same loading risks that have been associated with shoulder injury in other overhead sports.

# QUANTIFYING CONTACT LOADING DURING A VOLLEYBALL SPIKE

<sup>1</sup>Dylan G. Schmitz, <sup>1</sup>Glen C. Thompson, <sup>1</sup>Chad DeGraaf, <sup>1</sup>Boone DeKramer, <sup>1,2</sup>Kayt E. Frisch PhD

<sup>1</sup>Dordt College, Sioux Center, IA, USA

<sup>2</sup>email: Kayt.Frisch@dordt.edu

## INTRODUCTION

The occurrence of shoulder pain and injury in young volleyball players is increasing, and it is likely that this may result from high repetition volume of overhand motions like spiking and serving. Reeser [1] analyzed the pre-contact shoulder kinematics and inferred muscle forces during a spike motion up to the moment of contact. However, the forces between the ball and the hand are thought to be relatively large [2] and should also be considered.

This abstract proposes a method to quantify the forces acting between a volleyball and the hand during a spike or serve. The method requires two distinct parts: (1) Direct measurement of the forces between the ball and the hand via pressure sensors and (2) indirect calculation of the forces in a classical impulse-momentum analysis of motion capture data.

## METHODS

The contact forces were measured using force-sensitive resistors (FSR) (TekScan FlexiForce A201 Sensors), in an inverting op-amp circuit configuration. An ATmega328 microcontroller master-slave system, programmed via the Arduino IDE, read and digitized the analog data outputs.

The slave devices were located on a forearm-mounted apparatus, along with the op-amp chips and resistors. To keep the forearm-mount size to a minimum, the power, input signal, and returning digital data were transmitted to the circuit by shielded wire. Power regulation, signal inversion, and data logging were performed on a larger belt-mounted device.

The digitized sensor output signal was stored to an SD card as a .csv file. Initial calibration of the FSRs generates a linear voltage-to-force conversion

regression, which allows the A/D values to be converted to meaningful force values. Averaging all sensors for each sample time and accounting for the relative areas of the sensor and contact surface gives the contact loading of the volleyball.

Indirect measurement of the contact forces can be achieved by tracking the translation and rotation of a volleyball in 3D space using motion capture. The motion capture software, Motive (OptiTrack, Corvallis, OR), includes spherical rigid-body tracking, so a tetrahedral marker set (4 reflective markers) is used to track the volleyball.

To mitigate marker occlusion, protruding spherical markers were affixed to the surface of the volleyball. Since the protruding markers made serving the volleyball more difficult, some trials used flat sticker reflective markers, but the marker occlusion was so severe that these trials were not considered.

Motive tracked not only the position of each marker, but also the translation and rotation of the spherical rigid body. Using a classical discretized impulse-momentum analysis (Eqn. 1) allowed estimation of the force on the hand:

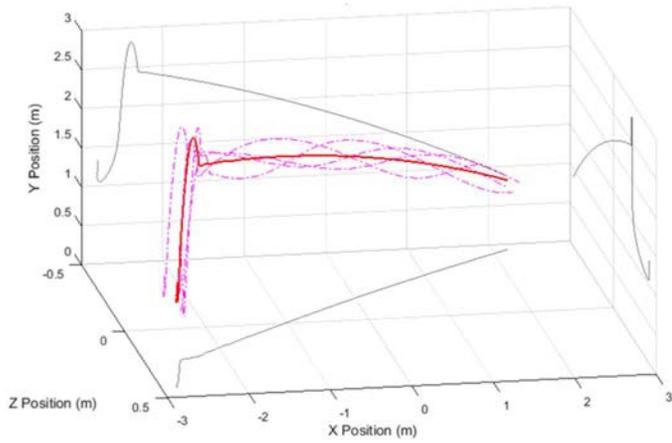

$$(F)(\Delta t) = m * (v_2 - v_1) \quad (1)$$

The impulse was obtained from the measured velocities immediately before and after hand contact. The impulse is approximated as a constant force over the duration of contact, so the impulse divided by the contact duration gave the average force applied.

## RESULTS AND DISCUSSION

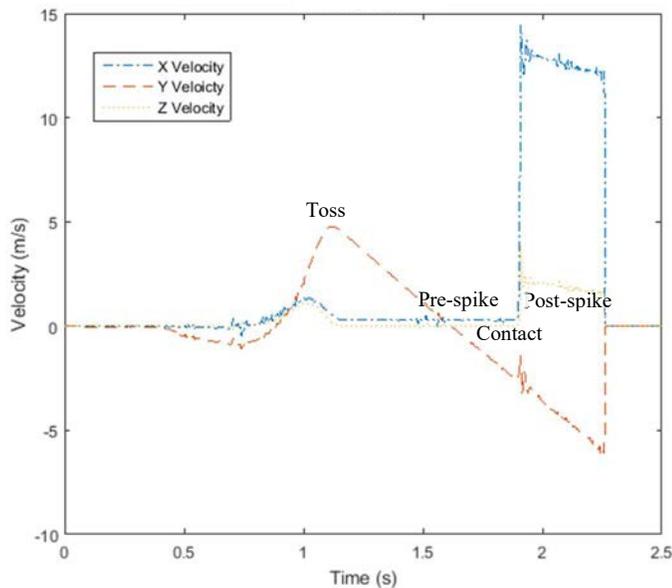

The tetrahedral marker set yielded satisfactory results for tracking the volleyball. The rigid body tracking feature in of Motive indirectly tracked the

geometric center of the ball. The motion capture system successfully logged the volleyball's center of mass (COM) in 3D, as well as the position of each marker (Fig. 1).

**Figure 1:** Trajectory of the volleyball in 3D. Solid line represents path of COM, dashed lines represent marker paths.

The custom MATLAB (MathWorks, Natick, MA) program used to determine force on the hand calculated the ball's translational velocity components in x, y, and z (Fig. 2). The velocities pre- and post-spike were used as  $v_1$  and  $v_2$ , respectively.

**Figure 2:** Velocity of the COM of the volleyball.

The duration of contact could not be accurately acquired from the motion capture data despite the fact that the frame rate was set to 240 fps. While this frame rate is sufficient for most applications, the duration of the impulse on the volleyball ranged from 10-15 ms, giving at most 3 samples during contact. Preliminary testing with the FSRs gave evidence that the contact duration would average 15 ms, which was used to estimate average loadings up to 400 N based on proof-of-concept tests with collegiate volleyball players.

## CONCLUSIONS

Complementary use of the direct (FSR) method and the indirect (impulse-momentum) analysis allowed estimation of the normal contact forces on the hand for a volleyball spike. Future work will focus on calculating the tangential forces that cause rotation of the volleyball. Additionally, the forces measured will be combined with a kinematics analysis to calculate shoulder loadings during contact.

# EVALUATION OF BICYCLE PEDALING ABILITY USING VERTICAL AND HORIZONTAL COMPONENTS OF PEDALING FORCE VECTOR

<sup>1</sup> Tomoki Kitawaki and <sup>2</sup> Tatsushi Tokuyasu

<sup>1</sup> Kansai Medical University, Hirakata, Osaka, Japan

<sup>2</sup> Fukuoka institute of technology, Fukuoka, Japan

email: kitawaki@hirakata.kmu.ac.jp

## INTRODUCTION

In recent years, a variety of power meters, devices that facilitate measurement of the pedaling force vector, for bicycles has become commercially available [1]. However, few consumer devices exist except for those used experimentally. In this study, the power meter is a pedaling monitoring system (SGY-PM900H90, SGX-CA900: Pioneer Corporation, Kawasaki, Japan) that displays a pedaling force vector to decompose the tangential and normal directions of pedaling force [2].

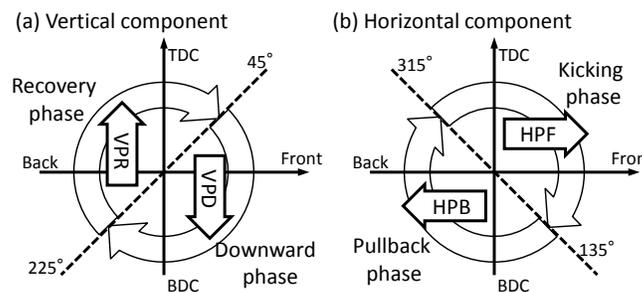

In order to evaluate bicycle pedaling ability, it is vital to know how riders can effectively exploit their own body weight (BW). However, it is difficult to determine how BW is used via an ability index calculation of the pedaling force vector [3]. Therefore, indices that are more accurate are required.

In this study, we aimed to evaluate the bicycle pedaling ability of amateur cyclists using new indices related to BW. These indices were calculated using the vertical and horizontal components of the averaged pedaling force vector signal obtained via a pedaling monitor system.

## METHODS

The pedaling load for twenty-eight male participants with written consent was increased from approximately 150–300 W in 1 min. intervals via a bicycle trainer (Powerbeam Pro-trainer: CycleOps, Madison, WI). The pedaling force vector output during incremental loading was recorded via a pedaling monitoring system (SGY-PM900H90). Cadence was not specified, i.e., each participant decided on a comfortable cadence. The pedaling

force vector was averaged at each load step, and the vertical and horizontal components, illustrated in Fig. 1, were calculated from the averaged value.

**Figure 1:** Vertical and horizontal components.

The indices calculated from these components of pedaling force are as follows:

- (1) The respective average vertical components in the downward phase (VPD: vertical power downward) and recovery phase (VPR: vertical power recovery).
- (2) The respective average horizontal components in the pullback phase (HPB: horizontal power back) and kicking phase (HPF: horizontal power front).
- (3) Applying a linear regression, standardized to 4.0 W/kg of each index using the corresponding load step value and normalized BW.

We then analyzed the respective correlations between VPD and sumVP (= VPD + VPR), HPB and HPF, and VPD and HPB.

## RESULTS AND DISCUSSION

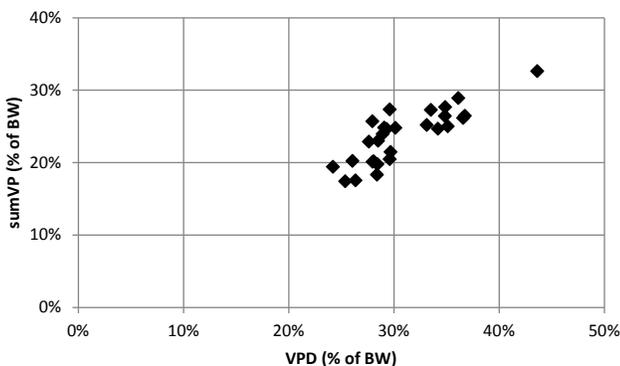

Participant condition, experimental conditions, and measurement values of indices are listed in Table 1 (mean  $\pm$  SD). Standardization at 4.0 W/kg is practical since the step load of each subject ranged from 2.75 to 5.26 W/kg. To clarify, vertical indices

VPD = 30.9% and VPR = -7.2% mean that 30.9% and 7.2% of BW are on the pedal in the downward and recovery phases, respectively; HPB = 11.9% means that a rearward force equivalent to 11.9% of BW is applied to the pedal in the pullback phase; the value of HPF indicates a small forward pedal force in the kicking phase.

**Table 1:** Participant condition, experimental conditions, and measured values of indices.

<b>Age</b>		39.4 ± 9.4
<b>BW (kg)</b>		63.3 ± 7.6
<b>Height (cm)</b>		170.4 ± 5.5
<b>Step load power (W)</b>	<b>from</b>	171.8 ± 15.4
	<b>to</b>	328.6 ± 39.5
<b>Power weight ratio (W/kg)</b>	<b>from</b>	2.75 ± 0.40
	<b>to</b>	5.26 ± 0.85
<b>Vertical indices (% of BW)</b>	<b>VPD</b>	30.9 ± 4.4
	<b>VPR</b>	-7.2 ± 2.4
<b>Horizontal indices (% of BW)</b>	<b>HPB</b>	11.9 ± 1.6
	<b>HPF</b>	1.0 ± 1.7

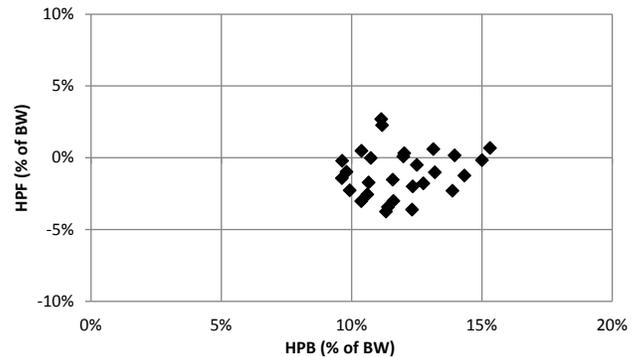

Figures 2 and 3 show the relationships of the indices. There is a significant correlation between VPD and sumVP ( $r = 0.832$ ,  $p < 0.001$ ). This means that a participant with a strong downward pedaling force in the downward phase tends to efficiently apply downward force with one leg while raising the other.

**Figure 2:** Correlation between VPD and sumVP.

In contrast, there is no significant correlation between HPB and HPF ( $r = 0.144$ ) or VPD and HPB ( $r = 0.265$ ). This indicates that most of the participants applied rearward force in the pullback phase and marginal forward force in the kicking phase, and that these forces are independent of each other. In addition, there is no relationship between vertical and horizontal power. From these results, it

is determined that indices are affected by the load applied to the pedal via the force of BW; this reflects the ability to harness one's own BW through pedaling ability. When downward force is large in the downward phase and pulling force is sufficient in the recovery phase, sumVP increases. Thus, the most effective measure of pedaling ability is suggested to be sumVP.

**Figure 3:** Correlation between HPB and HPF.

## CONCLUSIONS

To evaluate bicycle pedaling ability as related to body weight, the indices were calculated using vertical and horizontal components of the averaged pedaling force vector. Conclusions are as follows: (1) the most effective measure of pedaling ability seems to be the difference between downward force in the downward phase and pulling force in the recovery phase, and (2) the horizontal components in the kicking and pullback phases yield marginal influence on pedaling ability.

# LOWER LEG MORPHOLOGY AND PLANTARFLEXION STRENGTH IN DANCERS

Paige E. Rice, Herman van Werkhoven, Edward K. Merritt, Wilton J. Norris,

Jordan P. Rodrigues and Jeffrey M. McBride

Department of Health & Exercise Science, Appalachian State University, Boone, NC, USA

Email: ricepe@appstate.edu

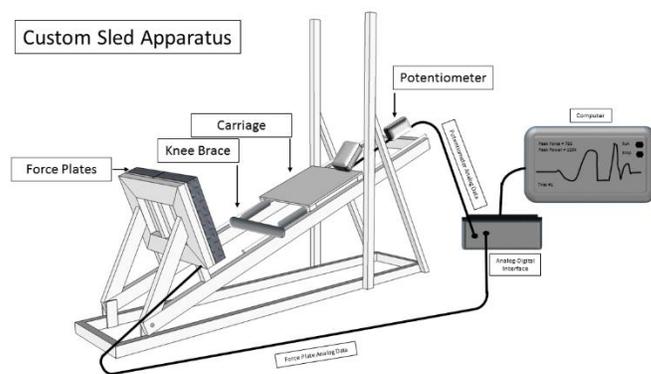

## INTRODUCTION

Rigorous training that involves leaping and jumping has been shown to influence skeletal and muscular characteristics. Many common dance movements are associated with high ground reaction forces imposed on the lower leg (LL), which might yield higher levels of bone and muscle strength to sustain such impacts similar to other weight-bearing activities. LL measurements such as bone failure load, similar to ultimate fracture load (UFL), bone stress-strain index (SSI), muscle cross-sectional area (CSA) and muscle power have shown to correlate with one another in a variety of athletes [1, 2]. Past findings have also indicated that muscle CSA is directly proportional to maximal strength levels. Dancers focus a great deal on plantarflexing and generating force about the ankle joint during leaps and jumps that might result in increased maximal voluntary isometric plantarflexion (MVIP) strength. By use of peripheral quantitative computed tomography (pQCT), bone and muscle characteristics can be easily identified without the imposition of overlaying tissues. To our knowledge, no research has reported LL morphology with pQCT and its relationship to strength levels in dancers. The aim of this investigation was to compare relative bone UFL, bone SSI, muscle CSA, fat CSA, and muscle + bone (M+B) CSA of the LL and maximal strength levels between dancers and untrained controls with pQCT.

## METHODS

Twenty healthy, college-aged females participated in the study with no musculoskeletal injury, neuromuscular disease, or LL injury within the past six months. Dancers (D;  $n = 10$ ; age =  $19.7 \pm 1.3$  yrs; height =  $163.9 \pm 6.6$  cm; body mass =  $62.0 \pm 10.3$  kg; dance training =  $17.0 \pm 1.2$  yrs) were required to

currently be training at least three times per week. Untrained controls (C;  $n = 10$ ; age =  $19.5 \pm 1.1$  yrs; height =  $166.0 \pm 6.8$  cm; body mass =  $69.6 \pm 14.5$  kg) were physically inactive and did not have any background in endurance training, strength training, or dance. LL measurements were recorded with pQCT scans at 14%, 38%, and 66% of the tibia length, with 0% representing the base of the tibia. Subjects underwent scanning of both right (R) and left (L) LL. UFL was determined in the x- and y-plane (medial-lateral, anterior-posterior) at the 14% site and normalized to subjects' body mass. SSI was measured at the 14% and 38% sites and again normalized to subjects' body mass. Muscle, fat, and M+B CSA measurements were obtained from the 66% site and normalized to the total area (girth of the leg) provided by the pQCT. Values between groups were then used for comparison. Subjects next completed a MVIP strength test on a custom-made sled at an inclination of  $20^\circ$  (Figure 1).

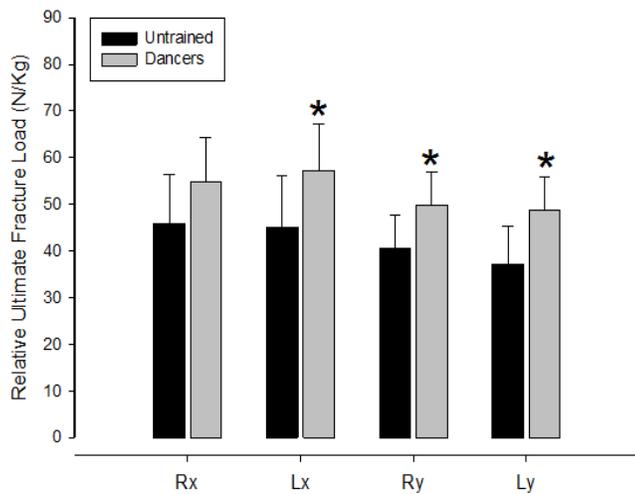

**Figure 1.** Custom Sled Apparatus.

Subjects laid on the sled with a pad behind the knees and a strap fixated proximal of the patella to isolate the ankle joint. Subjects were instructed to perform three, five-second MVIP trials with maximal effort. Two-minute rest intervals were provided in between

each trial. Subjects' trial with the greatest peak force was used for further analysis and normalized to body mass. MVIP data was collected and analyzed in a custom-designed LabVIEW program (National Instruments, Version 8.2, Austin, TX). Statistical significance was set at an *a priori* value of 0.05.

## RESULTS AND DISCUSSION

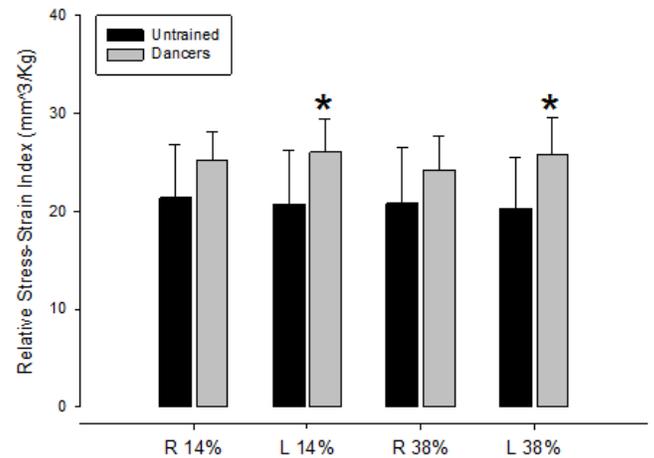

No significant ( $p \leq 0.05$ ) anthropometric differences existed between D and C. D had significantly greater L x- and R and L y-plane UFL at 14% of the LL (Figure 2), L SSI at 14% and 38% of the LL (Figure 3), and R and L muscle, fat and M+B CSA (Figure 4) than C. D possessed significantly greater MVIP relative peak force than C ( $27.7 \pm 5.7$  N/Kg;  $20.5 \pm 5.1$  N/Kg), which was significantly related to R ( $r = 0.67$ ) and L ( $r = 0.59$ ) LL muscle CSA.

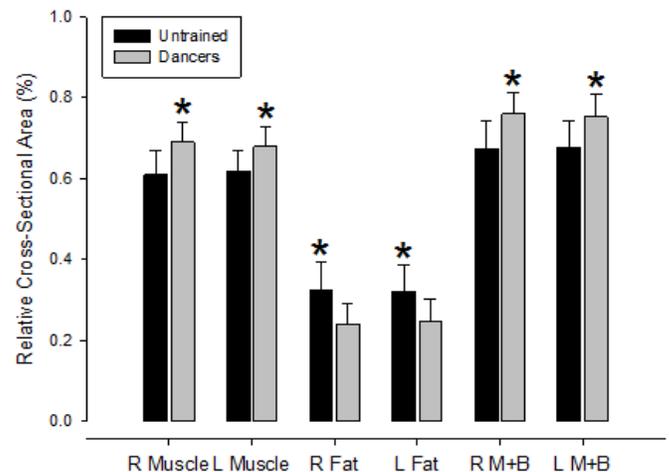

**Figure 2.** Right and left relative ultimate fracture loads at 14% of the lower legs in the x- and y-planes.

The data suggest that involvement in dance might be a stimulus for enhanced lower leg morphology and maximal strength levels. The shear forces that occur during dance leaps have revealed that a high amount of stress is introduced to the lower leg [3]. With improper nutrition, the dance community has been recognized to suffer from lower bone mineral density. However, our data provide evidence that healthily participating in ballistic activity not only fortifies bone strength but also influences muscle

maintenance and fat minimization. The physical demands of dance, therefore, might be contributors to muscle and bone features as well as maximal strength levels.

**Figure 3.** Right and left relative stress-strain indexes at 14% and 38% of the lower legs.

**Figure 4.** Right and left relative muscle, fat and muscle + bone CSA at the 66% of the lower legs.

# MORPHOLOGICAL AND FUNCTIONAL CHARACTERISTICS OF 110M HURDLERS: VOLUME AND ISOMETRIC STRENGTH OF THE HIP FLEXOR AND EXTENSOR MUSCLES

Hitoshi Okutani, Tadashi Suga, Tadao Isaka, and Akinori Nagano

Ritsumeikan University, Kusatsu, Shiga, JAPAN  
email: hitokku9pmzi@gmail.com

## INTRODUCTION

Sprint hurdle races, i.e., men's 110m hurdles and women's 100m hurdles, differ from others sprint events in that athletes are required to clear the hurdles. In these sprint hurdle races, hurdlers need to possess two types of techniques, i.e., hurdling technique and sprint technique. Hurdling technique includes take off motion, flight and clearance motion, and landing motion. In the flight and clearance motion, hurdlers swing up and down the leg, clearing the hurdle with flexion and extension of the hip joint. At the same time, hurdlers extend, abduct and supinate the other leg after taking off, in addition to extending and bending the knee joint. The former leg is the lead leg and the latter leg is the trail leg.

Hurdlers have a fixed lead leg and a fixed trail leg to clear the hurdles. The psoas major muscle, which is a hip joint flexor, plays a major role when the hurdlers swing up the lead leg over the hurdles. Therefore, it is assumed that the psoas major muscle of hurdlers have obtained specific morphological characteristics through their training. In addition, hurdlers are likely to show specific functional characteristics together with the morphological characteristics. However, this issue has not been reported in the literature. The purpose of this study was to investigate 110 m hurdlers' morphological and functional characteristics.

## METHODS

Two experiments were conducted in this study. In the first experiment, we determined the volume of the psoas major muscle. Six male collegiate hurdlers (height:  $179.4 \pm 2.5$  cm, body mass:  $65.7 \pm 2.9$  kg) participated in this experiment. The volume of psoas major muscle was determined using

magnetic resonance imaging (Figure 1). The images were taken from the trunk, between the intervertebral disk of the 5th lumbar vertebra to the 3rd lumbar vertebra. The gap between adjacent images was 5mm. We used analysis software (OsiriX Lite) to trace the area of each cross section of psoas major muscle, and calculated the volume using trapezoidal integral. The muscle volume was compared between the lead leg and the trail leg.

Figure 1: MR image of a hurdler

In the second experiment, we determined hip joint flexion/extension torque. Five male collegiate hurdlers (height:  $178.9 \pm 3.25$  cm, body mass:  $65.9 \pm 5.19$  kg) participated in this experiment. Isometric hip joint flexion/extension torque at  $60^\circ$  of hip joint flexion was measured by using Biodex dynamometer. Measurements were repeated for three times, five seconds for each trial, with forty seconds rest intervals. We determined the peak value of the torque from each trial. The average of peak values among the three trials was calculated. The values were compared between the lead leg and the trail leg.

## RESULTS AND DISCUSSION

The purpose of experiment 1 was to investigate if 110 m hurdlers' psoas major muscle has unique

morphological characteristics. The psoas major muscle volume of the lead leg ( $2.22 \pm 0.19 \text{ cm}^3/\text{kg}$ , Figure 2) was significantly greater than that of the trail leg ( $2.08 \pm 0.15 \text{ cm}^3/\text{kg}$ ,  $p < 0.05$ , Figure 2).

The results suggest that the psoas major muscle of the lead leg in hurdlers had hypertrophied through competition-specific training of the motion, i.e., repeated swinging up of the lead leg to clear the hurdles.

Figure 2: Volume of the psoas major muscle

The purpose of experiment 2 was to investigate if 110 m hurdlers' hip joint flexion/extension torque has unique characteristics. In the hip flexion torque, lead leg side ( $1.79 \pm 0.19 \text{ Nm/kg}$ , Figure 3) was significantly greater than that of the trail leg side ( $1.55 \pm 0.09 \text{ Nm/kg}$ ,  $p < 0.05$ , Figure 3). In the hip extension torque, lead leg side ( $3.81 \pm 0.82 \text{ Nm/kg}$ , Figure 4) was significantly greater than that of the trail leg side ( $3.43 \pm 0.76 \text{ Nm/kg}$ ,  $p < 0.05$ , Figure 4).

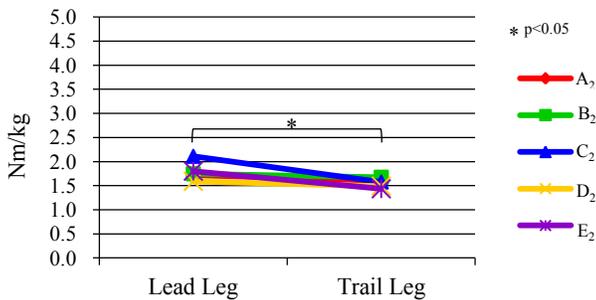

Figure 3: Flexion torque of the hip joint

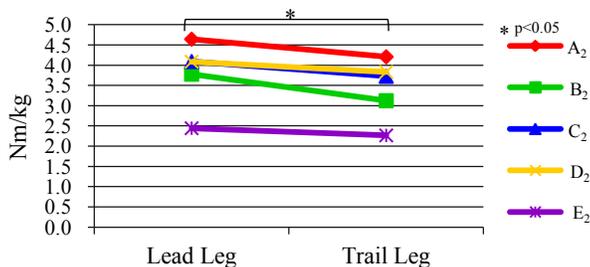

Figure 4: Extension torque of the hip joint

As is well known, muscle strength is related to muscle cross sectional area (Ikai and Fukunaga, 1968). In addition, muscle volume is a major determinant of joint torque (Fukunaga, et al., 2001). As shown in experiment 1, the volume of psoas major muscle of the lead leg was significantly greater than that of the trail leg. The fact that hip flexion torque of the lead leg was significantly greater than that of the trail leg was consistent with these preceding studies.

Similar to hip flexion torque, hip extension torque of the lead leg side was significantly greater than that of the trail leg side. Competition-specific motions of hurdling include rapid swinging down of the lead leg after clearing the hurdle. This may have caused strengthening of hip extensor muscles of the lead leg side compared to the trail leg side.

Okutani et al. (2016) reported that in sprinters, there was no significant difference in the psoas major muscle volume between the right side and the left side. It can be said that the characteristics found in this study are unique to hurdlers.

## CONCLUSIONS

The results suggest that hurdlers had obtained competition-specific morphological and functional characteristics through the training unique to hurdling. The results would be useful in the development of training programs to improve hurdle race performance in the future.

## INTRODUCTION

Gluteal strength plays a role in injury prevention, normal gait patterns, eliminating pain, and enhancing athletic performance. Research shows high gluteal muscle activity during a single-leg bridge compared to other exercises for gluteal strengthening; however, prior studies have only measured muscle activity with the active lower extremity in 90° of knee flexion with an extended contralateral lower extremity [1]. Hamstring cramping has been reported during this standard, which may impede optimal gluteal strengthening [1].

Alterations to the single-leg bridge exercise could result in more efficacious gluteal muscle outcomes. Therefore, the purpose of this study was to determine whether modifications to the dominant leg angles for the single-leg bridge could enhance gluteus maximus and medius activity.

## METHODS

Twenty-eight subjects (16 females, 12 males) were recruited for this cross-sectional study from a population between 18 and 30 years of age who able to perform one hour of low-intensity exercise completed testing in a biomechanics laboratory at the local university. The average age was  $23.4 \pm 2.3$  years, height was  $1.73 \pm 0.11$  m, and weight was  $72.7 \pm 14.0$  kg. The study was approved by the Wichita State University Human Subjects Review Board.

Subjects were familiarized with the testing procedures, electrode placement, stationary bicycle warm-up, maximal voluntary isometric contraction (MVIC) testing, and single-leg bridge variations. Surface electrodes were placed on subjects' dominant leg over the following muscles: ipsilateral

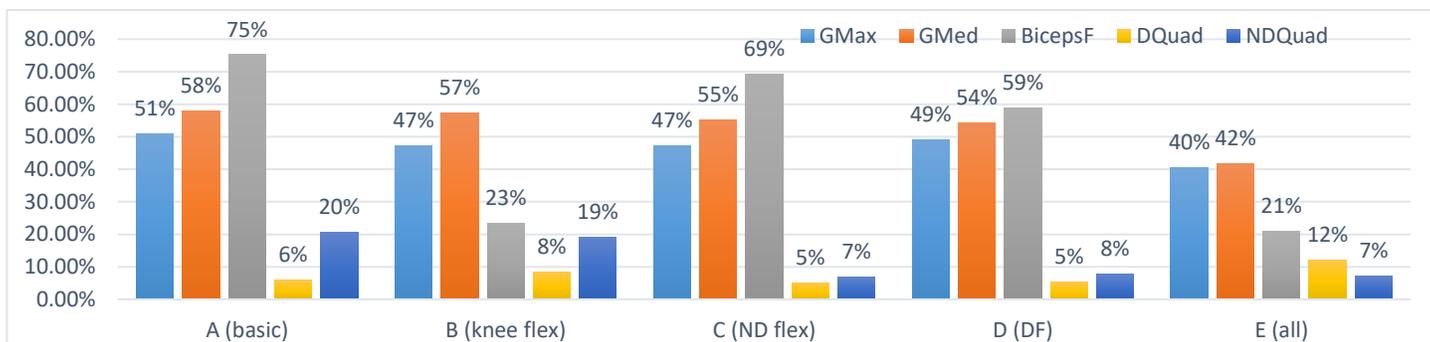

and contralateral quadriceps femoris, ipsilateral biceps femoris, ipsilateral gluteus medius, and ipsilateral gluteus maximus.

Subjects performed a five-minute warm-up on a stationary bicycle prior to performing five variations of the single-leg bridge (Table 1). Bridge variation order was randomized, and the data collector was blind to the position being performed. Subjects were blind to the electromyographic (EMG) activity of their working hip muscles. Subjects performed eight repetitions of each bridge variation to the beat of a metronome set at 60 beats per minute.

EMG data were collected at 3000 Hz (Noraxon, Scottsdale, AZ) as subjects performed maximum voluntary isometric contractions (MVIC) of the muscles of interest and five variations of the single-leg bridge. EMG data were high-pass filtered at 15 Hz and low-pass filtered at 500 Hz using a fourth order Butterworth filter. Filtered data were then smoothed with a 50-millisecond moving average prior to calculating %MVICs for each participant and bridge variation. The mean and standard deviation values of these %MVICs were used in final analysis. Repeated measures analyses of variance (ANOVAs) with Bonferroni corrections were performed for each muscle tested in the five bridge variations. An alpha level of 0.05 was used. SPSS version 23 was used for data analysis.

## RESULTS AND DISCUSSION

Mean EMG measures across subjects expressed as the %MVIC of each analyzed muscle in each of the five single-leg bridge positions are presented in

**Figure 1:** Mean EMG activity of five lower extremity muscles during five single-leg bridge variations (GMax = gluteus maximus; GMed = gluteus medius; BicepsF = biceps femoris; DQuad = dominant quadriceps; NDQuad = non-dominant quadriceps)

Figure 1. Gluteus maximus and gluteus medius activation was significantly different between positions A and E only. Biceps femoris activation was significantly different between all positions except A and C; and B and E. Dominant rectus femoris activation was significantly different among all positions except A and B; and C, D, and E.

Hamstring activity was minimized in positions B and E, in which the dominant knee was flexed to 135° instead of 90°. These positions appeared to preferentially activate both gluteal muscles, as gluteus medius and gluteus maximus activation surpassed and essentially doubled biceps femoris activation. However, of the two positions, position B displayed higher %MVIC values than position E for both gluteal muscles (47.35% and 57.23% versus 40.38% and 41.63% for the gluteus maximus and gluteus medius, respectively).

## CONCLUSIONS

The modified single-leg bridge position with 135° of knee flexion (position B) displayed preferential

activation of the gluteus maximus and gluteus medius. This position maintained similarly high gluteal activity while it significantly decreased biceps femoris activity compared to the traditional single-leg bridge position. This modified single-leg bridge position with increased knee flexion on the dominant side may allow more optimal training of the gluteal muscles than the traditional bridge position since the biceps femoris is less likely to be the limiting muscle of the exercise.

**Table 1:** Descriptions of the five single-leg bridge variations

Bridge Variation	Description
A (basic)	Subject supine; dominant lower extremity knee at 90 degrees of flexion, and foot flat; non-dominant lower extremity knee extended; arms crossed over chest
B (knee flex)	Identical to position A, except the dominant knee is flexed to 135 degrees
C (ND flex)	Identical to position A, except the non-dominant knee in a resting flexed position and hip in 90 degrees of flexion
D (DF)	Identical to position C, except the dominant ankle is fully dorsiflexed
E (all)	Identical to position D, except the dominant knee is flexed to 135 degrees

# THE EFFECT OF KNEE SUPPORT ON THE LOWER BODY JOINT LOADS AND MOTIONS OF BASEBALL CATCHERS IN DEEP SQUATS

## INTRODUCTION

It is estimated that 11.5 million baseball players will take the field this spring in the United States [1]. While not a contact sport, injury prevention and safety are still major areas of concern for amateur baseball players. One example of this is the risk to catchers' knees in both baseball and softball, due to the repeated and prolonged squatting required to play this position, especially for players who begin in little league and progress over the years to college and beyond. It has been determined from a cadaver model that deep knee flexion results in compressive forces across the knee that are 80% higher than normal [2]. This is enough force to reach the damage limits of articular cartilage. "KneeSavers" (Easton, CA) have been developed to try and alleviate some of the knee loads. These are foam wedges worn on the dorsal side of the calf that help support the catchers' weight as they squat (Fig 1). This work develops a method to quantify the kinetics associated with use of knee support.

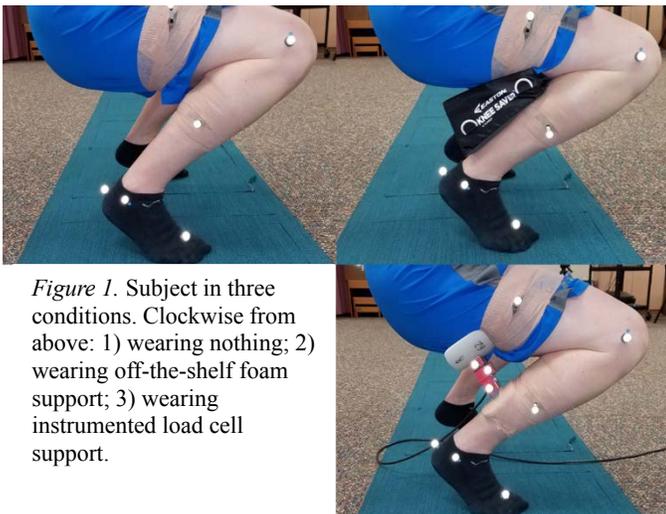

Figure 1. Subject in three conditions. Clockwise from above: 1) wearing nothing; 2) wearing off-the-shelf foam support; 3) wearing instrumented load cell support.

## METHODS

Data was collected for ten subjects, two females and eight males. Subjects were asked to squat into a catcher's stance ( $>130^\circ$  knee flexion) in three conditions: with no device, wearing off-the-shelf foam knee support, and wearing custom built instrumented knee support.

The instrumented knee support consisted of molded support surfaces, single axis load cells, and 3D-printed triad clusters (Fig. 2). The dimensions were set to match those of standard knee supports and were attached at the same location (midcalf).

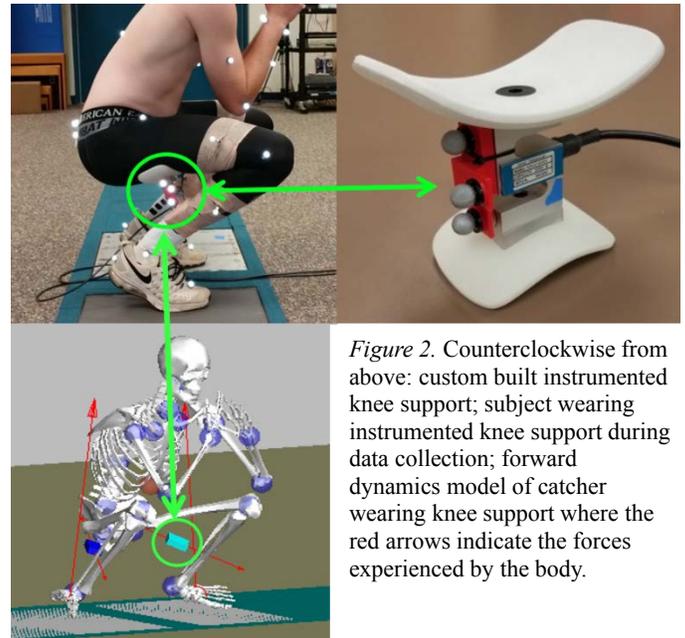

Figure 2. Counterclockwise from above: custom built instrumented knee support; subject wearing instrumented knee support during data collection; forward dynamics model of catcher wearing knee support where the red arrows indicate the forces experienced by the body.

Under each condition the subjects were asked to step onto the force plates, squat and hold to the count of two, rise, and step backwards off of the plates. Subject motion and ground reaction forces were collected via Vicon (PIG marker set) and Bertec force plates. These data were used to populate a custom 43 DoF model (MSC.Adams). The position and direction data from the clusters on the load cell savers combined with the analog force data recorded by the cell allowed the force experience by the knee supports to be incorporated into the model. Specifically, the load cell force was applied along the long axis of the load cell in equal and opposite directions onto the upper leg and lower leg at the point that the force vector from the load cell support crossed each of those bodies (Fig. 2). Sagittal joint kinematics were calculated for each condition. Kinetics were not able to be calculated for condition 2 (off-the-shelf knee support) as the loads they supported were not known. However,

simulations for condition 3 (instrumented knee support) were run twice, once with the measured forces applied and once without the measured forces. This allowed for a comparison of kinetics between knee support and no knee support with kinematics held constant.

## RESULTS

For all three conditions, there were no differences in the sagittal kinematics of the hip, knee, and ankle except in the no support condition where knee flexion was 6.4° greater.

Comparing the same kinematics of wearing the load cell savers, with and without the load cell force applied to the skeleton, there was no difference in hip and ankle sagittal torque, but there was a significant reduction in knee torque with knee support during deep squats. Specifically, a 47% reduction on the dominant side, and a 62% reduction on the non-dominant side (Fig. 3). Similarly, when comparing the condition of not wearing knee support and the instrumented support there was no difference in hip and ankle torque but knee torque differences were reduced with support, 43% and 63% respectively. This is a result of the average force supported through the load cells on each leg being 2.05 +/- .43 N/BM, or approximately 20% of body weight.

## DISCUSSION

The output torque from the no support condition was validated against previously reported knee torque during a squat at 90 degrees [3] results of both models were similar. The reduction in torque at

the knee joint is a critical result. This decrease in torque across the knee decreases the likelihood that the deep knee flexion necessary to squatting in the catching position will reach the damage limit for the cartilage in the knees. In the future this could potentially be modeled by incorporating the force of the quadriceps and patellar tendons about the knee joint center. Since the moment arm of these are approximately one-sixteenth the length of the moment arm to the center of mass, supporting the center of mass with a knee support could dramatically decrease the compressive force experienced in the knee. This compressive force often results in degradation/tears of the meniscus. This could save the catcher's knees from injury and extend the catcher's ability to play baseball.

Regarding the difference in knee angles between subjects wearing nothing and wearing the knee savers, while this angle was statistically significantly different this difference is not functionally different. This means that this difference would not be obvious to the player. It was then concluded that the reduction in torque between the conditions examined would be similar to the reduction in torque between wearing savers and wearing nothing. How knee support effects reaction time becomes a potential reason for not wearing support at higher levels, and should be investigated in the future.

## INTRODUCTION

Although golf is believed to be a low impact activity, previous research suggests up to 72% of golfers have experienced injury [1]. The lead limb knee joint is one of the most frequently injured areas [2]. Although the loads experienced on the knee during the golf swing are not typically large enough to cause acute injury, they might be sufficient to cause damage over time [2]. For instance, the external knee adduction moment, a variable strongly associated with the progression of knee osteoarthritis, is larger in the golf swing ( $0.63 \pm 0.23$  Nm/kg) than gait ( $0.49 \pm 0.19$  Nm/kg) [3]. Since golf is a popular sport, reducing loading and thus injury potential are critical to expand the longevity of one's playing career.

Altering movement patterns is a strategy that can be used to reduce loading on the knee joint. During gait, interventions such as increasing foot angle (angle the feet point outward) and stance width have both been shown to decrease the peak knee adduction moment [4, 5]. It is also possible that the same stance modifications have the potential to reduce loading during the golf swing. For instance, Lynn et al. [3] found a decrease in the knee adduction moment when both feet were externally rotated  $30^\circ$ . However, the aforementioned study did not examine loading in relation to a golfer's self-selected foot angle. Also, to our knowledge no studies have yet explored the effect that stance width has on knee moments during the golf swing.

Although altering stance has been shown to decrease loading at the knee, manipulations to a golfer's stance may have implications on performance. Swing velocity is a relatively simple marker of performance since it is strongly correlated to total driving distance [6]. Therefore, when considering alterations to swing technique, it would be useful to examine whether they have negative implications for swing velocity.

In summary, increasing a golfer's foot angle and stance width may have the potential to alter loading at the knee [3]. Therefore, the purpose of the current study was to examine the effects of various foot angles (i.e. self-selected,  $0^\circ$ ,  $30^\circ$ ) and stance widths (i.e. self-selected, narrow, wide) on the peak knee adduction moment of the lead limb during the golf swing. It was hypothesized that both an externally rotated foot angle and an increased stance width would decrease the peak knee adduction moment during the golf swing. A secondary purpose of the study was to determine what effect the altered stances had on performance (swing velocity).

## METHODS

To date, nine males and one female (age:  $26.0 \pm 5.8$  years, handicap:  $8.7 \pm 6.3$ , height:  $1.8 \pm 0.1$  m, mass:  $81.4 \pm 12.4$  kg) have completed the study protocol. Retroreflective markers were placed on the spine and bilaterally on the pelvis and lower extremity. Participants were then asked to hit three golf drives during each of the following randomly assigned stance conditions: self-selected,  $0^\circ$  (foot angle perpendicular to target line),  $30^\circ$  (foot angle externally rotated from  $0^\circ$ ), 20% narrow (from self-selected stance width), and 20% wider (from self-selected stance width).

3D marker co-ordinate data were collected using ten high speed cameras (Motion Analysis Corp, Santa Rosa, CA) at 200 Hz. An SC100 radar device (Voice Caddie Corp., La Mirada, CA) was used to measure swing velocity. Ground reaction force data were collected using two Bertec force plates (Bertec Corp., Columbus, OH) at 1000 Hz. Joint dynamics were calculated in Visual 3D (C-Motion Inc., Germantown, MD) and normalized to participant body mass. Furthermore, data were time normalized
