Figure 1 shows a comparison between the measured angular velocity on the leg model from one of the inertial motion sensor and the optically tracked markers for both the air and underwater conditions. The result of cross correlation analysis between the measured angular velocity from the three inertial motion sensor and the corresponding optically tracked markers is shown in Table 2. In all cases, there is a very high correlation between each pair of measurements. This study examined the validity using a GoPro Hero4 Black camera in the video analysis of kinematic data on human leg model during simulated hip flexion-extension in underwater and air conditions. The results indicate that the GoPro camera with manual digitization provides an inexpensive system to measure movement in air and underwater conditions. The system provided accurate and reliable kinematic data when compared to the results of inertial motion

sensors and also for known motion of a second-hand on a clock.

## INTRODUCTION

This project seeks to apply wearable sensors to rowing on an indoor stationary rowing ergometer. An existing body of research describes and analyzes the biomechanical aspects of the motion. Buckeridge et al. found approximately 35% of variance in force applied to the footboard on the drive can be attributed to hip flexion range of motion [1]. Performance improves when lumbar flexion at the catch is minimized, as this allows the force to be transmitted more effectively from the leg drive to the back. Kawalek et al. focused on joint mobility as a key to performance and decreased injury risk, particularly with regard to the lumbosacral joint [2]. Force is applied quickly with the legs in a relatively flexed lumbar spine at the initial point of the drive, and repeated over hundreds or thousands of repetitions. This repeated loading can lead to back trauma and disc herniation. The authors reason that increased hip flexion at the catch will reduce the required flexion in the lumbosacral joint and consequently reduce the stress in the spine.

The purpose of this project was to develop a method to collect and process data from wearable sensors to predict rowing performance. From the background research, it was hypothesized that minimizing the difference between lumbar and hip flexion will improve performance.

## METHODS

A variety of sensors were selected after hypothesizing which factors may influence performance. These included a Zephyr™ Bioharness™ 3 [Annapolis, MD] and an IMeasureU™ [Auckland, New Zealand] inertial measurement unit (IMU).

Sensor selection and proof of concept was initially determined through a series of six self-tests of 500m

ergometer [Concept2®; Morrisville, VA] rowing trials performed at 90% perceived effort. Two trials were rowed at each of the following strokes rates: 24 strokes per minute (spm), 26 spm, and 28 spm. For each pair of tests, the first trial was rowed with the best possible form, while the second trial was intentionally rowed with poor form, primarily initial hip displacement without proper force application to the handle. Ample rest time (>3 minutes) was allowed between trials. The ergometer was used to collect time to complete 500 m, known as 500 m split time and average force through the ergometer handle. Back angle was calculated using data from the 9 axis IMU which was sampled at 500 Hz. Only one IMU device was used during this first iteration as a proof of concept in order to develop the angle algorithm and calculate range of motion. Average heart rate and posture were collected from the Bioharness at a sampling rate of 1 Hz. The preliminary proof of concept data is shown below in Table 1.

Stroke Rating (spm)	Form	Split Time (s)	Avg Handle Force (lb)	Back ROM (deg)	HR (bpm)
24	Good	105	148	72.4	147.2
	Poor	111.2	113	63.3	140
26	Good	101.4	150	69.42	149.4
	Poor	107.8	133	46.14	144.4
28	Good	97.3	160	83.22	156.5
	Poor	105	126	54.26	146.9

We were able to effectively measure back angle by utilizing the wireless IMU, however the resolution of the Bioharness was too low to quantify posture rowing characteristics. Therefore we removed it from further analysis.

The second test session focused solely on the difference between lumbar and hip flexion using the two IMU sensors. Initial analysis of three male collegiate rowers, between the ages of 20 and 22, are reported in this pilot study. Two trials were rowed at 24 spm, and 28 spm, with similar conditions. One IMU sensor was placed under the right armpit and another placed at hip level below the iliac crest. Each subject rowed with constant perceived effort (between 70-90%). Ample rest time (>3 minutes) was allowed between trials.

MATLAB was used to translate the raw data from the IMU to relative range of motion. The code first employed Sebastian Madgwick’s implementation of Robert Mahoney’s Direct Complementary Filter to convert 9-axis IMU data into Euler angles. The filter incorporates quaternions, information about the earth’s magnetic field and magnetic flux, and normalization and integration techniques [3]. Only sagittal rotation about the mediolateral axis was investigated in this analysis. Conditional looping and the “findpeaks” MATLAB function were used to find the peak flexion and extension angles of each stroke. These peaks were then averaged and subtracted to determine the average angular range of motion (ROM) for the back and the hip during each trial. These average ROM variables were subtracted to find the difference between the back and hip for each trial.

No statistical analysis was performed at this time due to the limited sample and pilot nature of this investigation.

## RESULTS AND DISCUSSION

The results from the three participants are shown in Table 2. While limited, some information can be drawn from the data. The difference between Back ROM and Hip ROM tends to be larger during the poor form trial when compared to the good form trial. This is expected given that poor form creates a disconnection between the hips and the back. This increased difference aligns with an increase in split time and a decrease in average handle force, which indicates poorer performance. These differences do vary substantially between participants; which may be due to differences in personal rowing form between the participants.

**Table 2: Data – Second Pilot Test Session**

n	Stroke Rate	Form	Back ROM	Hip ROM	Diff	Split Time	Handle Force
1	24	Good	44.8	42.6	2.2	112.4	127
		Poor	64.0	57.1	6.9	115.5	123
	28	Good	49.9	46.9	3	107.7	133
		Poor	55.6	48.4	7.2	109.9	126
2	24	Good	77.8	17.9	59.9	111.6	105
		Poor	99.9	15.2	84.7	113.2	99
	28	Good	79.8	16.7	63.1	106.9	103
		Poor	101.2	19.5	81.7	110.4	90
3	24	Good	151.8	36.2	115.6	108.6	133
		Poor	160.8	30.6	130.2	112.7	120
	28	Good	135.3	29.8	105.5	101.3	138
		Poor	145.3	33.6	111.7	106.3	-

All data displayed as means for entire 500m rowing trial. Range of Motion (ROM); Difference (Diff)

## CONCLUSIONS

While hip and back ranges of motion varied substantially between rowers, the relative differences between these remained moderately consistent for each rower. Further testing on a larger and more diverse sample population is necessary to confirm these results and validate the original hypothesis. However, the primary concern of this pilot study was to develop a method for measuring, recording, and processing data from wearable sensors that could effectively analyze rowing mechanics and performance. The results indicate that this was achieved and further testing is planned.

# INFLUENCE OF ACCELEROMETER RANGE ON ACCURACY OF FOOT-MOUNTED IMU BASED RUNNING VELOCITY ESTIMATION

Michael V. Potter, Lauro Ojeda, Noel C. Perkins, and Stephen M. Cain

University of Michigan, Ann Arbor, MI, USA  
email: mvpotter@umich.edu

## INTRODUCTION

Miniature inertial measurement units (IMUs) are an attractive option for analyzing human performance due to their low cost, light weight, and relatively simple setup. Unlike optical-based motion capture, IMUs allow researchers to collect data in the field, where measurements are not restricted by limited capture volumes.

One application of this technology is to use foot-mounted IMUs to estimate a subject's running velocity in over ground running. Foot-mounted IMUs are an attractive option for this application because the foot is essentially stationary during specific times in the stance phase, which allows the application of zero velocity updates (ZUPTs) [2]. Commercially available IMUs offer a wide variety of sensor specifications (e.g. sampling rate and accelerometer and gyro ranges) that can greatly affect the quality of IMU-derived estimates for gait parameters. Bailey, et al. [1], examined the effect of sampling frequency and accelerometer ranges on estimations of average stride velocity and foot clearance. However, their evaluation was limited to a small range of speeds (2.3 - 3.4 m·s<sup>-1</sup>, much slower than competitive running) and two accelerometer ranges (16g and 100g).

In this pilot study, we investigate the effect of sensor accelerometer range (100, 75, 50, 24, 16, 10, and 6g) on estimates of average running velocity (up to 7.6 m·s<sup>-1</sup>). Doing so provides researchers information necessary to knowledgably select IMUs with the appropriate sensor specifications to meet study goals.

## METHODS

Two healthy male subjects were recruited for this University of Michigan IRB approved pilot study.

Each subject was equipped with two IMUs (Opal, APDM, 128 Hz, ±200g, ±2000 deg·s<sup>-1</sup>). One IMU was placed on each shoe on top of the lower laces and secured with athletic tape to prevent shifting. An instrumented treadmill (Quasar, h/p/cosmos) capable of speeds above 8 m·s<sup>-1</sup> was used to establish a ground truth measurement of gait speed.

After familiarization with the treadmill, each subject completed the following trials, each 20 seconds in duration: walking at speeds of 0.89, 1.79, and 2.24 m·s<sup>-1</sup> and running at speeds of 1.79, 2.24, 3.13, 4.02, 4.92, 5.81, 6.71, and 7.60 m·s<sup>-1</sup>. The subject rested as needed between trials. Neither subject was able to run the full 20 seconds at 7.60 m·s<sup>-1</sup> (stopped at 10 and 15 seconds) but they completed all other trials successfully.

Foot trajectory estimates for each foot and each trial were obtained by integrating a single IMU's sensor data and applying a ZUPT algorithm similar to that used in [2]. Zero velocity points were selected as the time of minimum angular rate magnitude during foot contact. Strides were then segmented by these zero velocity points. Each stride's length was calculated as the total calculated planar displacement of the foot between the beginning and end of the stride. We selected only strides in which the subject was fully on the treadmill (not holding the side rails) for analysis. For each trial the average velocity of each foot,  $v_{calc}$ , was calculated by summing the selected stride lengths of that foot and dividing this by the time elapsed during these strides. Velocity error,  $VE$ , was calculated as:

$$VE = \frac{v_{calc} - v_{treadmill}}{v_{treadmill}} \times 100 \quad (1)$$

where  $v_{treadmill}$  is the speed of the treadmill. This calculation was then repeated (without changing

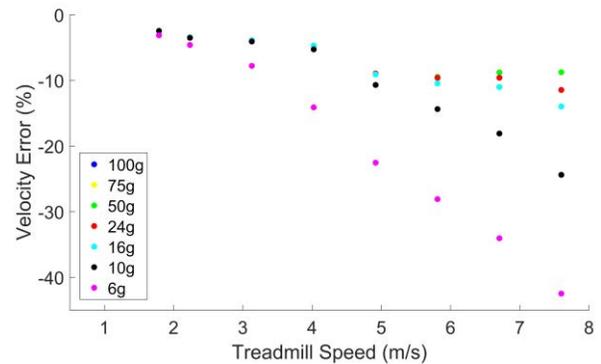

selection of steady state speed period) but by artificially modifying the accelerometer's range to typical commercial ranges of 100, 75, 50, 24, 16, 10, and 6g. This mimics the effect that using a sensor with these ranges would have on velocity estimation using this technique. This was accomplished by truncating the acceleration to that limit (e.g. any reading  $>50g$  or  $<-50g$  set to  $+50g$  or  $-50g$  respectively). The average error of the four calculated velocities at each speed (two subjects with two feet each) was then compared with respect to change in speed and change in accelerometer range.

## RESULTS AND DISCUSSION

The maximum acceleration measured along any sensor axis in this study was less than  $75g$ , therefore the velocity error in all  $100g$  and  $75g$  calculations was identical. Figure 1 shows mean velocity error vs. treadmill speed for each artificially enforced accelerometer range. It can be readily observed that in general, the IMU-estimated velocity using the aforementioned technique degrades with increasing running speed regardless of accelerometer range. A linear fit to the data for a  $100g$  accelerometer (velocity error vs. treadmill speed) yields a slope of  $-1.27\% \cdot s \cdot m^{-1}$ . This may be attributed to limitations in sampling frequency of the IMUs used in this study that could have a greater influence at higher speeds. Additionally, the zero velocity assumption may be invalid at these speeds or the zero velocity point may be misidentified during foot contact. Even at the highest speed tested, the difference in velocity error between a  $100g$  accelerometer and a  $16g$  accelerometer is only  $5.2\%$ , suggesting that for many running studies, where speeds are significantly lower than this, there may not be a significant benefit to having an accelerometer over  $16g$ . However, the velocity estimation severely degrades for an accelerometer range lower than  $16g$ . For example, at  $6g$  a linear fit to the velocity error vs. treadmill speed has a slope of  $-6.89\% \cdot s \cdot m^{-1}$ .

In comparing the walking vs. running trials at  $1.79$  and  $2.24 m \cdot s^{-1}$ , in six of the eight cases (2 subjects, 2 feet, 2 speeds) the average velocity estimated during walking had slightly lower error than that calculated during running. On average, walking trials produced a velocity error that was  $0.94\%$  better. More subjects

are necessary to determine whether this difference is significant.

**Figure 1:** Effect of accelerometer range on error in calculated mean velocity at various running speeds. Note that for almost all speeds, results of  $100g$ ,  $75g$ , and  $50g$  accelerometer are identical.

## CONCLUSIONS

Our pilot study demonstrates that velocity estimation using the ZUPT technique presented degrades with increased running speed and with lower accelerometer ranges (especially below  $16g$ ). Future work will require an expanded subject population to more fully describe the relationship between velocity estimation, speed, and accelerometer range. This expanded subject pool will also allow us to more fully determine whether walking vs. running has a significant impact on velocity estimation at the same speeds using the described techniques. Additionally, IMUs with higher sampling rates will be used to test the impact of sampling rate on velocity estimation at high speeds.

# Quantifications of the Relative Motion Between the Body and the Soldier Plate Carrier System: Applications of Accelerometry

Logan Leahy, Gabriela Barrera, Matthew Vest, Tyler Weaver, Gregory Freisinger and Becky Zifchock  
The United States Military Academy, West Point, NY, USA  
email: logan.leahy@usma.edu

## INTRODUCTION

As warfare has evolved, the amount of weight soldiers have been asked to carry has increased (Fig. 1) [1]. For those serving in the infantry or similar dismounted units, carrying heavy loads is required. The typical U.S. Rifleman carries a 29kg fighting load; however, during long marches approaching an objective, a soldier will carry approximately 43kg, or 94.6lbs [2].

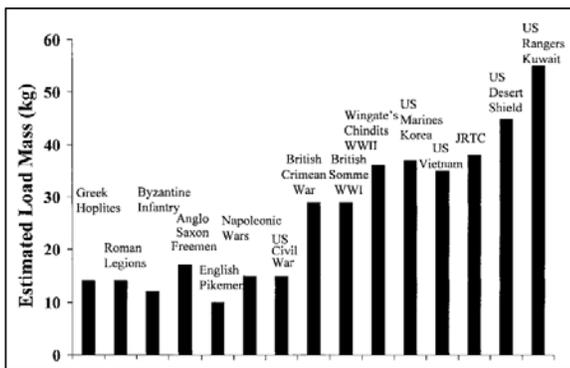

Fig. 1. Loads carried on the march by various infantry units throughout history [1].

In order to decrease the amount of compressive loads felt on the spine and lower back, there is a need for a device that redistributes weight. With more load redistribution devices undergoing research, and eventually reaching the market, there is also a need to evaluate the effectiveness of such devices. One such way is by the relative motion between the carried load and the torso. Load stability is important to soldiers, and could be used to gauge the effectiveness of loadbearing equipment. The movement of a heavy load with each step may not be in sync with the movement of the trunk, leading to cyclic loading of the spinal column [1]. This cyclic loading could lead to fatigue and overuse injuries with the potential to lead to further, more serious complications [1].

In an effort to evaluate passive load redistribution devices, the goal of this study was to quantify the relative acceleration between the torso and body armor with and without a hip-borne load redistribution device. The hypothesis was that the load redistribution device would decrease relative motion.

## METHODS

Data for seven participants has been collected, to date, for this IRB-approved study. Of the seven, 2 were female, 5 were male, and the average height and mass of the participants was 179 ( $\pm 9$ ) cm and 82 ( $\pm 10$ ) kg, respectively. All participants were active duty military.

Two inertial measurement units (IMUs) [IMeasureU: New Zealand] were used to measure the relative acceleration between the torso and the body armor. The IMUs output acceleration in three axes (x, y, and z) at a full scale range of  $\pm 16g$  at a 16 bit resolution. The IMUs were mounted to the torso at C7, and at the top, back side of the body armor (Fig 2a). They were secured in place by using adhesive sport spray and medical tape on the skin, and a sewn strap on the body armor. The mounting positions attempt to align the 3 axes of the IMUs as closely as possible (Fig 2b).

Figure 2a: Load Redistribution Device (ATLAS) and Figure 2b: IMU mounting locations and axes

Data was collected from each IMU simultaneously at 500 Hz during the final two minutes of each of two seven-minute treadmill walking trials: with and without the ATLAS device. Walking speed was standardized to 1.5 m/s.

The raw data in the x, y, and z axes was first processed in LabView [National Instruments; Austin, TX] using a low-pass Butterworth filter with a cutoff value of 10 Hz. After filtering, the data analysis was conducted using a custom code written in MATLAB [MathWorks, Inc.; Natick, MA]. For each condition (with/without ATLAS), the root mean squared error (RMSE) was calculated for each respective axis of the simultaneously-sampled IMUs, which is shown by Equation (1).

$$(1) RMSE = \sqrt{\frac{\sum_{t=1}^n (a_{armor} - a_{torso})^2}{n}}$$

$$(2) a_{Res} = \sqrt{(a_{torso_x} - a_{body_x})^2 + (a_{torso_y} - a_{body_y})^2 + (a_{torso_z} - a_{body_z})^2}$$

$$(3) RMSE_{Res} = \sqrt{\frac{\sum_{t=1}^n (a_{res})^2}{n}}$$

Figure 3: Equation Definitions

To calculate the RMSE for the difference of the resultant acceleration, the difference vector for resultant acceleration was created by using Equation (2). This value illustrates general the difference in motion in all three axes. Equation (3) was then used to calculate the resultant RMSE. RMSE values were then compared between two conditions using paired t-tests.

## RESULTS AND DISCUSSION

The results are displayed in figure 4. The t-test values do not support the initial hypothesis, and in fact support the opposite of the initial hypothesis in the y axis and resultant with P values of 0.04 and 0.02, respectively. The P values for the x and z axes do not support the null hypothesis, but do suggest a possible trend because of the effect size values of 0.50 and 0.59, respectively.

The results suggest the opposite of the initial hypothesis. A contributing factor could be the nature of the design. The ATLAS device lifts the body armor off the body, which may result in the additional motion between the torso and body armor.

## CONCLUSIONS

This study suggests that the ATLAS device and possibly other load redistribution devices that displace the load away from the body create greater relative motion between the torso of the wearer and the body armor. The clinical implications of this are unclear, however, it is possible that devices that create greater relative motion could create additional torques on the musculoskeletal system.

## INTRODUCTION

Spatiotemporal parameters of gait can be used to assess an individual's walking performance [1]. For prosthetic users, walking performance can be an indicator used to guide prosthesis prescription, as well as assess prosthetic fit and rehabilitation outcomes [2]. The most accurate method to quantify spatiotemporal parameters is to conduct an instrumented gait analysis using force platforms and motion analysis cameras. However, the time and cost associated with conducting a gait analysis often makes it prohibitive for use in clinical practice.

Newer accelerometer-based technology provides a potential tool to assess spatiotemporal parameters of gait in a clinical setting. For example, the G-Walk BTS® is a small, portable device that uses tri-axial accelerometers, gyroscopes, and magnetometers to measure various spatiotemporal parameters of gait [3]. The G-Walk rests on the fifth lumbar vertebra and transmits data via Bluetooth technology, allowing for quick and easy data collections. However, the accuracy of G-Walk's spatiotemporal parameters has not yet been assessed for individuals with lower-limb amputations. The aim of this study was to determine the accuracy of the G-Walk BTS® for individuals with unilateral transtibial amputations.

## METHODS

Nine prosthetic users with unilateral transtibial amputations (6 males, 60.9 ±11.4 years, 1.74 ±0.11 meters, 85.9 ±25.7 kilograms) participated in this IRB-approved study. Upon arrival to the laboratory, subjects completed a 10 Meter Walk test to determine their self-selected walking speed. Then, subjects underwent an instrumented gait

analysis with concurrent data collected from the G-Walk BTS®.

For the instrumented gait analysis, retro-reflective markers were placed on the pelvis and lower extremities. Kinematics and kinetic data were collected at 240 Hz and 1200 Hz, respectively, using a six-camera optical motion capture system (Motion Analysis Corporation, Santa Rosa, CA, USA) and two force plates embedded in the floor (AMTI, Watertown, MA, USA). As per manufacturer's instruction, the G-Walk BTS® was placed at the fifth lumbar vertebra by use of Velcro belt supplied with the device [3]. Data were recorded from the G-Walk on a laptop via Bluetooth technology. With this equipment in place, subjects were asked to walk across a designated laboratory pathway approximately six meters long, which contained the embedded force plates, at their self-selected walking speed. Photocell beams were used to measure velocity for each trial, and subjects were given verbal cues to guide them to their self-selected speed as determined by the 10 Meter Walk Test. A minimum of three acceptable trials were collected (self-selected speed ±0.2 statures/sec with contact of feet entirely on the force plates).

Cadence, walking speed, step length on both the prosthetic and sound limbs and gait cycle duration on both the prosthetic and sound limbs were calculated from the instrumented gait analysis data using Visual 3D (C-Motion Inc., Germantown, MD, USA). Each parameter was averaged within trials for each subject. The same spatiotemporal parameters were automatically calculated in the software supplied with the G-Walk. To assess the G-Walk's accuracy, the percent error in each parameter as measured by G-Walk (compared to the

instrumented gait analysis as the gold standard) was calculated ( $\%_{error} = \frac{G-Walk - Gait\ Analysis}{Gait\ Analysis} \times 100\%$ ).

This percent error was calculated for each trial, then the absolute percent difference was averaged across trials and then across subjects for each parameter.

## RESULTS AND DISCUSSION

Out of the spatiotemporal parameters assessed, all but one parameter had less than 10% error when measured by the G-Walk BTS® compared to the gold standard. All of the spatiotemporal parameters were within the 10-15% error threshold deemed acceptable for clinical use [4]. The G-Walk's measure of cadence (steps/min) was the most accurate, with an average error of  $1.43 \pm 1.28\%$  (Table 1). The G-Walk's measure of gait cycle duration and step length for both limbs also had less than 10% error. Interestingly, the G-Walk BTS® was more accurate in measuring gait cycle for the prosthetic limb than the sound limb. For the step length, there was negligible difference in the level of error between limbs measured by the G-Walk BTS®. Speed as measured by the G-Walk had the greatest error with a mean percent error of  $14.56 \pm 11.10\%$ .

Spatiotemporal Parameter	Absolute Average Percent Error (%)
Cadence (steps/min)	$1.43 \pm 1.28$
Speed (m/s)	$14.56 \pm 11.10$
Gait Cycle Duration (Prosthetic Limb) (s)	$3.07 \pm 5.00$
Gait Cycle Duration (Sound Limb) (s)	$6.53 \pm 9.45$
Step Length (Prosthetic Limb) (m)	$7.32 \pm 4.85$
Step Length (Sound Limb) (m)	$7.38 \pm 5.32$

**Table 1:** Absolute average percent difference in spatiotemporal parameters between the gait analysis and G-Walk (mean  $\pm$ SD).

## CONCLUSIONS

Validation is a necessary step in all research when implementing a new technology. Given that a clinically acceptable level of error is 10-15%, results from this study suggest the G-Walk BTS® is an accurate tool for collecting spatiotemporal parameters of gait assessed in this study for individuals with unilateral transtibial amputations during forward walking at a self-selected speed. While results supported accuracy of this device, this study was limited in that it only assessed the G-Walk's validity during a short data collection. Before wide scale implementation, this device should be validated over a longer period (both distance and time) as well as on a more diverse population of prosthetic users (transfemoral amputations, bilateral amputations, etc.). Ultimately, if thoroughly validated, the G-Walk BTS® may provide a clinically-viable tool to facilitate prostheses prescription as well as assess prosthetic fit and rehabilitation progress.

# EVALUATION OF AN ACCELEROMETER TO ASSESS SAGITTAL PLANE KNEE MECHANICS DURING A DROP LANDING

Alexander M. Morgan and Kristian M. O'Connor

Department of Kinesiology  
University of Wisconsin-Milwaukee, Milwaukee, WI, USA  
email: morgan28@uwm.edu

## INTRODUCTION

Non-contact anterior cruciate ligament (ACL) injuries account for around 70% of all ACL injuries annually and are two to eight times more prevalent in women [1]. Prior studies have examined neuro-mechanical factors that contribute to this prevalence and have found decreased knee flexion angles, increased posterior ground reaction force, and increased internal knee extension moments to be contributors to developing an ACL injury [2,3]. Furthermore, inertial measurement units (IMUs) have been used previously to reliably assess knee flexion during a drop landing task [4]. A biofeedback protocol using this IMU system that intended to increase knee flexion was successful in doing so and decreased further risk factors for ACL injury [5]. However, the IMUs being utilized above contain both an accelerometer and a gyroscope, and as such are more expensive. A less expensive IMU measuring only accelerations may also be useful in evaluating ACL injury risk.

Thus, the purpose of this study was to compare accelerations in the sagittal plane near the knee during a drop landing maneuver with commonly assessed kinetic risk factors for ACL injury across three landing conditions using only an accelerometer.

## METHODS

Eighteen subjects (six male and twelve female) participated in this study (average: 23.7 years, 1.68 m, 65.9 kg). Three-dimensional kinematic data were collected for the right leg using a Motion Analysis Eagle motion capture system (Santa Rosa, CA) at 200 Hz. Kinetic data were collected with a Bertec force plate (Columbus, OH) at 1000 Hz. Anterior-posterior accelerations at the tibial tuberosity of the

right leg were collected using a Noraxon DTS 3D Accelerometer (Scottsdale, AZ) at 1000 Hz. Positive accelerations indicated acceleration of the knee posteriorly. Reflective markers were placed on the pelvis and dominant leg at relevant anatomical landmarks for three-dimensional kinematic analysis.

A standing calibration trial was captured, after which subjects were instructed to stand on a 30-cm tall box located next to the force plate. Subjects were instructed to perform a bilateral drop landing task in which the individual stepped off the box and landed on the ground. Subjects were instructed to land with the foot of the right leg on the force plate, with the left foot off the force plate. Three landing conditions were implemented, with ten drop landing trials collected for each condition. Subjects were instructed to land in preferred, soft, and stiff manners. Soft landings were described as occurring with knees flexed, while stiff landings were described as occurring with knees extended.

All data reported occurred in the sagittal plane. Differences in peak positive knee acceleration, knee angle at initial contact, peak internal knee extension moment, and maximum knee flexion across the three conditions were reported. Pearson product-moment correlation coefficients were computed to assess the linear relationship between peak internal knee extension moment and peak positive acceleration during the preferred condition. Average correlation coefficients were computed to assess the relationship between peak positive accelerations and peak knee extension moments within subjects and across conditions.

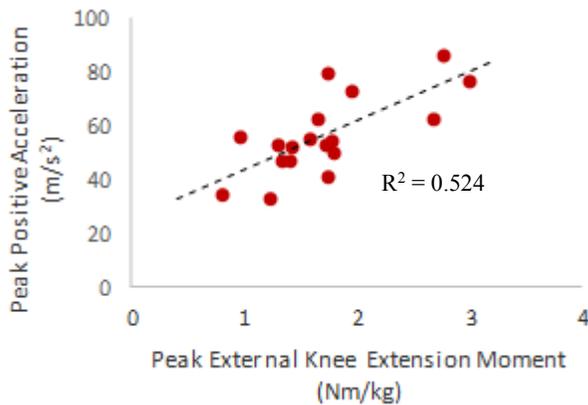

## RESULTS AND DISCUSSION

Significant differences in average knee flexion at initial contact, maximum knee flexion, peak internal

knee extension moment, and peak positive acceleration were found across conditions (Table 1). Furthermore, a significant correlation between peak internal knee extension moment and peak positive accelerations was found for the preferred condition (Figure 1). Peak values were found within the first 30 ms after initial contact (Figure 2). This suggests that, as the knee accelerates more towards extension, a larger peak internal extension moment during landing will be present. A strong positive association ( $R^2 = 0.76$ ) was found between peak internal knee extension moment and peak positive acceleration across conditions within subjects, when averaged across all subjects. This indicates that, on average, both variables increase or decrease from preferred values during stiff or soft landings, respectively. Overall, it appears that peak positive knee acceleration predicts peak internal knee extension moment both within and across subjects.

## CONCLUSIONS

Knee accelerations were related both within and across subjects to peak internal knee extension

**Figure 1:** Peak positive acceleration displays a significant correlation with peak internal knee extension moment during preferred landings.

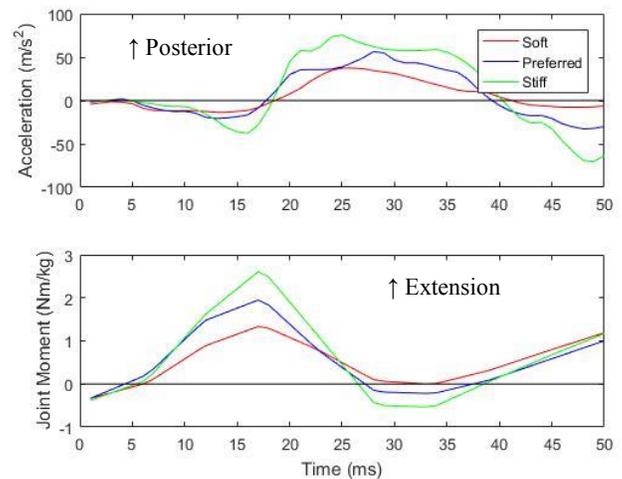

**Table 1:** Significant differences in sagittal plane knee kinematics and kinetics between landing conditions. Like letters are not significantly different ( $p < .05$ )

	Soft	Preferred	Stiff
Flexion at Initial Contact (°)	22.2 <sup>a</sup>	14.5 <sup>b</sup>	12.2 <sup>b</sup>
Maximum Flexion (°)	94.5 <sup>a</sup>	70.8 <sup>b</sup>	56.1 <sup>c</sup>
Peak Internal Extension Moment (Nm/kg)	1.4 <sup>a</sup>	1.7 <sup>a,b</sup>	2 <sup>b</sup>
Peak Positive Acceleration (m/s <sup>2</sup> )	38.3 <sup>a</sup>	56.5 <sup>b</sup>	68.1 <sup>c</sup>

moments across different landing conditions. It was hypothesized that sagittal plane acceleration of the knee might predict kinetics at the knee associated with ACL injury based on previous work associating knee flexion with these same kinetic variables [2]. This was indicated in the reported findings. As such it appears that accelerometer data is effective in detecting both within- and between-subject variation in sagittal plane moments for different landing mechanics. Future work should examine the applicability of using an accelerometer to assess ACL injury risk and alter landing mechanics to decrease risk for injury.

## INTRODUCTION

Upper extremity pain and injury are highly prevalent in manual wheelchair users [1]. While upper extremity loading in manual wheelchair users (MWUs) can be analyzed in the laboratory environment, previous studies have shown that clinically relevant biomechanical variables differ significantly in community settings [2].

While Force Sensitive Resistors (FSRs) have been implemented in many areas of biomechanics research, they have a number of issues that must be accounted for during calibration. Traditionally, these sensors have been considered to be more qualitative devices, as they can lack repeatability, accuracy, and display considerable hysteresis and time drift. Though there are concerns, it has been suggested that these effects can be minimized with quality sensors and proper calibration techniques [3]. Instrumented force gloves with adequate technical performance would provide the ability to capture loading experienced at the hand in manual wheelchair users outside of the laboratory. Therefore, the purpose of this study is to calibrate and validate a custom instrumented glove for measuring high and low upper extremity loading in manual wheelchair users.

## METHODS

*Glove Description:* Each instrumented glove system consisted of a glove and data-logging box. Each glove had 4 FSRs (40mm diameter, sensing range 0.1-150kg) stitched into its palm and was connected to a data logging box which was stored in sleeve on the users forearm (Figure 1). The data logging box contains a custom circuit board and is capable of collecting load data from each of the 4 sensors at 20Hz for 18 continuous hours. Data is recorded onto a microSD card and can be exported as a .csv file [4].

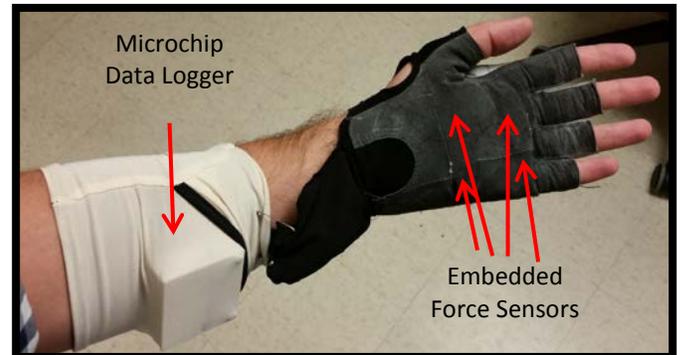

Figure 1: Instrumented glove with data logging box in arm sleeve

*Calibration:* Three factors known to influence the accuracy of an FSR's calibration were investigated: the load application method, the substrate on which the FSR is calibrated, and the temperature of the FSR. Gloves were loaded using a servo-hydraulic test system (MTS 858 Mini Bionix II) at 80N static load intervals from 80-800N. Each load was applied and released for 10 seconds. Loads were applied to the gloves using two applicators of varied size and shape. 1) A round applicator with a flat contact surface (110mm diameter) applied the calibration loads to all sensors simultaneously. 2) A custom force applicator built from a generic wheelchair rim applied the calibration loads to all sensors simultaneously.

To replicate the glove-hand interface that will be experienced during use, two substrate materials were tested by placing them inside of the glove during calibration: (1) a ballistic gelatin and (2) a synthetic flesh (Syndaver Labs, Tampa, USA). Both materials were cut into palm-sized, rectangular shapes and placed in the glove during calibration. To replicate the temperature that will be experienced during use, calibration trials were carried out at both room temperature and 35 °C via a flexible 5V DC heating pad inserted into the glove. A linear fit was performed on each set of calibration conditions.

*Validation:* The predictive power of each tested calibration method was determined via the use of the FSR equipped gloves while operating a wheelchair equipped with Smartwheel rims (Three Rivers Holdings Inc., Mesa, AZ). Each linear calibration was applied to a series of 12 level-ground propulsions and 9 weight reliefs performed using the Smartwheel rims. The RMSE comparing the Smartwheel resultant force and force recorded at the FSR equipped gloves was then computed for each calibration method.

## RESULTS AND DISCUSSION

All calibration techniques that were investigated showed a strong linear fit with all techniques having an  $R^2$  value over 0.97 with no statistically significant difference between them (Table 1). A series of exponential and polynomial fits were also attempted, but pilot results showed notably lower correlation vs. the linear fits during calibration and these techniques were not pursued further.

Applicator	Substrate	Temp	$R^2$

Flat	Ballistic Gel	Body	0.982
Rim	Ballistic Gel	Room	0.984
Flat	Syn. Flesh	Room	0.993
Flat	Syn. Flesh	Body	0.981

Table 1: Results of linear fits for tested calibration techniques

A representative weight relief trial displaying the Smartwheel values and the corresponding calibrated glove values are shown in Figure 2. The validation of the FSR equipped gloves showed that all calibration techniques using flat applicator were significantly more accurate than the rim applicator. The error of the gloves during peak loading could be brought down to ~30% during propulsion and ~15% during weight relief with the strongest calibration identified as the flat applicator combined with the ballistic gel at room temperature (Table 2). While more advanced calibration techniques will continue to be developed, these values are likely close to the optimal level of accuracy attainable given the limitations of both the

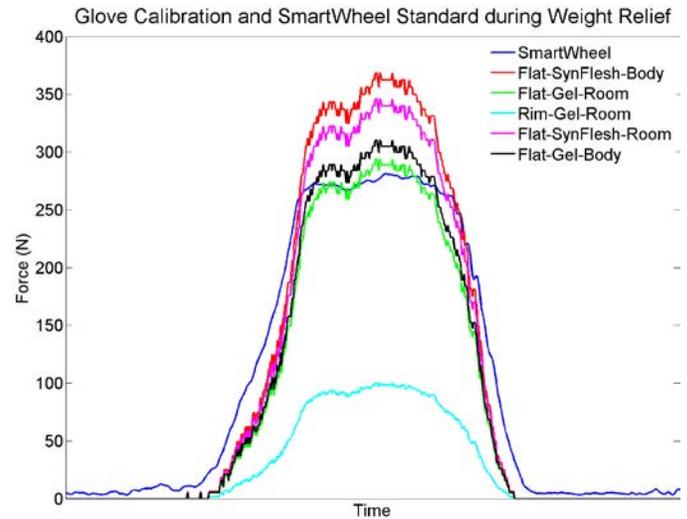

Figure 2: Representative weight relief trial. The Smartwheel values and glove values with each of 5 calibration techniques are shown.

FSRs deployed and the desirable form factor of the gloves for in-field data collections during daily living.

## CONCLUSIONS

The development of the instrumented force glove and identification of a valid calibration technique will enable the collection of in-field data for extended periods of time.

# ACCURATE AND ROBUST GAIT EVENT DETECTION USING FOOT-MOUNTED INERTIAL MEASUREMENT UNITS

Stephen M. Cain, Michael V. Potter, Lauro Ojeda, and Noel C. Perkins

The University of Michigan, Ann Arbor, MI, USA  
email: smcain@umich.edu

## INTRODUCTION

Detection of foot contact with the ground is critical for determining temporal gait characteristics and for the analysis of kinematic, kinetic, and physiologic signals during stride cycles. In addition, detecting when the feet are in contact with the ground can aid the identification of appropriate zero velocity update (ZUPT) locations (when the foot is close to or at zero velocity during its contact with the ground). ZUPTs are used for calculating drift-corrected estimates of foot trajectories, which enable calculation of spatiotemporal gait metrics [1, 2].

Typically, accurate detection of ground contact requires foot-switches, insole pressure sensors, motion capture, or an instrumented treadmill. However, researchers have demonstrated that gait events can be detected reliably with inertial measurement units (IMUs) [3-5]. IMUs do not confine data collection to a capture volume or treadmill and are not subject size specific. However, many methods require known orientation of IMUs on body segments, are limited to specific types of gaits or gait speeds, and expect certain kinematic features to be present in the measurements.

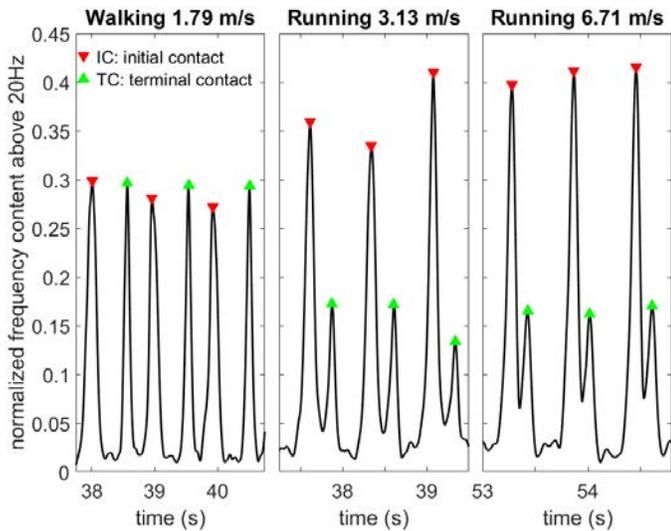

The goal of this study was to demonstrate that our gait event detection algorithm is accurate relative to an instrumented treadmill and is robust to changes in gait type, gait speed, sensor type, and subject.

## METHODS

We recruited two healthy male subjects for this University of Michigan IRB approved pilot study. For each trial, we secured an IMU to the instep of each foot on top of the subject's chosen footwear, using athletic tape to prevent shifting. Two types of IMUs were used for this study: 1) APDM Opal (128

Hz,  $\pm 200g$ ,  $\pm 2000\text{deg/s}$ ) and 2) Yost Labs 3-Space (400Hz,  $\pm 24g$ ,  $\pm 2000\text{deg/s}$ ). Both subjects completed the following trials twice (once with each type of IMU): walking at speeds of 0.89, 1.79, and 2.24m/s and running at speeds of 1.79, 2.24, 3.13, 4.02, 4.92, 5.81, 6.71, and 7.60m/s. Trials were 20 seconds in duration and subjects rested as needed between trials. An instrumented treadmill (quasar, h/p/cosmos, 100Hz) recorded the vertical ground reaction force (VGRF) for each foot during each trial. VGRFs were used to determine foot contact with ground ( $\text{VGRF} > 0$ ) and therefore ground truth times for initial contacts (ICs) and terminal contacts (TCs). The systems (IMU and treadmill) were synchronized using data from synchronization events (foot stomps) at the beginning and end of each data collection period; we used decimation to match the sampling rate of the IMUs to that of the treadmill.

Data from a given IMU was used to identify ICs and TCs by locating times in which the acceleration and angular velocity measured by the IMU contained significant high frequency content; this is based on the idea that there are sudden changes in the force acting on the foot when the foot hits/leaves the ground, and that the sudden changes will cause rapid (high frequency) changes in the acceleration and angular velocity signals. We identified times with high frequency content by first performing a separate continuous wavelet transform (CWT) using FFT (cwtft, MATLAB, MathWorks) on each measured signal of acceleration and angular velocity (six total). For each signal, we summed the CWT coefficients for frequencies above 20Hz and divided this result by the total sum of the CWT coefficients, yielding a measure of the frequency content above 20Hz for each signal. By summing the measures of frequency content for the six signals, we obtained a single resulting output signal suitable for detecting ICs and TCs (Fig. 1).

**Figure 1:** Normalized frequency content above 20Hz versus time for three sample gaits.

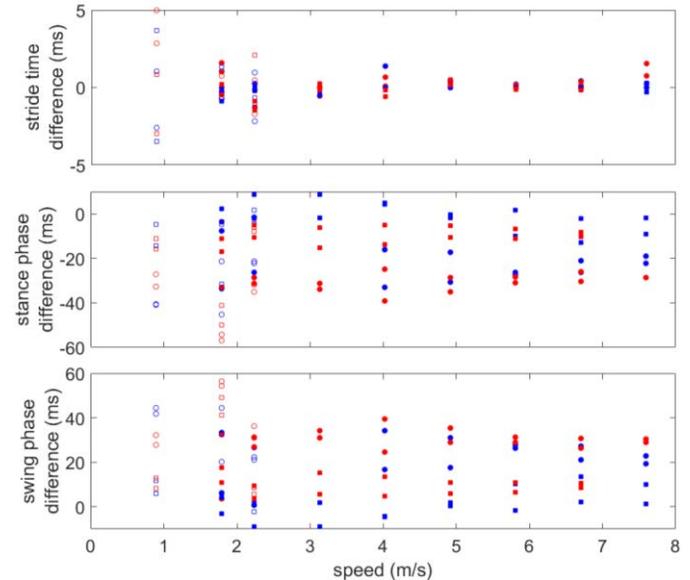

As illustrated in Fig. 1, we used the peaks of the resulting output signal from our CWT algorithm to identify ICs and TCs. Note that our methodology uses no information about IMU orientation and does not expect certain gait patterns to help identify candidate ICs and TCs.

To evaluate the accuracy of our gait event detection algorithm relative to the instrumented treadmill, we chose to compare stride times, stance times, and swing times; this allowed us to exclude differences due to imperfect synchronization of the IMUs with the treadmill. Significant differences in these parameters were detected using t-tests. For this pilot study, we used 95% confidence intervals to explore effects of gait type, speed, sensor type, and subject.

## RESULTS AND DISCUSSION

Results are illustrated in Fig. 2. There were no significant differences between IMU and treadmill-derived stride times ( $t = 0.51$ ,  $p = 0.61$ ). IMU-derived stance times were significantly less than ( $t = -11.49$ ,  $p < 0.001$ ) and swing times were significantly greater than ( $t = 11.29$ ,  $p < 0.001$ ) those calculated using the treadmill. Gait speed had no effect on the accuracy of any of the gait parameters. Our pilot data suggests that gait type, sensor type, and subject have no effect on stride time estimates, but may have small effects on stance and swing times. Despite these differences, we believe our approach is accurate and robust enough to be used to study gait that may challenge

existing gait event detection algorithms. In particular, our approach will enable accurate detection of ZUPTs (and therefore calculation of spatiotemporal gait parameters) during sprinting, irregular gaits, or other highly dynamic gaits in real-world environments. Data from additional subjects will allow us to more fully characterize our gait event detection approach.

**Figure 2:** Differences (in milliseconds) between instrumented treadmill and IMU-derived stride, stance, and swing times versus gait speed. Symbols are used as follows: circle/square (subject 1/subject 2), open/filled (walk/run), blue/red (APDM/Yost).

# EVALUATION OF GROUND REACTION FORCE ASYMMETRY IN WALKING AND RUNNING USING FORCE PLATES VS. ACCELEROMETER

Rana Karimpour, Rebecca L. Krupenevich, Kyung Koh, Ross H. Miller, and Jae Kun Shim

University of Maryland, College Park, MD, USA  
email: ranakp@umd.edu, <https://sph.umd.edu/neuromechanics>

## INTRODUCTION

Evaluation of gait asymmetry is of interest in both human movement research and clinical settings. Specifically, force asymmetry is frequently attributed to the risk or presence of pathologies and injuries [1]. Evaluation of gait asymmetry with a wearable device, such as an accelerometer, will provide a tool for the objective assessment of rehabilitation progress, and diagnosis of pathologies associated with force asymmetries during locomotion under free-living conditions, without the requirement of laboratory settings.

Considering the previously reported effect of the speed and mode of locomotion on the accelerometer readings [2], the purpose of this study was to investigate and compare the relationship between asymmetries measured from ground reaction forces (GRF) and accelerometer data during walking and running.

## METHODS

A total of 25 young healthy adults (5 male and 20 female, 20.8±0.76yrs, 1.64±0.13m, 67.18±8.96kg) volunteered to participate in the study after giving written informed consent. Participants performed three trials under each of six conditions: normal gait at their preferred speed of walking and running (average: 1.53±0.17m/s, 2.7±0.17m/s respectively), and five conditions of simulated asymmetry. During simulated asymmetry trials, participants walked/ran at ±5% of the preferred speed established during normal trials. To simulate asymmetry, the subjects were told to move their dominant leg differently (e.g. swinging it more strongly) compared to their non-dominant leg.

Linear acceleration was measured at 1000 Hz with a lightweight tri-axial wireless accelerometer sensor

(Trigno; Delsys, Boston, MA, USA) placed on the skin near the L3 vertebrae. Ground reaction forces were measured at 1000 Hz using eight force plates (Kistler, Switzerland) embedded in a 12-m long platform. Locomotion speed was determined using electronic timing gates located on either side of the force plates.

The 3D resultant magnitudes of the acceleration and GRF signals were calculated in Matlab. Peak values were used in the calculation of the left/right asymmetry index (AI), using Eq. 1 which was developed by Robinson et al. [3] and has been widely used to quantify gait asymmetry:

$$AI = \frac{(R-L)}{0.5*(R+L)} \quad (1)$$

where R and L are the peak 3D magnitudes of the signals in the right or left stance leg, respectively.

To account for the differences in the number of trials with complete GRF per participant (e.g. range: 9-22, mean±SD: 18.7±2.9 in walking), from the correlation coefficients between accelerometer and GRF AIs in individual participants a weighted average was calculated. To test the statistical significance of the overall correlation coefficient, we conducted Student's *t*-test on its corresponding Fisher-transformed *z*-score.

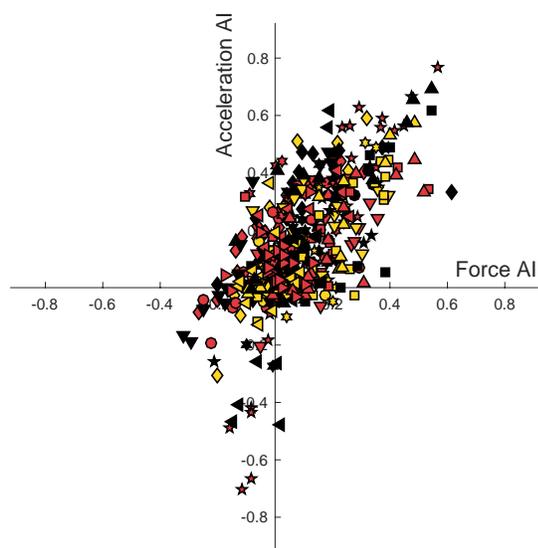

In addition, to assess the disparity between accelerometer AI and the gold standard (GRF AI) root identity squared deviation (RISD) was calculated using Eq. 2.

$$RISD = \sqrt{\frac{\sum_i d_i^2}{n}} \quad (2)$$

where  $n$  is the number of trials, and  $d_i$  is the distance between the measured accelerometer AI from the identity function (GRF AI = accelerometer AI).

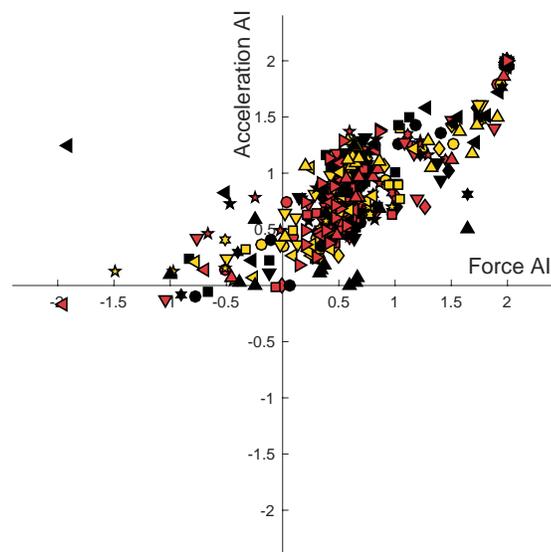

## RESULTS AND DISCUSSION

In both walking and running there was a significant positive correlation between accelerometer AI and GRF AI ( $r = 0.70$  and  $0.91$  in walking and running respectively). The 99% confidence interval was  $r = 0.63-0.76$  for walking, and  $r = 0.88-0.93$  for running.

**Figure 1:** The relationship between the asymmetry indices calculated from GRF and accelerometer data in all conditions for all the participants during walking. Each point represents one trial. Colors and markers do not signify any particular condition.

Although running exhibited a stronger positive correlation compared to walking ( $r = 0.91$  vs.  $r = 0.70$ , respectively), the one-to-one identical mapping between the two AI measures -assessed by the RISD- was weaker. A greater RISD in running (average across participants =  $0.27 \pm 0.1$ ) compared to walking (average =  $0.11 \pm 0.4$ ) indicates that the accelerometer AI may not be an immediate measure of force asymmetry during gait particularly in running.

**Figure 2:** The relationship between the asymmetry indices calculated from GRF and accelerometer data in all conditions for all the participants during running. Each point represents one trial. Colors and markers do not signify any particular condition.

## CONCLUSIONS

There is a strong positive relationship between the AI calculated from an accelerometer and the AI calculated from GRF during both walking and running. This preliminary finding suggests that an accelerometer may be a feasible tool for measuring force asymmetry in clinical settings. Further investigation of the factors contributing to this relationship may have practical implications regarding the clinical evaluation of gait asymmetry during walking and the assessment of asymmetry during gait in daily living. Investigating the sources of between and within subject variations in future studies may help provide a more accurate predictive relationship.

# VALIDATION OF AN EMBEDDED INERTIAL MEASUREMENT UNIT FOR TRUNK MEASUREMENTS DURING SIMULATED SITTING AND STANDING POSTURES

Jonathan Park, Lois A Sy, Mamiko Noguchi, Jack P Callaghan

University of Waterloo, Waterloo, ON, CA  
E-mail: j56park@uwaterloo.ca

## INTRODUCTION

Globally, low back pain (LBP) is considered the leading cause of disability [1]. Characterizing physical exposures related to occupationally relevant low back disorders is important for implementing appropriate ergonomic interventions for prevention of injury and reoccurrences [2]. Several posture-based measurement techniques (e.g., direct, observational, and self-report) have been previously developed for assessing physical exposures during occupational work [2 – 4]. Optoelectronic motion capture (OMC) systems have been deemed the gold standard for direct, non-invasive trunk kinematic measurements [5]. Generally, OMC systems are restricted to laboratory simulations of occupational work [6]. This may result in potential disagreements between laboratory and on-field physical exposures [7]. However, on-field occupational measurements outside the laboratory with OMC systems are limited by the equipment's practicality [2, 5, 8].

Researchers have shown interest in inertial measurement units (IMUs) for direct measurements of trunk kinematics [2, 5, 8]. This interest is due to IMU's lightweight, portable, wireless, and integrated sensing characteristics from various electromechanical sensors [5, 8]. A commercially available device, called the Myo™ gesture control armband (MYO) (Thalmic Labs Inc., Waterloo, ON), encapsulates an IMU and surface electromyography (sEMG) system. The validity of an IMU is specific to the anatomical site and task being assessed [5]. Determining MYO's validity against a gold standard system is a necessary step to determine its validity for field use. Thus, the aim of this study was to investigate the concurrent validity of the MYO armband's IMU system with a laboratory-based motion capture system during simulated sitting and standing office workplace postures.

## METHODS

Sixteen healthy, asymptomatic participants, 8 females (age =  $21.3 \pm 1.1$  years; height =  $1.67 \pm 0.04$  m; mass =  $64.3 \pm 11.6$  kg) and 8 males (age =  $22.3 \pm 1.5$  years; height =  $1.77 \pm 0.07$  m; mass =  $75.6 \pm 5.9$  kg), were recruited from the university population.

The MYO armband contains eight pods. One pod comprises of a nine-axis IMU, which encapsulates a three-axis accelerometer, gyroscope, and magnetometer. The MYO armband was repurposed and secured around the torso with the IMU-containing pod (POD) overlying the participant's T12 spinous process. Trunk angular displacement estimates from the IMU were reported in quaternion values (via manufacturer proprietary sensor fusion algorithms) and retrieved via wireless Bluetooth® connection.

A laboratory-based OMC system (Optotrak Certus®, NDI, Waterloo, Canada) was used as the reference system. A rigid body of smart markers were superimposed onto the POD. Both the MYO and OMC system were sampled at 50 Hz.

Participants were instructed to adopt 8 sitting and 7 standing postures, in a randomized order, for 30 seconds each. These simulated office workplace postures were previously observed in the literature [9, 10]. Each posture was repeated 3 times.

The quaternion values obtained from the MYO armband were converted into Cardan angles using custom code in Matlab R2016a (The Mathworks, Natick, MA, USA) in the corresponding Cardan rotation sequence of flexion/extension (sagittal), abduction/adduction (frontal) and axial rotation (transverse). Kinematic data from Optotrak Certus® was imported into Visual 3D™ software (Version 5, C-Motion, Inc., Germantown, MD, USA) and smoothed with a low-pass filter (Butterworth, 2nd

order, dual-pass) with a cut-off frequency of 3 Hz. Cardan angles were then calculated with the same rotation sequence used for the MYO armband. The two systems were synced in Matlab using custom correlation code based on three transient perturbations applied to the MYO armband during the collection. The 20 second midmost trial of each posture was used for further data analysis.

Concurrent validity was assessed by calculating the root mean squared error (RMSE) and Bland-Altman (BA) plot analysis. RMSE was calculated for each posture trial in each participant. Data were then averaged and collapsed across all postures and participants to achieve a single averaged RMSE value in each posture category (sitting or standing) and cardinal plane. BA plots were generated and analysed using methods previously outlined [11].

## RESULTS AND DISCUSSION

Overall, trunk angles during sitting and standing postures in the sagittal and frontal plane exhibited less RMSE ( $1.17^\circ - 2.37^\circ$ ) and standard deviation ( $\pm 0.78^\circ - \pm 1.55^\circ$ ), relative to the transverse plane ( $6.04^\circ - 6.63^\circ$ ) ( $\pm 3.56^\circ - \pm 4.68^\circ$ ). Except for the transverse plane, the averaged RMSE results compare well in sagittal/frontal planes with previous literature on trunk angular displacement and validity of IMU with an OMC system [2, 8, 12]. These studies reported the following: 1)  $4.1^\circ - 6.6^\circ$  [2]; 2)  $1.8^\circ - 5.9^\circ$  [8]; and 3)  $\leq 2.1^\circ - 3.1^\circ$  [12]. However, these studies did not include axial rotation.

The BA analysis reveals the MYO armband over- or under-estimates trunk angular displacement relative to the OMC system (Table 1). Similarly, a previous study found mean difference varied across several sitting and standing tasks with a different device [6]. Although mean differences between the two systems are low, the 95% limits of agreement revealed the

cardinal plane of least to greatest error: sagittal, frontal, and transverse planes. For instance, 95% of measurements in the sagittal plane can be expected to be between  $-3.66^\circ$  and  $5.07^\circ$ , relative to the reference system. Whereas 95% of measurements in the transverse plane can be expected to be between  $-16.22^\circ$  and  $19.8^\circ$ .

## CONCLUSIONS

These findings suggest that depending on the magnitude of accuracy chosen for one's purpose, the MYO armband can be used in the field to estimate the sagittal and frontal planes of trunk motion with an "acceptable" magnitude of error [2, 8, 12]. However, transverse plane trunk measurements should be used with caution, as the results demonstrated a large magnitude of error during the postures chosen for this study.

email: {wyatt\_hahn,marres,moeinnazifi,pilwonhur}@tamu.edu, web: <http://hurgroup.net/members>

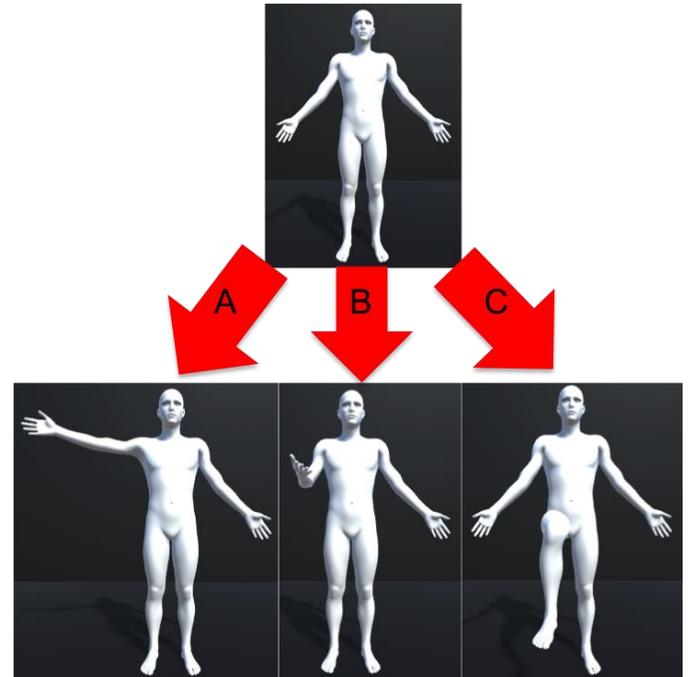

## INTRODUCTION

Optical motion capture systems (MCSs) are widely used to capture the kinematics of different motor-tasks. However, optical MCSs are often expensive and require long and complicated preparation/collection procedures. An alternative method, however, is to use inertia measurement units (IMUs). IMUs are significantly cost-effective and convenient compared to the optical MCSs. Moreover, unlike optical MCSs, an IMU-based MCSs will not be limited to the vision field of the surrounding cameras or be disrupted by its markers being hidden. Lastly, IMUs do not require labeling/cleaning, making them even more convenient.

The objective of this study is to develop an IMU-based MCSs with graphical user interface (GUI) that can facilitate the accurate biomechanical kinematic analyses of the human and/or animal movement. Successful accomplishment of this application will enable a more affordable, accessible, and portable biomechanics lab of human movement analysis for researchers and provide simple ways for clinicians to diagnose pathological movements of their patients.

## METHODS

The motion capture system developed in this study comprises 16 wireless IM sensors (Delsys Trigno, Natick, MA) bilaterally attached to major upper and lower extremity links as follows: Back of the shoulders (scapula), upper arms, forearms, back of the hands, thighs, shanks, feet, and unilateral at lumbar (L3), and sternum. IMUs captured three-dimensional angular velocity (gyroscope), acceleration (accelerometer), and magnetic field (magnetometer) at 60 Hz. The incoming data was low-pass filtered using a third-order zero-lag Butterworth with a cutoff frequency of 5 Hz [1]. The algorithm built quaternions from the gyroscope data and mathematically rotated the vector representing the corresponding link to which the sensor was attached. Since this rotation was performed only on the vector from the previous time step, the system was susceptible to drift due to the existing noises. To account for this drift, the algorithm simultaneously used the magnetometer and accelerometer data to create a right handed coordinate system using cross products. At each

**Figure 1:** The tasks performed by the subject.

time step, a new coordinate system was created in the same manner. The rotation was found from the new coordinate system to the initial coordinate system, and was applied to the initial position of the vector. The rotated orientations found from both methods were then averaged. The result from the magnetometer and accelerometer readings were only viable for low accelerometer readings where the total acceleration was close to that of the gravity. Thus, the algorithm implements calculations to only use the magnetometer and accelerometer data at low to zero angular rates to rid the system of drift and use more of the gyroscope data when accelerometer readings were high.

To test the accuracy of this novel system, we simultaneously collected kinematic data using our device along with an optical motion capture system (Qualisys Oqus, Göteborg, Sweden). The optical motion capture had 30 markers on the bony landmarks of the body to collect the full-body kinematics at 100Hz. The markers were placed bilaterally on toe tip, heel, medial/lateral malleolus, medial/lateral condyle of tibia, trochanter, ASIS, PSIS, acromion, medial/lateral humeral epicondyle, and ulnar/radial styloid process, plus unilateral C7 and T10 markers. One recruited subject

performed three tasks (Fig. 1, A, B, C). Starting from reference anatomic position, task A encompassed ten consecutive bilateral shoulder abduction/adductions (90 degrees), task B included ten bilateral elbow flexion/extension (90 degrees), and task C was to perform ten hip flexion/extensions (90 degrees, right limb first then left limb). During each task, subject were asked to keep other parts as still as possible.

The IMU data was processed using Microsoft C# (Redmond, WA) and used to calculate joint angles. The data was then filtered (4<sup>th</sup> order zero-lag Butterworth, cutoff 1Hz) using MATLAB (v2016a, Mathworks, Natick, MA) [2]. Optical motion capture data was processed offline using MATLAB and the corresponding joint angles were calculated using costume codes.

Finally, the RMS error and the Pearson's correlation coefficients ( $r$ ) were calculated to reveal the accuracy of the IMU-based motion capture system.

## RESULTS AND DISCUSSION

**Table 1:** RMS errors (deg) and  $r$  values.

Task	Right Shoulder		Left Shoulder	
	RMSE	Correlation	RMSE	Correlation
A	10.73	0.95	2.56	0.99
B	Right Elbow		Left Elbow	
	RMSE	Correlation	RMSE	Correlation
	9.00	0.99	8.55	0.99
C	Right Knee		Left Knee	
	RMSE	Correlation	RMSE	Correlation
	5.93	0.99	5.58	0.99

Results revealed small RMS errors as well as a strong correlation between the majorly activated joints (Table 1) of each task (e.g. shoulder in task A). The IMU-based MCS was able to calculate the joint angles with less than 10° of error and a correlation over 95% in all cases.

Other non-essential joints for each test showed a lower correlation due to the noticeable noise. However, this happened only when the body segment has no significant movement or is stationary. When the body segment is moving, we saw the high correlation between the two systems (Fig. 2). Note that unilateral plots were chosen due to the symmetry.

The errors can be due to the inappropriate filtering (e.g., too low cutoff frequency) and misalignment of local coordinate systems between the optical MCS and the IMU-based MCS. Further refinement and calibration will be performed to enhance the accuracy of the IMU-based MCS. More experimental validation with various tasks including walking will be tested.

## CONCLUSIONS

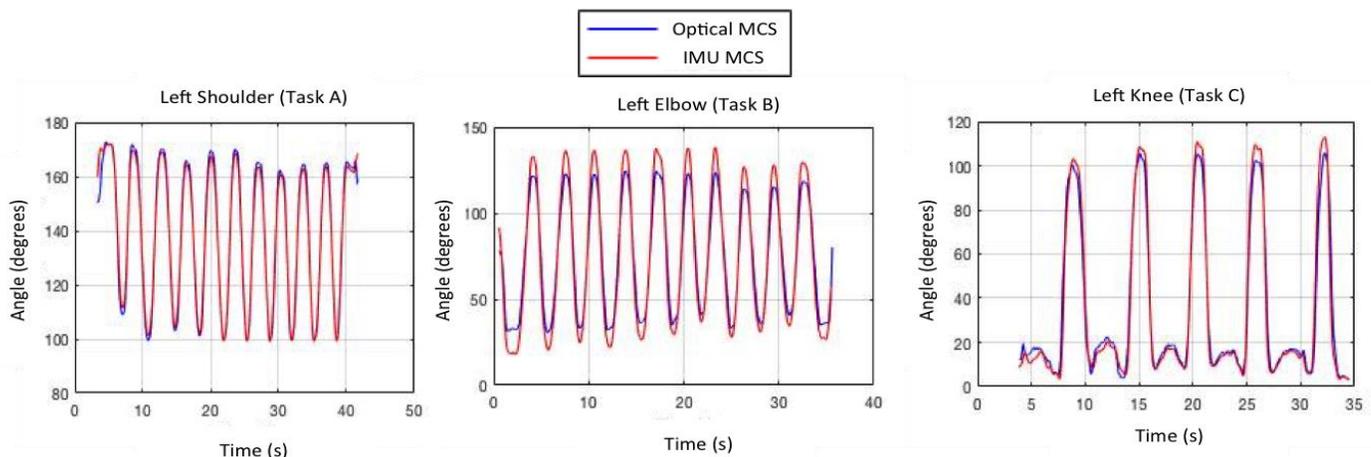

The system developed in this study uses IMU sensors to capture human kinematics. The preliminary test involving shoulder abduction, elbow flexion, and hip flexion revealed strong correlations and minimal RMSE values. These results substantiate feasibility of usage of IMU-based MCSs due to their ease of use with their only draw-back being their minor inaccuracy. Future works will include refinement of filtering and examination of various tasks including walking trials and more elaborate motor-tasks. Upon completion, the codes will be made open-source for public use and desired customizations.

# AGE-RELATED DIFFERENCES IN POSTURAL CONTROL: EFFECTS OF DIFFERENT VISUAL MANIPULATIONS ON DYNAMIC BALANCE RESPONSES

Andresa M. C. Germano\*, Daniel Schmidt, Claudio Zippenfennig, and Thomas L. Milani

Chemnitz University of Technology, Department of Human Locomotion, Chemnitz, Saxony, Germany

\*email: andresa.germano@hsw.tu-chemnitz.de, web: <https://www.tu-chemnitz.de/index.html.en>

## INTRODUCTION

Assumptions that balance control is based on the integration of afferent inputs and that this integration process changes with age are well accepted [1,2]. Studies have confirmed that the elderly are more susceptible to balance instability after visual manipulation [2]. Different manipulation approaches have been used to investigate the importance of visual inputs on balance, e.g. eyes closed, dark glasses, and different visual surroundings [3,4]. Therefore, we examined whether different approaches of visual manipulation would affect dynamic balance responses differently, and whether balance responses of young and older adults would be affected differently by visual manipulation. Greater instability was expected for the various visual manipulation conditions compared to eyes open and for older compared to younger adults. In addition, no changes within visual manipulation conditions (Eyes Closed, Blackout Glasses, Dark Room) were expected.

## METHODS

36 healthy subjects participated and were divided into two groups: 20 young (mean±SD: 22.9±2.5yrs, 70.9±11.8kg, 1.8±0.08m) and 16 older adults (mean±SD: 69.3±4.2yrs, 73.8±10.4kg, 1.7±0.10m). All procedures were conducted according to the recommendations of the Declaration of Helsinki.

To induce unexpected perturbations, the horizontally moveable bottom platform of a Posturomed device (Haider Bioswing GmbH, Germany) was deflected by 20mm and released by triggering an electromagnet. A GK-1000-Koordinator force platform was affixed to the bottom platform (IMM Holding GmbH, Germany; sampling rate 1kHz). The protocol consisted of three trials performed in antero-

posterior perturbation direction for each randomized condition: Eyes Open (EO), Eyes Closed (EC), Blackout Glasses (BG), and Dark Room (DR). During BG and DR conditions, subjects kept their eyes open. Prior to the tests, subjects had an acclimatization period of 10min (room temperature 23±2°C) and performed three training trials to become familiar with the apparatus. Total center of pressure excursions (COP) as well as medio-lateral (ML) and antero-posterior (AP) ranges were calculated to quantify balance ability. In this study, all data were analyzed in two intervals: anticipatory responses (-200ms to 0ms (trigger) pre perturbation) and compensatory responses (70ms to 260ms post perturbation). Normal distribution was tested using the Shapiro-Wilk test. Differences within conditions were examined using ANOVA repeated measures following a Bonferroni post-hoc test (parametrical data), and Friedmann test following Wilcoxon test (non-parametrical data). Differences within groups were analyzed using the Mann-Whitney-U test. Level of significance for all tests was  $\alpha=0.05$ .

## RESULTS AND DISCUSSION

Changes in COP are presented in Fig. 1 (a and b), while ML and AP ranges are shown in Table 1. When comparing groups, larger AP ranges were found for older compared to young adults, but only for BG and DR. Surprisingly, COP and ML range showed no significant differences between young and older adults for any analyzed condition. This was contrary to previous studies, which showed differences between young and older adults, especially when the visual system was deprived [5]. However, more than 65% of our older adults were physically active, which may explain these results, since physical activity may improve sensory integration for balance control [2]. Regarding the comparison within groups, no differences were found between EC, BG, and DR

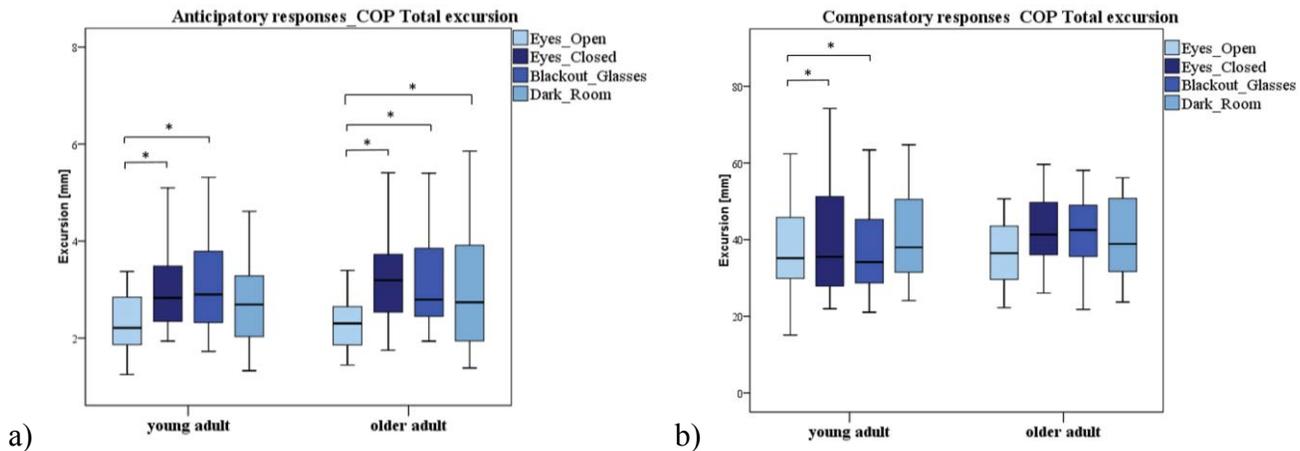

for either age group. This may be because the amount of information available during those situations was similar [4]. Hafström et al. [4] also found no differences between balance responses comparing eyes closed with eyes open in darkness. As expected, most of the significant differences in the current study were present when comparing EO with EC or BG, in which eyes open was the more stable balance condition. This is in accordance with Hafström et al., since visual inputs play a dominant role as contributor during balance control [4]. Surprisingly, decreased stability after visual manipulation was not evident in all comparisons. For example, older adults presented no differences between any of the analyzed conditions during compensatory responses. Note that the most challenging postural task was present during compensatory responses due to the unexpected perturbation. In the case of an additional balance challenge, afferent re-weighting and integration are needed. For example, in the case of reduced visual information, other available afferent inputs may be re-weighted to compensate the unavailable information to maintain balance [4]. Although this re-weighting process declines with age

[2], this was probably not the case in our older subjects. They were still capable of successfully controlling dynamic balance even without the presence of visual inputs. It is unclear whether this is due to this group's level of physical activity. For our young subjects, it seems that the amount of challenge during compensatory responses was not high enough to require changes in integration processes. Hence, differences between EO and EC or BG were present.

Further studies should investigate age and physical activity factors related to possible changes in afferent information reweighting.

## INTRODUCTION

Survivors with post-stroke hemiparesis have impaired balance control during quiet standing [1]. The typical characteristics of early stage post-stroke standing balance are increasing sway and asymmetrical lower limb weight distribution during quiet standing. A decreased weight bearing on the paretic side causes asymmetrical weight distribution and may be a compensatory strategy to overcome muscle weakness and perceptual deficits. Previous studies showed that the area of center of foot pressure (COP) sway pattern was significantly increased in stroke patients, particularly in the mediolateral (ML) direction [2]. Recent studies revealed weight-bearing asymmetry and reduced amplitude of COP fluctuation under the paretic compared with the non-paretic limb.

In studies on upper limb rehabilitation, a significant portion of stroke patients are forced to change their dominant hand after stroke because of their severe weakness of dominant hand and the increased neural activity in unaffected hemisphere [3]. So the dominant side of paretic upper limb is considered during conventional therapies. However the limb dominance has been negligible in lower limb rehabilitation since only paretic side is considered in conventional lower limb rehabilitation.

Therefore the objective of this study was to show the differences in postural symmetry and COP displacement during 30 second quiet standing between dominant and non-dominant paretic groups in chronic post-stroke survivors before and after the 3-D ankle movement training (AMT).

## METHODS

Fourteen patients with post-stroke hemiparesis (5 women; duration 119.8 months (from 36.5 to 277.4); age 64.9 years (from 52 to 78); Right-paretic 5;

Right-dominant 14, were volunteered in this study. All patients walked independently with and without ankle foot orthosis and walking assistive devices. Inclusion criteria were normal gait pattern before first-ever stroke and Functional Ambulation Category score of 3 or more. Patients were excluded with any presence of neurologic or orthopedic disorder. Recruitment and informed consent procedures were approved by National Rehabilitation Center ethics commission of South Korea (NRC2015-03-020).

All patients performed AMT, 30 minutes a session, 3 times a week for 4 weeks. 3-D ankle movements using AMT were constituted in simple (20 dorsiflexion-plantarflexion; 20 inversion-eversion) and constrained movements (40 everted dorsiflexion-plantarflexion; 40 dorsiflexed inversion-eversion) at 30 degrees per seconds. The symmetry index measured from ground reaction forces (GRF) and displacement of COP from paretic and non-paretic limbs were measured during 30 seconds bipedal standing with both eyes-open (EO) and eyes-closed (EC) condition before and after AMT intervention.

Kolmogorov-Smirnov test was used to validate normal distribution of measured data. The training effects for each group were analyzed using paired t-test (SPSS ver. 21.0, IBM, Armonk, NY, USA). The difference was considered to be significant at  $p < 0.05$ .

## RESULTS AND DISCUSSION

In the weight shift percent of measured from GRF, both the dominant hemi-paralysis group (DP) and the non-dominant hemi-paralysis group (nDP) showed the increases in weight bearing distribution in the dominant limb in before and after the AMT training (**Table1**).

In the COP displacement, the results after AMT

training in patients with stroke did not show a significant difference between dominant paralysis and non-dominant paralysis (**Table2**). However, there was a tendency that the COP displacement increases more in non-paretic than paretic side, more in EC than EO condition, and the COP of DP tends to increase in both lower limbs than the COP of nDP.

**Table1:** Weight shift percent in ground reaction force between dominant and non-dominant limbs

(%)		Pre-EO	Post-EO	<i>p</i>	Pre-EC	Post-EC	<i>p</i>
DP	D	50.5	51.9	.35	50.1	51.2	.4
	nD	49.5	48.1	.35	49.9	48.8	.4
nDP	D	52.3	53.8	.57	53.9	55.4	.55
	nD	47.7	46.2	.57	46.1	44.6	.55

Abbreviations: DP, dominant hemi-paralysis group; nDP, non-dominant hemi-paralysis group; D, dominant side; nD, non-dominant side, Pre-EO, pre-test eyes open; post-EO, post-test eyes open; pre-EC, pre-test eyes closed; post-EC, post-test eyes closed.

The movement of the lower limb is mostly in the closed chain and walking is a rhythmic and alternating movement. For that reason, the factor of dominant side has a small impact on the strategy for maintaining the balance during gait and quiet standing. Although the dominant side of the lower limb is likely to have a minor effect, this study suggest that the symmetry index measured from ground reaction forces and the COP displacement during quiet standing is related to dominant paralysis.

This study was conducted only 14 patients with

	L	.74	.56	.57	.53	.55	.79		L	.19	.21	.45	.25	.45	.22

Abbreviations: DP, dominant hemi-paralysis group; nDP, non-dominant hemi-paralysis group; A, Anterior displacement; P, Posterior displacement; M, medial displacement; L, lateral displacement Pre-EO, pre-test eyes open; post-EO, post-test eyes open; pre-EC, pre-test eyes closed; post-EC, post-test eyes closed(\* denotes  $p < 0.05$ ).

chronic stroke who had an average onset of 10 years, which may have affected the results. However, considering there is a dominant side both with the lower limbs and upper limbs, and most of the stroke patients have been used to the dominant side on their lifetime, we propose that the rehabilitation program of the stroke patients considers not only the paralyzed side but also the dominant side.

## CONCLUSIONS

There was a tendency but not significant difference in increase of the symmetry index measured from GRF the COP displacement of dominant paralysis compared with non-dominant paralysis during quiet standing in post-stroke hemiparesis. Therefore, in the lower limb rehabilitation program, not only paretic side but also dominant side is considerable as a factor that contributes to postural control in quiet standing.

# INFLUENCE OF SHORT-TERM VISUAL DEPRIVATION AND REDUCED AUDITORY CAPABILITY ON QUASI-STATIC BALANCE PERFORMANCE IN HEALTHY ADULTS

Tina Drechsel\*, Daniel Schmidt, Thomas L. Milani

Chemnitz University of Technology, Department of Human Locomotion, Chemnitz, Saxony, Germany

\*email: tina.drechsel@hsw.tu-chemnitz.de, web: <https://www.tu-chemnitz.de/index.html>

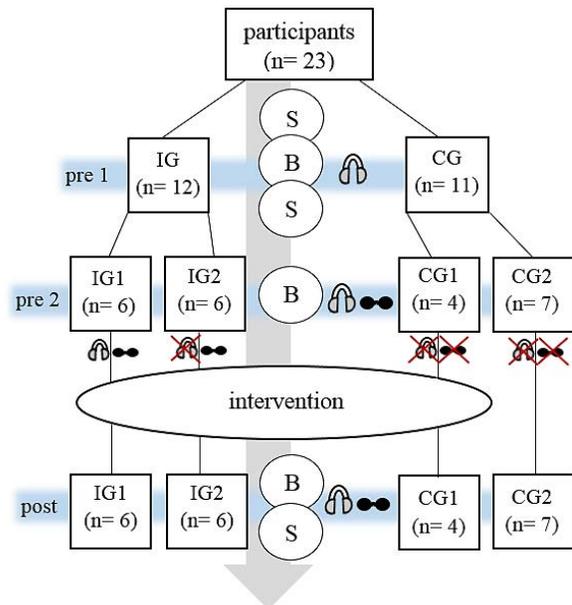

## INTRODUCTION

Human balance performance is based on interactions of different sensory systems, namely visual, somatosensory (e.g. plantar mechanoreceptors), and vestibular inputs [1]. Visual cues are important for maintaining balance [2]. Various studies have investigated long-term [3] and acute [4] effects of blindness on balance. Furthermore, studies have also examined how auditory cues contribute to balance regulation, which is, however, still controversial (e.g. [5]). Therefore, this study aimed to investigate acute adapting effects of short-term visual deprivation and reduced auditory capability on quasi-static balance performance. It was hypothesized that balance ability would decrease more when visual and auditory cues were deprived compared to only visual deprivation.

## METHODS

Forty-eight healthy subjects participated in this study. In some subjects, plantar temperatures varied considerably ( $>5^{\circ}\text{C}$ ), which was shown to deteriorate plantar sensitivity [6]. Therefore, only 23 subjects (11♀, 12♂; mean±SD: 24.1±3.3yrs; 172.7±8.7cm; 70.8±10.1kg) were included. Participants were informed about the aim of this study and were instructed to stop trials if they experienced discomfort. All measurements were conducted according to the recommendations of the Declaration of Helsinki. The protocol is presented in Fig. 1. Subjects completed three measurement sessions: before (pre1, pre2) and after (post) the intervention. The following parameters were evaluated during each measurement session: a) single-leg quasi-static balance performance (B, 10s) using a force plate (IMM Holding GmbH, Germany; 1kHz); b) plantar vibration sensitivity (S) at the first Metatarsal head (Met I) and Hallux using a TiraVib vibration exciter (Model TV 51075, Germany, 200Hz). During balance and sensitivity tests subjects wore ear

protectors and blackout glasses. Plantar temperatures (Hallux, Met I) were monitored using an infrared thermometer (UNI-T UT301C).

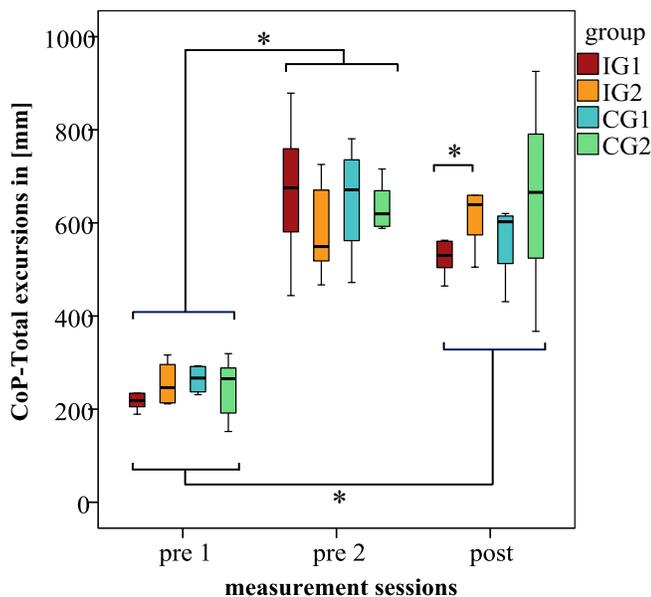

**Figure 1:** Both intervention groups (IG1, IG2) and control group 1 (CG1) performed the intervention: IG1: deaf & blind; IG2: hearing & blind; CG1: hearing & sighted. Control group 2 (CG2) did not attend the intervention and remained seated in the laboratory wearing neoprene socks (hearing & sighted); S foot sensitivity, B balance performance.

Subjects were randomly divided into the intervention (IG1, IG2) or control groups (CG1, CG2) (Fig.1). The intervention consisted of a standardized outdoor-walk (30min) on different surfaces (e.g. grass, grit, stairs), during which different balance exercises (e.g. balancing over curb) were executed. Participants wore thin neoprene socks to stimulate plantar mechanoreceptors, but also to protect the feet. Subjects were guided by a band held by the examiner. Information regarding obstacles etc. were only given through tactile cues using the band. For all parameters, three trials were collected and the median was used for further analysis. Center of

pressure (COP) total excursions were analyzed to examine balance. Vibration perception thresholds (VPTs) were calculated to examine plantar sensitivity. Statistical analysis was performed using SPSS (IBM SPSS Statistics 24). The Shapiro-Wilk-Test was used to determine distribution of data ( $\alpha=0.05$ ). The Wilcoxon Signed-Rank Test, Mann-Whitney-U-Test, Median-Test, and Sign-Test were used for further analysis. For VPTs, due to the two anatomical locations investigated, the level of significance was corrected to  $\alpha=0.05/2=0.025$ .

## RESULTS AND DISCUSSION

Comparing between the measurement sessions, only COP total excursions at pre2 and post were significantly greater compared to pre1 for all four groups (see Fig. 2). The deteriorating effect of blindness on balance was shown by Horak et al. [1]. Our study showed no significant differences for pre1 or pre2 when comparing the four groups within each measurement session (Fig. 2).

**Figure 2:** COP total excursions for all intervention (IG1, IG2) and control groups (CG1, CG2) before (pre1, pre2) and after (post) the intervention. Significant differences:  $*p \leq 0.05$ ,  $\alpha = 0.05$ .

For post, however, COP total excursions for IG1 were significantly smaller compared to IG2. This means that subjects performing the intervention deaf and blind exhibited improved balance ability

compared to subjects performing the intervention blind only. This is supported by our findings that IG2 remained constant when comparing pre2 vs. post, and that IG1 exhibited a trend-like decrease at post. The absence of auditory cues seemed to help the subjects focus on the new sensory condition and, therefore, improve their balance performance after the 30min outdoor walk. In other words, hearing ambient noise may have decreased balance ability in IG2. Similarly, it was also shown that blindness may cause conflicts in processing auditory cues [7]. Hence, it is possible that auditory cues were not processed properly for IG2 in order to provide supportive input for balance control.

VPTs for Met I and Hallux revealed no significant differences in any of the comparisons. We did not expect this finding, since daily step activity may increase plantar sensitivity [8], which in turn contributes to balance regulation. The thin neoprene socks used on various stimulating undergrounds did not change plantar sensitivity in our study, although plantar temperature changes were small (Hallux:  $0.7^{\circ}\text{C}$ ; Met I:  $2.1^{\circ}\text{C}$ ).

This study showed that balance ability deteriorates when vision is deprived; and that subjects with deprived vision and auditory inputs exhibited improved balance performance compared to subjects with deprived vision only. Further research is necessary to strengthen these results with a larger sample size.

# CORRELATION BETWEEN PLANTAR VIBRATION SENSITIVITY AND COP-PARAMETERS DURING DYNAMIC BALANCE

Bert Wynands\*, Claudio Zippenfennig, Andresa M.C. Germano, Daniel Schmidt, Tina Drechsel, and Thomas L. Milani

## INTRODUCTION

It is known that the mechanoreceptors in the foot sole play an important role in postural control. It has been reported that decreased plantar sensitivity results in greater instability in quasi-static balance tasks [1]. However, since 70% of human foot sole receptors are rapidly adapting receptors [2] that code dynamic events [3], it is reasonable to assume that plantar afferents might also play a dominant role in dynamic balance ability. However, to our knowledge, no study has analyzed the relationship between plantar sensitivity and Center of Pressure (CoP) parameters for dynamic balance tasks. Therefore, our aim was to examine whether a correlation exists between plantar vibration thresholds (VTs) and CoP-parameters during unexpected perturbations. We hypothesized that participants with low plantar sensitivity show larger CoP-excursions than those with high sensitivity.

## METHODS

Forty (20♀, 20♂) healthy subjects (mean±SD: 22.7±2.2yrs, 73.5±12kg, 1.76±0.08m) participated in this study. Prior to the test, subjects were informed about the study's purpose and were instructed to stop at any point if experiencing discomfort. All procedures were conducted according to the recommendations of the Declaration of Helsinki. Before the trials started, subjects underwent a 10min barefoot acclimatization on a temperature plate (25°C). To test plantar sensitivity, VTs were collected at the first metatarsal head (MET1) and the heel of the left foot using a TiraVib vibration exciter (Model TV 51075, Germany, 200Hz). Subjects sat with their feet resting on a box, with their knees and hips at a 90° angle. They wore noise cancelling earphones (Quiet comfort 20i, Bose, Framingham, USA)

which played pink noise to mask any distracting sounds of the vibration exciter or the environment. Pressure against the vibrating probe (diameter 7.8mm, elevation 2mm above box level) was controlled via a single axis force transducer. To acquire VTs, we used the Method of Limits (MoL) protocol described by [5]. The mean of five consecutive trials was calculated for heel and MET1. To test dynamic balance, a force plate (IMM Holding GmbH, Germany, 1kHz) was attached to the bottom platform of a customized Posturomed device (Haider Bioswing GmbH, Germany). Using an electromagnet, the platform of the Posturomed was released, resulting in an unexpected perturbation of the subject. Subjects stood on their left leg and were randomly perturbed in the antero-posterior (AP) and medio-lateral (ML) directions. For each perturbation direction, the mean of three consecutive trials was analyzed. We acquired four CoP-parameters (CoP total, ML-range, AP-range and CoP-velocity) in both directions for compensatory response, which extends from 90ms to 260ms after perturbation [6]. The Shapiro-Wilk-test was used to test for normality ( $\alpha=0.05$ ). To study differences between genders, Mann-Whitney-U-tests and Median-tests were used ( $\alpha=0.05$ , respectively). Pearson correlations were performed to investigate the relation between VTs and CoP-parameters ( $\alpha=0.05$ ).

## RESULTS AND DISCUSSION

Since VT and CoP data did not show any differences between genders, all data were examined altogether. Table 1 presents mean±SD for all parameters and the correlation coefficients between VTs and CoP data. At MET1, four of eight correlation analyses produced significant results (Table 1). Surprisingly, correlation coefficients were negative, implying that high VTs are linked to

small CoP-excursions. However, all coefficients lie between -0.3 and -0.35, which is considered a weak correlation [7] and probably not relevant. VTs at the heel did not demonstrate any significant correlations with balance parameters. The data do not support our hypothesis that subjects with low plantar sensitivity also feature higher CoP-excursions during a dynamic balance task, like perturbation. In contrast to our study, other investigations found positive correlations between balance and plantar sensitivity in quasi-static balance tasks [8,9]. It could be reasoned that plantar sensitivity is more influential in quasi-static than in dynamic tasks. However, subjects in [8] and [9] had some form of sensitivity impairment, which may have been large enough to influence balance ability and cause a correlation. Subjects in our study represent unimpaired sensitivity, which covers a comparatively small range of sensitivity, due to the low variation between subjects (Table 1). Such small variations may not have an effect on balance, possibly explaining why we could not find the expected correlation. A clear limitation of this study is that we did not investigate the sensitivity of FA1-receptors. Therefore, our results are only expressive for FA2-receptors.

## CONCLUSIONS

In conclusion, weak correlations were found between VTs (200Hz) and CoP-parameters during

perturbation. Most correlation analyses did not find any interaction, which suggests that small sensitivity variations in healthy subjects do not influence dynamic balance ability during perturbation as much as originally thought. Moreover, CoP-parameters may not be sufficient parameters for dynamic balance studies. Future studies should include the sensitivity of FA1-receptors to get a better understanding of the influence of rapidly adapting plantar afferents on dynamic events.

# ASSESSING CHANGES IN THE REACTIVE CONTROL OF BALANCE DUE TO MODIFICATIONS OF STEP LENGTH ASYMMETRY

<sup>1</sup>University of Southern California, Los Angeles, CA, USA  
Email: jmfinley@usc.edu

## INTRODUCTION

One of the primary challenges for human locomotion is to maintain balance when faced with unexpected perturbations. The ability to maintain dynamic balance in these situations relies on proper reactive control strategies to restore the center of mass (COM) within the base of support. One established metric used to characterize dynamic balance is whole-body angular momentum. This measure reflects the net contribution of all body segments to the body's rotation about a given axis, commonly taken to project through the COM. Specifically, whole-body angular momentum ( $L$ ) is highly regulated during human locomotion (Herr & Popovic, 2008) due to momentum cancellation between the limbs.

Here, we are interested in understanding how reactive control of balance is influenced by gait asymmetries. Recent studies have demonstrated that people post-stroke have impaired control of whole-body dynamics as captured by higher peak-to-peak ranges of angular momentum (Vistamehr et al., 2015; Nott et al., 2014). However, no studies have quantified how direct modification of asymmetry influences reactive balance control.

In this study, we used a biofeedback paradigm that allows participants to systematically adopt different levels of asymmetry to test the hypothesis that walking asymmetrically impairs reactive control of balance. Perturbation recovery was quantified using measures of integrated angular momentum ( $\int L$ ) and step length asymmetry (SLA) to understand how performance and whole-body posture change pre- and post-perturbation. We hypothesized that asymmetry would be associated with a higher angular momentum than walking symmetrically and may also lead to increased recovery time following the perturbations.

## METHODS

Ten healthy individuals were instructed to walk on a split-belt treadmill at 1 m/s. After conducting a baseline evaluation to find their natural step length, visual feedback was provided to induce symmetric walking (0% SLA) and asymmetric walking ( $\pm 10\%$  SLA,  $\pm 15\%$  SLA). SLA is defined as follows:

$$SLA = 100 * \frac{\text{left step length} - \text{right step length}}{\text{left step length} + \text{right step length}}$$

During each trial, 10 unexpected perturbations where the treadmill accelerated to 1.5 m/s were randomly applied to each side (right or left) at heel strike. Full body kinematics were captured using a 10-camera Qualisys Oqus system (Qualisys, Sweden) and a set of reflective markers. From this data, whole-body angular momentum ( $L$ ) as well as  $\int L$  over each step cycle were calculated about a mediolateral axis projecting through the COM for analysis of pre- and post-perturbation steps.

$$L = \frac{\sum_i [M_i (R_{CM-i}^i \times V_{CM-i}^i) + I^i \omega^i]}{MVH}$$

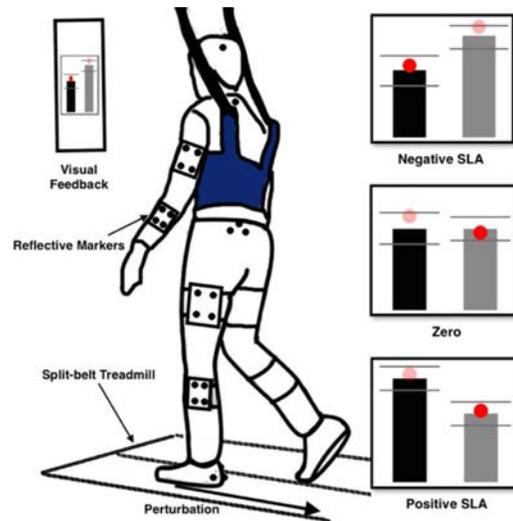

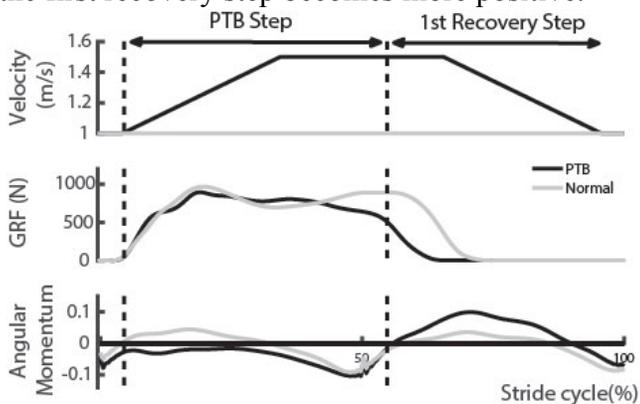

Fig 1: Experiment Setup

The number of recovery steps was also determined as the point when the participant's asymmetry was restored within  $\pm 5\%$  of the assigned SLA.

## RESULTS AND DISCUSSION

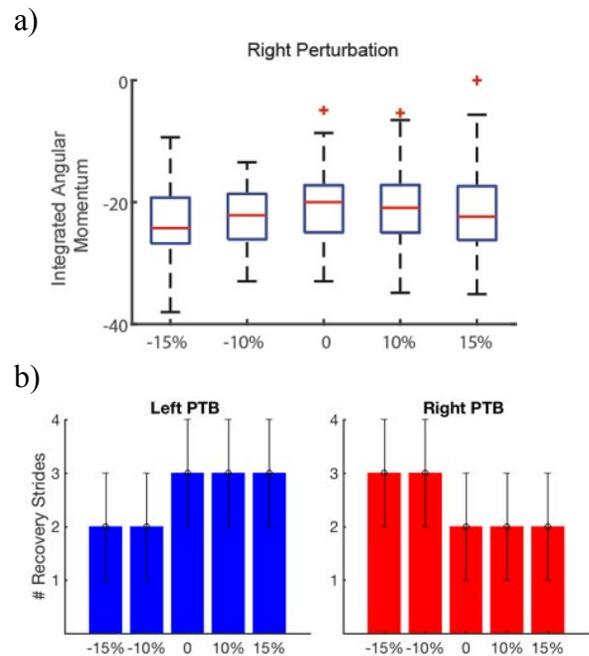

Our pre-perturbation measures of angular momentum during symmetric walking were similar to previous reports (Herr & Popovic, 2008). We found systematic variations in perturbation recovery in response to changes in step length asymmetry. A representative example illustrates the change in angular momentum during a perturbation and subsequent recovery step (Fig 2). Momentum was more negative compared to the pre-perturbation condition due to the participant's forward rotation. In order to regain balance, angular momentum for the first recovery step becomes more positive.

**Fig 2.** Treadmill speed, ground reaction force, and whole-body angular momentum across a stride.

Integrated angular momentum at the perturbation step was lowest during symmetric walking for perturbation to the dominant limb (Fig 3a). The magnitude of the integrated angular momentum was increased by 12.84% (SLA -15%), 8.4% (SLA -10%), 1.5% (SLA 10%), and 5.5% (SLA 15%), respectively, when compared to symmetric walking patterns.

Furthermore, the number of recovery strides varied with the direction of asymmetry and the side of the perturbation. One additional recovery stride was necessary when the perturbed side possessed a longer step length (Fig 3b).

**Fig 3.** a) Integrated angular momentum at the perturbation step for different asymmetries and b) # of recovery strides for left and right perturbations.

## CONCLUSIONS

To our knowledge, this study is the first to test how modification of step length asymmetry affects the reactive control of balance during walking. For healthy individuals, symmetric walking patterns may reduce the destabilizing effects of unexpected perturbations, while asymmetrical patterns impair balance. Future studies will address how asymmetry influences segmental contributions and limb coordination strategies to recovery from perturbations.

# GESTATIONAL LUMBAR LORDOSIS INTERACTIONS WITH DYNAMIC BALANCE CONTROL DURING PREGNANCY

W. Connor Wolcott, Christopher P. Connolly, Robert D. Catena,

Washington State University, Pullman, WA, USA

email: [robert.catena@wsu.edu](mailto:robert.catena@wsu.edu), web: <https://labs.wsu.edu/biomechanics/>

## INTRODUCTION

Fall rates among pregnant women reach levels comparable to individuals over the age 70 [1]. Falls pose a serious threat to the mother and unborn child, however we still don't fully understand the underlying causes toward increased fall rates. Our ongoing research indicates that mass changes contribute only partially to balance changes during pregnancy. Moreover, the literature describing dynamic balance control changes during pregnancy is thin.

When describing dynamic balance control, we often discuss the center of mass (COM) and base of support (BOS) interactions that occur during a moving task (e.g. gait). Considering the unique changes to the body that pregnancy causes, we could expect that any change that influences the position or motion of the COM in relation to the BOS would influence dynamic balance control.

It has been previously reported that the lumbar curvature of pregnant women increased steadily as gestation progresses [2]. This occurs exclusively in bipedal hominids as it readjusts the COM posteriorly over the hips in response to ventral fetal weight gain. It is currently unknown if, and how, dynamic balance is correlated with these lumbar curvature changes. Presumably, not all pregnant women experience lumbar change to the same degree. Is more change better for dynamic balance in terms of repositioning the COM or detrimental to dynamic balance because of the altered rotational kinetics at surrounding joints? In this study, we examined the correlations between lumbar curvature and dynamic balance control throughout pregnancy.

## METHODS

We have recruited 33 participants total to our study, however due to the longitudinal nature of our testing, data from only 6 of those participants is included here. Our participants' mean age was 27.7 (sd = 4.14) with a mean gestational age at start of testing of 14.5 weeks (sd = 39.9 days).

Testing sessions were conducted monthly, involving full body anthropometry measurements followed by a static standing trial and a 60 second walking trial on a treadmill at a self-selected pace. We utilized a forty-eight retroreflective marker set captured by a ten-camera motion capture system at 100 Hz using Cortex and Biosuite software (Motionanalysis Corp., Santa Rosa, CA) and then low-pass filtered at a 6 Hz cutoff. The entire sixty-second capture was split into individual gait cycles at right heel strikes. The body COM was calculated using a 13-segment anthropometric model; supported by currently in-review findings. COM data were then passed through a custom MatLab program that calculated COM and BOS interactions as well as step width and other balance measures. Average lumbar angle while standing and walking was calculated from markers at the approximate levels of T12, L2, L4 and S2.

Statistical analysis was carried out using a stepwise multiple regression analysis in SPSS v23 to determine correlations between lumbar angle, step width, and balance measures.

## RESULTS AND DISCUSSION

Moderate positive correlations were found between lumbar curvature and measures of balance. In other

words, as lumbar curvature increases during pregnancy, the minimum distance of the center of gravity (COG) to the BOS is greater (Tables 1 and 2). In most cases, we describe a smaller separation of the COG to the BOS as reduced dynamic balance control. From our data it appears that the increase in lumbar curvature that occurs during pregnancy aids in dynamic balance control.

c. Predictors: BAS, BAW, BRW

d. Predictors: BAS, BAW, BRW, Days2Birth

We also observed correlations between the angular range of motion of the COM around the ankle joint during stance in the sagittal plane and lumbar curvature. This suggests that individuals are taking shorter steps as pregnancy progresses. One explanation is that this may be another alteration to improve balance. Alternatively, shorter steps during pregnancy may be a result of a cascading effect of increased lumbar curvature on the moment arms and

lengths of muscles involved in gait performance. So whereas increased lumbar curvature may improve balance control, the trade-off may be that forward gait progression is adversely affected. We discovered that not every participant experienced the same change in lumbar curvature. Future study will involve comparing the balance measures of individuals, who do experience curvature changes throughout pregnancy versus those who do not. Furthermore, we intend to examine correlations between muscular strength to the occurrence of lumbar curvature change.

## CONCLUSIONS

Lumbar curvature changes during pregnancy may be adaptive to increase dynamic balance control. As we increase our analysis sample size we will be able to determine if curvature changes result in diminished gait progression or if gait progression changes naturally occur with gestation. Furthermore, lumbar curvature changes occur at differing magnitudes between women, potentially creating varying balance effects. These effects, in addition to the contribution of muscular strength to the development of gestational lumbar lordosis, should be studied further.

## INTRODUCTION

Idiopathic normal pressure hydrocephalus (iNPH) is generally known as a pathological process with abnormal intracranial fluid dynamics resulting in progressive ventricular enlargement and reduced intracranial compliance [1]. The symptomatic of this disease is usually characterized as a triad of progressing dementia, urinary incontinence, and movement disorders, which are frequently the first and most prominent symptoms [2]. Besides gait disturbance, postural instability is a clinical challenge, because of the associated risk of falling [3]. Commonly, iNPH is treated via surgical implantation of a ventriculoperitoneal shunt to normalize intracranial fluid dynamics and consequently ease symptoms. Hence, clinical balance scales (e.g. Berg Functional Balance Scale, Functional Reach Test) are frequently applied for diagnosis and to determine and assess posturographic changes after shunt treatments. However, these tests often lack objectivity, sensitivity, and specificity compared to data collected with force or pressure distribution platforms [4]. Therefore, the aim of this study was to investigate postural instability in patients with iNPH in contrast to healthy control subjects using computerized methods. Furthermore, we aimed to analyze the impact of a shunt treatment in hydrocephalic patients. Based on comparable study findings [3,5,6] it was hypothesized that patients with iNPH have poorer postural stability compared to healthy controls, whereas shunting improves balance performance.

## METHODS

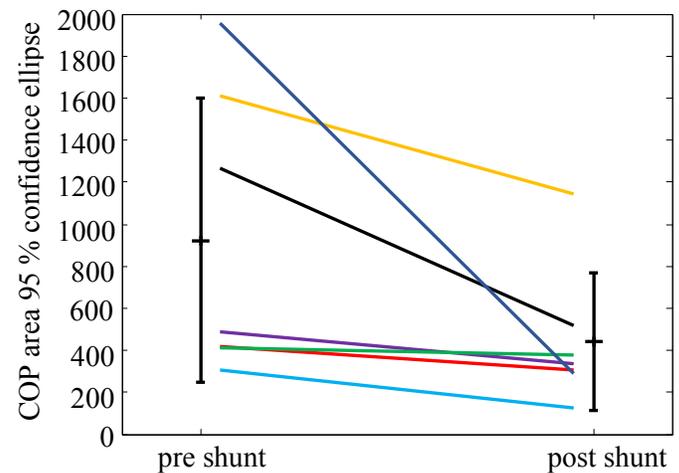

All procedures were conducted according to the recommendations of the Declaration of Helsinki and were approved by the local ethics committee. This study comprised three groups: iNPH, consisting of

19 diagnosed patients (12 male, 7 female; age: 72.9±5.5 years, height: 168.5±8.9 cm, weight: 79.2±16.1 kg); HC, consisting of 19 healthy control subjects matched for sex, age, and anthropometrics (12 male 7 female; age: 72.1±6.1 years, height: 171.5±10.7 cm, weight: 78.5±11.6 kg); and iNPH shunt, comprising 16 iNPH patients, which had already undergone shunt surgery previous to this study (12 male, 4 female; age: 72.7±6.5 years, height: 173.5±6.8 cm, weight: 84.5±13.3 kg). Additionally, seven hydrocephalic patients were evaluated both pre and 3-12 months post operatively to investigate the intrasubjective effect of shunting. Patients were diagnosed with iNPH by positive clinical testing, including invasive and non-invasive measures according to the previously published protocol [7]. Furthermore, ventricular enlargement was proved by standard cMRI scan. Aqueductal stenosis and other secondary pathologies were excluded. A pressure distribution platform (Zebris FDM 1.5, Medical GmbH, Isny Germany) was used for measuring postural performance during quite stance. Therefore, all participants were instructed to stand upright as still as possible with both feet next to each other on the platform, pointing their gaze ahead with both arms hanging down loosely. To ensure reproducibility for the repeated pre vs. post shunt measurements, foot distance and rotation angle were controlled. Two trials of 30 seconds each were collected at 100 Hz for each participant. Pressure distribution data were analyzed using MATLAB (R2008b, MathWorks, Massachusetts) to calculate the mean of the center of pressure (COP) parameters: COP area of the 95% confidence ellipse, COP path length, and mean COP velocity. SPSS Statistics 24 (IBM) was used to compare between groups with a Kruskal-Wallis-Test followed by post hoc-tests. Due to the three investigated parameters, the level of significance was Bonferroni adjusted to  $\alpha=0.0166$ .

## RESULTS AND DISCUSSION

Table 1 displays the results of the group comparison. All COP parameters showed statistically significant differences between HC vs. iNPH and HC vs. iNPH shunt. Healthy control subjects revealed significantly lower COP areas, path lengths, and mean velocities compared to hydrocephalic patients without (iNPH) and with shunt (iNPH shunt). Higher COP values are generally associated with less postural stability. This implies poorer postural stability in patients with iNPH, regardless of whether they have a shunt or not, compared to healthy subjects. Nevertheless, iNPH patients with shunts showed a tendency toward better postural control, due to lower COP values compared to patients without shunt. Despite improvement, shunted iNPH patients still have worse postural stability than healthy subjects.

The intrasubjective pre vs. post shunt comparison revealed diminished COP areas for all seven patients, indicating improved postural control (Figure 1). The mean values of this specific parameter decreased from  $922.5 \pm 676.1 \text{ mm}^2$  to  $441.2 \pm 329.5 \text{ mm}^2$ , which indicates an overall reduction of 52.2%. Noteworthy, not all patients showed equal improvements: patients with higher pre shunt COP areas improved more than patients with smaller pre shunt COP areas. However, six out of the seven patients reduced their COP area >25 %, and therefore can be considered as positive shunt responders. Our findings are in accordance with those of other studies [3,5,6]. Their results revealed equal postural deficits for patients with iNPH compared to healthy controls. They also characterized hydrocephalic postural instability in quiet stance with increased COP areas and velocities [3,6]. After shunt surgery, Czerwoszcz et al. [3] found reductions for the COP area of approximately 75 %, meaning substantial improvement in postural control. Considering all results of the present study, the stated hypotheses can be confirmed.

**Figure 1:** Pre vs post shunt changes of the COP area for all seven iNPH patients separately and together (mean  $\pm$  standard deviation).

## CONCLUSIONS

Patients with iNPH suffer from poorer postural stability in quiet stance compared to healthy controls. Shunting positively effects postural control. Computerized posturography in quiet stance may be used as a quantitative, valuable tool for diagnostics, treatment, and rehabilitation purposes in iNPH.

## INTRODUCTION

From a mechanical perspective, human vertical posture is regarded as an unstable system requiring control mechanisms to maintain center of gravity, and therefore postural control [1]. Standing without assistance is a fundamental skill for independent mobility. Previous studies [1-3] suggest multiple muscles are involved in quiet standing balance, and the degree of activation of muscle synergies is a good indication of postural stability.

Plyometric training (PT) is popular amongst trained athletes, and involves exercises such as hopping and jumping over a short period of time [2]. These exercises utilize the elastic energy stored in the stretching phase of the lower limb muscles as they undergo stretch-shortening contractions [2]. PT has been shown to positively impact numerous biomechanical, sensory acuity, and motor control, measures; such as balance control, aerobic/anaerobic power, and capacity [2]. Most plyometric training studies explored low impact training. The very few, high intensity training programs which positively impacted dynamic measures and vertical jump performance involved trained athletes, such as soccer players [2].

The aim of this study was to investigate the effects of a ten-week, high intensity bilateral plyometric training program on young adults to observe and characterize changes in their performance, motor control and postural stability. This is the first part of a larger study, which aims to investigate these measures in adults with impaired standing balance. We hypothesized that over time, there would be a reduction in the overall center of pressure (CoP) velocity, postural sway and 95% ellipse area. Our second aim was to determine the effect of this training on muscle activity in the lower limbs by evaluating vertical jump performance, EMG-EMG coherence of synergistic muscles, and gross innervation input of a select muscle for the task.

## METHODS

### *Participants*

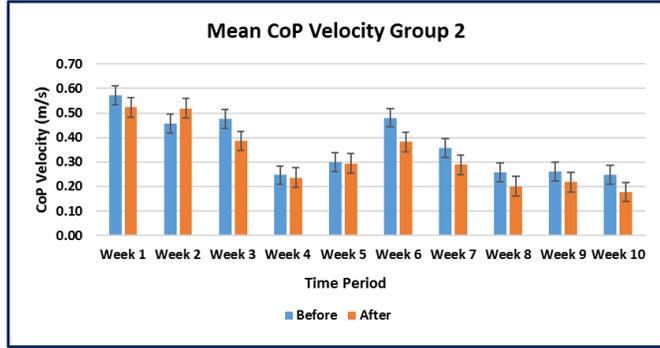

Ten healthy, young participants (Age:  $20.1 \pm 1.4$  years; Group 1: 2 Females, Body Mass:  $49.70 \pm 7.77$  kg, Height:  $1.58 \pm 0.04$  m; Group 2: 4 Males, Body Mass:  $67.80 \pm 0.80$  kg, Height:  $1.65 \pm 0.04$  m; Group 3: 4 Males, Body Mass:  $85.90 \pm 12.70$  kg, Height:  $1.91 \pm 0.04$  m) provided written informed consent to participate in this protocol, which was approved by the local institutional review board.

### *Procedures*

This ten-week study consisted of three plyometric training sessions a week, per person. The experiment consisted of two independent, bilateral standing measurements (pre-exercise and post-exercise), which involved analyzing CoP measurements using a portable force platform (AMTI AccuSway, Watertown, MA) sampled at 500 Hz, and muscle activity measurements using six surface wireless Electromyography (EMG) sensors (Trigno, Delsys Inc. Natick, MA), sampled at 1926 Hz. Participants were instructed to stand with feet shoulder width apart on the force platform with eyes open for 90s, with the EMG sensors placed on the right and left muscle bellies of the vastus lateralis (VL), biceps femoris (BF) and lateral gastrocnemius (GL). These muscles were chosen as they are known to affect postural sway and do not require filtering against cardiac artifacts [3]. After this pre-test recording, the participants were led through a short warm-up, before beginning the exercises. The training itself consisted of four sets of stationary hopping for 30s as fast and as high as possible (maximal effort) with 60s rest in between each set. This was followed by a cool down for 5 minutes and slow walking. Post-test measures were then taken, using the same pre-test procedure as described above. Vertical jump performance was recorded bi-weekly throughout the study to monitor and evaluate the ability to generate multi-joint power in the lower extremities [2].

## RESULTS AND DISCUSSION

Data analysis was performed using MATLAB R2015a (Mathworks Inc., Natick, MA). CoP and muscle activity measures were pre-processed, synchronized and normalized as described in [3]. Significant differences in CoP velocity and 95% ellipse area were found across all three groups of participants, especially *Group 2* (Fig. 1):

**Figure 1:** Mean CoP velocity comparison *Group 2*

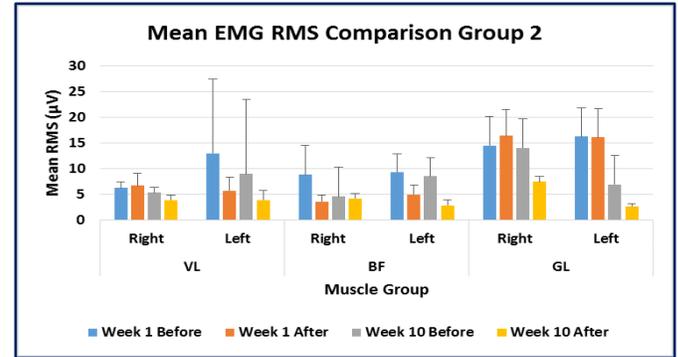

A 61.40% decrease in the overall mean CoP velocity in both directions show increased stability. Postural sway in the medio-lateral and anterior-posterior directions did not show substantial differences, but stabilized after week five.

EMG-EMG coherence estimations using the Welch method [2-3] was used to analyze the coordination between synergistic pairs of muscles:

$$|R_{xy}(\lambda)|^2 = \frac{|f_{xy}(\lambda)|^2}{|f_{xx}(\lambda)f_{yy}(\lambda)|} \quad (1)$$

where  $R_{xy}(\lambda)$  is the intermuscular coherence,  $f_{xy}(\lambda)$  is the cross-spectrum between both EMG signals,  $f_{xx}(\lambda)$  is the auto-spectrum of the first EMG signal, and  $f_{yy}(\lambda)$  is the auto-spectrum of the second. Higher amplitudes of muscle activity were observed in lower frequencies, and overall coherence of muscle pairs increased over time ( $\sim 0.63$ ). Mean EMG root-mean-square (RMS) comparisons between different muscle groups assessed the gross innervation input of select muscles during both testing conditions. All groups

showed a reduction in the mean RMS ( $\sim 0.60\mu V$ ), especially *Group 2* (Fig. 2):

**Figure 2:** Mean EMG RMS comparison *Group 2*

Improved vertical jump performance (Table 1) further validates significant adaptation in lower limb power, as high impact forces are produced during these movements.

## CONCLUSIONS

This ten-week high intensity plyometric training program consisting of maximal intensity bilateral exercises in young adults induced major improvements in lower extremity power and postural control. This decrease in muscle activation/force production can be associated with neural components of adaptation accompanied by improved intermuscular coordination and/or changes in the mechanical characteristics of the muscle-tendon complex [1-3]. High intensity PT provides an alternative approach in treating impaired standing balance and improving postural control. This could potentially provide a training regimen to be incorporated into rehabilitation programs.

## INTRODUCTION

During locomotion, humans often make cognitive decisions and respond to external stimuli that result in cuts (changing direction), transitions to uneven terrain, or complex combinations thereof. The mechanics of these destabilizing locomotor transitions are also affected by whether a change in direction is made towards (crossover) or away from (sidestep) the leading, implanted leg [1]. Finally, these tasks are influenced by cognitive factors such as if a task is unanticipated—conditions in which neuromotor task planning is interrupted. During running, unanticipated cuts influence ground-reaction forces, joint angles, joint moments, and muscle activity, which are thought to lead to knee loading mechanics that are deleterious to knee ligament strain [e.g., 2]. However, during walking, it is unknown how specific contextual factors influence dynamic balance of locomotor transitions, which could inform how we assess balance deficits of fall-prone individuals or inform device interventions to target specific destabilizing and non-steady locomotor scenarios.

One metric to assess dynamic balance of walking is whole-body angular momentum ( $H$ ), which has been shown to be tightly regulated by unimpaired individuals [3] via the generation of appropriate muscle forces [4]. The purpose of this study was to apportion the effects of task anticipation, cutting style, and complexity on the time evolution of frontal-plane dynamic balance during locomotor transitions of healthy, unimpaired individuals. We hypothesized that the magnitude of  $H$  would be larger during unanticipated conditions of increased complexity (i.e., combined cut/stair-ascent).

## METHODS

Data were collected from five healthy unimpaired subjects (27.7±3.8 years; 52.6±5.0 kg; 1.68±0.09 m). Straight-line walking (STR), crossover (CO), sidestep (SS), crossover/stair-ascent (COS), and sidestep/stair-ascent (SSS) were performed overground under anticipated and unanticipated conditions. First, each participant completed 10 baseline STR trials, followed by 20 anticipated cut trials (5 of each style and complexity), and a subsequent 30 unanticipated trials (5 cuts of each style and complexity and 5 STR corresponding to either left or right leg leading). In unanticipated trials, a randomized auditory cue of “stair”, “cut”, or “walk” was given at the initiation of single-leg support of the leading leg, approximately one-half step preceding a visible transition point. The lab setup consisted of an overground straight-line walkway, a level-ground cutting (45°) direction to the right, and a mobile staircase at 45° to the left for cut/stair-ascent.

A 10-camera motion capture system (Motion Lab Systems, Inc.) was used to track body segment movement. An 8-segment model of each subject (torso, pelvis, thighs, shanks, and feet) was constructed using Visual3D (C-Motion, Inc.).  $H$  about the body center-of-mass was calculated using a standard kinematic formulation [e.g., 3] and normalized by body mass and height of each subject. To analyze the time evolution of  $H$ , consecutive maxima and minima of  $H$  were computed during two consecutive strides spanning each condition. These metrics were compared statistically ( $\alpha=0.05$ ) with two, two-way ANOVAs (anticipation, complexity; anticipation, cutting style).

## RESULTS AND DISCUSSION

Anticipatory changes in frontal-plane balance were influenced by style, but not complexity. Prior to the trailing-leg toe-off (i.e., cue onset in unanticipated conditions), a significant style main effect and anticipation by style interaction effect were observed (P1, Fig. 1).  $H$  in anticipated crossovers was more positively directed toward the leading foot (the cutting direction), while  $H$  in sidesteps was reduced to approximately zero momentum (away from the cut), relative to walking and unanticipated conditions. These changes suggest that in the frontal plane, anticipating upcoming demands associated with modifying walking direction is of greater value for task planning than changes in surface.

Our hypothesis was largely supported. However, specific combinations of contextual factors showed unique magnitudes of dynamic balance. In the subsequent heel-strike after the cue, anticipation, complexity, and style main effects and an anticipation by style interaction effect were found (N1, Fig. 2). Unanticipated sidestep had the largest magnitude of negative  $H$  (Fig. 1), possibly due to inability to fully execute a sidestep cut within the available response time, which resulted in a mixed style that most resembled a crossover. In the second stride of the transition, complexity and style main effects were observed (P2, Fig. 1), and anticipated and unanticipated crossover/stair-ascent resulted in the largest frontal-plane  $H$  toward the cut direction (P2, Fig. 1). Later in the second stride of the

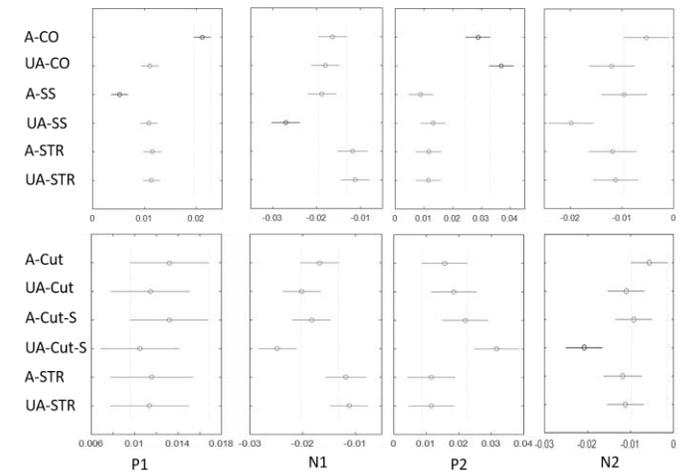

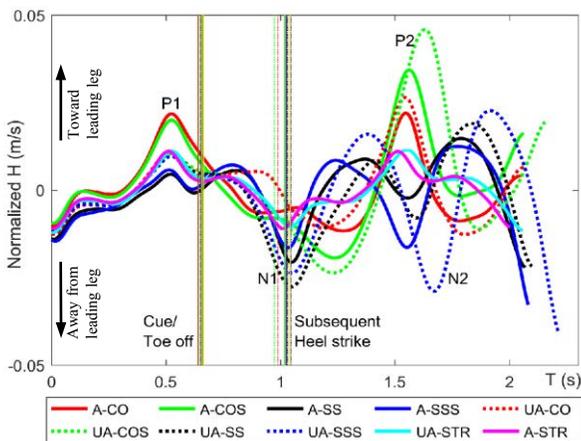

transition, anticipation, complexity, and style main effects and anticipation by complexity and anticipation by style interaction effects were found (N2, Fig. 1), with unanticipated sidestep/stair-ascent resulting in the largest negative  $H$  (away from the leading leg toward the cut direction). Collectively, these findings suggest there are adverse downstream effects of unanticipated states on dynamic balance.

## CONCLUSIONS

Anticipatory modifications of balance, transient changes in balance immediately following the interruption of task planning, and subsequent adverse effects were observed by altering task anticipation. All of these changes appear to be important when negotiating locomotor transitions, with respect to frontal-plane balance, and could be targeted in balance-impaired individuals through training or device interventions. However, with respect to only anticipatory modifications, healthy individuals appear to prioritize directional changes over changes in walking surface.

## INTRODUCTION

The ability to stand is requisite for performing many activities of daily living. The active control of standing balance is known to be facilitated by a wealth of sensorimotor processes [1]. The manner in which the center of pressure (COP) moves over time during quiet standing may be revealing of these underlying control processes.

Postural sway can be characterized according to its velocity patterns. For example, sway may be described to exhibit ‘persistence’ when a COP velocity change in one direction is more likely to be followed by a change in the same direction. Conversely, sway may exhibit ‘anti-persistence’, when a change in one direction is more likely to be followed by a change in the opposite direction. Intriguingly, sway patterns of healthy young adults demonstrate both persistent and anti-persistent behavior, but at different timescales [2]. When examining the patterns within small time increments (i.e. within 1 second) the fluctuations are persistent, whereas at longer time scales (i.e. over several seconds) the fluctuations are anti-persistent. It has been postulated that this transition from ‘short term persistence’ to ‘long term anti-persistence’ reflects the action of a control mechanism that evokes a directional change when a threshold of velocity is exceeded [2].

Given that cutaneous receptors beneath the foot are ideally positioned to detect these movements, it seems reasonable to speculate that their sensory contributions may play a direct role in the mediation of this velocity-based control mechanism. We aimed to test this by comparing the COP velocity patterns of adults with no impairments to individuals with a unilateral transtibial amputation. Following a

unilateral lower extremity amputation, the tactile sensation from one foot will be absent resulting in an asymmetric sensory deficit. We hypothesized that, due to this sensory loss, amputees would exhibit less short term persistence and less long term anti-persistence. In effect, this would be illustrated with a convergence towards similar dynamics at both timescales.

## METHODS

Eleven individuals with a unilateral transtibial amputation ( $60.2 \pm 15.9$  yrs,  $1.8 \pm 0.1$  m,  $98.8 \pm 13.7$  kg) and seven individuals with no impairment ( $40.6 \pm 9.7$  yrs,  $1.7 \pm 0.1$  m,  $85.3 \pm 24.3$  kg) consented to participate. Participants stood for 90 s with their feet on parallel force plates (Optima, AMTI, Watertown, MA), with their feet ‘as close together as possible’ and arms crossed in front of their torso, fixating on a wall-mounted target. COP trajectories at 60 Hz were computed from the two force plates, low-pass filtered at 10Hz and differenced to obtain COPv.

Detrended fluctuation analysis (DFA [3]) was used to quantify persistence in COPv in anterior-posterior (AP) and medial-lateral (ML) directions. DFA estimates the relationship between the size of fluctuations  $F(n)$  within a time series for windows of observation of size  $n$ . A linear slope in bi-logarithmic coordinates reveals a power-law relationship, such that  $F(n) \sim n^\alpha$ , where  $\alpha$  is the slope or scaling exponent. An  $\alpha > 0.5$  reflects persistent fluctuations while  $\alpha < 0.5$  reflects anti-persistent fluctuations, and  $\alpha = 0.5$  indicates randomness. Short and long term exponents were estimated over approximately 0.2-0.6 seconds ( $\alpha_{\text{short}}$ ) and 1.8-11.3 seconds ( $\alpha_{\text{long}}$ ), respectively. This velocity-based control mechanism would be indicated by  $\alpha_{\text{short}} > 0.5$  and  $\alpha_{\text{short}} < 0.5$ . Group differences between individuals with and

without an amputation were determined using Welch's t-tests for unequal variances in R (R core team, Vienna, Austria).

## RESULTS AND DISCUSSION

In partial support of our hypothesis, in the AP direction the participants with transtibial amputation exhibited less persistent sway patterns at the short timescale in comparison to controls ( $\alpha_{\text{short}} = 1.2 \pm 0.2$  vs  $1.4 \pm 0.1$ ,  $p = 0.04$ ). However, reduced persistence (i.e. increased antipersistence) was similarly observed at long timescales ( $\alpha_{\text{long}} = 0.2 \pm 0.1$  vs  $0.4 \pm 0.1$ ,  $p = 0.01$ ). There was no difference between groups in the ML direction ( $\alpha_{\text{short}}$ :  $p = 0.36$ ;  $\alpha_{\text{long}}$ :  $p = 0.53$ ).

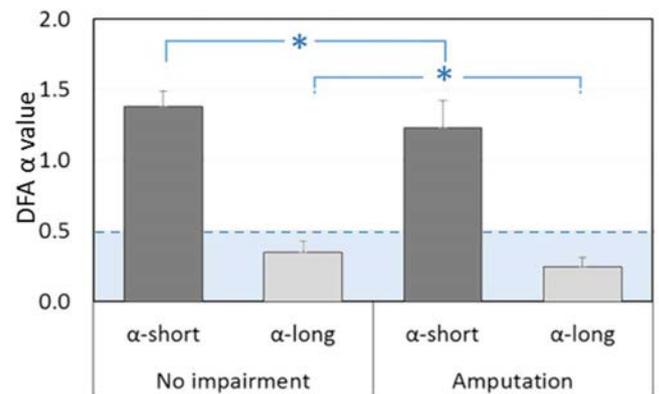

Although group differences were observed in the AP direction, the marked disparity between short term persistence and long term anti-persistence remained evident in both AP and ML directions of the individuals with amputation, potentially indicating similar velocity-based control. The lack of a group difference in the ML direction was surprising given the absence of cutaneous plantar sensation from half of the base of the support in prosthesis users.

## CONCLUSIONS

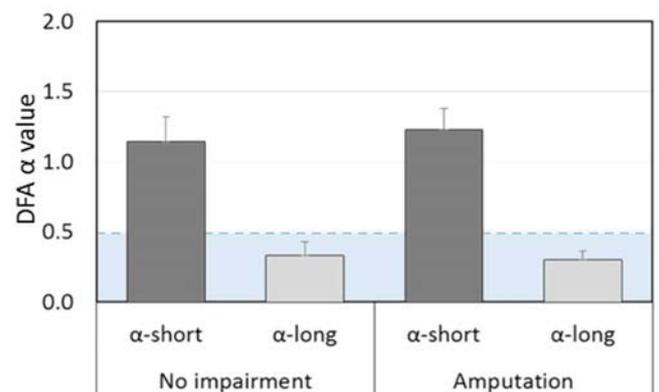

The overall trend to exhibit 'short-term persistence' and 'long-term antipersistence' in the COP velocity was preserved in unilateral transtibial amputees despite the deficit in sensation from one foot. Our results indicate that cutaneous plantar sensation may only play a minor role in the mediation of the proposed COP velocity-based control mechanism (change in direction is exerted when a velocity threshold is exceeded). Alternatively, the residual limb may be able to take on a greater sensory role than we anticipated. We are currently exploring these possibilities.

## INTRODUCTION

While able-bodied individuals use both vision and proprioception to control posture, amputees rely more heavily on vision [1]. Reliance on vision increases attention required to safely complete tasks and hinders mobility in poor lighting conditions and when terrain is uncertain or variable.

In a below-knee human amputee, we have developed a system that can provide natural sensory feedback perceived as coming from the lost limb by stimulation of sciatic, tibial, and common peroneal nerves through nerve cuff electrodes implanted in the popliteal fossa. Although a similar technology has been previously used to elicit sensation in upper limb amputees [2], we report, for the first time, the feasibility of this technology to restore sensation in people with lower limb amputation. Based on our preliminary observations, the stimulation signal delivered to the nerves can be finely tuned to elicit sensations of toe movement in the missing limb.

As a first step toward understanding how natural sensation can be used to improve functional performance, we examined responses during standing balance to randomly-timed stimuli that induced the sensation of toe movement.

## METHODS

A volunteer who had undergone below-knee amputation 48 years ago as a result of trauma on his left leg (male, 67 years old, 234 pounds) was implanted with 16-contact nerve cuff electrodes around the sciatic, tibial and fibular nerves above the knee in his residual limb in an IRB-approved surgical procedure. Stimulation applied to different

contacts in the cuffs elicited sensations of touch or movement projected to discrete locations on his missing limb. Specific contacts and stimulation parameters (pulse amplitude and duration) that produced four distinct sensations of toe movement (medial toes moving down, lateral toes moving down, medial toes lifting, and lateral toes lifting) were identified and subsequently utilized during quiet stance.

The subject stood wearing his conventional prosthesis with eyes closed, arms by his side, and feet positioned on two different force plates (OR6-6, AMTI). Body position was recorded using a 16-camera motion capture system and the Plug-In Gait marker set (collection Nexus 1.6.1, post-processing Nexus 1.8.5, Vicon). An interactive pen display screen in front of the subject provided cues and recorded drawn responses (CINTIQ, WACOM).

The set of stimulation parameters corresponding to each of the four perceived toe movements was applied at least five times in a random sequence with catch trials where no stimulation was applied interspersed. The subject took breaks to sit every 10-15 minutes to limit fatigue. The sensation of toe movement was induced much like a perturbation by applying stimulation for a random 5 second interval during a 20 second trial with eyes closed. Thus the subject was unaware of the timing and intended sensation defined by stimulation. Having completed a trial, the subject described any sensation felt along with its location and intensity.

Postural sway in response to sensory stimulation was characterized by the range of the net center of pressure (COP) in the anteroposterior (AP) and mediolateral (ML) directions as well as COP path

length. These values were averaged across trials with similar perceived sensations (MATLAB, MathWorks, Inc.). Differences caused by stimulation (5 levels) were assessed using one-way analysis of variance ( $\alpha = 0.05$ ).

## RESULTS AND DISCUSSION

A trend towards greater fore-aft sway, as measured by the range of AP COP, was observed when stimulation inducing the sensation of movement was applied compared to no stimulation (Figure 1). Similarly, COP path length tended to increase with sensory stimulation (Figure 1). With the perception of the medial toes lifting, the ML COP range was slightly lower than the other conditions (Figure 1). None of these differences were large enough to be statistically significant.

In able-bodied individuals, AP COP is controlled by pushing or lifting the toes through adjustments at the ankle [3]. The perturbation-like sensations we provided were similar to sensations that are felt in able-bodied adjustments to AP COP, so the observed changes are consistent with strategies used to control variations in AP COP. The greater range of AP than ML COP in all conditions is consistent with previous standing balance studies in lower-limb amputees and able-bodied individuals [1, 3].

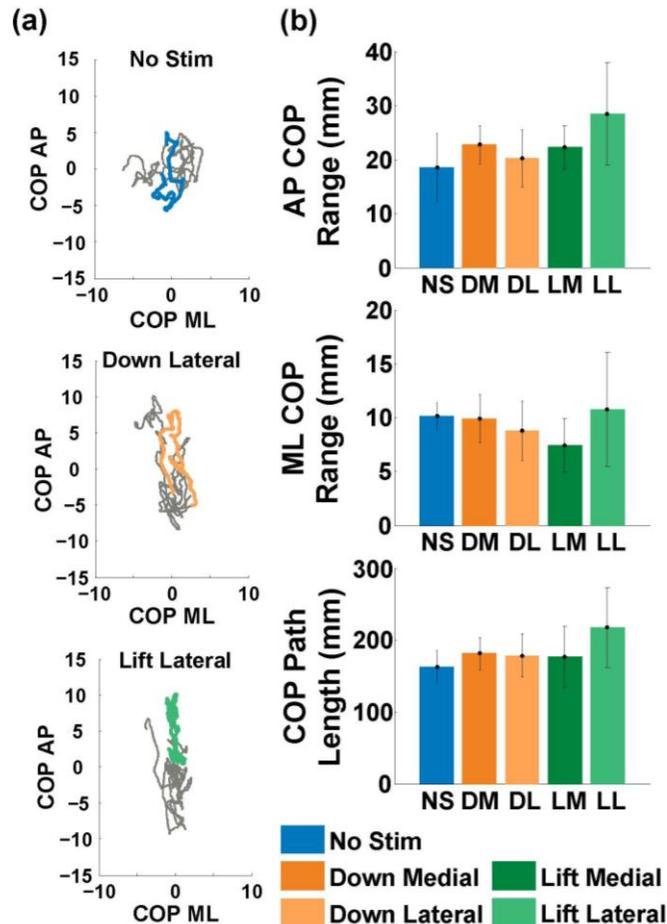

While the changes observed were not statistically significant, trends show that slight postural adjustments were made as a result of sensation. Future work will explore this effect at further post-implantation times, in additional subjects, and in more challenging conditions (e.g., standing with eyes closed on foam). Our system, which allows us to direct sensory feedback by electrical stimulation through nerve cuff electrodes, provides a unique opportunity to study the role of proprioception in amputee balance control tasks.

## INTRODUCTION

Nonlinear methods such as approximate (ApEn) and sample (SampEn) entropy have been used as a measure of regularity to quantify the complexity of the center of pressure (CoP) trajectory in those with lower extremity amputations [1,2]. More complex and irregular CoP trajectories result in higher ApEn or SampEn values, which is often interpreted as more randomness and less neuromuscular control of movements. Lower entropy values have been reported for the affected side of those with unilateral, transtibial amputation (TTA) [1], which is indicative of greater neuromuscular control of the affected limb [3].

The structural properties within the residual limb of a TTA may also play a role in how well the affected limb adapts to changes in surface or visual input. The osteomyoplastic procedure (Ertl) creates a “bone-bridge” between the tibia and fibula, while a Non-Ertl procedure leaves the two bones free floating within the residual limb. The bone bridge in the Ertl technique may provide more structural support and assist with postural control, but little evidence of this exists in the current literature.

It was hypothesized that the affected limb would exhibit lower ApEn and SampEn values compared to the unaffected limb during quiet standing. It was further hypothesized that standing on a rigid surface compared to a compliant surface and standing with eyes open rather than with eyes closed would result in higher entropy values, indicating more complexity and less neuromuscular control. Finally, it was also hypothesized that ApEn and SampEn would be similar for Ertl and Non-Ertl amputation groups.

## METHODS

Fifteen participants with unilateral, TTA were recruited from two groups: Ertl ( $n = 9$ ,  $49 \pm 10$  years,  $75.0 \pm 15.3$  kg,  $1.76 \pm 0.07$  m); Non-Ertl ( $n = 6$ ,  $56 \pm 8$  years,  $85.1 \pm 14.8$  kg,  $1.76 \pm 0.06$  m). Participants gave their informed written consent prior to participation. Participants were asked to stand comfortably with each foot on an individual force plate. Foot placement was measured with respect to the force plates to provide consistent foot positioning when standing on both surfaces. CoP data were collected (2000 Hz) for 30 seconds in four conditions: 1) rigid surface eyes open (RSEO), 2) rigid surface eyes closed (RSEC), 3) compliant surface eyes open (CSEO), and 4) compliant surface eyes closed (CSEC).

The raw CoP data were down sampled to 100 Hz for consistency with common sampling frequencies reported in the literature for quiet standing analyses. The middle 20 s of each trial was used for analysis because participants began each trial with the arms outstretched and the shoulders abducted to 90°. In the last few seconds of each trial, participants were asked to abduct their shoulder to 90° again. So the middle 20 s were data from when the arms were not moving and participants were standing quietly with arms at their side.

ApEn and SampEn were calculated for the anteroposterior (AP) and mediolateral (ML) CoP trajectories (Matlab, MathWorks, Inc., Natick, MA). Entropy parameters for the time series embedded dimension ( $m = 2$ ), tolerance ( $r = 0.2 * \text{stdev}$ ), and time delay ( $\tau = 1$ ) were chosen in accordance with previous literature [4]. A MANOVA ( $\alpha = .05$ ) with a Bonferroni adjustment was performed to identify

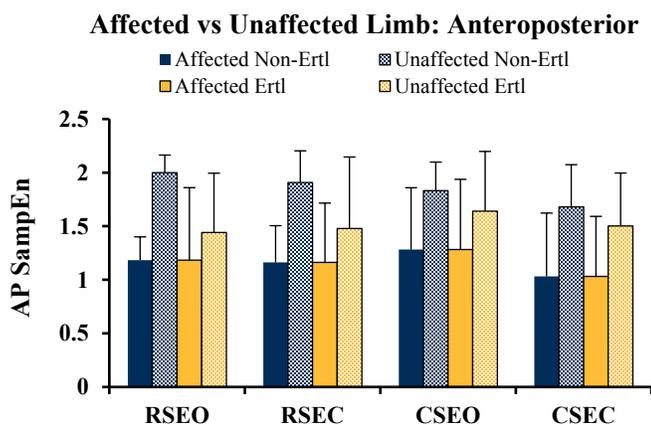

significant effects due to limb, surface, vision, and amputation technique, (SPSS 23, IBM, USA).

## RESULTS AND DISCUSSION

Limb ( $p < .001$ ), surface ( $p = .004$ ), and amputation type ( $p < .001$ ) exhibited significant effects at the multivariate level. No significant vision ( $p = .871$ ) or interaction effects were observed.

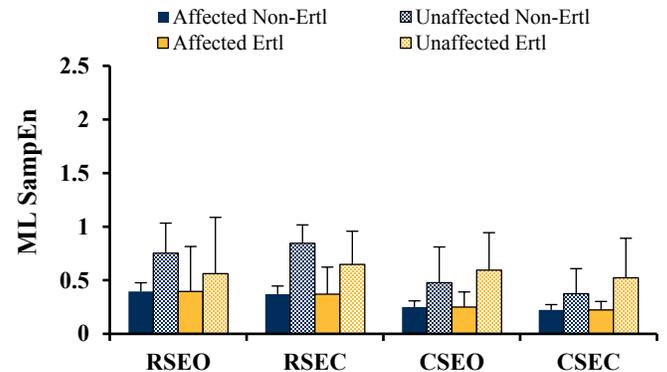

In both the AP and ML directions, the affected limb had significantly lower ApEn ( $p < .001$ ) and SampEn ( $p < .001$ ) than the unaffected limb. This is similar to results of Wurdeman et al. [1] suggesting that the affected limb requires more neuromuscular control. Comparing across directions, ApEn and SampEn values were larger in the AP direction than the ML direction suggesting a greater level of complexity and lower attentional control in the AP direction. It should be noted that the entropy values in the AP direction are larger than previously reported [5].

The Ertl group had significantly lower entropy values than the Non-Ertl group in the AP direction (Fig. 1) for both ApEn ( $p = .005$ ) and SampEn ( $p = .006$ ). This indicates the Ertl group showed more control than the Non-Ertl group. Considering this outcome in combination with the limb effect from above, the difference between groups appears to be driven by differences between the unaffected limbs rather than differences between affected limbs.

**Figure 1:** Mean SampEn in the AP direction across the four conditions for Non-Ertl (blue) and Ertl (yellow) amputation groups. Errors bars indicate standard deviations.

## Affected vs Unaffected Limb: Mediolateral

**Figure 2:** Mean SampEn in the ML direction across the four conditions for Non-Ertl (blue) and Ertl (yellow) amputation groups. Errors bars indicate standard deviations.

The compliant surface resulted in significantly lower entropy values compared to the rigid surface in the ML direction (Fig. 2) for both ApEn ( $p = .004$ ) and SampEn ( $p = .001$ ). This suggests that the standing on the compliant surface requires greater neuromuscular control.

Increased entropy values in the current study are likely due to the low standard deviations in the AP direction observed for our groups. Entropy values are sensitive to changes in the tolerance ( $r$ ), which is an input to the model for entropy and depends on the standard deviation of the time series data being analyzed.

## CONCLUSIONS

Consistent with our hypothesis, the affected limb exhibited greater attentional control, based on lower entropy values, than the unaffected limb. Removing vision and standing on a more compliant surface resulted in lower entropy values, which was also consistent with our hypotheses. Contrary to our hypothesis, however, SampEn and ApEn values were different between groups for the unaffected limbs, but similar between the affected limbs.

## INTRODUCTION

Balance is an important element of mobility and functional performance, and errors in balance may contribute to injury risk and hinder locomotor success. Several effective injury prevention programs appear to improve dynamic balance and the resistance to falls from perturbations such as collisions with objects or other individuals that can result in injuries[1]. Evaluating the mechanisms by which fall prevention programs reduce injuries is difficult because strength and balance improvements overlap. Several tests of balance have been developed, but each represents a complex construct of essentially static movements where excessive movements are ranked as errors. Some tests involve maintaining static balance near the base of support, and some tests explore the limits of static stability in more challenging ways. These tests may evaluate covariate domains of balance that are complementary or they may represent unique domains of balance that are differently influenced by injury prevention programs. The purpose of this project was to evaluate the covariance relationship between two commonly used balance evaluation measures: the Balance Error Scoring System (BESS) and the Y-Balance test.

## METHODS

Sixteen healthy, recreationally active adults gave informed consent to participant in this IRB-approved protocol (9 females, 7 males 29 +/-5 yrs; low to high intensity exerciser 2-6 x week). Over a 10-day period, each participant completed the BESS and the Y-Balance protocol four times following a standardized warm up (Figure 1). The total error score on the BESS test for both firm and foam

surfaces was compared to the total distance achieved in the anterior, posteriolateral and posteromedial directions on the Y-Balance test on each day using simple linear regression. It was hypothesized that the  $R^2$  would be in the 0.25 to 0.50 range, indicating some overlap in balance construct domains evaluated by the Y-Balance and BESS tests.

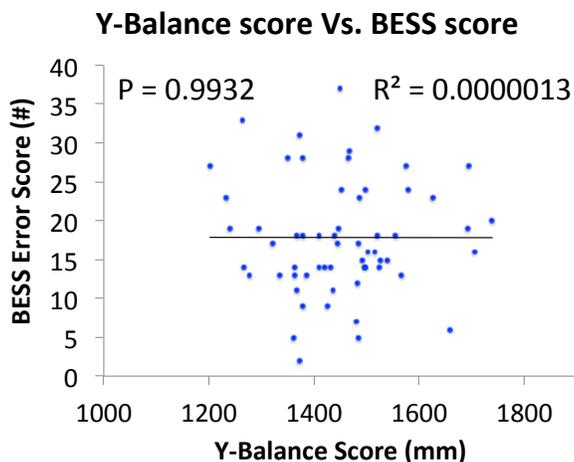

**Figure 1.** Balance Error Scoring System (BESS) and Y-Balance tests.

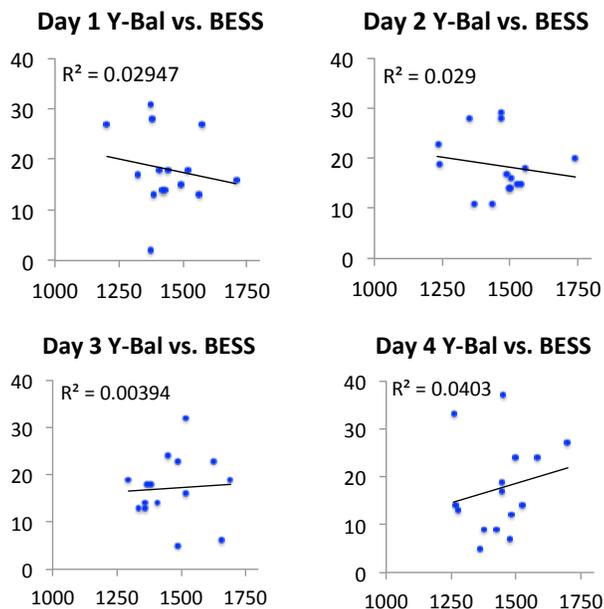

## RESULTS AND DISCUSSION

Contrary to the hypothesis, the combined data over all 4 days produced an  $R^2 = 0.0000013$ , with a slope of  $-0.00007$  ( $n = 60$ ;  $P = 0.99$ ; Figure 2). Individual day comparisons produced similar results (Figure 3). Day 1:  $R^2 = 0.0295$ ; Day 2:  $R^2 = 0.0290$ ; Day 3:  $R^2 = 0.0039$ ; Day 4:  $R^2 = 0.040$ .

These data suggest that there was no construct covariance between these two balance tests in this small cohort of recreationally active adults. The range of motion achieved on the Y-Balance test and the requirement to remain stable at the extreme end range of motion in all three directions appears to have little relationship to the BESS error scores

**Figure 2.** Y-Balance scores vs. BESS scores for 16 subjects over 4 days.

**Figure 3.** Y-Balance vs. BESS for each day.

during static standing balance on firm and foam surfaces. The Y-Balance test is likely to have a much larger strength component, especially for the knee and ankle joints. Greater quadriceps strength may improve performance in Y-Balance test scores but may not be a factor for the BESS test errors. These data suggest that the Y-Balance and BESS tests are unique domains of the complex construct of balance.

Dynamic balance may be improved with injury prevention programs, as demonstrated by risk reductions for both lower and upper extremity injuries that often occurs as a result of collisions

with other individuals[1]. These programs include exercises to improve core strength, lower extremity strength, drills with planned collisions with a teammate in a controlled setting, and drills designed to increase awareness of other players in close proximity. Since injury prevention programs have been shown to produce statistically significant and substantial reductions in injuries to the chest, spine, neck, shoulder, elbow, wrist, and hand this suggest that collision-related falls occur less often after implementation.

Neither the BESS nor the Y-Balance are dynamic balance tests that demand joint moment or power production on the time scale that real world impact perturbations must require. It is very likely that preparatory muscle activation in anticipation of potential collisions is one aspect of the effectiveness of an injury prevention program. This likely plays an interactive roll with the core and lower limb muscle strengthening achieved by the injury prevention program. Therefore, the interaction of increased muscle strength and more rapid force production, improved balance, and increased awareness of potential collisions are likely to contribute to the effectiveness of injury prevention programs. If these interactions could be better understood, more effective injury prevention programs could be designed.

It is possible that an additional dynamic balance test may need to be developed that more closely mimic the improvements in balance that appear to occur when injury prevention programs are implemented.

## CONCLUSIONS

The BESS and Y-Balance tests appear to evaluate distinctly separate domains of the complex construct of balance.

## INTRODUCTION

Quiet standing under various conditions is often assessed in order to understand postural deficits in various populations [1]. Individuals with transtibial amputation (TTA) are at an increased risk of falling due to functional deficits created by the amputation [2]. During quiet standing with both feet on one force plate, persons with TTA exhibit increased center of pressure (COP) displacements and increased COP velocities compared to non-amputees [2-4]. The increase in these measures is often associated with increased instability. Differences between limbs, however, cannot be assessed with both feet on a single force plate.

Two primary TTA amputation techniques are used; Non-Ertl and osteomyoplastic amputation (Ertl). Non-Ertl amputations leave the tibia and fibula disconnected, whereas a bone bridge connect the tibia to the fibula in the Ertl technique [5]. Due to the differences in these two amputation techniques, functional differences may exist between the groups.

The purpose of this study was to compare postural control of individuals with Ertl and Non-Ertl transtibial amputations during quiet standing under two surface and two vision conditions. Our goal was to establish if a difference exists between the two groups. To this end, we established the null hypothesis there would be no differences in COP displacements, velocities, or frequencies between Ertl and Non-Ertl techniques. However, we hypothesized that both groups would be more unstable as surfaces changed from rigid to compliant and vision was removed. Additionally, we hypothesized that the affected limb would be more unstable than the unaffected limb, as reflected by increased COP measures.

## METHODS

Individuals with Ertl ( $n = 9$ ,  $49 \pm 10$  years,  $75.0 \pm 15.3$  kg,  $1.8 \pm 0.1$  m) and Non-Ertl amputations ( $n = 6$ ,  $56 \pm 8$  years,  $85.1 \pm 13.5$  kg, height  $1.8 \pm 0.1$  m) participated in this study. Inclusion criteria included: amputation resulting from trauma, no concomitant musculoskeletal injuries, no neurological or visual impairments, physically active at least 3 days a week, and classified as K3 or above.

Participants stood shod with each foot positioned on separate force plates. Vertical ground reaction force (GRF, 2000 Hz) and center of pressure (COP) data were collected during each trial. Participants maintained a quiet standing position for 30 s under four separate conditions: 1) rigid surface, eyes open (RSEO), 2) rigid surface, eyes closed (RSEC), 3) compliant surface, eyes open (CSEO), and 4) compliant surface, eyes closed (CSEC). Vertical GRFs and COP data were down sampled at 100 Hz which is a common sampling frequency for quiet standing. Only the middle 20 s of each 30 s trial were analyzed to remove the influence of the upper extremities at the beginning and end of the trial. Dependent variables were calculated according to methods described by Prieto et al. [1] in both the mediolateral (ML) and anteroposterior (AP) directions. Weight distribution was expressed as the average vertical GRF under the foot, divided by the sum of vertical GRF under both feet. A 4-factor MANOVA (amputation technique x vision x surface x leg,  $\alpha = .05$ ) with Bonferoni adjustment was used to evaluate differences in dependent variables.

## RESULTS AND DISCUSSION

There was a significant multivariate effect observed between amputation type, vision, surface, and leg

conditions ( $p < 0.001$ ). No interaction effects were identified.

The affected limb was found to bear significantly ( $p = .005$ ) more weight than the unaffected limb across all conditions (Ertl:  $50.9 \pm 4.1\%$  vs  $48.0 \pm 4.2\%$ ; Non-Ertl:  $50.2 \pm 4.6\%$  vs  $48.6 \pm 4.4\%$ ).

The mean AP (Fig.1) and ML COP velocities increased from rigid to compliant surface ( $p < .001$ , AP;  $p = .004$ , ML) and from eyes open to eyes closed conditions ( $p < .001$ , AP;  $p = .020$ , ML). Mean COP velocity was higher in the affected limb than the unaffected limb for both groups ( $p < .001$ , AP and ML). The Ertl group had higher mean COP velocities in both the AP and ML directions than the Non-Ertl group across all conditions ( $p < .001$ ). The larger COP velocity in the Ertl group suggests they were less stable than the Non-Ertls.

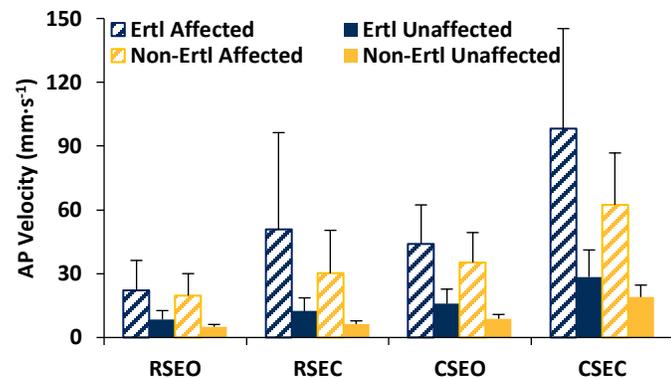

Figure 1. Mean (sd) COP AP velocities for each condition.

Both groups increased mean ML frequency ( $p < .001$ ) and mean AP frequency ( $p < .001$ ) with eyes closed. The Ertl group had higher frequencies in the AP ( $p = .011$ ) and ML ( $p < .001$ ) directions compared to the Non-Ertl group across all conditions. The affected limb exhibited higher AP ( $p = .009$ ) and ML ( $p < .001$ ) frequencies than the unaffected limb. Only the ML frequency increased between surfaces ( $p = .005$ ). Again frequency analysis suggests the Ertl group was adjusting posture more than the Non-Ertl group, suggesting greater instability for the Ertl group.

The 95% confidence ellipse area (95% CE area; Fig. 2) was larger in the affected limb compared to the unaffected limb ( $p = .001$ ). Both groups had a larger 95% CE area when their eyes were closed ( $p = .012$ )

and on a compliant surface ( $p < .001$ ). The Ertl group had a significantly larger 95% CE area across all conditions than the Non-Ertl ( $p = .001$ ), again suggesting greater postural instability in the Ertl group.

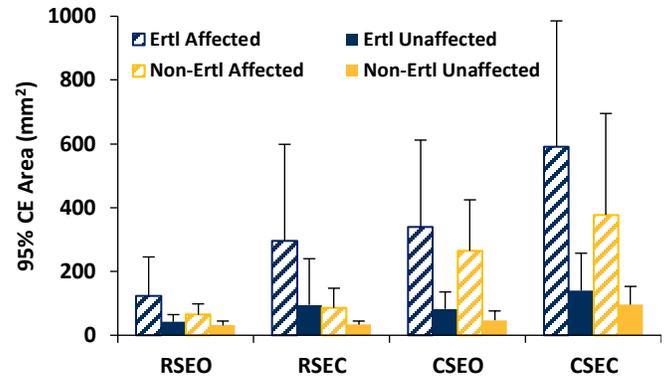

Figure 2. Mean (sd) 95% CE area for all four conditions.

## CONCLUSION

In general, both groups showed increased COP velocities, 95% CE area, and frequencies when their eyes were closed or on the compliant surface, supporting our hypothesis. This would suggest that closing one's eyes or standing on uneven surfaces increases instability. It is not unexpected to see increased instability during these tasks as the proprioceptive or visual feedback has been altered; this has been demonstrated in multiple populations [6, 7]. Our results support our hypothesis that differences between the affected and unaffected limbs exist and that these differences are exacerbated by standing on unstable surfaces and closing the eyes.

However, it was surprising to note the Ertl group showed a tendency to be more unstable than the Non-Ertl group contrary to our hypothesis. Further investigation into the mechanisms behind the differences between these two amputation techniques is needed.

## INTRODUCTION

It is well known that postural control declines with age, as evidenced by age-related changes in center of pressure (COP) metrics during postural sway. Several authors have modeled the postural control system as an inverted pendulum with proportional-integral-derivative (PID) feedback control, which produces ankle torque to maintain stable positioning of the body's center of mass (COM). Such models have demonstrated effects consistent with age-related changes in COP, including increased postural stiffness and damping, noise, and sensory delay time [1-3]. Age-related declines in strength likely play a role in these observations. In our previous work, we investigated the use of skeletal muscle-specific troponin T (sTnT), a binding site for  $Ca^{2+}$  ions enabling formation of actin-myosin crossbridges, as a biomarker for age-related strength loss and sarcopenia. Initial results suggest that blood levels of sTnT were negatively correlated with grip strength [4] and with scores on a balance assessment instrument [5]. Still, the mechanisms by which strength declines affect postural sway are not fully understood. To investigate this, we tested the hypothesis that control parameters derived from an inverted pendulum sway model would be positively correlated with blood levels of sTnT, and negatively correlated with grip strength.

## METHODS

Eleven female older adults (M=88.3, SD=4.6 years) and eight female young adults (M=22.4, SD= 3.1 years) were recruited for the study, which was approved by UMKC's Institutional Review Board. A phlebotomist collected blood samples, from which sTnT levels were measured using an ELISA kit (USCN Life Science Inc., Houston, TX, USA). Maximum grip force for subjects' left ( $F_L$ ) and right

( $F_R$ ) hands were measured with a grip strength dynamometer (Detecto Scale Company, Web City, MO, USA). Subjects performed quiet stance trials under both eyes open (EO) and eyes closed (EC) conditions while standing on a force platform (AMTI, Watertown, MA, USA), which measured COP time series at a sampling rate of 1 kHz. Each subject was modeled as a single-link inverted pendulum with PID ankle torque feedback (Fig. 1). Models were characterized by PID controller gains

**Figure 1:** Inverted pendulum model and controller:  $T_c$ , control torque;  $T_d$ , disturbance torque;  $T_a$ , applied ankle torque;  $\theta$ , sway angle.

$K_p$ ,  $K_i$ , and  $K_d$ , disturbance torque noise gain  $K_N$ , and time delay  $\tau$ . Initial model simulations were run iteratively to find, using a genetic algorithm, control parameters that minimized the error between simulated and experimental COP metrics as quantified by the cost function:

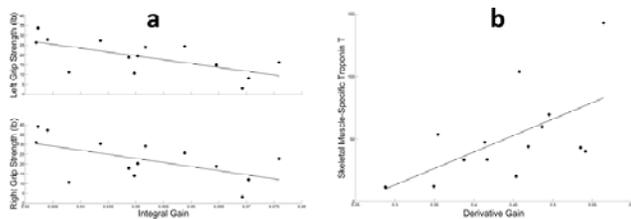

$$E = \sum_{i=1}^N \left( \frac{C_{sim,i} - C_{exp,i}}{C_{exp,i}} \right)^2$$

where  $C_{sim}$  and  $C_{exp}$  are simulated and experimental COP metrics, respectively and  $N = 7$  represents the number of COP metrics included in the cost function (including root-mean-squared distance, mean velocity, centroidal frequency, frequency dispersion, and short-term scaling coefficient, critical point time, and critical point amplitude derived from

stabilogram – diffusion analysis [1]). Following paired-samples t-tests to confirm that no significant differences existed between  $C_{sim}$  and  $C_{exp}$  metrics, bivariate correlation analyses were performed between control parameters and sTnT metrics. For comparisons exhibiting significant correlations, follow-up stepwise regression analyses were performed with sTnT level as the dependent variable and control parameters ( $K_P$ ,  $K_I$ ,  $K_D$ ,  $K_N$ , and  $\tau$ ) as the predictor variables. All COP analyses and modeling were performed with MATLAB R2014a (The Mathworks, Inc., Natick, MA, USA), and statistical analyses were performed with IBM SPSS Statistics (IBM Corporation, Armonk, NY, USA).

## RESULTS AND DISCUSSION

In the EO condition, regression analysis revealed that  $K_I$  significantly predicts both  $F_L$  ( $b=-391.99$ ,  $p=.011$ ) and  $F_R$  ( $b=-416.99$ ,  $p=.027$ ). In the EC condition, regression analysis revealed that  $K_D$  significantly predicts sTnT level ( $b=263.51$ ,  $p=.026$ ), both  $K_P$  ( $b=-43.84$ ,  $p<.001$ ) and  $K_N$  ( $b=0.11$ ,  $p=.021$ ) significantly predict  $F_L$ , and that both  $K_P$  ( $b=-51.95$ ,  $p<.001$ ) and  $K_N$  ( $b=0.14$ ,  $p=.011$ ) significantly predict  $F_R$ .

**Figure 2:** Regression plots depicting: (a) relationship between  $K_I$  and grip strength force for EO; (b) relationship between  $K_D$  and sTnT for EC.

These results suggest at least some relationship between postural control parameters and muscle-related measures of strength. Grip strength force was significantly predicted by  $K_I$  in the EO condition, and by  $K_P$  and  $K_N$  in the EC condition. The strong negative correlation between  $K_P$  and grip strength may indicate a compensation mechanism serving to increase postural stiffness, and thus decrease sway amplitude, in the presence of reduced strength. This result is consistent with other work reporting age-related increases in postural stiffness [1]. The modest positive correlation between  $K_N$  and grip strength

may indicate that increases in strength available for postural control are accompanied by slight reductions in the postural control system's sensitivity to changes in sway. Interestingly, the association between  $K_P$ ,  $K_N$ , and grip strength was only observed in EC conditions, suggesting that the presence of visual input in the EO condition eclipsed any association that may have been present. However,  $K_I$  was observed to have a negative correlation with grip strength force in the EO condition. Since  $K_I$  controls steady state error, it is possible that the observed correlation may again represent a compensation mechanism, this time serving to minimize COP-COM error in the presence of reduced strength. Our results also demonstrate that sTnT levels are significantly predicted by  $K_D$ . This suggests that declines in muscle contraction strength and efficiency that presumably accompany an increase in sTnT levels are at least partially compensated for by increased postural damping, which serves to minimize overshoot and ultimately minimize COP-COM error. Again this effect was only observed in the EC condition, suggesting that such a compensation mechanism is not needed or possibly obscured in the presence of visual input.

## CONCLUSIONS

In this study, we demonstrated relationships between strength-related measures and postural control parameters, providing further insight into the role of muscle strength in postural sway and balance impairment. Our results were primarily apparent in the EC condition, suggesting that any strength-related performance declines were not severe enough to be observable with visual input available. Our work provides new evidence for the potential utility of both grip strength testing and skeletal muscle-specific troponin T as biomarkers of strength-related declines of postural sway and balance impairment.

## INTRODUCTION

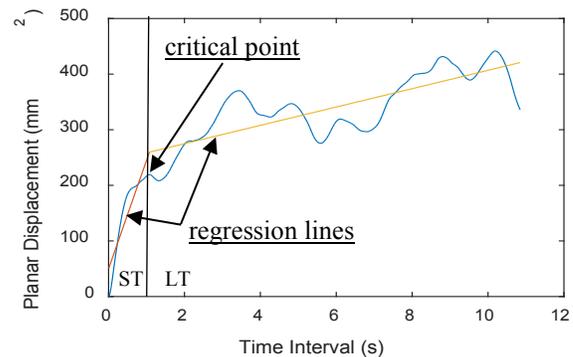

Analysis of postural control attempts to gain insight into systemic control strategies. Center of pressure (COP) movement during quiet standing is commonly analyzed to understand postural control. Collins and DeLuca [1] proposed a stabilogram analysis method which attempts to yield more physiologically meaningful results. Stabilogram-diffusion analysis (SDA), assumes that COP trajectories can be modeled as a system of one- and two-dimensional random walks. SDA computes mean squared displacement between COP coordinates at various time intervals to determine displacement (Figure 1). A critical point is identified as the point where the steep initial slope transitions to a shallower slope as the time interval between points increases. It is thought that the critical point is related to short-term (ST) and long-term (LT) postural control strategies. A linear plot in the time domain produces associated diffusion coefficients (D) and a log-log plot of this data produces scaling exponents (H) for each timeframe. These coefficients provide insight into the variability (D values) and randomness (H values) of the measure being analyzed. Implications are then made about the use of open- or closed-loop control.

SDA is regularly applied to single- and double-leg quiet stance [1], however, it is unclear if quiet stance is immediately preceded by a dynamic task, such as hopping, whether results would be similar to these previous quiet stance tasks. Direction may also be important, as Wikstrom et al. [2] showed that single-leg stability decreases as the direction of the hop changed from forward to lateral.

Leg dominance is also commonly considered regarding postural control, as the general belief is that control strategies differ by leg dominance. Yet, Huurnink et al. [3] reported that leg dominance is

task specific and did not produce significant differences when analyzing postural stability.

The current study investigated differences between SDA values after stability was attained during single leg quiet stance after landing from a hop. Differences were analyzed based on the hop direction and the leg used. We aimed to provide insight into how static stance is controlled after a dynamic task.

**Figure 1:** A representative SDA plot (mean square planar displacement ( $\text{mm}^2$ ) vs time interval) of a single hop from one participant in the present study. The vertical line denotes the time interval at which the critical point occurs.

## METHODS

Nineteen healthy, recreationally active men ( $n = 8$ ) and women ( $n = 11$ ) volunteered for this study ( $26 \pm 5$  yrs,  $70.3 \pm 9.8$  kg,  $172.7 \pm 9.4$  cm). Participants (all right leg dominant) completed four barefoot hopping tasks onto an AMTI force platform, one with each leg, from both the forward and sideways directions. For the forward hop, the participant took two steps forward and hopped from 50% of their leg length. They took off from the second step on the contralateral foot and landed on the test leg. For the sideways hop, the participant hopped laterally onto the plate from 10 cm away, starting in a single leg stance on the test leg and landing on the same leg. Participants were instructed to remain balanced on the single leg for 20 s after landing.

Ground reaction forces (GRF) were collected at 1000 Hz. To analyze the mean square displacement, the values for the current study were processed to remove the initial COP deviation away from center due to landing, starting the analysis at the point of stability. Stability was defined when vertical GRF was within 5% of body weight for the remainder of the trial. SDA was then used to calculate the critical point to identify the short- and long-term regions and resulting D and H values.  $D_S$  and  $D_L$  were calculated as one-half the slope of each least-squares linear fit of the linear plot (Figure 1). Similarly,  $H_S$  and  $H_L$  were calculated from log-log plots of the data [1]. A two-factor (leg, hop direction) MANOVA was used to test for differences in the critical point, D, and H values between conditions ( $\alpha = .05$ ).

## RESULTS AND DISCUSSION

No significant main effect of leg or direction was observed for any values, nor was there an interaction effect between the main factors. As no difference was found between legs, which agrees with prior findings [3], the means presented (critical point, D, H) are pooled to include both legs per directional condition.

**Table 1:** Mean(SD) SDA diffusion coefficients (D,  $\text{mm}^2 \cdot \text{s}^{-1}$ ) and scaling exponents (H) for the short- (S) and long-term (L) regions.

Hop	$D_S$	$D_L$	$H_S$	$H_L$
Forward	94.91 (41.9)	8.7 (9.66)	.58 (.08)	.15 (.13)
Sideways	94.34 (52.7)	9.57 (10.46)	.56 (.1)	.17 (.13)
<b>Comparative Data</b>				
Heise[4]	450.59	36.86	0.49	0.13
Collins[1a]	6.74	1.76	0.76	0.28
Collins[1b]	11.21	3.05	0.76	0.34

Note: Mean values of current study represent both legs ( $n = 38$ ). Means from Collins [1] are from two different groups (a – 30 x 30 s trials, b – 10 x 30 s trials) during a static bipedal stance. Heise [4] represents a forward step-step-hop task from 100% of leg length.

The mean critical point occurred at (1.13 s, 173.8  $\text{mm}^2$ ) in the forward direction, and at (1.29 s, 193.1  $\text{mm}^2$ ) in the sideways direction, which was not significantly different between directions. This is contrary to results from Wikstrom et al. [2] indicating that mediolateral stability decreases as a hop task becomes more lateral. However, the absolute mean values did trend in the direction of Wikstrom et al. [2].

Critical points in the current study occurred at a longer time intervals than previously reported for a forward hop (0.72 s, 587  $\text{mm}^2$ ) reported by Heise et

al. [4]. Differences from Heise et al. [4] are due to methodological differences. The forward hop distance was from 100% of leg length [4] and the analysis started immediately after ground contact, as opposed to the current study's time of stability starting point. Interestingly, our time interval for the critical point of the forward hop was more consistent with the critical point (1.04 s, 13  $\text{mm}^2$ ) reported by Collins and De Luca [1] for double legged quiet standing. Thus, the process of stabilizing may switch from open loop control to closed loop control at shorter time intervals compared to standing quietly.

In general, the diffusion coefficients (D) were greater when compared to static tests [1], but were lower than the values from a similar forward hop [4]. The data from the present study and comparison data are shown in Table 1.

The scaling exponents for both hop directions in the short-term region were trending towards pure Brownian motion ( $H = 0.5$ ), indicating postural control was mostly random. This is supported by the high D values as well, indicating high variability. In comparison, the low  $H_L$  values, combined with low D values, indicate closed-loop control of posture in the long-term region. These long term scaling exponents are smaller compared to those of Collins and DeLuca [1] for double legged stance, but similar to values of forward hops reported by Heise et al. [4]. Thus, regardless of what occurred immediately prior to stability being achieved, it appears that control of single-leg stance over short time intervals is more randomly controlled compared to double legged quiet stance.

## CONCLUSIONS

SDA illustrated that once postural stability was gained following a single-leg hop, there were no significant differences between the direction of the hop or the leg used in terms of measures of variability and randomness within the postural control system.

## INTRODUCTION

Postural control during quiet stance is often portrayed as corrective responses to small perturbations caused by the inverted pendulum nature of the body. These corrective responses, otherwise known as postural sway, have been used to assess postural stability [1]. Static postural stability is frequently challenged by changes in sensory input (e.g., surface or vision) and/or perturbations during quiet stance. Leg dominance has also been suggested as a potential influencer for postural stability. It is believed that the dominant leg may display increased postural control during single-leg stability tasks. However, previous work has indicated that leg dominance had no significant effect on postural stability [2].

Center-of-pressure (COP) trajectories during quiet stance are commonly used to assess postural stability [3]. Temporal displacements provide a traditional understanding of stability, but offers minimal insight into the physiological meaning of the variables.

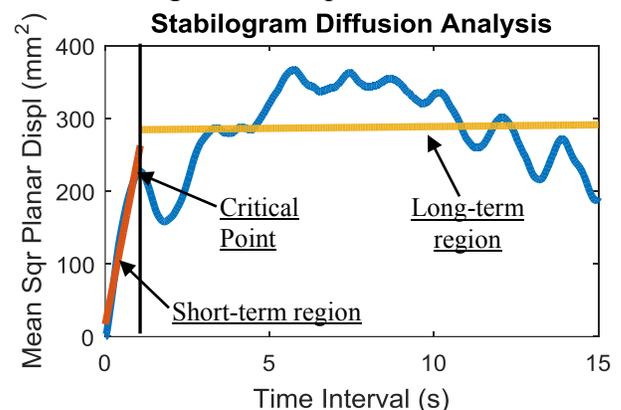

Collins and De Luca [4] presented the stabilogram-diffusion analysis (SDA) as a method to physiologically interpret COP trajectories. SDA models the COP during quiet stance as a system of coupled, correlated random walks [4]. A stabilogram-diffusion plot is created by plotting the mean square displacement between COP coordinates against various time intervals between successive points (Fig. 1) [4]. The critical point in this analysis is defined as the point where the initial steep slope changes to a more shallow slope. Collins and De Luca suggested that the critical point represents where the postural control system changes from open-loop to closed-loop control. Collins and De Luca proposed that the critical point may be

representative of pre-programmed central commands that are used during quiet stance [4].

The purpose of this investigation was to use SDA to determine differences in postural control strategies during single-legged quiet standing on rigid and compliant surfaces. The effect of leg dominance during single-leg quiet standing as assessed by SDA, was also evaluated.

## METHODS

Nineteen healthy, recreationally active men (n=8) and women (n=11) volunteered for this study ( $26 \pm 5$  years,  $70.3 \pm 9.8$  kg,  $172.7 \pm 9.4$  cm). For all trials participants (all right leg dominant) were asked to stand barefoot, with their eyes open on an AMTI force platform (Watertown MA, USA) under two conditions: rigid and compliant surfaces.

**Figure 1.** A stabilogram-diffusion plot of one representative participant during quiet standing on a compliant surface. Least squares linear fits are shown in each region.

Ground reaction force data were collected at 1000 Hz for 30 s. SDA [4] was then applied to the COP trajectories to create a stabilogram-diffusion plot (Fig. 1). Diffusion coefficients were computed using their respective slopes (short-term,  $D_s$ ; and long-term,  $D_L$ ) for the COP displacement versus time

intervals [4]. Scaling coefficients (short term,  $H_s$ ; long term,  $H_L$ ) were determined from log-log plots of the mean square displacement against time curves [4]. Critical point values, diffusion coefficients and scaling exponents were compared to double leg static stability results [4,5]. A two-factor MANOVA ( $\alpha = 0.05$ ) was performed to identify any significant effects of leg dominance and surface type on SDA values (SPSS 23, IBM, USA).

## RESULTS AND DISCUSSION

Means between each leg were analyzed to compare the effect of leg dominance on postural control using the SDA. However, no significant differences were found between legs, which is in agreement with previous research [2]. This variable was collapsed and taken as a collective average for the rest of the analysis. Surface type revealed a significant difference between  $D_s$  ( $p = 0.003$ ),  $H_L$  ( $p < 0.001$ ), and critical point ( $p < 0.001$ ) indicating a difference between rigid and compliant surfaces.

The mean critical point coordinates were (1.23 s, 134 mm<sup>2</sup>) for the rigid surface and (1.14 s, 297 mm<sup>2</sup>) for the compliant averaged across both legs. Compared to (1.03 s, 13 mm<sup>2</sup>) from Collins and DeLuca [4] and (1.02 s, 16 mm<sup>2</sup>) from Doyle et al. [5] the values for single-leg standing were greater. These critical time intervals have been proposed to represent the transition of the postural control system from open-loop to closed-loop control [4]. Compared to double-legged quiet standing, single-leg standing transitions to closed-loop control occurred at longer time intervals on both rigid and compliant surfaces. However, the increased instability created by the compliant surface in single leg standing appears to result in transition to closed-loop control at shorter time intervals.

Furthermore, both the mean square displacement for the critical point and diffusion coefficients are greater than those seen in Collins and De Luca [4] and Doyle et al. [5] which analyzed double-leg static stability. The increased mean square displacement is likely due to the increased COP sway during single-leg static stability. A significant difference was also

noted over the  $D_s$  coefficients between surface types. This suggests compliant surfaces demonstrated increased levels of variability about the base of support during single-leg static stance.

Short-term scaling exponents ( $H_s$ ) resulted in a value for rigid surface of 0.58, while compliant surface was 0.60. These values are trending towards the value of 0.5 where COP movements over short-term intervals are said to be purely random based on Brownian motion. For the long-term scaling exponent ( $H_L$ ) the rigid surface resulted in a value of 0.12, while compliant demonstrated a value of 0.07. Significance was noted for the scaling coefficient of  $H_L$  indicating a difference between surface types. Thus, these scaling coefficients suggest that posture during single-leg standing was more tightly controlled than double-legged standing, with even tighter control of posture while standing on a compliant surface.

**Table 1:** Mean and standard deviation diffusion coefficients ( $D$ , mm<sup>2</sup>·s<sup>-1</sup>) and scaling exponents ( $H$ ) for the short- (S) and long-term (L) regions of the SDA.

	$D_s$	$D_L$	$H_s$	$H_L$
<b>Compliant</b>	171.39 ± 91.03	3.71 ± 6.19	0.60 ± 0.07	0.07 ± 0.07
<b>Rigid</b>	71.83 ± 0.08	4.01 ± 4.73	0.58 ± 0.09	0.12 ± 0.09
<b>[Collins(a)]</b>	6.74	1.76	0.76	0.28
<b>[Collins(b)]</b>	11.21	3.05	0.76	0.34
<b>[Doyle]</b>	11.00	2.10	0.80	0.24

Note: Mean values from [Collins] are from two different groups a (30 trials, n = 10), b (10 trials, n = 15), mean values from [Doyle] are from 30 s trials (they also analyzed data after 60 and 90 s).

## CONCLUSIONS

Single-legged standing transitions from open-loop control occur at increased time intervals compared to double-leg standing. Changing from a rigid surface to a compliant surface during single-leg standing suggests the transition to closed-loop control occurs over slightly shorter time intervals. Leg dominance does not influence postural control.

# IMPACT OF BABY CARRYING METHOD ON POSTURAL SWAY IN PROLONGED STANDING

<sup>1,2\*</sup>Erin M. Mannen, <sup>1</sup>Alexandra Kahney

## INTRODUCTION

Babywearing, the practice of carrying an infant or young child on the caregiver's body in a carrier, has been shown to have numerous emotional, physical, and physiological benefits for babies [1]. The practice of babywearing is becoming more common as parents reap the benefits of close-proximity to their children while remaining "hands-free".

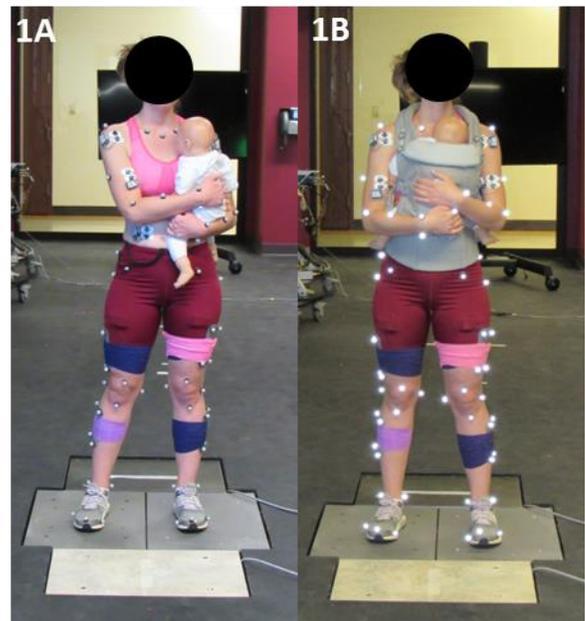

It is known that increased postural sway and asymmetrical loading are linked to pain and increased fall risk [2,3]. While several studies have documented the impacts of backpack load-carriage for military applications and schoolchildren, women are under-represented in load-carriage studies despite research showing women have increased risk of musculoskeletal injuries compared to men [4]. During their lifetimes, many women serve as primary caregivers to children, so a child is a common and relevant load to study. However, no research has been done to analyze the impact of child-carrying methods on the biomechanics of a woman's body. *The purpose of this study is to quantify the impact of two infant carrying methods on a woman's postural sway during prolonged standing.*

## METHODS

Ten female subjects (age:  $27.4 \pm 4.1$  years; BMI:  $21.5 \pm 2.5$  kg/m<sup>2</sup>) with no ongoing musculoskeletal problems and no previous babywearing experience were enrolled in the IRB-approved study. Men, pregnant women, or those with a pregnancy within the past nine months were excluded. Participants underwent testing in the Human Dynamics Lab at the University of Denver.

Each subject completed fifteen-minute quiet standing tasks with each foot placed on a separate force plate (Bertec Corporation, Columbus, OH) for three conditions: **unloaded**, holding a 9-month old infant sized mannequin (Dietz, Freiburg, Germany) **in-arms**, and wearing a 9-month old infant sized mannequin in a baby carrier (**in-carrier**) (Ergobaby,

Inc., Los Angeles, CA) (Figure 1). For the in-carrier trial, subjects watched an instructional video from a certified babywearing professional, and self-fit the baby carrier with the infant mannequin inward-facing. Subjects were instructed to quietly stand for the fifteen minute trials while keeping each foot on its respective force plate. Subjects rested between fatigue trials, and conditions were performed in a random order.

**Figure 1:** In-arms condition (1A) and in-carrier condition (1B).

Data was analyzed at three separate four-minute intervals within the fifteen minute trials: first (0:30 to 4:30), second (5:30 to 9:30), and third (10:30 to 14:30). Custom code (MathWorks, Natick, MA) was written to evaluate postural sway parameters including center-of-pressure (COP) path length, 95% confidence ellipse sway area, medial-lateral (ML) sway variability [root mean square (RMS)], anterior-posterior (AP) sway variability (RMS), and percentage of time of uneven weight distribution (>65% total weight on one limb) for each time period

for each condition. Multiple paired Student's t-tests ( $p < 0.05$ ) were used to compare between conditions (unloaded, in-arms, and in-carrier).

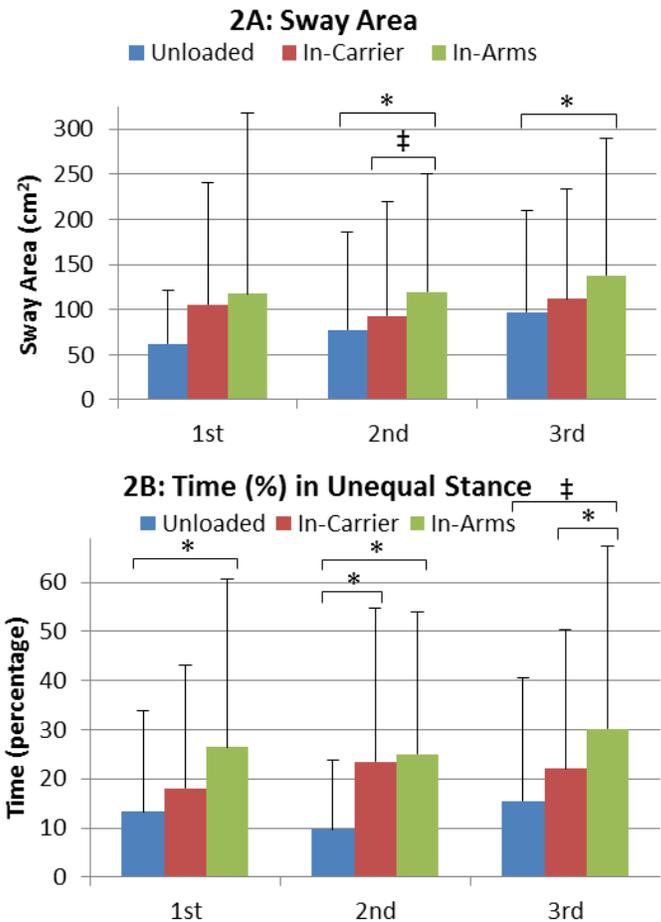

## RESULTS AND DISCUSSION

Baby carrying method was found to impact postural sway parameters during prolonged standing (Table 1). Sway area was 53.3% and 41.3% greater during the in-arms trials v. unloaded trials for the second and third time periods, while the in-carrier condition was not significantly different from the unloaded trials (Figure 2A). Time spent in unequal standing was 2 times greater for the in-arms condition compared to the unloaded condition across all time periods (Figure 2B). ML RMS of the in-arms condition was up to 78% higher than the unloaded condition, while the in-carrier condition was not significantly different than the unloaded condition.

There is greater motion of the COP and more time spent in an asymmetrical stance while carrying an infant in-arms. Both increased COP motion and asymmetric loading have been linked to pain and increased fall risk [2,3]. One goal should be to improve the biomechanics of baby carrying methods to limit COP motion and asymmetry. The current study is limited by sample size, yet significant findings and trends are clear with only ten subjects. Future work will include testing more subjects and performing additional analyses using whole-body motion capture and muscle fatigue using electromyography.

## CONCLUSIONS

Babywearing may offer more postural stability to the caregiver than carrying a baby in-arms, reducing the risks for pain and falls.

**Figure 2:** Sway area (2A) and time spent in unequal stance (2B) for each condition over all three time periods. \* $p < 0.05$  ‡ $p < 0.1$

## INTRODUCTION

Mediolateral stability during human walking is influenced by the active control of center of mass (COM) trajectory and step-to-step adjustments in foot placement [1]. Based on the inverted pendulum model, margin of stability (MOS) has been proposed as a measure to quantify walking balance. Dynamic MOS is defined as the distance between the lateral margin of the base of support and the extrapolated center of mass (xCOM) – a metric that accounts for COM position and velocity [1]. Based on this model, a smaller MOS would indicate a decreased ability to resist mediolateral perturbations, resulting in an increased risk of a loss of balance.

Individuals with gait deficits often walk with wider steps, generally thought to be a compensatory strategy to maintain lateral stability. Surprisingly, the direct effects of increased step width on lateral stability are not entirely understood. In young healthy controls, *instructed* increases in step width increase mediolateral MOS, presumably increasing stability [2]. However, the natural preference for wider steps among stroke survivors is not accompanied by larger mediolateral MOS values [3-4]. While this discrepancy may be due to the altered control of mediolateral stability in stroke survivors, it could alternatively be an artifact of the difference between instructed and naturally preferred increases in step width.

The purpose of this study was to determine if manipulating the preferred step width in healthy controls would influence the control of mediolateral stability. We hypothesized that encouraging (not prescribing or instructing) wider steps would increase the mediolateral margin of stability.

## METHODS

The preferred step width was manipulated using a novel elastic force-field described previously [5]. Briefly, steel wires in series with extension springs ran parallel to our treadmill belts, and allowed mediolateral forces to be exerted on the legs during swing without affecting forward progression.

Eleven healthy adult subjects (8F/3M; age=25±1 yrs; height=169±9 cm; mass=68±13 kg) completed 7 randomized-order, 6-minute treadmill walking trials. One trial involved normal (no force-field) walking. In three trials, participants interfaced with a “strong” (mediolateral stiffness = 250 N/m) force-field set to encourage step widths of 15, 22.5, or 30 cm. In the remaining three trials, participants interfaced with a “weak” (125 N/m) force-field set to encourage the same range of step widths.

A 16-camera motion capture system (PhaseSpace, Inc.) was used to measure kinematic data at 120 Hz from LED markers placed on the pelvis and feet. Mean step width was calculated as the mediolateral distance between the heel markers upon heel-strike. Center of mass displacement and velocity were estimated using the average location of bilateral ASIS and PSIS markers. Mediolateral margin of stability was calculated as the difference between the xCOM and the lateral boundary of the base of support upon heel-strike. All outcome measures were calculated across the last 3 minutes of each trial.

We used repeated measures ANOVAs to test for significant effects of walking condition on several kinematic measures (mean step width; mediolateral mean COM displacement and velocity upon heel-strike; mean MOS; step-by-step MOS variability).

## RESULTS AND DISCUSSION

The force-field was effective in manipulating preferred step width (Fig. 1A). Significant ( $p < 0.05$ ) increases in step width were observed with the strong force-field set to 22.5 or 30 cm, and with the weak force-field set to 30 cm. Across walking conditions, wider steps were accompanied by significantly ( $p < 0.05$ ) larger mediolateral COM displacements and velocities upon heel-strike.

The combination of these changes in COM displacement and velocity produced a net effect on mediolateral MOS. While a trend was observed for larger MOS with wider steps, this only reached significance ( $p < 0.05$ ) for the condition with the widest steps (Fig. 1B). For this walking condition, the step-by-step variability in MOS was also significantly increased relative to normal walking (Fig. 1C).

Our results match the previous finding that increasing step width in healthy controls causes an increase in MOS and MOS variability [2]. Therefore, this prior result was not simply an artifact of verbally instructing participants to walk with wider steps.

One possible interpretation of these results is that wider steps are subject to greater step-by-step errors, as evidenced by increased MOS variability. In response, humans may choose to actively increase their average margin of stability to reduce the risk of a lateral loss of balance (e.g. by restraining COM

motion). While this explanation is reasonable, the opposite interpretation can also be proposed. Specifically, the larger average margins of stability that accompany wider steps may allow humans to “slack” in the precision of their active control over foot placement location, thus increasing MOS variability. Future work will seek to distinguish between these two distinctly different possible explanations for the observed behavior, and to extend this work to clinical populations.

## CONCLUSIONS

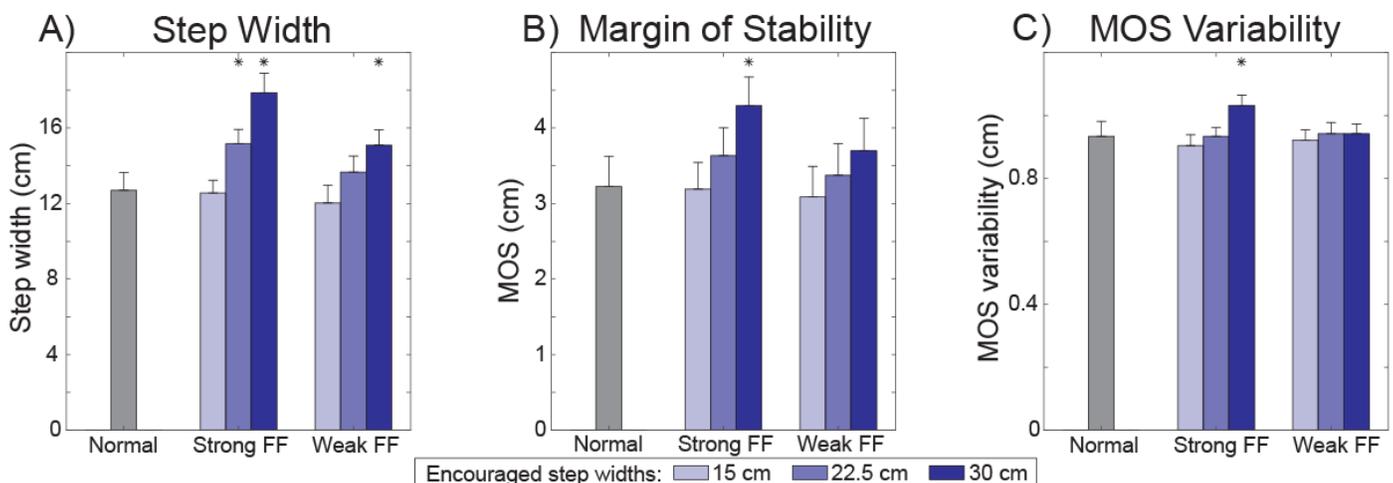

Step width manipulation affects common measures of mediolateral balance. Further investigation of the mechanism underlying changes in margin of stability measures may provide insight into fall risk and gait instability within clinical populations.

# EFFECTS OF LOCAL MUSCLE FATIGUE ON DYNAMIC POSTURAL CONTROL: A PILOT STUDY

Toshiyuki Kurihara, Tadao Isaka  
Ritsumeikan University, Kusatsu, Shiga, Japan  
Email: t-kuri-a@st.ritsumei.ac.jp

## INTRODUCTION

Muscle fatigue, defined as an acute impairment to produce maximum force, has been shown to impair postural control in single leg stance.<sup>1</sup> Whereas, Shirazi et al.<sup>2</sup> indicated that localized muscle fatigue caused deficits in postural control regardless of the location of fatigue. Winter et al.<sup>3</sup> showed that, in order to control postural stability, human utilize two separate mechanisms: ankle strategy and hip strategy.<sup>3</sup> They explained that the ankle plantar flexors and dorsiflexors play a large role in minimizing anterior-posterior (A/P) movements while the hip abductors and adductors control medio-lateral sway of COP.<sup>3</sup> In addition, the constraint of the great toe deteriorated the A/P weight shifting on dynamic balance.<sup>4</sup>

Common techniques to assess dynamic postural control is a clinical assessment known as the Star Excursion Balance Test (SEBT).<sup>5</sup> The SEBT evaluates the ability to maintain a stable base of support in single limb stance while the opposite limb performs maximal reach excursions in various reach directions. The directional dependency of the muscle activation during SEBT depends on the muscle.<sup>6,7</sup> For example, biceps femoris (BF) electromyographic (EMG) activity was higher during the posterior, posterolateral, and lateral excursions than during the anterior and anteromedial excursions.<sup>6</sup> While, vastus lateralis (VL) activity was less during the lateral excursion than all other directions.<sup>6</sup> Gluteus medius (GM) activity was greater in the anterior and medial directions than in the posteromedial direction.<sup>7</sup>

The purpose of this study was to examine the effects of localized muscle fatigue on dynamic postural control. We choose the fatiguing tasks for the hip abductors, ankle plantar flexors, and toe plantar flexors. It was hypothesized that the each localized fatigue would be effective in each specific direction.

## METHODS

Seven healthy young men free from pain and lower extremity injury were recruited for the study (Age:  $21.1 \pm 0.9$  years; Height  $172.7 \pm 6.0$  cm; Weight:  $67.0 \pm 7.3$  kg) according to guidelines by the Institutional Review Board.

The SEBT is a series of single limb stance using the nonstance limb to touch a point along the lines arranged in a grid that extends from a center point and are  $45^\circ$  from one another. The reaching directions are named in orientation to the stance limb as anterior, anteromedial, anterolateral, medial, lateral, posterior, posteromedial, and posterolateral. While standing on a single limb, the participant reaches as far as possible; lightly touches the line without shifting weight to the reaching limb; and then returns the reaching limb to the center of the grid, reassuming a bilateral stance. Mean reach distance was normalized by the leg length. The participant performed 3 trials in every directions before and after the completion of the fatiguing tasks. The order of the reach directions during the SEBT was randomized for each participant.

Muscular fatigue was induced in either the hip abductors, ankle plantar flexors, or toe plantar flexors with repeated maximum voluntary isometric contractions (MVICs). A maximal load was first determined, and after sufficient rest the participants were asked to perform repeated MVICs following the beat of a metronome (15 contractions/min: 2sec contraction/2sec rest) as many times as possible until peak-torque values declined below 70% MVIC for 2 consecutive trials.

Surface electromyography (EMG) was collected from 11 muscles: erector spinae (ES), adductor magnus (ADD), GM, BF, VL, rectus femoris (RF), gastrocnemius medialis (GS), soleus (SOL),

peroneus longus (PER), tibialis anterior (TA), and abductor hallucis (ABDH). EMG data were collected at 1000 Hz using a wireless system (KinAnalyser, Kissei Comtec co., Japan). Average of rectified EMG signal was calculated over single limb stance phase and normalized to the maximal voluntary contractions of manual muscle testing.

A paired t-test was conducted to test the changes of the SEBT and muscle activities after fatiguing protocols. The level of significance was set at 0.05

## RESULTS AND DISCUSSION

Table 1. summarizes the results of the change of the SEBT, and averaged EMG of 11 muscles after the fatiguing tasks.

After fatiguing hip abductors, SEBT significantly decreased in medial and posteromedial directions, with significantly decreasing VL and GS activities in posteromedial and GM activity in medial. After fatiguing ankle plantar flexors, SEBT significantly decreased in medial, posteromedial, and posterior directions, with decreasing ABDH in posterior and posteromedial directions and a tendency in increased GM activity in posterior and RF activity in posteromedial. After fatiguing toe plantar flexors, SEBT significantly decreased in posterior medial directions with no significant change in muscle activities.

Interestingly, after fatiguing ankle plantar flexors and toe plantar flexors, there was a tendency to increase GM, BF, ADD, VL, and RF. Which implies that the impairment of the distal muscles could be compensated by the activity of the proximal muscles. These compensation did not observe after fatiguing hip abductors.

# DECREASED PLANTAR SENSATION WORSENS POSTURAL CONTROL

<sup>1</sup>Toyin Ajisafe, <sup>1</sup>Ferdinand Delgado, <sup>1</sup>Poonam Mankar, Mikaela Boham<sup>1</sup>

<sup>1</sup>Texas A&M University, Corpus Christi, TX, USA.

email: toyin.ajisafe@tamucc.edu

## PURPOSE

A review (2) recently concluded that although plantar cooling decreases tactile sensitivity, it did not affect postural sway in healthy young adults during static sensorimotor tasks, including single limb stance with eyes closed. The authors concluded that sensory redundancy, e.g., visual and vestibular systems, appeared to have sufficiently compensated for the deficits in decreased plantar sensation.

It is unclear whether decreased plantar cutaneous sensation impacts postural response during dynamic non-locomotor tasks that involve propulsion using the feet's plantar surface. This study investigated the effect of decreased plantar sensation on postural response during bilateral standing calf raise.

## METHODS

Eleven young adults (four females and seven males) ( $24.18 \pm 4.35$  years;  $171.58 \pm 8.21$  cm;  $76.64 \pm 18.25$  kg) participated in this study.

There were two conditions: no icing and icing.

In the no icing condition, subjects stood barefoot in the middle of an AMTI force plate and performed standing calf raises at a cadence of 48 beats per minute for 90 seconds. The force plate acquired anterior-posterior (AP) and medial-lateral (ML) center of pressure (CoP) excursion area. Participants were asked to maximally push up and stand on their toes at each audible beat of a metronome, then lower back down in readiness for the next.

In the icing condition, participants' forefeet were cooled on bagged ice (while seated) until their forefoot plantar temperature read  $6^{\circ}\text{C}$  on an infrared thermometer. Icing was immediately intervened by the foregoing movement task on the force plate. The order of conditions was

randomized. Participants returned to the lab after 24 hours to complete the second condition.

CoP excursion area was estimated by calculating the 95% prediction ellipse area of CoP stabilogram in MATLAB(1). The area ( $A$ ) of an ellipse is the dot product of pi and its principal axes ( $a$ ,  $b$ ) (equation 1).

$$A(\text{ellip}) = \pi ab \quad (1)$$

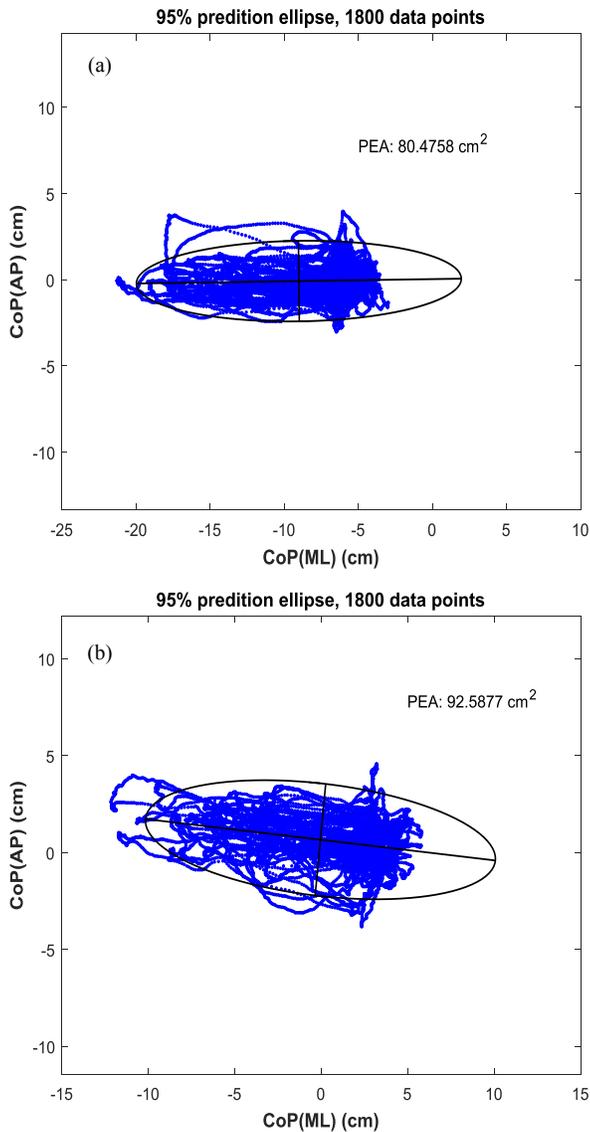

We calculated a paired-samples t-test to determine the effect of decreased plantar sensation on CoP excursion area. Statistical significance was set at  $p < .05$ .

## RESULTS AND DISCUSSION

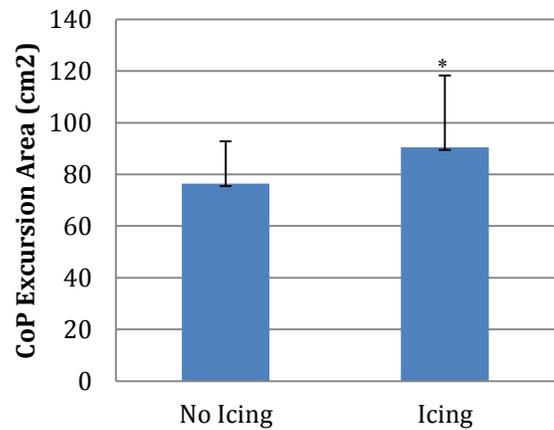

A paired-samples t-test ( $t(10) = -2.526$ ,  $P = .030$ ) showed a significant difference in CoP excursion area between the conditions (Fig. 1).

Previous research found that young adults shifted CoP trajectory away from the insensate region of the foot during walking (3). The current study imposed a constraint such that the insensate foot region (forefoot) could not be avoided and had to be used for propulsion.

Although it was previously reported that plantar cooling did not affect postural sway in healthy young adults (2), the current research found greater CoP excursion area following forefoot cooling (Fig. 2).

**Fig. 1:** A subject's CoP excursion area (95% prediction ellipse) (a) no plantar cooling, (b) plantar cooling.

**Fig. 2:** Mean CoP Stabilogram Area. \* Indicates significant difference between conditions.

## CONCLUSION

It is concluded that in spite of sensory redundancy, decreased plantar sensation deteriorates postural control in intact young adults during bilateral standing calf raise.

This finding demonstrates a clear influence of plantar cutaneous sensation on postural control during a non-locomotor task that involves propulsion at the plantar surface of the foot. This may have implications for conditions like obesity that have been associated with decreased plantar cutaneous sensation, and the confidence and capacity to engage in physical activity.

## INTRODUCTION

Musculoskeletal extremities exhibit a multi-layer tissue structure that is composed of skin, fat, and muscle tissue. Anatomical measurements of these tissues provide an understanding of body composition, which is used to assess health status, diagnose disease severity, and identify potential health risks [1,2]. In addition, biomechanical models rely on such data for accurate representation of limb structure and material properties [3]. However, there is a lack of data describing limb soft tissue variations across diverse populations. Therefore, the goal of this study is to provide a publicly available database of skin, fat, and muscle tissue thicknesses for *in vivo* human musculoskeletal extremities. Ultrasound [4,5], an inexpensive imaging modality, will be leveraged to visualize the layered soft tissue structure along limbs for a large group of subjects. With its portability, this imaging modality will facilitate expansion of measurements to the field.

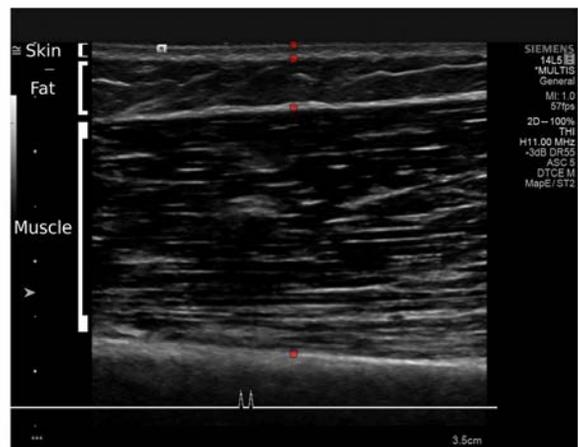

## METHODS

A total of 50 subjects were tested (22 female, 28 male). The mean ( $\pm$ SD) age, height, mass, and body mass index were  $26.8 \pm 13.6$  yrs (range of 20 to 70 yrs),  $170 \pm 8.7$  cm,  $78 \pm 17.6$  kg, and  $26.8 \pm 5.6$  kg/m<sup>2</sup>, respectively. Activity level, ethnicity and race were also noted for each subject. The study was approved by the Cleveland Clinic Institutional Review Board and the Human Research Protection Office of the U.S. Army (USAMRMC ORP HRPO) and participant consent was received prior to data collection.

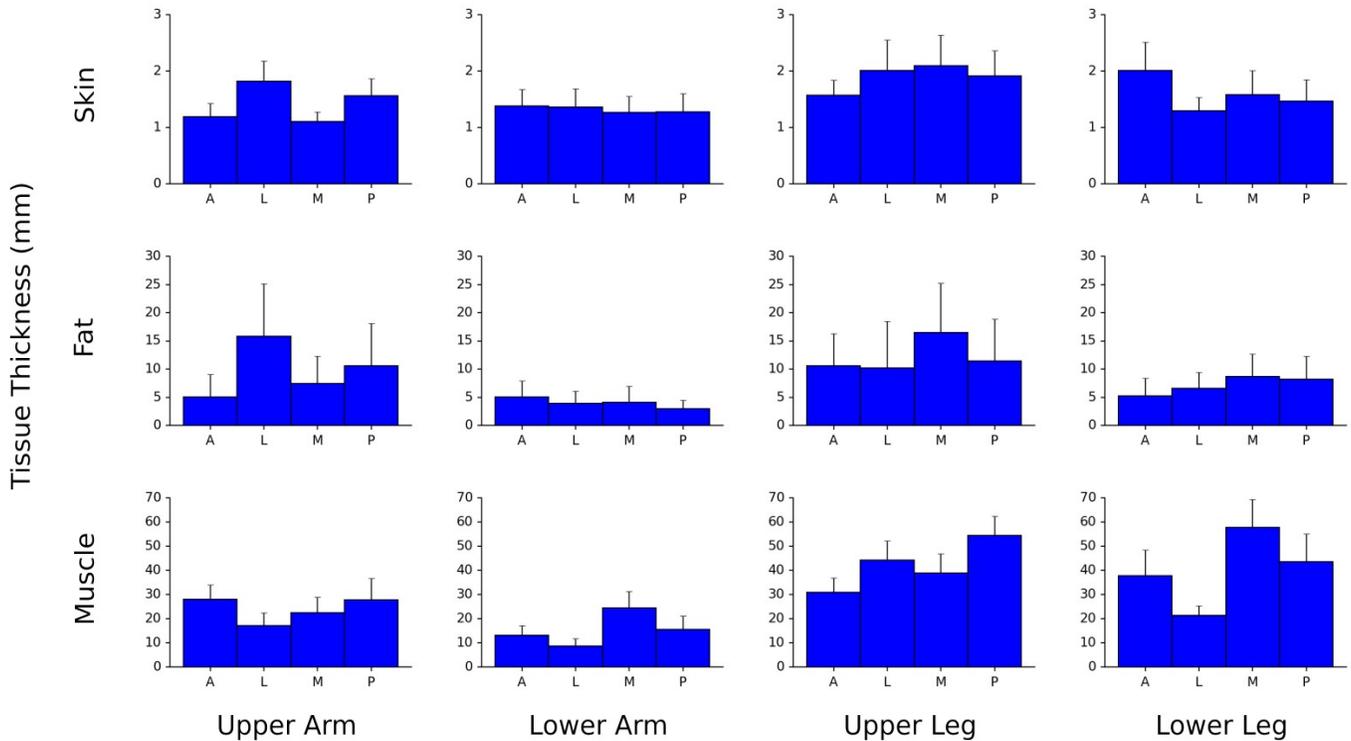

A custom load transducer instrumented ultrasound device was used to image skin, fat, and muscle

layers in the upper and lower extremities (Acuson S3000, Siemens, USA) [6]. The ultrasound probe (14L5 or 9L4) was attached to a 6-axis load transducer (Nano25, ATI Industrial Automation, USA), to ensure that the bulk tissue was minimally loaded (force magnitude  $< 2.2$  N) during imaging. Four segments (upper/lower arm/leg) of the right extremities were imaged along posterior, anterior, medial, and lateral locations (proximally, centrally, and distally), giving a total of 48 collection sites. The lower leg segment was imaged to the fibula, except for posterior locations (tibia) and the lower arm segment was imaged to the radius, except for medial locations (ulna).

Skin, fat, and muscle thicknesses were measured from the B-mode ultrasound images using a custom graphical user interface developed in Python. The analyst manually dragged markers to each tissue boundary (transducer/skin, skin/fat, fat/muscle, and muscle/bone) (Figure 1). The tissue thicknesses and forces were extracted and recorded for the frame corresponding to the minimum force.

**Figure 1:** Sample ultrasound image of the central anterior upper arm. Red dots show the tissue boundaries.

**Figure 2:** Mean ( $\pm$ SD) skin, fat, and muscle thicknesses for the central locations of the arms and legs (N = 50). Horizontal axis key: A = anterior, L = lateral, M = medial, P = posterior.

## RESULTS AND DISCUSSION

Mean ( $\pm$ SD) thicknesses of skin, fat and muscle tissues for the central locations are shown in Figure 2. Results from the proximal and distal locations are not shown, but will be available after data dissemination (visit project website for updates [7]).

During ultrasound imaging there were several bone boundaries that were difficult to locate (i.e. outside of rated probe depth or weak ultrasound signal). In addition, the fat/muscle boundary was difficult to distinguish in some areas, specifically when the image was not taken perpendicular to the muscle fascia plane. Such limitations were documented for each subject that was tested [7].

## CONCLUSIONS

This study has established a site-specific tissue thickness database of musculoskeletal extremities. Future work will include expansion of this database

to include 100 subjects with data dissemination on a publicly available online platform.

## INTRODUCTION

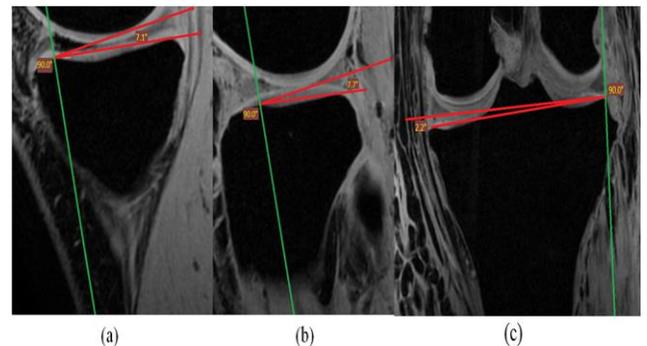

Intrinsic factors, including hormonal and anatomical measures, have been identified as risk factors for anterior cruciate ligament (ACL) injury.[1] The sagittal plane tibial slope angle is an anatomical measure that can contribute to an increased ACL injury risk due to its effects on loading of the ACL.[2] Increased tibial slope angle has been shown to lead to increased anterior tibial translation; a 10° increase in tibial slope angle can lead to 6 mm of increased anterior tibial translation.[2] Increased anterior tibial translation increases the load on the ACL, making it more vulnerable to injury. The aims of this study were 1) to determine the reliability of an MRI-based method of tibial slope measurement and 2) to evaluate the relationship between tibial slope angle and ligament strain measured during an *in vitro* landing simulation. We hypothesized that the measurement method would exhibit excellent reliability and that tibial slope would be a predictive factor for ACL strain in our simulation model.

## METHODS

Thirty-five cadaveric lower extremity specimens were obtained from an anatomical donations program. Magnetic resonance images (MRI) were obtained on 34 specimens prior to testing. After MRI acquisition, a novel mechanical simulator was used to simulate the impulse ground reaction force generated during an *in vivo* drop vertical jump (DVJ) landing.[3] External knee abduction moment, anterior shear, and internal tibial rotation loads were applied to the specimen via pneumatic actuators. Differential variable reluctance transducers (DVRTs) were implanted on the ACL and MCL to record ligament strains.

Two researchers measured tibial slope three times

for each specimen in RadiAnt DICOM (Medixant; Poznan, Poland).[4] Tibial slope was defined as the angle between the perpendicular line and the parallel line of the diaphysis axis and the line that goes through the osseous tibial plateau peaks. (Figure 1).[4] Sagittal plane anterior/posterior tibial slope in the medial and lateral compartments, and coronal plane tibial slope were evaluated for reliability using interclass correlation coefficients (ICC). Inter-rater (ICC (2, 1)) and intra-rater (ICC (2, k)) correlations were performed. Classifications of ICC values were: ICC < 0.4 poor, 0.4 < ICC < 0.75 fair-to-good, and ICC > 0.75 excellent.[5] Pearson correlations were used to determine significant relationships ( $p < 0.05$ ) between tibial slope angle and ligament strain. To be included in a predictive model for ACL injury risk,  $r^2 = 0.2$  was the linear cutoff criteria.[6]

**Figure 1:** Anatomical landmarks used for tibial slope measurements. a) Medial tibial slope b) Lateral tibial slope and c) Coronal tibial slope.

## RESULTS AND DISCUSSION

A published method to measure tibial slope angle from MRI images demonstrated excellent intra-rater reliability and fair-to-good inter-rater reliability. For the sagittal plane anterior/posterior tibial slope, both intra-tester and inter-tester reliability for the medial compartment were excellent (ICC  $\geq 0.823$ ). Lateral

compartment tibial slope demonstrated excellent intra-tester (ICC  $\geq 0.761$ ) and fair-to-good inter-tester (ICC = 0.631) reliability (**Table 1**). Coronal measurements were less reliable than the frontal plane, as intra-tester was fair-to-good (average ICC = 0.739) and the inter-tester was poor (ICC = 0.309).

**Table 1:** Intra- and inter-rater reliability for sagittal and coronal plane tibial slope measurements.

Intra-tester			
	Medial	Lateral	Coronal
<b>Rater 1</b>	0.916	0.867	0.756
<b>Rater 2</b>	0.906	0.761	0.722
<b>Mean</b>	0.911	0.814	0.739
Inter-tester			
	Medial	Lateral	Coronal
	0.823	0.631	0.309

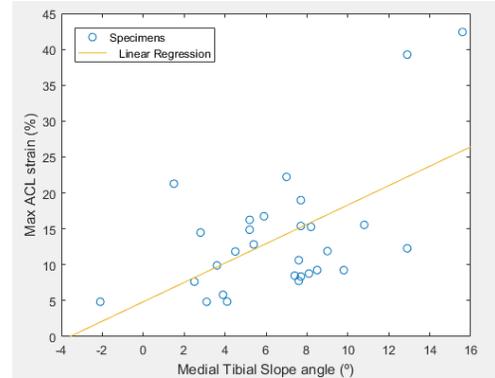

Correlations between tibial slope angle and maximum ACL strain were statistically significant ( $p < 0.015$ ) for both the medial and lateral tibial slope angles. Correlation with the coronal tibial slope was not significant nor did it reach the  $r^2 = 0.2$  linear regression cutoff criterion (**Table 2**).

The positive correlations between tibial slope angle and ACL strain indicate that sagittal plane medial and lateral compartment tibial slope accounts for at least 20% of the variance in ACL strain during a simulated landing. Therefore, tibial slope could be incorporated as a factor in models to predict ACL injury risk (**Figure 2**). This supports previous research that reported increased tibial slope angle corresponded to increased ACL loading.[2]

The current study is not without limitations. The measurement of the tibial slope angle was affected by the specimen orientation during MRI acquisition as well as the image quality of the MRIs.

**Table 2:** Correlations between tibial slope angle and maximum ACL strain.

	R <sup>2</sup> rater 1	p value	R <sup>2</sup> rater 2	p value
<b>Medial</b>	0.220	0.010	0.322	0.001
<b>Lateral</b>	0.213	0.012	0.201	0.015
<b>Coronal</b>	0.061	0.199	0.022	0.439

**Figure 2:** Correlation between medial tibial slope and ACL strain.

Furthermore, DVRTs are known to have significant variability when implanted in soft tissue structures. The current analysis did not investigate anterior tibial translation directly; however, the increased strain that was measured during the simulated DVJ may be caused by increased anterior tibial translation.

## CONCLUSIONS

The method proposed by Hashemi et. al [3] demonstrated excellent reliability for the sagittal plane medial and lateral tibial slope measurements; however, the coronal plane demonstrated poor reliability between testers. Correlations between tibial slope angle and ACL strain reported in this study support previous findings that indicate increased tibial slope may be a risk factor for ACL injury due to increased ACL strain.

# Preliminary Biomechanical Analysis of Superior Capsular Reconstruction Grafts

<sup>1</sup> Andrea Simi, <sup>1</sup> Matthew Chin, <sup>1</sup> John Kelly IV, <sup>1</sup> Josh Baxter, and <sup>1</sup> Michael Hast  
<sup>1</sup> University of Pennsylvania, Philadelphia, PA, USA  
email: [hast@upenn.edu](mailto:hast@upenn.edu)

## INTRODUCTION

Rotator cuff tears are painful and often debilitating injuries that are especially prevalent in older adults [1]. While many cuff tears can be surgically repaired, massive ‘irreparable’ tears present a special challenge for patients and shoulder surgeons alike. Recently, a superior capsular reconstruction (SCR) technique has been developed to address this problem, which utilizes a dermal allograft spanning the superior region of the glenohumeral joint that inserts into the glenoid rim and the greater tuberosity of the humerus. While SCR does not restore the cuff, the graft reinforces the superior capsule – thereby providing leverage and support to the proximal humerus that is normally provided by cuff tendons [2]. Preliminary studies indicate that SCR is effective in improving shoulder function [2,3]; however, the biomechanical limitations of this repair technique have yet to be sufficiently explored.

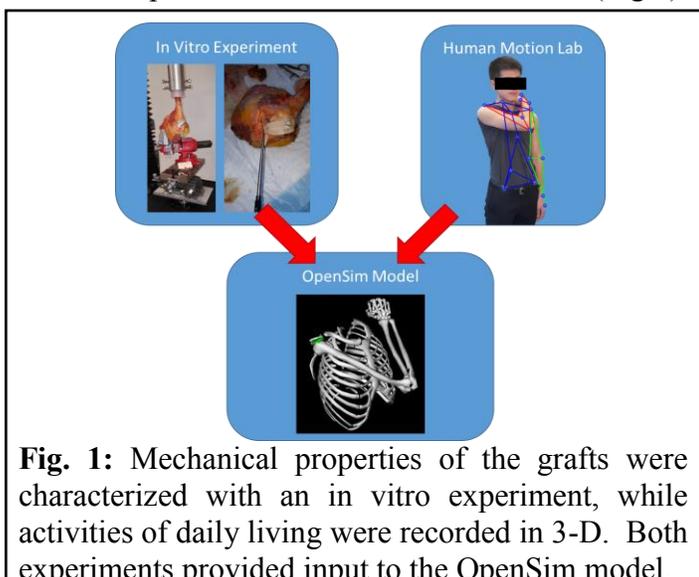

The goal of this study was to identify physical activities that may overburden the implanted graft and cause premature failure. To achieve this task, results from an in vitro experiment and an in vivo 3-D motion tracking session were used as inputs for the development of a musculoskeletal model (Fig 1).

A single cadaveric upper extremity (female, 96 y.o.) was used in this experiment. The specimen was skeletonized such that all muscle, tendon, and capsule tissues surrounding the shoulder joint were removed. The SCR repair was performed by an experienced surgeon using a single-row suturing technique. The scapula was secured to a test frame (TA ElectroForce 3550) and the potted humerus was secured to the actuator in the anatomic position. The humerus was driven superiorly at a rate of 0.5 mm/s until failure of the graft occurred.

Upper extremity kinematics during activities of daily living were captured using motion analysis on a young male (22 y.o.). Reflective markers were adhered the xyphoid process, sternum, C7 vertebra, right acromion, medial and lateral condyles of the elbow, radius and ulna of the wrist, and back of the hand. The subject performed six activities of daily living: combing his hair, a forward reach, an overhead reach, tucking the back of his shirt, washing his back, and washing his opposite shoulder, and marker traces were used to inform the computational model of upper extremity motions in 3-D space.

The musculoskeletal model of an SCR shoulder was developed in OpenSim and was based on a previously published upper extremity model [4]. The model consisted of 6 segments (thorax, clavicle, scapula, humerus, forearm, hand) and had 13 degrees of freedom. No active muscles were included, as this study was purely a kinematic assessment of glenohumeral motions to make estimations of strain and loads imparted onto the SCR graft.

The graft was modeled with four parallel ligament elements that were attached on the rim of the glenoid and the greater tuberosity to mimic the cadaveric insertion points. A wrapping sphere was used to represent the humeral head. Ligament resting

**Fig. 1:** Mechanical properties of the grafts were characterized with an in vitro experiment, while activities of daily living were recorded in 3-D. Both experiments provided input to the OpenSim model.

## METHODS

lengths were based on fiber lengths when the shoulder was in the anatomic position. A simple simulation consisting of prescribed superior translation of the humerus at a rate of 0.5 mm/s was performed to mimic the in vitro experiment. Physiological cross sectional area forces and normalized force-length curves were adjusted to reproduce the force displacement data that was measured experimentally.

Joint kinematics were calculated using the OpenSim inverse kinematics tool to track in vivo data collected using motion analysis. Individual ligament forces and lengths, as well as average fiber lengths and total graft forces were quantified for each motion.

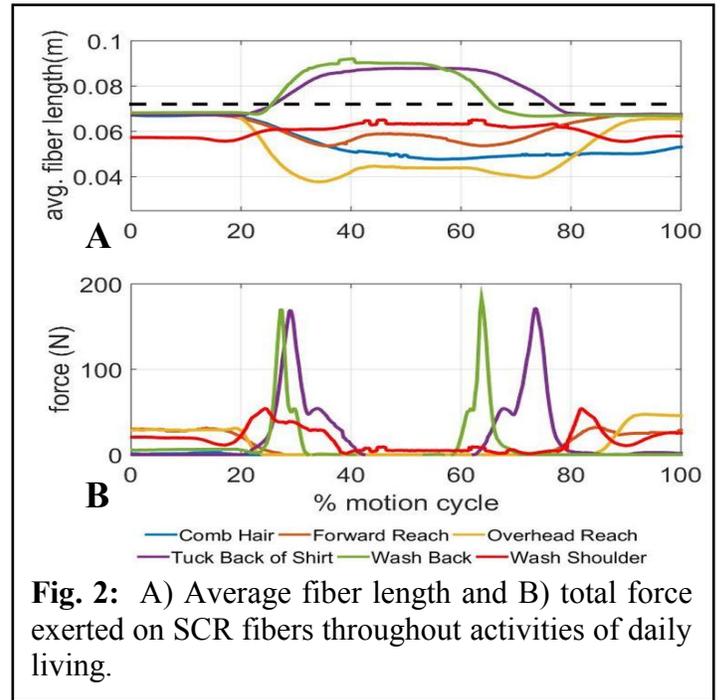

## RESULTS AND DISCUSSION

Activities involving ligament-lengthening posterior shoulder rotation (back washing and shirt tucking) excessively loaded the graft, which may cause graft failure. Throughout these motions the average fiber length exceeded the experimentally determined ultimate strain (dashed line, Fig. 2A). Simulated graft failure is shown as sharp decreases of total force near 180N (Fig. 2B). These values are slightly lower than the experimentally measured ultimate force of 216N. This is explained by the fact that individual fiber lengths differed during motions, causing some fibers to reach ultimate strains and “break” while others remained intact. Fibers did not exceed their failure points during hair combing, forward reaching, overhead reaching, or shoulder washing motions.

This study was preliminary in nature and has several limitations. While the results suggest that this model is capable of identifying high-risk activities, the small sample size precludes our ability to make strong conclusions about its efficacy. Additionally, the modeling could be improved by including muscle forces and articular joint contact, so that the influence of internal and external loads on the shoulder joint could be assessed. Finally, failure of the in vitro graft occurred at the glenoid insertion, so graft failure biomechanics could be improved with stronger fixation (i.e. double-row suture techniques).

## CONCLUSIONS

While SCR has shown promise as a repair strategy for massive irreparable rotator cuff tears, the biomechanical limitations of the grafts are still not

**Fig. 2:** A) Average fiber length and B) total force exerted on SCR fibers throughout activities of daily living.

well-defined. This model identified post-surgical activity limitations that may better inform surgical outcome expectations. These preliminary results also demonstrate the capacity of coupling in vitro, in vivo, and in silico modeling techniques in one cohesive experiment. This approach has potential to provide valuable information to clinicians and rehabilitative specialists to manage patient expectations and guide rehabilitation.

More work is needed to explore the full implications of this preliminary study. In future experiments, we intend to repeat cadaveric simulations, assign validated biomechanical properties to our model ligaments, and validate the model with motion capture data collected in patients treated with SCR.

## INTRODUCTION

One of the most common overuse injuries is midportion Achilles tendinopathy. This clinical syndrome is characterized by pain during loading activities, impaired athletic performance, and tissue degeneration (tendinosis). Progressive tendon-loading programs, which promote increased collagen synthesis and improved viscoelastic properties, are currently the treatment of choice. However, evidence indicates that symptoms may be better addressed by supplementing these programs with laser-induced photobiomodulation therapy [1]. Despite these positive results, it remains unknown if there are immediate effects of a single photobiomodulation treatment on tendon morphology and viscoelastic properties, which may influence the effects of a loading program.

The purpose of this study was therefore to evaluate the immediate effects of photobiomodulation therapy on tendon morphology and viscoelastic properties in a healthy subjects. Additionally, we investigated change with photobiomodulation in individuals with Achilles tendinosis.

## METHODS

To evaluate the effects of photobiomodulation therapy on healthy tendon, 19 healthy subjects (9 females; 10 males) with a mean (SD) age of 28 (4) years and weight of 81 (18) kg were enrolled after a clinical examination and ultrasound screening was performed to ensure tendons were healthy. Blinded subjects received an active photobiomodulation treatment following an established protocol [1] to one side (Laser) and a sham treatment to the other side (Sham). The side and order of treatment application were randomized. Average tendon thickness (mm), cross-sectional area (CSA) (cm<sup>2</sup>), shear modulus (kPa) and viscosity (Pa\*s) were

quantified using three long-axis and short-axis B-mode ultrasound images obtained with a LOGIQ *e* Ultrasound system (GE Healthcare, Chicago, IL) at the midportion of the Achilles tendon and three trials of continuous shear wave elastography [2] at the same location. Each outcome variable has been shown to have good-excellent test-retest reliability (ICC=0.67-0.99). These procedures were performed on both the laser and sham side before, immediately post, 2 hours post, and 4 hours post treatment.

To describe the effects of photobiomodulation therapy on degenerative tendons, 3 subjects (1 female; 2 males) with a mean (SD) age of 62 (14) years, weight of 83 (15) kg, and confirmed Achilles tendinosis were enrolled in this preliminary study. All procedures remained identical to the healthy cohort, except the treatment was completed on the side of the greatest symptoms and tendinosis.

To analyze differences in tendon morphology and viscoelastic properties between laser and sham treatments and between the four time points in healthy subjects, a 2x4 repeated measures ANOVA was performed for each variable. To begin analyzing the effects of photobiomodulation therapy in subjects with Achilles tendinosis, descriptive statistics were used to describe the laser side. Descriptive statistics for both cohorts are presented in mean (SD) baseline values and change from baseline for the three post-treatment time points. These changes were then compared against the minimal detectable change (MDC<sub>(95%)</sub>) for each variable, which were calculated using measures obtained from baseline and immediate post treatment on the sham side for the healthy cohort. All statistical analyses were performed with IBM SPSS Statistics 24 at a significance level of  $p < 0.05$ .

## RESULTS AND DISCUSSION

In the healthy cohort, there were no significant main effects of treatment side ( $p=0.12-0.98$ ;  $\eta^2_{\text{Partial}}=0.01-0.13$ ) or time ( $p=0.51-0.93$ ;  $\eta^2_{\text{Partial}}=0.01-0.04$ ) and no significant treatment by time interaction effects ( $p=0.37-0.89$ ;  $\eta^2_{\text{Partial}}=0.01-0.06$ ) for all outcome variables (Table 1). Additionally, there were no changes in morphology or viscoelastic properties greater than the  $MDC_{(95\%)}$ , other than thickness on the laser side at the 2 hour time point.

In our preliminary analysis of 3 subjects with Achilles tendinosis, we observed an increase in tendon thickness greater than the  $MDC_{(95\%)}$  (0.12 mm) immediately and 2 hours post treatment (Table 2). Conversely, we found a decrease in CSA that was greater than the  $MDC_{(95\%)}$  (0.01  $\text{cm}^2$ ) at all post treatment time points. Looking at changes in viscoelastic properties, shear modulus reduced greater than the  $MDC_{(95\%)}$  (6.0 kPa) immediately and 4 hours post treatment, but no changes in viscosity were greater than the  $MDC_{(95\%)}$  (3.8  $\text{Pa}\cdot\text{s}$ ).

## CONCLUSIONS

Our results indicate a single photobiomodulation treatment does not have immediate effects on tendon morphology or viscoelastic properties in healthy Achilles tendons. However, in patients with Achilles tendinosis, we observed greater changes in tendon morphology and shear modulus compared to the healthy cohort. This suggests that greater effects of photobiomodulation therapy may be observed in degenerative tendons, however a larger sample size is needed to confirm this speculation.

# EFFECT OF PRESSURE ON THE FORMATION OF CREASES IN A SOFT TISSUE

Mir Jalil Razavi, Xianqiao Wang

<sup>1</sup> College of Engineering, University of Georgia, Athens, GA, USA  
email: mjrazavi@uga.edu

## INTRODUCTION

When a soft material without a hard skin is compressed, creases with sharp edges usually form on the free surface of the material. Critical condition for the onset of creases cannot be determined by classical linear perturbation analysis, in stark contrast to the conditions for the onset of wrinkles [1]. Creasing in soft biological tissues, in contrast to wrinkling, has not been thoroughly explored and addressed before. Hence, it is essential to study crease formation in soft tissues and set up a systematic approach to quantify the phenomenon. Among different parameters that may have effects on crease formation, our current focus is the effect of pressure. External pressure or internal pressure from intraluminal fluids exist to a greater or lesser extent in organs like airways, esophagi, and brain. Recent studies have shown that internal or external pressure has effects on the critical growth rate and mode number of surface wrinkling in soft tissues [2,3]. Here, the main goal of this work is to find a simple way to demonstrate pressure effect in crease formation of a compressed soft material, and then as a case study to show how theoretical formulation can be applied to the creasing of a soft growing tissue.

## METHODS

**Analytical.** When a block of neo-Hookean hyperelastic incompressible material is compressed under the plane-strain condition, creases develop on the free surface of the block after a certain amount of compression (strain). A study showed that as long as the length and width of the block are large enough compared with crease size, the critical compressive strain for the initiation of creases is  $\varepsilon_0 \approx 0.35$ , and this value does not depend on the shear modulus of the material [1]. In this situation, the principal stretch ratio of the normal and

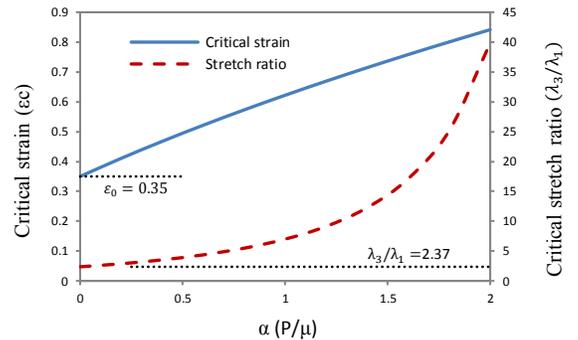

compression directions should be larger than  $\lambda_3/\lambda_1 \gtrsim 2.4$ . For this derivation, it is supposed that the free surface of the block is pressure-free and the block is compressed from a free state. Here, we want to incorporate the effect of the free surface normal pressure on the critical compressive strain required for the onset of creasing. By a lengthy derivation, we have

$$\lambda_{ext} = \sqrt{\frac{\alpha + \sqrt{\alpha^2 + 4}}{2}}, \quad \varepsilon_{ext} = \lambda_{ext} - 1 \quad (1)$$

where  $\alpha = P/\mu$  and  $P$  and  $\mu$  are the normal pressure and shear modulus of material, respectively.  $\lambda_{ext}$  and  $\varepsilon_{ext}$  are extra stretch and strain in compression direction that show the contribution of the normal pressure. If just the absolute value of the strains are considered,  $\varepsilon_{ext}$  should be added to the critical strain without pressure,  $\varepsilon_0$ , to find the critical strain  $\varepsilon_c$  when there is a normal pressure on the free surface of the block

$$\varepsilon_c = \varepsilon_0 + \varepsilon_{ext} \quad (2)$$

Figure 1 shows that the presence of pressure on the surface retards crease formation, and also that the critical strain is a function of both pressure and material modulus.

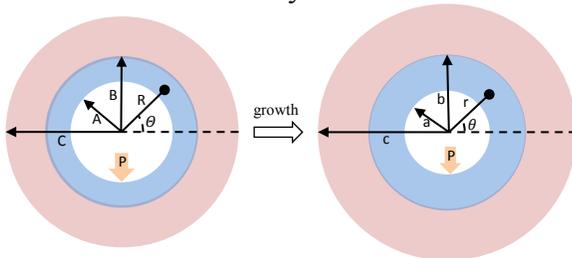

**Figure 1:** Effect of pressure on the critical strain required for the initiation of crease formation in a compressed soft neo-Hookean material.

**Numerical.** Nonlinear finite element (FE) analysis is performed to show the postsecondary morphological evolution after the system reaches

the critical growth ratio predicted from the theoretical analyses.

## RESULTS AND DISCUSSION

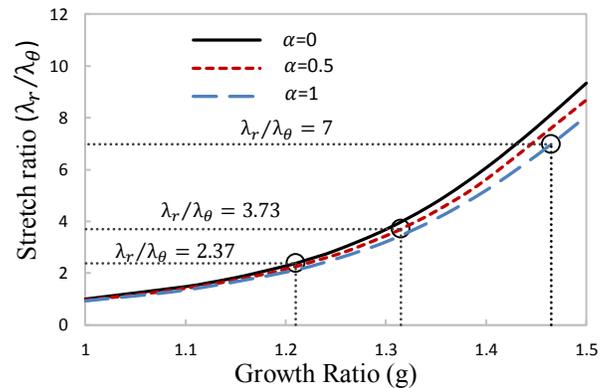

Consider a neo-Hookean bilayer tubular soft tissue growing in the plane-strain condition with a pressure applied on the free surface of the inner layer, as demonstrated in Figure 2. The outer layer of the tissue is supposed to be traction-free. In the presence of pressure, we strive to find the critical growth ratio for triggering crease formation at the free surface of the inner layer.

**Figure 2:** Initial and current states of a growing soft bilayer tube in the presence of internal pressure.

By applying the continuum growth theory [4] along with the cylindrical coordinates for this specific case, both stretch ratios and deformation field can be determined. Figure 3 shows the dependency of the stretch ratio at the free surface of the inner layer on the growth ratio and internal pressure for a special case with  $A/C = 0.5$ ,  $B/C = 0.7$  and  $\mu_2/\mu_1 = 50$ , where  $\alpha$  is defined as  $\alpha = P/\mu_1$ . Figure 3 also shows the relevant critical growth ratio for each certain internal pressure. From Figure 2, the critical stretch ratio ( $\lambda_r/\lambda_\theta$ ) for  $\alpha = 0, 0.5$ , and 1 are 2.37, 3.73, and 7, respectively. When these values intersect their counterparts on the growth ratio-stretch ratio graph, the critical growth ratios are obtained. For example, when  $\alpha = 0.5$ , the critical stretch ratio from Figure 2 is 3.73, from

Figure 3 the critical growth ratio is given as  $g_c = 1.32$ . Results show higher internal pressure leads to a higher critical growth ratio required for the formation of creases.

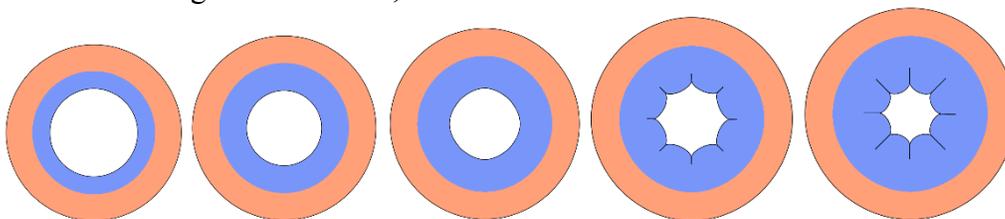

**Figure 3:** Dependency of stretch ratios and deformation of structure on growth ratio and internal pressure,  $A/C = 0.5$ ,  $B/C = 0.7$ ,  $\mu_2/\mu_1 = 50$ .

FE models also predict the same result for the growth and crease formation of the structure, as shown in Figure 4. When the growth ratio of the inner layer reaches the critical value, the system starts to lose stability and form creases at the free surface of the inner layer. This happens in order to partially release the elastic energy in the system and therefore reach a more stable configuration.

## INTRODUCTION

Hip joint stability is inherently provided by the bony articulation between the femoral head and quasi-sphere acetabulum. Function in conjunction with bony components of the hip, soft tissues, such as joint capsule, labrum, and ligamentum teres, constrain excessive translations during complex joint movements. Acetabular labrum tears are often diagnosed in the young athletic population. Acetabular labral repair or reconstruction is a surgical method addressing this clinical issue.

Biomechanically, the labrum has been shown to create a seal against fluid flow in and out of the hip joint, and thereby regulating fluid pressurization and stress distribution of the joint [1]. The negative pressure (or vacuum) the seal maintained also help resist distraction of the femoral head from its socket [2]. A tear or significant loss of the labrum may play a significant role in altering mechanical environment of intra-articular cartilage and potentially causing early onset of osteoarthritis.

The objective of this study was to quantify the peak suction force during manual pullout to dislocate the hip joint as a measure of sealing function of the labrum, and assess the effect of labral tear and repair.

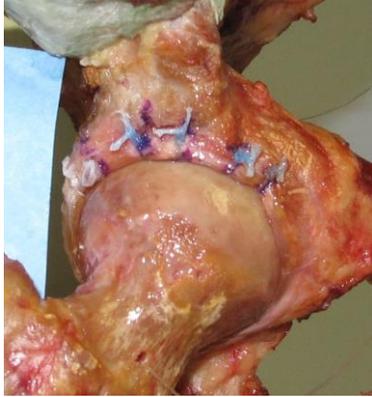

## METHODS

Four pairs of cadaveric hemi-pelvic specimens with proximal femur were obtained from skeletally normal donors (mean age: 55.5 yrs, range 46-61 yrs, two males and two females), and stored at -30°C till the day of testing. Full pelvis specimens were first skeletonized and potted in the upright position (with ASIS and the pubic symphysis were aligned in the

same frontal plane) onto a custom mounting jig secured at the iliac wings using bolts and dental cement. The joint capsules were removed, but the ligamentum teres was preserved.

The manual pullout tests were performed by the same investigator on all specimens. With the mounted pelvis raised to a height just above the investigator's shoulder, a pullout handle with a 6-axis load cell (AMTI, Watertown, MA) on board was secured in the lateral aspect of the femur, 1-inch below the greater trochanter. Manual pullout was performed along the axis of femoral neck in a steady fashion until the hip dislocated. Suction force induced by the negative pressure was measured by the load cell during the process. Loadcell data were collected at a rate of 100Hz. Prior to the tests, approximately 1ml of baby oil gel (Johnson & Johnson's) was applied to the femoral head surface to mimic the synovial fluid. Several trials were repeatedly performed until a consistent peak force was achieved.

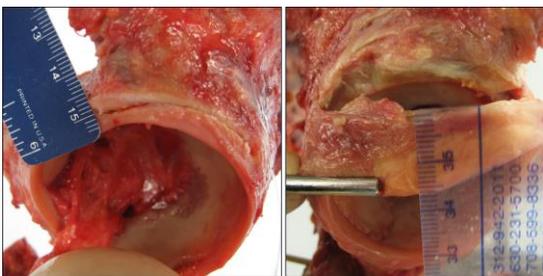

The experiment was conducted in three stages: 1) with native labrum, 2) following simulated labral tear by releasing the labrum directly off the bony acetabular edge from the 11 o'clock position to the 2 o'clock position (12 o'clock is the superior); 3) following labral repair using five suture anchors with one simple suture per anchor (Fig.1). The size of the labrum was measured with a ruler at 12 o'clock position in its native condition and again after simulated labrum tear. The labrum length was defined as the width from bony edge of the acetabulum to the tip of the labrum. The differences in peak suction force before the hip dislocation were analyzed using repeated measures ANOVA followed by Fisher's PLSD pair-wised comparison. Significant level was set at 5% for all tests.

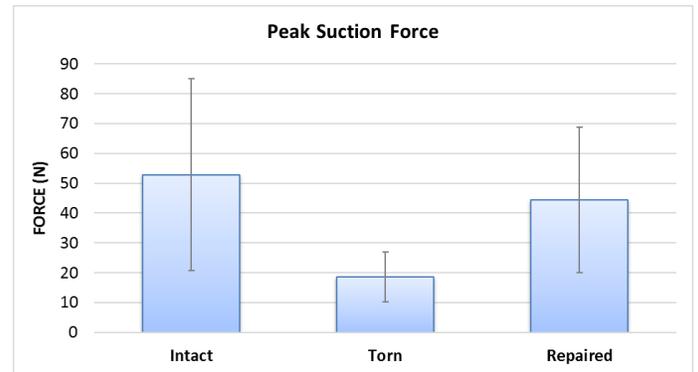

**Figure 1:** Labrum repair with five suture anchors.

## RESULTS

The size of the labrum varied considerably among the eight specimens (Fig. 2). The mean length of the labrums was  $6.1 \pm 4.0$  mm. The peak suction forces measured from the 6-axis load cell was  $52.9 \pm 32.1$  N in the native stage,  $18.5 \pm 8.4$  N after labrum was torn, and  $44.5 \pm 24.4$  N after labrum was repaired (Fig. 3). The peak force obtained from the torn labrum was significantly smaller than those from the native intact ( $p < 0.01$ ) and the repaired labrum ( $p < 0.04$ ), while difference between the intact and repaired labrums was not statistically significant. The suction force data also showed large inter-specimen variations. However, no significant correlation was found between the labrum length and the peak suction force in any labral conditions. When normalized the peak forces with respect to the value of individual intact labrum, there was a mean 54% reduction in peak force with the torn labrum. The mean percentile peak force of the repaired labrum was 91% of the intact.

**Figure 2:** Large variations in size of the labrum between specimens.

**Figure 3:** The mean (sd) peak suction force for the three labrum conditions: intact, torn, and repaired.

## DISCUSSION

The present study investigated the role of acetabular labrum in resisting distraction of the hip joint in a cadaver model consisted of middle-aged donors. Results demonstrated that labral tear had significant impact on labral seal. A typical tear from 11-2 o'clock can cause over 50% reduction in the vacuum seal. Labral repair can restore significant level of sealing function of the native hip.

Large morphologic variations were found in the specimens included in this study, but no correlation was found between the size of the labrum and peak suction force. This may have been due to the small sample size of this study. Further investigations are needed.

Young patients with compromised or absent labrums are at risk for the development of early arthritis of the hip. The ability to reconstruct the labrum and restore the mechanics of the hip joint could potentially alter the natural history of early hip osteoarthritis in this population.

# EFFECTS OF BULLET SPEED AND THE DISTANCE BETWEEN SHOT POSITION AND AN ARTERY ON ARTERY RUPTURE PROBABILITY OF A HUMAN THIGH BY GUNSHOT

<sup>1</sup> Young Nam Jo, <sup>1</sup> Gil Ho Yoon, <sup>1</sup> Moon Jeong Kang, and <sup>1</sup> Hong Hee Yoo

<sup>1</sup> Hanyang University, Seoul, Korea

email: hhyoo@hanyang.ac.kr, web: <http://hydyn.hanyang.ac.kr/>

## INTRODUCTION

Gunshot wounds are one of the major injuries of combatants on the battlefield. In Operation Iraq Freedom and Operation Enduring Freedom, about 20% of all injuries were caused by gunshot wounds and over 90% in the civil war [1]. In addition, about 54% of all combat wounds were in the extremities [1]. If someone is shot on their extremities, excessive bleeding due to artery rupture is usually the major cause of death. But previous studies about gunshot wound simulation usually focused on the human mandible or cranium. Because most of death by firearms are caused by suicide. Therefore, the objective of this study is to conduct gunshot wounds simulation for a human thigh using a finite element method and to predict artery rupture probability depending on bullet speed and the distance between shot position and an artery.

## METHODS

In this study, a finite element method was used to predict artery rupture by a gunshot wound. A human thigh including two major arteries was modeled based on human 3D scan data. The model was simplified to conical shape to minimize computational effort assuming that detailed shape of the thigh has little effect on artery rupture. Properties of thigh muscle were assumed to be equal to those of 10% gelatin. Kelvin solid model and Maxwell fluid model were used as linear viscoelastic model. Mie Gruneisen equation of state and Johnson Cook failure model were also used. Explicit solver (ANSYS AUTODYN) was used for finite element simulation. The simulation method was verified by comparing the gelatin penetration analysis results with experimental results (figure 1) [2].

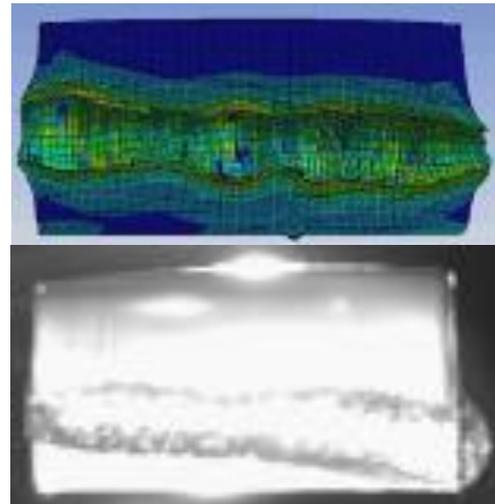

We decided whether the arteries are ruptured or not by comparing analysis results of the artery maximum strain with experimental results of artery yield strain [3]. In other words, the artery rupture probability is the probability that artery yield strain is less than the artery maximum strain. Artery rupture probability can be calculated from below equation.

$$P = \int_{-\infty}^x f_Y(x) dx$$

$x$  : maximum strain of the artery

$f_Y$  : probability density function of artery yield strain

Probability density function of artery yield strain is obtained from fourteen yield strain experimental results. The arteries were removed within 5 hours post-mortem from fourteen healthy male individuals.

**Figure 1:** A comparison of an analysis result with an experimental result.

## RESULTS AND DISCUSSION

Artery rupture probabilities depending on the distance between shot position and an artery were obtained (Figure 2). Bullet speed is 345m/s and angular speed is 8400rad/s. As shown in the figure, artery rupture probabilities decreased in the quadratic form as the distance increased. In addition, artery rupture probabilities depending on the bullet speed were obtained (Figure 3). Angular speed of bullet was assumed to be changed at the same rate as the bullet speed. Also in this case, artery rupture probabilities increased in the quadratic form as the bullet speed increased. Since the kinetic energy increases in the quadratic form as speed increases, this result seems to be physically reasonable.

## CONCLUSIONS

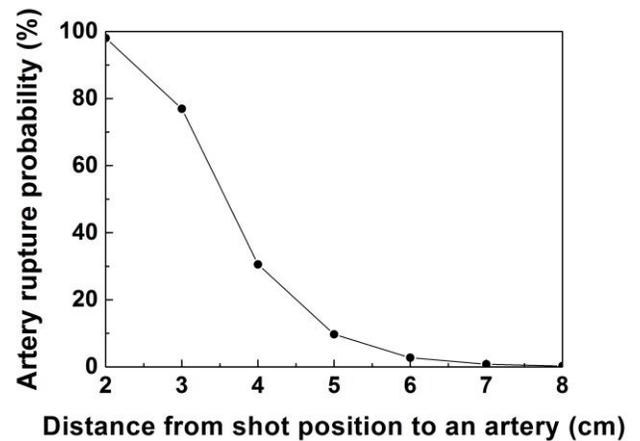

In this study, the artery rupture probabilities considering various shot location and bullet speed were predicted. However, validation of the simulation results is limited because it is impossible to experiment on a human body. But we were able to find out the qualitative characteristics of artery rupture probability depending on gunshot conditions. This research can be used to predict survivability of combatants who perform combat mission through battlefield simulation.

# OBSERVATION PERIOD HAS AN IMPACT ON THE OUTCOME OF SOFT TISSUE MATERIAL PROPERTIES IN VIVO. A COMPARISON OF THE INFLUENCE OF RUNNING IN MINIMAL SHOES FOR 8 AND 24 WEEKS.

Freddy Sichting, and Florian Ebrecht

Chemnitz University of Technology, Department of Human Locomotion, Chemnitz, Saxony, Germany  
email: [freddy.sichting@hsw.tu-chemnitz.de](mailto:freddy.sichting@hsw.tu-chemnitz.de)

## INTRODUCTION

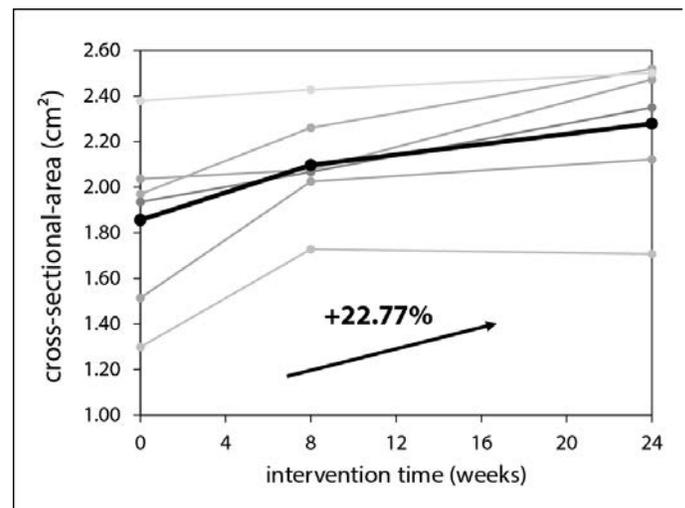

Prospective longitudinal research study designs are often used in the field of biomechanics. This involves repeated observations of the same variables over longer periods of time to uncover adaptational effects of certain interventions or predictors of certain diseases. The chosen observation period has an important influence on later discussions of the data. As the adaptation processes and responses of the human body are highly variable, inadequate observation periods can favor misinterpretation. This study used a minimal-shoe running intervention to investigate how the observation period impacts the outcome measures. Specifically, we measured the change of foot muscle size and mechanical properties of selected soft tissues of the foot over a time period of 8 and 24 weeks. We hypothesized that all measures show a gradual positive or negative progression over time.

## METHODS

A total of 13 subjects (6 female, 7 male) participated in this study. The longitudinal 24-week study included a 30-minute running protocol twice a week. The training intensity was gradually increased during the first six weeks. A cross sectional area (CSA) of the m. abductor hallucis (ABH) was measured using ultrasound prior to, during (week 8), and after the intervention (week 24). To evaluate the effect of the intervention on selected tissue properties of the foot, we measured the stiffness parameters of the m. gastrocnemius, Achilles tendon, plantar heel pad, plantar aponeurosis, and ABH using myometric measures. Due to the limited number of participants, we performed descriptive data evaluation only.

## RESULTS AND DISCUSSION

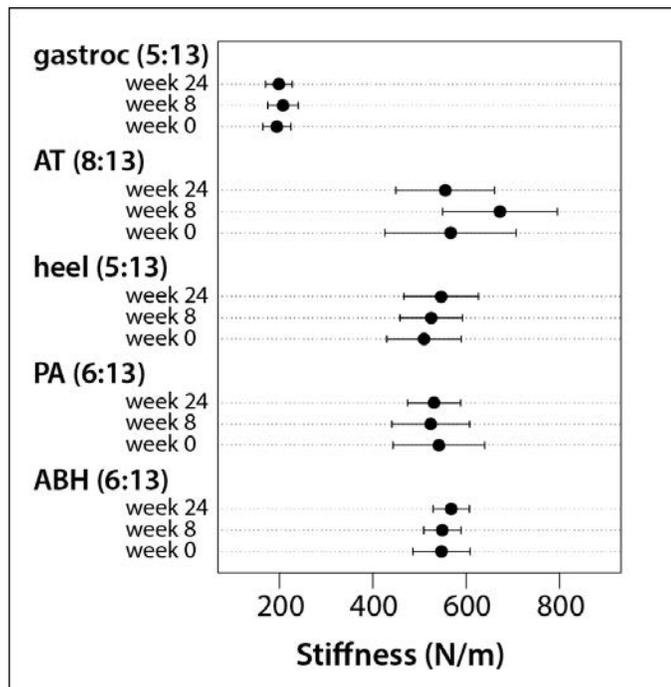

Our hypothesized gradual progression over time was confirmed for the CSA measurement of ABH. The CSA of ABH increased steadily by 22.77% over the observation period of 24 weeks. Over the first eight weeks, the CSA increased by 13.01%, followed by a further but less pronounced increase of 8.64% between week 8 and week 24 (Fig. 1). This data are in accordance with existing literature [1, 2]. Consistent series of reliable ultrasound recordings of all three measurement points were only available for six subjects. However, all six showed the same progression regarding the change of CSA in ABH. This is in contrast to the measured stiffness properties.

**Figure 1:** Influence of minimal-shoe running on the cross-sectional-area of the m. abductor hallucis. The black line represents the mean value, grey lines represent individual values.

Our hypothesized gradual progression over time must be rejected for the stiffness properties of m. gastrocnemius, Achilles tendon, plantar heel pad,

plantar aponeurosis, and ABH. With the exception of the plantar heel pad, all selected tissues showed a non-gradual progression over the time period of 24 weeks (Fig. 2). Even though the mean stiffness properties of the heel pad showed a gradual increase, the individual analysis showed a rather non-uniform pattern. Only 5 of 13 subjects followed the mean progression. This non-uniformity by the individual subjects also held true for the m. gastrocnemius (5 of 13), plantar aponeurosis (6 of 13), and ABH (6 of 13). We presume that this mismatch between the mean and the individual course limits further general data interpretation.

**Figure 2:** Influence of minimal-shoe running on stiffness properties of soft tissues (gastroc - m. gastrocnemius, AT – Achilles tendon, heel – plantar heel pad, PA – plantar aponeurosis, ABH – m. abductor hallucis). Dots represents mean values, error bars represent standard deviations. Numbers in parenthesis state the number of individuals that follow the mean progression, e.g. (5:13) – 5 of 13 subjects.

Only the mean course of the Achilles tendon stiffness was shared by most individual datasets (8 of 13). Interestingly, the AT stiffness increased over the first eight weeks (week 0:  $566.6 \pm 141.6$  N/m vs. week 8  $672.5 \pm 124.1$  N/m) but subsequently decreased

almost to the initial value (week 0:  $566.6 \pm 141.6$  N/m vs. week 24:  $555.1 \pm 107.0$  N/m). Running in minimal shoes for the first time might have caused a temporary increase in the muscle tone of m. gastrocnemius. The increased muscle tone may have increased Achilles tendon tension and thereby changed the stiffness properties. Over time, the subjects adapted to the additional stress of minimal-shoe running and thus the tension of the Achilles tendon, represented by the stiffness value, decreased again.

## CONCLUSIONS

The course of the Achilles tendon stiffness highlights the importance of an appropriate observation period. In contrast to the CSA of ABH, Achilles tendon stiffness did not show a gradual course over the observation time of 24 weeks. Regarding the CSA data, eight weeks seem to be sufficient to show the long-term effects of running in minimal shoes on muscle size. In contrast, eight weeks do not seem to be sufficient to draw clear conclusions regarding changes in the material properties of soft tissues of the foot when running in minimal shoes. Without the data from the measurements after 24 weeks, the increase in Achilles tendon stiffness after 8 weeks cannot be associated with a clear underlying mechanism. This might be misleading with regard to the further progression of Achilles tendon stiffness. In conclusion, we found that changes in the material properties of soft tissues, such as tendons and ligaments, require observation periods that exceed eight weeks.

# DYNAMIC RESPONSE OF THE HUMAN PENIS TO TENSILE LOADING AT VARIOUS STRAIN RATES

Blake Johnson, MS; Naira Campbell-Kyureghyan, PhD  
University of Wisconsin-Milwaukee, Milwaukee, WI, USA  
Email: john2742@uwm.edu

## INTRODUCTION

External genitourinary injury is increasing among soldiers [1]. This shift from internal to external injury can be contributed to improvements in internal injury protection as well as the increase in the use of explosives in the battlefield [2]. Although penile injuries have risen, little research has been conducted to help protect this organ from such traumatic events.

One reason for such limited research in this area could be that there is a lack of finite element models developed to investigate these types of injuries for the human penis. Previous penile finite element models have focused on analyzing normal function, prosthesis function, and Peyronie's disease [3,4,5]. What could be preventing finite element modeling of this organ to shift to traumatic injury prevention is the lack of material properties. Currently there is very limited research in the material properties of the human penis, and no studies have attempted to capture the material properties of the human penis at various dynamic loading rates.

The goal of this study is to determine the compressive and tensile material properties at various dynamic loading rates for the human penis. It is expected that the material properties will exhibit loading rate dependence.

## METHODS

Three penises were procured from donated cadavers. The specimens were removed from the body by severing it at the base of the shaft.

Each penis was dynamically tension tested using an MTS (Plymouth, MN) material testing system. The penises were tested until failure at rates of 25% $S^{-1}$ , 100% $S^{-1}$ , and 500% $S^{-1}$ . Initial failure was defined at the point where force first dropped and complete failure was defined when the force dropped to 0 N.

Forces and displacements were recorded and converted into stress and strains.

After failure testing on the complete specimens, non-destructive testing was conducted on samples that were cut out of the portions of the penises that were not involved in the failures. Non-destructive compression tests were done at the rate of 1% $S^{-1}$ , 10% $S^{-1}$ , and 25% $S^{-1}$ . The secant slope of the stress strain curve was calculated to determine the elastic modulus.

A general linear model ANOVA was used to determine if differences in elastic moduli at different strain rates were statistically significant at a 5% level. A Tukey's post hoc test was used to determine the statistical difference between the three strain rates.

## RESULTS AND DISCUSSION

The human penis exhibited strain rate dependent behavior. The average elastic modulus was 51% higher ( $p=.019$ ) at 25% $S^{-1}$  (.044 MPa) versus 1% $S^{-1}$  (.029 MPa). For every specimen, the elastic moduli increased from 1% $S^{-1}$  to 10% $S^{-1}$ , and from 10% $S^{-1}$  (.033 MPa) to 25% $S^{-1}$ , but the differences were not statistically significant. The elastic moduli ranged from .015 MPa to .068 MPa.

The measured failure stress and strain are presented in Table 1. Large differences were seen between the 25% $S^{-1}$  condition versus the 100% $S^{-1}$  condition. Initial failure stress was over 5 times greater and the failure strain was 41% lower at 100%  $S^{-1}$ . Similarly, complete failure stress at 100% $S^{-1}$  was over twice the value and strain was 23% lower than at 25% $S^{-1}$ . Differences in initial and complete failure stress and strain also existed between the 100% and 500% conditions. The initial and complete failure stresses were 0.24 MPa (12%) and 1.45 MPa (116%) greater in the 500% condition. The difference in initial and complete failure strain varied between 100% $S^{-1}$  and

500% $S^{-1}$  with an increase of 28% for initial failure stress and a decrease of 23% for complete failure strain. This could suggest that at higher rates the strain rate dependency diminishes.

Table 1: Failure stress and strain of the human penis at different loading rates

Specimen	1	2	3
Strain Rate (% $S^{-1}$ )	25	100	500
Initial Failure Stress (MPa)	0.37	2.06	2.3
Initial Failure Strain	136%	80%	102%
Complete Failure Stress (MPa)	0.502	1.15	2.6
Complete Failure Strain	237%	183%	140%

The larger difference in complete failure stress versus initial failure stress between specimens 2 and 3 (100% $S^{-1}$  and 500% $S^{-1}$ ) was possibly due to how the specimen initially failed. Specimen 2 severed most of the skin and corpus cavernosum at the initial failure, causing a large drop in stress (Figure 1). Specimen 3 only ruptured the surrounding skin of the penis at the initial failure, causing the stress to continue to increase with only a minor drop.

With the increased knowledge of penis material properties, better and more accurate models can be developed. Using the properties found at the appropriate strain rates and the knowledge that strain rate dependency seemingly diminishes as rate increases, scientists can create models to better understand injuries from traumatic events. Data

regarding how the penial tissue fails under these loading conditions can lead to creation of better personal protective equipment.

## CONCLUSION

This study determined the dynamic material properties of the human penis under compression and tension testing at various rates. At lower levels and under compression, the tissue behavior is highly reliant on strain rate, but this dependency decreases as strain rate increases. Such knowledge will enable scientists to build more accurate and efficient models to study mechanisms of injury for this organ, but more testing is needed to establish the full range of properties.

## INTRODUCTION

Osteoporosis and low bone mass are major health problems affecting 50% of adults over 50 years old and 30% of postmenopausal women in the U.S. [1, 2]. Osteoporotic fractures are a major cause of morbidity and disability, and incur costs of nearly \$20 billion annually in the U.S.. Hip fractures account for the majority of the disability, morbidity, and financial burden of osteoporosis [3], and can lead to premature death [2]. Hip fracture incidence increases exponentially with age and manifests disproportionately in women over men [4].

Dual-energy X-ray absorptiometry (DXA) is the clinical standard for measuring bone mineral density (BMD) and allows physicians to diagnose osteoporosis. While BMD is an important biomarker of fracture risk, as a standalone measure it lacks information on modifiable causal factors. Convincing evidence indicates that physical activity with both low and high impact forces is beneficial in the prevention of osteoporotic fractures and is one of the main modifiable risk factors [5].

A well-defined relationship between physical activity and hip BMD has not been determined. Quantifying hip BMD and physical activity-based cumulative estimates of skeletal dynamic loading in the free-living environment could provide a biomarker for tracking and prescribing physical activity changes in high risk patients.

## METHODS

Fourteen post-menopausal women (age: 64.7 (7.2) yrs, BMI: 26.0 (3.9) kg/m<sup>2</sup>) were included in this study. Exclusion criteria include current use of prescribed medication which could result in BMD

changes, use of an assistive device while walking, any amputations or use of orthotics, and a history of hip surgery or hip or knee joint replacement on the non-dominant side. The study protocol was approved by the Mayo Clinic IRB and written informed consent was obtained prior to subject participation. To develop a dynamic loading estimation method for use in the free-living environment, tri-axial acceleration and ground reaction force (GRF) data were collected as subjects each performed 30 to 50 walking trials barefoot in the lab at slow, normal, and fast self-selected speeds. Continuous acceleration data were collected at 100 Hz from ActiGraph GT3X+ (ActiGraph LLC, USA) activity monitors worn on the bilateral ankles. GRF data were collected at 600 Hz for one to three steps per trial using three force plates (AMTI, USA; Kistler Instruments, Switzerland) and continuous video data were simultaneously acquired at 60 Hz. Linear regression was used to develop a general peak vertical GRF equation based on peak vertical acceleration data from all 14 subjects.

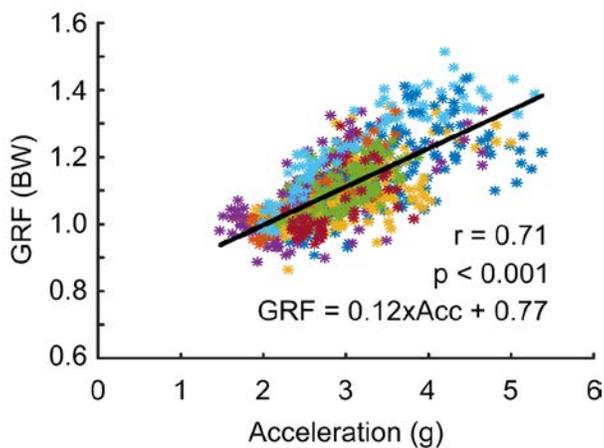

The same 14 subjects received DXA scans using the Lunar iDEXA (GE Medical Systems, USA) to measure total hip BMD on the non-dominant side and wore the activity monitors for 7 days in their free-living environments. Steps taken in the free-living environment were detected from ankle acceleration data using our previously developed and validated step detection algorithm [6] in MATLAB (Mathworks, USA). Peak vertical GRF, in units of body weight (BW), was calculated for each step using the GRF equation derived from the lab data. A bone density index (BDI), an index of cumulative loading, for each day was determined as the cumulative sum of the peak vertical GRF estimated for each detected step [7]:

$$BDI = [\sum_{i=1}^n (\beta \cdot GRF_i)^m]^{1/2m} \quad (1).$$

$\beta$  is the ratio of the individual subject's BW to the cohort's mean BW and  $n$  is the daily step count. The exponent  $m$  weights the relative importance of force magnitude and loading cycles and was set to a value of 6 [7]. Linear regression with Pearson correlation analysis was used to assess correlations of peak vertical GRF with peak vertical acceleration and of each subject's BMD with their mean BDI.

## RESULTS AND DISCUSSION

Peak vertical GRF had a strong and significant correlation with peak vertical acceleration across all subjects (Fig 1).

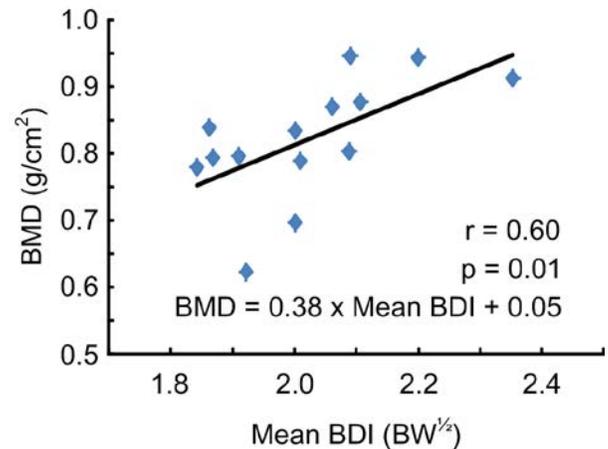

**Figure 1:** Lab data demonstrating the relationship between peak vertical ground reaction force (GRF) and peak vertical ankle acceleration. Each subject is denoted by a different color,

In this study, we observed an RMS error of 0.078 BW and a mean (SD) absolute difference of 5.4% (4.2%) for GRF estimations. These results are similar to our previous study utilizing the same lab-based methods on younger adults [8]. In comparison, a much larger RMS error of 0.185 BW was obtained in a study using the NASA GRF activity monitor [9].

The mean (SD) daily step counts across participants were 10257 (3942). BMD had a moderate and significant correlation with BDI with 51% of the variance accounted for (Fig. 2) compared to 19% for two previous studies using less accurate methods

[7, 9]. Data is currently being collected on an additional 56 participants for further algorithm development and validation. Future work will determine if this ankle acceleration-based BDI tool can be used to predict BMD changes.

**Figure 2:** Free-living data demonstrating the relationship between each subject's bone mineral density (BMD) and their mean acceleration-based bone density index (BDI).

## CONCLUSIONS

The results strongly suggest that accelerometers worn at the ankle could be a very useful tool for relating cumulative dynamic loading in the free-living environment to bone health.

## INTRODUCTION

The ability to adapt to applied mechanical loads is an important characteristic which determines the architecture and strength of bone (Wolff's Law). Specifically, the magnitude of load and number of loading cycles influence whole body and site-specific bone mineral density and bone mineral content (BMC). The individual bones in the foot have been shown to respond to a reloading program and relate specifically to gait loading pattern [1]. While loading plays an important positive role in bone health, bone stress injuries (BSI) will occur when the bone can no longer withstand the loading [2]. The prevalence of BSI in athletes may be due to rapid increases in the duration and frequency of loading with certain sports and physical activities. BSI risk may relate to site-specific bone strength characteristics. Furthermore, the relationship between loading and site-specific BMC may help identify potential risk for both acute and overuse foot injuries. A method to measure metatarsal BMC was recently developed using dual x-ray absorptiometry (DXA) [3]. Therefore, the purpose of this study was to identify differences in metatarsal BMC and whether metatarsal BMC differences elicit different relative metatarsal loading patterns during gait in young athletes.

## METHODS

72 participants were included in the study (26M, 46F, age:  $17.0 \pm 4.8y$  and BMI:  $22.5 \pm 5.7kg/m^2$ ). The participants participated primarily in the following sport categories: basketball (n=19), dance (n=13), soccer (n=24), and running (n=16). A DXA method was used to scan the left foot second (MET2) and fifth (MET5) metatarsals (Figure 1) to calculate BMC for the proximal and shaft regions.

Each participant also performed barefoot gait at a self-selected speed over a 6m walkway to collect plantar pressure distribution. An emed-x system (novel) was mounted in the middle of the walkway and level with the surface. Three separate trials were collected for the left foot and averaged. The platform consisted of a matrix of capacitive sensors (4 sensors/cm<sup>2</sup>) that was sampled at 100Hz. Force-time integral for each metatarsal region (Figure 1) was calculated. The force-time integral in each individual region was divided by the force-time integral for the total foot surface to determine the relative load in each metatarsal region.

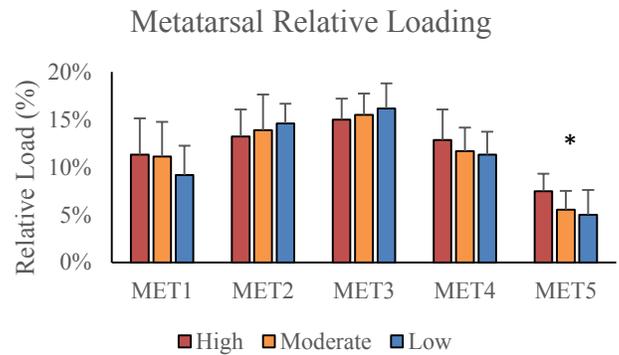

**Figure 1.** Left: DXA image of proximal and shaft regions of the 2<sup>nd</sup> and 5<sup>th</sup> metatarsals. Right: Representative example of emed plantar pressure distribution. Five metatarsal regions were defined based on width and length percentages.

BMC asymmetry between the proximal MET2 and MET5 was established based on the calculated ratio (MET2/MET5). The MET2/MET5 proximal ratio was utilized to classify high asymmetry, moderate asymmetry, and low asymmetry groups based on an equal tertile distribution. Paired t-tests ( $p < 0.05$ ) were used to determine if differences existed between MET2 and MET5 BMC in both the shaft and proximal regions. One-way ANOVA was used to determine if relative loading differences existed among asymmetry groups.

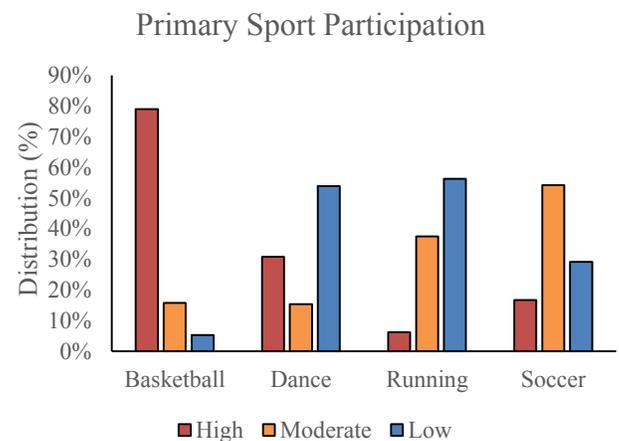

## RESULTS AND DISCUSSION

The proximal MET5 (1.55g) had significantly greater BMC compared to MET2 (1.09g;  $p < 0.001$ ). The shaft was not different between MET5 (1.12g) and MET2 (1.21g;  $p = 0.13$ ). The ratio of MET2/MET5 was significantly different in proximal (0.77) and shaft (1.14) regions ( $p < 0.001$ ) indicating the higher relative BMC in the proximal MET5 compared to the MET2.

Metatarsal relative loading was analyzed from barefoot pressure distribution (Figure 2). A main effect of asymmetry group was found in relative loading of the MET5 ( $p = 0.002$ ). There were no significant group differences between the relative loads of the first, second, third and fourth metatarsals. Post-hoc pairwise comparison indicated that the high ( $7.5 \pm 3.2\%$ ) asymmetry group had significantly greater relative load than both the moderate ( $5.5 \pm 1.8\%$ ;  $p = 0.02$ ) and low ( $5.0 \pm 2.0\%$ ;  $p = 0.002$ ) asymmetry groups. While gait loading may help explain the differences in BMC asymmetry, sport-related loading may play a larger role depending on the type of movements. For instance, various types of loading patterns observed during different sports such as jumping, cutting, and running may provide the mechanical stimuli necessary to increase BMC [4]. In our study, the distribution of primary sport participation was significantly different among asymmetry groups ( $\chi^2 = 32.4$   $p < 0.001$ , Figure 3). 79% of the basketball players were classified as high asymmetry, indicating higher bone mineral content of the proximal MET5 compared to MET2. Future investigations within different sports may be useful to determine sport-related risk of BSI.

**Figure 2.** Relative loading during gait in the metatarsal regions (MET1-5.) Group main effect \* $p = 0.002$ .

**Figure 3.** Distribution of primary sport participation among high, moderate, and low asymmetry groups.

## CONCLUSIONS

The proximal area of the MET5 overall had higher BMC compared to the MET2. Greater lateral metatarsal loading during gait was found in individuals with greater magnitude of metatarsals BMC asymmetry. The functional relationship among metatarsal mechanical loading, bone characteristics, and bone stress injury should be prospectively investigated.

# THE EFFECT OF INFLAMMATION ON THE BIOMECHANICAL PROPERTIES OF THE INTERVERTEBRAL DISC

Brigitte Laird<sup>1</sup>, Matthew Guerreiro<sup>2</sup>, Stephanie DeWitte-Orr<sup>2,3</sup>, Diane Gregory<sup>1,3</sup>,  
<sup>1</sup>Kinesiology, <sup>2</sup>Biology, <sup>3</sup>Health Sciences, Wilfrid Laurier University, Waterloo, ON, CAN  
lair8260@mylaurier.ca

## INTRODUCTION

The intervertebral disc (IVD) is composed of the annulus fibrosus (AF), which surrounds and contains the nucleus pulposus (NP). The IVD is an immune privileged site, meaning in a healthy IVD, the NP is isolated from the adaptive immune system [1]. In addition, the IVD is largely avascular and therefore lacks the capacity to effectively repair itself once damaged. It is hypothesized that when the IVD becomes injured, in the case of IVD herniation, a localized innate immune response is initiated. This response causes the production of pro-inflammatory cytokines at the site of injury leading to macrophage recruitment, inflammation and likely further tissue degradation [2]. Although the presence of pro-inflammatory cytokines in injured IVDs has been well documented, the extent to which inflammation affects the mechanical properties of the IVD remains poorly understood. The aim of this study was to evaluate how the initiation of the innate immune response alters the mechanical properties of the IVD.

## METHODS

Up to four motion segments (bone-IVD-bone) were dissected and removed from the tails of eleven Sprague Dawley rats (42 motion segments in total). In half of the motion segments (2 from each animal), a full AF puncture model (19G) was used to mimic IVD herniation. Further, from each tail, one punctured and one non-punctured IVD were cultured in control media containing DMEM, Penicillin-Streptomycin (1%), Fetal Bovine Serum (10%) and HEPES free acid (25mM). The remaining punctured and non-punctured IVDs were placed in media containing the same concentrations as previously listed with the addition of 10ug/mL of lipopolysaccharide (LPS). LPS is an endotoxin found in the outer membrane of gram-negative bacteria, is an innate immune stimulant, and is pro-

inflammatory. [3]. Through pilot testing, it was confirmed that IVD cells exposed to LPS produce over 100x increase in cytokine production compared to regular media which is supported in previous research [3]. LPS was therefore used to create an inflammatory environment for the motion segments. After 6 days in culture, motion segments were removed and mechanically tested in order to determine changes in IVD mechanics as a result of exposure to inflammation and/or IVD puncture.

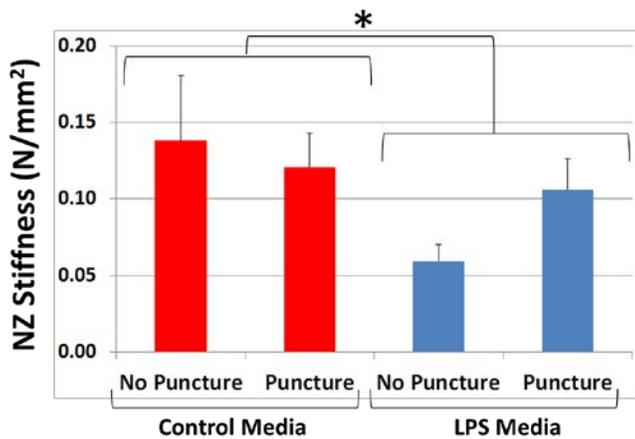

A quasi-randomization protocol was used in order to decrease the effects that IVD level may have on the outcome parameters. All motion segments were subject to a preconditioning cycle followed by 20 phases of cyclic mechanical loading in compression and in tension (0.1mm/sec) using a displacement controlled protocol (UStretch, CellScale, Waterloo, Ontario) (Fig.1). From the load displacement data obtained, the neutral zone (NZ) size (mm) and stiffness (N/mm<sup>2</sup>) of the 20<sup>th</sup> cycle was calculated and compared across the conditions. A two way ANOVA was run in order to determine the effect of damage (puncture/ no puncture) and inflammation (LPS media/ control media) on NZ size and stiffness.

**Figure 1:** Image of a mounted motion segment; each sample was subjected to 20 phases of cyclic compression/tension.

## RESULTS

There was no main effect of damage (puncture vs. no puncture) on NZ size or stiffness ( $p=0.38$ ). There was, however, a significant main effect of inflammation (LPS vs. control media) (Fig. 2). When collapsed across damage (puncture vs. no puncture), IVDs cultured with LPS showed a 37% drop in NZ stiffness compared to those in the control media ( $\bar{x} = 0.130\text{N/mm}^2$  (control) vs.  $\bar{x} = 0.081\text{N/mm}^2$  (LPS);  $p=0.019$ ). No interaction was observed between damage and inflammation for NZ stiffness. Further, no significant change in NZ size in any of the groups was observed ( $p=0.384$ ) (Fig. 3).

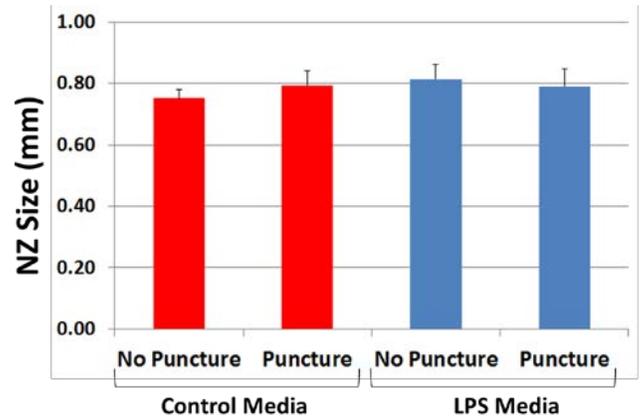

**Figure 2:** Average NZ stiffness ( $\text{N/mm}^2$ ) and standard error in all four conditions. Significant differences denoted by a \*. Red bars indicate regular media; blue bars indicate LPS media. Standard error bars shown.

## DISCUSSION

Based on current analysis it appears as though the mounting of an inflammatory response has a destabilizing effect on the spinal joint marked by a decrease in NZ stiffness in the LPS group compared to the control group. This destabilization may be indicative of tissue degradation in response to inflammation. Interestingly, after 6 days in culture, the puncture did not appear to have a significant effect on the mechanics of the IVD as indicated by the non-significant main effect of damage. It is

possible that the puncture affected the mechanical properties of the IVD immediately following the damage, but that by the 6-day mark it was no longer evident. Further research is needed to confirm this.

**Figure 3:** Average NZ size (mm) and standard error in all four conditions. No significant differences were observed. Red bars indicate regular media; blue bars indicate LPS media. Standard error bars shown.

## CONCLUSION

Understanding the complex interaction between inflammation and IVD mechanics is a critical step in the overall knowledge base of IVD damage and the development of low back pain. This research will help bolster the growing foundation of research required to eventually develop adequate treatment and rehabilitation options for those affected by low back pain.

# THE MATERIAL PROPERTIES OF STABILIZING ROTATOR CUFF TENDONS RELEVANT IN REVERSE SHOULDER ARTHROPLASTY

Vijay Permeswaran, M. James Rudert, Donald D. Anderson, Carolyn Hettrich, Jessica E. Goetz

The University of Iowa, Iowa City, IA, USA  
email: vijay-permeswaran@uiowa.edu, web: <https://uiowa.edu/uiobl/>

## INTRODUCTION

Reverse shoulder arthroplasty (RSA) is an effective treatment for relieving pain and restoring function to individuals suffering from glenohumeral arthritis secondary to rotator cuff deficiency [1]. However, instability is a commonly reported complication after RSA. In order to study instability following RSA using finite element analysis [2, 3], accurate representation of stabilizing soft tissues must be included. We therefore measured the material properties of individual rotator cuff (subscapularis, infraspinatus, and teres minor) tendons.

## METHODS

Two fresh-frozen female cadaveric shoulders were dissected and prepared for testing. The scapular attachments of the subscapularis, infraspinatus, and teres minor muscles were removed, and the muscle bellies were bluntly dissected away from the tendons. The distal humerus was transected 13 cm distal to the lesser tubercle and potted in PMMA bone cement while maintaining the humeral insertions. The subscapularis and infraspinatus tendons were dissected into two equal-width superior and inferior sections, duly respecting fiber orientation and bundles.

The tendon segments were tested using an MTS 858 Bionix Material Testing System (MTS Systems Corporation, Eden Prairie, MN). The potted section of the humerus was held in a custom machined fixture and oriented perpendicular to the loading direction. This allowed the tendons to be tested in a direction parallel to their primary fiber axis. The fixture was attached to an x-y table, allowing the humerus to float freely in a plane perpendicular to

the loading. The proximal end of each tendon was fixed in a serpentine clamp that was connected to a thrust bearing, allowing free rotation about the direction of pull.

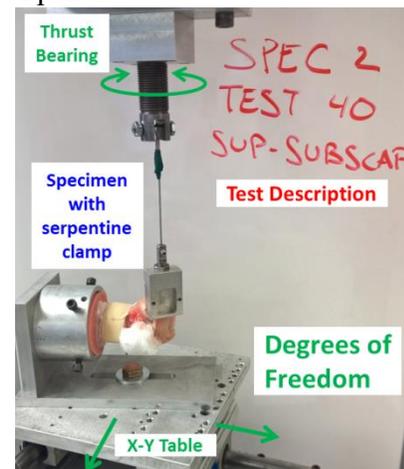

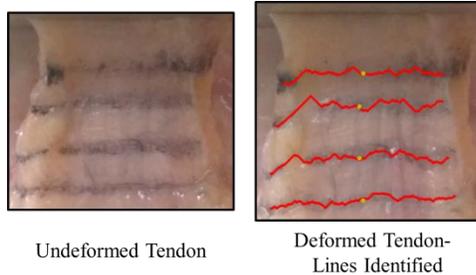

Figure 1: Physical testing setup

A tensile pre-load of 10 N was placed on the tendon, and a suture coated in ink was used to create 3-4 fiducial lines across the tendon specimen, perpendicular to the loading direction. The specimen was then hydrated copiously in saline and tested. The subscapularis and infraspinatus tendon sections were tested in load control over 10 seconds at a rate of 30 N/s for three tests. The loading was then increased to 40 N/s and 50 N/s over 10 seconds for three tests each until the final loading was achieved or failure occurred, whichever happened first. The teres minor, due to its small cross sectional area, was tested starting at 20N/ s, but followed the same testing pattern.

Video was recorded for all tests at 1080p, 30 frames/second using a Nokia Lumia Icon 929 (Microsoft Corporation, Redmond, WA). During testing, audio queues were created for every 50 N of additional load placed on the tendon. Videos were

later analyzed in Matlab (MathWorks, Natick, MA). The ink lines were first identified manually on 6-10 representative frames. The video was split into individual sections for each fiduciary line, and then lines were identified using a Dijkstra's algorithm automated method (Figure 2).

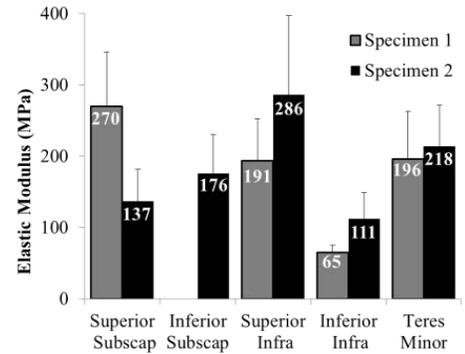

**Figure 2:** Identification of fiduciary lines in video

The centroids of each line were used to calculate strain in the tendons, with the zero-length defined by the distance between adjacent centroids at the initial frame of the video. The strain data were synched to the MTS load data through the audio queues. The tendon stress was defined simply as the load divided by the tendon cross sectional areas. Elastic modulus values were calculated as the best fit line to the linear portions of each stress-strain curve. The moduli values were compared using ANOVA.

## RESULTS AND DISCUSSION

Both shoulder specimens demonstrated clear patterns in elastic moduli values (Figure 3) for the posterior rotator cuff. The superior infraspinatus was found to have significantly stiffer material properties than the inferior infraspinatus ( $223 \pm 88$  vs.  $81 \pm 31$  MPa,  $p < .001$ ), the teres minor was found to be stiffer than the inferior infraspinatus ( $202 \pm 63$  vs.  $81 \pm 31$  MPa,  $p < .001$ ), and no statistically significant difference was found between the stiffness values of the superior infraspinatus and teres minor ( $223 \pm 88$  vs.  $202 \pm 63$  MPa,  $p = .427$ ).

Less clear trends emerged from the subscapularis sections, primarily due to the failure of the inferior subscapularis section on the first trial of specimen 1. No statistically significant difference was observed between the inferior and superior sections of the subscapularis ( $204 \pm 98$  vs.  $176 \pm 64$  MPa,  $p = .481$ ).

**Figure 3:** Elastic modulus values for the tendon sections tested of both specimens across all tests.

These results indicate that the stiffness and elastic moduli values for the rotator cuff tendons are much higher than previously reported [4, 5]. For example, the teres minor tissue was found to be much stiffer than values reported in Halder et al. ( $201 \pm 63$  vs.  $17 \pm 10$  MPa). In our study, we utilized video measurements of strain in order to isolate any deflection of the humeral bone or testing construct, which may explain why our values are much stiffer. The stiffness of our construct was  $49 \pm 8$  MPa, underscoring the importance of testing soft tissue strain visually.

## CONCLUSIONS

We tested the elastic moduli of rotator cuff tendons present following RSA using video techniques to measure strain. The values calculated were much stiffer than previously reported. We plan to use these data to inform a FE model studying instability in RSA.

## INTRODUCTION

Exercise is widely known to play an important role in improving bone health to prevent injury, while more sedentary lifestyles are often associated with bone loss. Regular physical activity, especially weight-bearing exercise, provides a positive influence on bone health [1]. Wolff's law helps explain this, stating that bone formation and remodeling occurs as a result of the stress or mechanical load applied to the body, and therefore bone adapts to meet its mechanical demands [2]. Athletes that participate in sports involving weight-bearing exercise such as basketball, soccer or running tend to have higher bone mineral content (BMC) than those who do not (i.e. swimmers or cyclists) [3]. This is likely due to various types of loading patterns observed amongst different sports and leads to the conclusion that activities such as jumping, cutting, and running provide the mechanical stimuli necessary to increase BMC [4].

Previous studies have reported how loading can affect site specific BMC, though few have measured that of the metatarsals. While foot, ankle, and knee injuries during sports are common, an increasingly serious injury with significant participation time loss involves acute and overuse fracture to the proximal 5<sup>th</sup> metatarsal (met5). In-shoe and barefoot plantar loading are methodologies that may help identify risk factors that predispose an athlete to this type of devastating injury. Our long-term goal is to reduce foot injuries in athletes. The objective of this study was to determine the relationship of both in-shoe loading during sport-related tasks and barefoot plantar loading during walking on proximal met5 BMC in basketball players, soccer players, and recreational runners.

## METHODS

Fifty-two athletes (26M, 30F, age:  $18.7 \pm 2.5$  yrs, height:  $173.3 \pm 12.3$  cm, weight:  $70.1 \pm 13.5$  kg) were included in this study and divided into subcategory by sport: basketball (n=18), soccer (n=19), and running (n=15). BMC of met5 was calculated using dual-energy X-ray absorptiometry (DXA) on a Hologic Discovery System (Figure 1). Dynamic plantar pressure distribution was obtained as each participant walked barefoot at a self-selected pace over a platform emed-x system (novel). Three separate trials of barefoot walking were collected for the left foot and averaged.

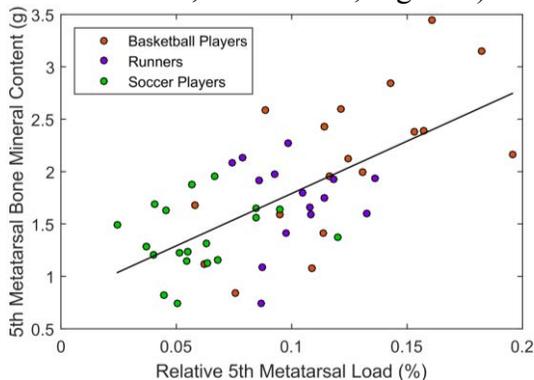

**Figure 1:** DXA scan of the left foot. Regions of interest were masked to the size of the pedar insole and to the size of each participant's foot.

A flexible in-shoe pressure distribution measuring insole was inserted into the left shoe (pedar-x, novel) to calculate in-shoe loading during sport-related tasks for each type of athlete. These tasks included a single leg side drop jump, an unanticipated cutting task, and running at a self-selected speed for basketball players, soccer players, and runners, respectively. A regional analysis of the foot was performed utilizing separate

“masks,” or areas, of the foot consisting of the 5 metatarsal regions using predefined areas in barefoot and in-shoe data (Figure 1). Force time integral for each region was calculated and divided by the force time integral for the total foot surface to determine the relative load in each region.

## RESULTS AND DISCUSSION

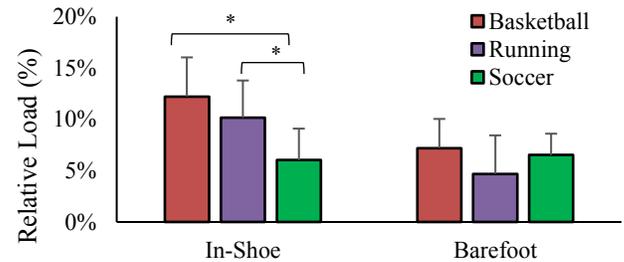

A stepwise linear regression was performed (SPSS) to determine the predictors of proximal BMC of met5. Relative loading during stance phase from all 5 metatarsal regions of the sport-related tasks and barefoot walking were included as independent predictor variables as well as sport type. The relative loading of the met5 region during sport-related tasks was significantly predictive of proximal met5 BMC ( $R^2=0.426$ ,  $p<0.001$ ); with a secondary predictor of met5 loading during barefoot walking ( $R^2_{\text{change}}=0.055$ ,  $p=0.027$ ;  $R^2_{\text{Total}}=0.482$ , Adjusted  $R^2=0.460$ ,  $SEE=0.434$ ; Figure 3).

**Figure 3:** Proximal met5 BMC and relative in-shoe loading during sport-related tasks.

Differences in proximal met5 BMC and in-shoe plantar loading of met5 were determined among the three different sport groups using an analysis of variance (ANOVA) with a Bonferroni correction. A main effect for sport group was found in the proximal met5 BMC ( $p<0.001$ ) (basketball:  $2.10\pm0.70\text{g}$ , soccer:  $1.38\pm0.32\text{g}$ , runners:  $1.73\pm0.40\text{g}$ ). However, when controlling for potential covariates (ANCOVA: age, height, mass) the main effect of sport in met5 BMC was not significantly different ( $p=0.14$ ). A main effect was found for relative in-shoe loading of met5 during sport-related tasks when controlling for age, height and mass ( $p<0.001$ ). Specifically, higher met5 in-shoe loading was found in the basketball sport-

related task compared to the soccer sport-related task ( $p=0.002$ ) and running compared to soccer ( $p<0.001$ ) (basketball:  $12.2\pm3.9\%$ , soccer:  $6.0\pm2.3\%$ , runners:  $10.2\pm1.8\%$ ; Figure 4).

**Figure 4:** Relative load of the met5 region during sport-related tasks and barefoot walking.  $*p<0.05$

Plantar loading of met5 during sport-related tasks was a better independent predictor ( $R=0.653$ ) of met5 BMC than plantar loading during barefoot walking ( $R=0.360$ ). Furthermore, tasks more specific to basketball players resulted in higher loading of met5 than those specific to soccer players or runners, possibly relating to higher BMC in that region. The results of this study imply not only does loading of the foot help explain BMC, but the type and location of loading may be important.

## CONCLUSIONS

The results should be cautiously interpreted due to the cross-sectional nature of the study design. However, bone appears to adapt to site specific in-shoe loading during sport-related tasks. Furthermore, this is highlighted in basketball players that appear to load the met5 region more which may increase the risk of proximal met5 fracture if the loading exceeds the threshold dependent strength of the bone which may occur with extreme changes in training.

# ASSESSING FRACTURE SEVERITY IN THE TMJ: CAN FRACTURE ENERGY BE COMPUTED USING CBCT?

Kevin N. Dibbern, Kyungsup Shin, Megan Andrew, and Donald D. Anderson

The University of Iowa, Iowa City, IA, USA

email: kevin-dibbern@uiowa.edu, web: <https://uiowa.edu/uiobl/>

## INTRODUCTION

Assessing injury severity is a critical step in treating articular fractures, with important implications in both clinical and surgical decision making. One of the treatment goals is to forestall the development of post-traumatic osteoarthritis (PTOA). This is of particular concern in temporomandibular fractures, as the etiology of temporomandibular joint (TMJ) arthritis is not well understood [1]. Fracture energy has been utilized previously as an objective method for assessing fracture severity in the lower extremities and predicting PTOA risk [2].

Prior assessments of fracture energy have relied upon a standard CT scan, with its calibrated Hounsfield Unit (HU) values, to estimate location-specific bone density. Most TMJ fractures at our institution are scanned instead utilizing a Cone Beam CT (CBCT) system. CBCT systems acquire scans in a fundamentally different manner and do not obtain the same uniform image reconstructions. Therefore, they do not directly provide calibrated HUs with which to estimate bone density. Fortunately, Reeves et al. previously established a linear relationship between HU values and the grey-level intensities derived from CBCT machines [3]. This study aims to determine if automatic HU correction built into a CBCT system enables reliable fracture energy computation.

## METHODS

Fracture energies were computed on a sample of convenience – the first 2 standard CT and 5 CBCT scans to come available after having been acquired to evaluate a TMJ fracture. Patients were consented and enrolled in this IRB approved study. The standard CT scans were performed using a Siemens Somatom Definition AS+ while the CBCT scans were performed in a Xoran Technologies scanner

that automatically applies a rescaling factor to approximate HU intensity values.

The fracture energy computation involves scaling interfragmentary surface area by location-specific densities of the fractured bone. To obtain the interfragmentary surfaces of the bone, the CT scan data are segmented to provide 3D surface models of the fracture fragments. The interfragmentary surfaces are then identified using an automated classifier (Fig. 1) [4]. The location-specific density of the interfragmentary surface is derived directly from the HU values in the CT scans. Finally, the fracture energy is computed by summing the product of the local bone density and an empirically derived fracture energy release rate, which is a function of the bone density.

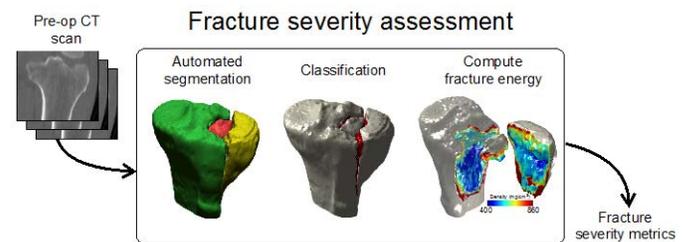

Figure 1. Methods for computing fracture severity.

Fracture energies were computed for all of the fractures, and the fracture energy values were then compared between cases for which standard and CB CT scans were acquired. Additionally, as the interfragmentary surface area is independent of the CT scanner, the average fracture energy release rates for the standard and CB CT scans were directly compared.

## RESULTS AND DISCUSSION

The average fracture energy from the two standard CT scans was  $11.0 \pm 5.5$  J, while the average fracture energy for the five CBCT scans was  $4.8 \pm 1.1$ . These data suggest a large difference between the fracture energies calculated from standard CT vs. CBCT (Fig. 2). However, controlling for area by examining the energy release rates directly, there was no significant difference observed between the different scanner types. The average energy release rate was  $3.31 \pm 0.15$  mJ/mm<sup>2</sup> for the standard CT scans and  $3.42 \pm 0.24$  mJ/mm<sup>2</sup> for CBCT. Therefore, the average energy release rates demonstrated that perceived differences in fracture energy values obtained from the different CT scanners were more attributable to underlying differences in the injuries studied. This observation is further supported by an examination of disparate fractures analyzed using the CBCT scan vs. that of the standard CT (Fig. 3).

## CONCLUSIONS

The automatic rescaling factor by the Xoran Technology's CBCT scans of temporomandibular fractures at our institution produced similar fracture energy release rates when compared to normal

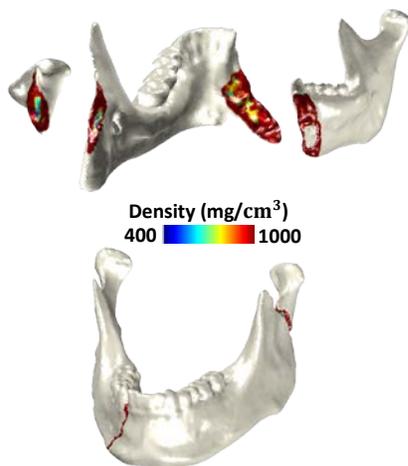

medical CT scans. This indicates that CBCT scans with a HU intensity correction can be utilized to evaluate fracture energy. Fracture energies calculated in this manner have the potential to objectively predict PTOA development in the TMJ with standard of care CBCT scans at our institution.

## INTRODUCTION

Tibial stress fracture (TSF) is common in both running and military populations [1, 2]. Elevated levels of tibial bone stress, which is influenced by both bone geometry and bone loads, has been observed during running in individuals with a history of TSF [3]. Regardless of sex, TSF is more common in individuals with smaller bone geometries [2, 4]. Specific gait dynamics have also been linked with TSF [5, 6]. Together, smaller bone geometry and greater dynamic loads may explain reports of elevated bone stress in runners with a history of TSF [3]. However, the relationship between TSF-related bone structure, running dynamics and tibial stress has not been explicitly examined. Understanding factors that directly contribute to stress applied to the tibia during running may better guide interventions. As a first step to this, we evaluated the relationship between both structural and dynamic biomechanical factors associated with TSF and distal tibial bone stress during running.

## METHODS

20 female runners (25.2±3.3 yrs; 168.1±6.2 cm; 57±9.3 kg; 32.8±18.5 km/wk; 2.82 m/s preferred pace) and 20 male runners (24.9±4.4 yrs; 181.3±6.1 cm; 80.1±8.4 kg; 14.6±7.6 mi/wk; 2.97 m/s preferred pace) participated in this study. All participants were currently free of injury. During an 8-minute progressive warm up and accommodation period on an instrumented treadmill (Bertec, Worthington, OH), each participant's self-selected running speed was determined. Self-selected running speed was operationally defined as the pace utilized during a standard, endurance-paced training run. Once determined, biomechanical data were collected for 15 sec. Kinematic data (Qualysis, Gothenburg,

SWE) and force plate data were sampled at 200 Hz and 1000 Hz, respectively, using a real-time data acquisition system (Innovative Sports, Inc., Chicago, Ill). Marker trajectory and ground reaction force data were filtered with a 4th order, zero lag low-pass Butterworth filter with a 15 Hz cutoff and exported for analyses. 10 stance phases were extracted for analysis. To develop subject-specific bone models, participants then underwent MR imaging of their right tibia (Philips Achieva 1.5T, Best, NLD). The MRI axial slice corresponding to the distal 1/3 location, a common site of TSF [1] was extracted for analysis. A cross-sectional finite element mesh, represented by 600 elements, was created using VA-Batts software [7].

For 10 stance phases, 3D kinematics and kinematics were input to a musculoskeletal model that estimated 3D internal tibia forces and moments at a level corresponding to the distal 1/3 tibia. Internal bone forces and moments at this site were estimated at each 1% of stance and served as inputs to a cross-sectional finite element model. VA-Batts software was used to obtain normal and shear stresses across the stance phase in each element of the bone mesh [8]. Peak normal and shear stresses during the stance phase of running of each trial were extracted and averaged for statistical analysis.

Tibial cross sectional area (CSA), maximum and minimum moment of inertia ( $I_{max}$  and  $I_{min}$ ), and polar moment of inertia (J) have been associated with TSF [2, 4]. These bone geometries were obtained via the VA-Batts software and served as structural inputs for regression analyses. Based on the TSF literature [5, 6], the following running related factors were extracted for analysis to serve as dynamic inputs to the regression analyses: peak hip adduction (HADD), knee adduction (KADD and internal

rotation (KIR), rearfoot eversion (RFEV), instantaneous loading rate of the vertical ground reaction force (VLR), and tibial frontal plane angle at peak vertical ground reaction force (TFA).

For each directional component of bone stress, linear regression analyses were performed to identify key structural and dynamic indicators of peak bone stress (IBM SPSS Statistics 22, Armonk, NY). Co-linearity among predictors was assessed during each iteration of analysis. When the variance inflation factor exceeded 5, one or more of the violating predictors was removed from the regression model. The proportion of the variation in dependent variables explained by independent variables was then adjusted based on the number of independent variables in the model (Adjusted R<sup>2</sup>).

## RESULTS AND DISCUSSION

Peak compression (-201.0±98.3 MPa) occurred posterior-medially, tension (145.9±84.5 MPa) anterior-laterally and shear (21.7±7.8 MPa) medially during mid stance. The most meaningful combination of factors acting together to increase posterior-medial tibial compression were CSA, KADD, VLR, and REV (R<sup>2</sup>=.47, p<.001). For tension, KADD, REV, HADD and VLR were most strongly associated with bone stress (R<sup>2</sup>=.55, p<.001). A combination of bone structure (I<sub>min</sub>) and dynamics (KADD; R<sup>2</sup>=.40, p <.001) best predicted shear stress.

Bone structural characteristics and dynamic biomechanical factors associated with TSF in previous studies of injured populations appear to act in concert to increase distal tibial bone stress during running. Although, a fair portion of bone stress variance remains unexplained. Smaller CSA combined with higher vertical loading rates, knee adduction and reduced rearfoot eversion appear to contribute to higher compressive stress. Tension increased with hip and knee adduction and reduced rearfoot eversion. Like compression, shear was influenced by bone geometry and dynamics. Low bending strength along the narrowest aspect of the

tibia combined with knee adduction resulted in increased shear stress.

Bone stress appeared to be consistently related to frontal plane motion of the lower extremity and loading. Frontal plane motion of the lower extremity during running has been linked to the free moment [8] potentially influencing tibial bending and torsional angles [9]. The free moment has been associated with TSF [5] but was not examined here due to methodological constraints with use of an instrumented force treadmill. Other limitations include assumptions inherent to musculoskeletal modeling and lack of stratification by sex. Future work will examine sex-specific associations as well as associations runners with recent TSF.

## CONCLUSIONS

Overall, this analysis suggests a combination of bone structure and running dynamics contribute to elevated bone stress. Individuals with small bone geometry, excessive frontal plane running mechanics and high loading rates were more likely to experience elevated tibial stress during running. Interventions to address frontal plane running mechanics and loading rates as well as to increase bone size through targeted exercise programs may be beneficial in reducing risk of TSF.

## INTRODUCTION

As our population ages, the incidence of osteoporosis and osteoporosis-related fractures increases along with the associated costs and challenges to our health care system. Hip fractures are associated with high medical costs and decreased quality of life following fracture [1].

Currently, the best tool available for predicting risk of hip fracture is a dual x-ray absorptiometry (DXA) scan to calculate bone mineral density (BMD) of the whole body, spine, and hip regions [1]. While this measure gives a general measure of fracture risk, the sensitivity of the imaging to differences in bone sizes and subtle changes in bone structure is low. One study recently suggested that the addition of more specific femoral BMD measures to standard DXA derived BMD provided an improved capacity to predict femoral fractures [2].

Various forms of computed tomography (CT) can assess these more bone-specific BMD measures, and improve upon the sensitivity of DXA-derived measures. However, assessing the BMD at the femoral neck and head exposes the patient to a large amount of radiation. Peripheral quantitative CT (pQCT) offers the best compromise between image clarity and minimal radiation. The pQCT can achieve an image clear enough to distinguish the cortical and trabecular bone compartments, however it is a quick scan and performed on peripheral bone sites, such as the distal tibia or radius, which will be less affected by radiation compared to the more central bone sites [2].

The purpose of this study is to assess the predictive strength of distal bone measures for replacing

femoral BMD values in predicting hip fracture risk. We hypothesize that a regression model using the distal radius and tibia measures derived from pQCT will be able to predict specific BMD of each bone compartment at the femoral head and neck.

## METHODS

The bones from seven cadavers were dissected and used for this study. All available sets of femora, radii, and tibia were dissected and scanned using a Stratec XCT3000 pQCT scanner (Remeda, Zurich, Switzerland). Radial and tibial scans were taken at clinically standardized locations at the distal end calculated as a percentage of total length (33% and 4% respectively). The femoral head, neck, and greater trochanter were scanned along the direction of the femoral neck. The femoral head was defined as the distal most portion with the largest diameter, the neck was the narrowest diameter, and the trochanter was identified as the region where the trochanteric protuberance was greatest along the axis of the femoral neck.

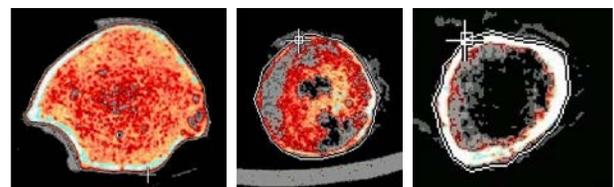

Figure 1: Representative scans of the distal 4% scan of the tibia, femoral head, and femoral neck, respectively.

The scanner software was used to calculate all parameters of interest for each bone after semi-automatic bone contouring to distinguish cortical and trabecular compartments (Figure 1). For the radius, the cross-sectional moment of inertia ( $R\_xMOI$ ), polar moment of inertia ( $R\_pMOI$ ) and

orthogonal sectional stress-strain indices (R\_XSSSI, R\_YSSSI), total bone mineral content (R\_totBMC), total BMD (R\_totBMD), and trabecular BMD (R\_tBMD) were calculated. For the tibia, similar parameters were calculated (T\_XSSSI, T\_YSSSI, T\_totBMD). For the femur the BMD at the trochanteric region and neck region were calculated (F\_BMD.t and F\_BMD.n). In addition, the trabecular BMD was calculated at the trochanteric, neck, and head regions (F\_tBMD.t, F\_tBMD.n, F\_tBMD.h). Each femoral parameter chosen has been previously shown to be predictive of femoral neck fractures [3-4].

Regression models were generated for each femoral parameter using backward stepwise regression analysis (entry  $p < 0.05$ , removal  $p < 0.1$ ).

## RESULTS AND DISCUSSION

The seven cadavers (4 male, 3 female) had an average age of  $78.4 \pm 7.3$  yrs, height of  $1.64 \pm 0.12$  m, and mass of  $71.2 \pm 26.6$  kg. A wide range of causes of death were present, including vascular, renal, pulmonary, and immune related illnesses.

A combination of parameters from both tibia and radius resulted in the best prediction of most femoral parameters (Table 1). Only F\_BMD.t incorporated only one tibial parameter, T\_XSSSI. Indicating the likelihood that trochanteric fractures are more related to the bone structure inferred by another weight bearing bone than by any other factor. All other predictive models included both mechanical strength indicators such as the moment of inertia or stress-strain index and compositional parameters such as BMD or BMC. Interestingly, only F\_tBMD.t required a trabecular bone predictor

(R\_tBMD), otherwise all other predictions were sufficient with total BMD or BMC. These results agree with the existing predictive models relating tibial [2] and radial [5] parameters separately with femoral parameters.

The findings from this study provide evidence that a combination of imaging parameters can be used to predict specific femoral BMD at various fracture-prone sites. In combination with standard DXA-derived BMD the additional knowledge provided by these specific femoral BMD values provides a more complete prediction of hip fracture. The additional information provided in the present study may allow investigators to bypass the challenging process of obtaining femoral-specific BMDs. These pQCT measures can be attained easily from a distal bone site using a small, lower-cost imaging option, which exposes the patient to less radiation than other conventional measures.

## CONCLUSIONS

pQCT of distal bone sites may be used to supplement conventional DXA to provide an improved potential for osteoporotic fracture risk prediction.

## INTRODUCTION

Injury risk functions and biofidelity corridors for the human mandible are critical for the evaluation of maxillofacial protection devices that are under development. Currently the mandible is the only facial bone without any injury criterion for use with the Facial and Ocular Countermeasures Safety (FOCUS) headform. Previous attempts to develop an injury criterion for anterior-posterior (A-P) impacts to the mandible have been unsuccessful due to the mandible opening when impacted [1]. In order to investigate the fracture tolerance of the mandible to A-P impact and determine a mandible injury criterion for the FOCUS headform, a closed jaw boundary condition was needed to mitigate the previous limitation. Additionally, the proposed condition would be representative of a helmeted population (military, athletics, etc.), where movement of the mandible is restricted by headgear.

## METHODS

A restraint fixture was designed to prevent the jaw from opening during blunt impacts using a Monorail Drop Tower (MDT). The restraint consisted of an angled ridge aluminum plate (2.5 cm wide, 15.2 cm long) with beveled edges positioned against the body of the mandible. The aluminum plate was connected to a six degree of freedom load cell (Humanetics) and braced against the MDT (Fig. 1). The load cell was used to measure any forces transferred through the mandible into the restraint fixture and allowed for the angle of the aluminum plate to be adjusted. The entire restraint fixture was designed to be adjustable in the vertical and

horizontal directions, allowing the aluminum plate to be aligned with the mandible of the specimen.

**Figure 1:** (A) Restraint fixture attached to MDT. (B) Experimental test setup with restraint fixture aligned with the mandible.

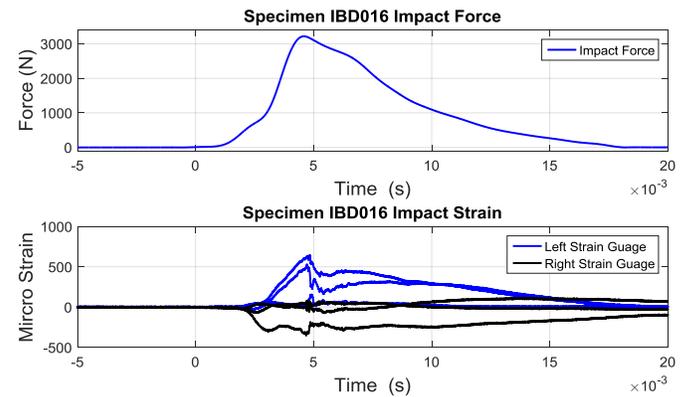

Two fresh-frozen male cadaveric heads (IBD012, 67 yrs; IBD016, 69 yrs) were used to assess proof of concept in accordance with the Army Policy for Use of Human Cadavers [2]. Each specimen was sectioned between the C2 and C3 vertebrae to keep the foramen magnum from being exposed. Extraneous tissue was removed. The specimen was potted in a polyurethane resin (Golden West Manufacturing) using screws and polymethylmethacrylate. To align the specimen while potting, the Frankfurt plane was identified by the exterior auditory meatus and the infraorbital foramen and oriented vertically, ensuring reproducibility and a natural position of the head. The mandible of each specimen was instrumented at both rami with strain gauges and acoustic emission sensors to assist with fracture detection. The specimen's jaw was exercised by hand before being closed with a 10 N force using the restraint fixture. Impacts were performed at 5 J increments until

fracture was detected using a guided impactor mass with a circular 6.45 cm<sup>2</sup> impact area. After each test, the presence of fractures was detected using specimen mounted sensors, x-ray imaging, and palpation. Additionally, 5 J baseline impacts were conducted to aid in fracture detection. The presence of a fracture was verified using a computed tomography (CT) scan and then the dissection of the mandible. During each test, impact velocity was recorded using a velocimeter (GHI Systems). Impact force and acceleration were measured using a load cell (Honeywell, NJ) and accelerometer (Endevco) on the impactor mass. Force transmitted through the specimen to the base of the MDT was measured using a load cell (Humanetics). Data were collected at 1 MHz using a Synergy Data Acquisition System (Hi-Techniques Inc.) and analyzed using MATLAB (MathWorks) scripts. All data were filtered using a 4<sup>th</sup> order low-pass Butterworth filter with a 500 Hz cutoff frequency. High-speed video was collected for all tests using a MIRO and a Phantom v9 (Vision Research Inc.) camera at 2,000 frames per second.

## RESULTS AND DISCUSSION

A total of sixteen impacts were conducted on the two specimens. The tested impact energies ranged from 4.6 J to 22.4 J. Test velocities ranged from 1.7 m/s to 3.4 m/s. Fracture was observed in the strain data collected (Figure 2) during testing. Post-test CT imaging and dissection confirmed the presence of fractures in both specimens. Specimen IBD012 had a subcondylar non-displaced transverse linear fracture on the left side of the mandible. Specimen IBD016 had a commuted transverse liner fracture of the right mandible condyle. Fracture patterns were consistent with those reported in the literature [2]. Measured impact peak force (Table 1) for both fracture cases compared well with fractures produced during previous work examining A-P

mandible impacts [3] and mandible impacts directed through the temporomandibular joint [4].

**Figure 2:** Impact force and strain recorded for specimen IBD016.

## CONCLUSIONS

A method has been developed that is able to reliably allow for the creation of mandible fractures during A-P impacts. Future investigation of mandible impact biomechanics will focus on evaluation of mandible fracture tolerance and the development of an injury criterion for the FOCUS headform.

## INTRODUCTION

Bone can be described as a multi-level composite arranged in a hierarchical form. At the macrostructure scale, bone is grouped into two types: cortical bone (also known as compact bone or dense bone) and trabecular bone (known as cancellous bone or spongy bone) [1]. Generally, cortical bone surrounds trabecular bone. While cortical bone has a porosity of five to fifteen percent, trabecular bone has a porosity that varies from forty to more than ninety percent [1]. Because cortical bone has low porosity, continuum based finite element methods have been used for most FE modelling. Similarly, homogenized continuum methods have been used for trabecular bone. Recent FE approaches have meshed the trabecular architecture (i.e., non-homogenized) using continuum elements, however, these meshes are difficult to produce, may require detail CT or MRI imaging, and are costly to solve. The proposed paper studies a representation of the trabecular micro-architecture using beam elements. The proposed approach may permit lower meshing and computational cost while capturing the behavior sought with detailed trabecular models. Further, the proposed approach readily admits stochastic analysis incorporating both porosity level and other inputs and model outputs. The FE models in this work will be compared to published biomechanical experiments and cadaver studies [2].

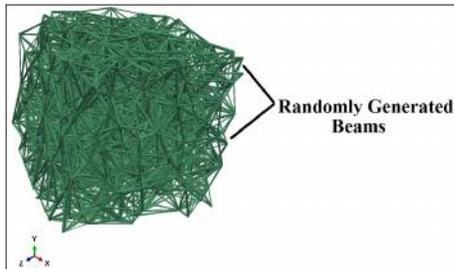

## METHODS

Trabecular bone consists of a three-dimensional network structure mainly composed of rod-shaped and plate-shaped fundamental units named “trabeculae.” In this work, the trabeculae were

modelled as beam elements. Two methods were investigated using differing assumptions. The first method assumed repetition of beam elements arranged as hexagonal unit-cells (henceforth, Hexagonal Network Model or HNM) over a cubic trabecular bone specimen with 4 mm sides. The second method assumed randomly oriented beams (henceforth, Random Beam Method or RBM) also within a 4 mm cube. The cross section of the beams for the hexagonal network method was defined as a circular shape with a 0.1 mm radius. For the random beam method, beams were created algorithmically so that beam properties could be applied stochastically, Fig. (1). The algorithm is general to apply a stochastic approach to all beam properties. However, in this article, stochastic properties included length and orientation while the cross section was assumed to be a circular shape with a 0.025 mm radius. For both methods, the beam element type was a 2-node linear beam element (B31). Abaqus (V. 6.14, Simulia Ltd) was used as an FE solver.

Boundary conditions were applied on the beam structure using multi-point constraints (MPCs). These constraints were placed on two parallel faces of the cubic structure. The MPCs rigidly connected the nodes of the face to a control node. All degrees of freedom were fixed for one control node and a concentrated force load was applied on the opposite face’s control node. Apparent stress was calculated by dividing the applied force by the apparent area of the relevant face. Apparent strain was obtained by calculating the ratio of resulting displacement of the moving control node to the distance between the control nodes (i.e., change in length over length), Fig (1). Apparent moduli were computed from apparent stress and apparent strain. Apparent

densities were calculated by obtaining the ratio of the beams' mass to the volume of the unit cube. The models' materials were assumed orthotropic for the purpose of material property extraction and three moduli (representing an orthogonal set of normal-normal stress-strain relationships) were extracted.

**Figure 1:** Trabecular bone (representative model).

## RESULTS AND DISCUSSION

The Individual FE models created in this study exhibited the mechanical properties listed in Table (1). Each model demonstrated effective moduli within published ranges of trabecular bone [3]. For the HNM, the three apparent moduli varied by hundreds of megapascals as is consistent with the directionality of the unit cell beam orientations. Apparent  $E_{xx}$  and  $E_{yy}$  in the RBM were similar in value as is consistent with the random nature of the beam orientations. The apparent densities of the current models are also within the published ranges [1, 3]. In the present work, the apparent density of the HMN model is slightly greater than that of the RBM model. In a fully random stochastic model with a sufficient number of randomly oriented beams, the effective moduli should produce approximately isotropic effective properties. In models with a finite number of beam elements randomly oriented, the effective moduli will not be isotropic but will not have predictable preferred directions. Trabecular bone has been reported to be

anisotropic material with preferred directions in line with mechanical loads [3]. Such anisotropy can be introduced into the stochastic model by controlling the parameters such that they are not fully random. Rather, they should follow some stochastic process with a distribution of properties that resulting in anisotropy. For example, the beam elements can have a distribution of orientations centered on a preferred orientation. The apparent densities of the FE models are dependent on the number of beams and on their cross sections which were dissimilar between the models. Future models will emphasize cross sections and lengths that are consistent with the nominal (and stochastic) geometry of physical trabecular architecture.

## CONCLUSIONS

The stochastically driven beam element approach may prove useful for efficiently modeling trabecular bone, structural open cell foams, grid stiffened core composites, and other structures. The need for efficiencies in meshing and computation are particularly relevant for current areas of interest to the composites and medical communities including the modeling of mechanical fasteners and bonding, damage evolution, and the modeling of aging. The proposed paper may provide a detailed description of the methodology in future research.

## INTRODUCTION

Impairments of the arm and hand are the most common disability post-stroke [1]. These impairments are related to a loss of descending corticofugal neural tracts that cause motor impairments (weakness, hypertonicity, and loss of independent joint control). In addition to these motor impairments, secondary musculoskeletal changes may result in increased passive joint stiffness [2].

Increases in stiffness at the hand, as seen about the elbow and ankle [3, 4], could make hand opening and function exceedingly difficult, yet there are no studies showing how passive joint stiffness changes at the hand of individuals with chronic hemiparetic stroke.

Therefore we aim to determine how the passive stiffness of the structures about the fingers alter post-stroke to aid in the development of targeted interventions that may prevent its development.

## METHODS

Passive torques about the 4 MCP joints were quantified in the paretic and nonparetic hand of 9 subjects ( $\mu=64.3\pm 7.9$  yrs old,  $\mu=13.2\pm 8.0$  yrs post-stroke) with moderate hand impairments based on their Chedoke-McMaster Stroke Assessment hand scores (CMSA-HS 4-5,  $n=9$ ).

Due to hypertonicity of the paretic muscles, torques were quantified while the subjects were in a sleep or near sleep state using a custom built device (Fig. 1). Additionally, EMGs were continuously monitored to ensure no muscle activity. The torques about the

MCP joints were collected throughout the MCP ( $\theta$ ) joint's range of motion in static 15 degree increments at 9 randomized wrist postures ( $\omega$ ) from 60° flexion to 60° extension in 15 degree increments.

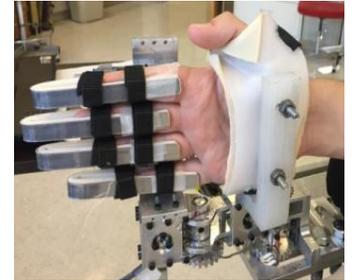

The PIP & DIP joints were splinted to prevent distal movements. Measured MCP torques were normalized to forearm volume. Forearm volume was estimated as the volume of a conical cylinder measured by the length of the forearm, wrist circumference, and largest circumference of the forearm.

For each subject the normalized torque data throughout all wrist and MCP postures were fit to an exponential analytical model [5]:

$$T_t(\theta, \omega) = T_{sj}(\theta) + T_e(\theta, \omega)$$

The model is comprised of two components. The first component consists of the torques contributed by the single-joint structures,  $T_{sj}(\theta)$ , (intrinsic muscles, skin, ligaments, joint capsules, etc.) assumed to be a function of MCP joint posture only. The other component contributed by the extrinsic finger muscles,  $T_e(\theta, \omega)$ , is a function of both MCP and wrist posture.

Stiffness was calculated as the derivative of the analytical model. Significant differences between the stiffness of the paretic and non-paretic hands for each impairment level were analyzed using a linear-mixed model analysis.

**Figure 1:** Image of the device and splinted fingers

## RESULTS AND DISCUSSION

We found significant differences ( $p=2.17e-4$ ) in the total, normalized, MCP joint stiffness between the paretic and non-paretic hands across all wrist angles using a linear mixed model analysis (Fig 2a-c). However, contrary to previous studies that report up to 200% increases in ankle and elbow stiffness in the paretic vs. nonparetic limb following stroke, we observed relatively small increases in total MCP joint stiffness between limbs. The most notable increases were observed when the wrist was fully extended (Fig 2a). At neutral and flexed wrist postures, changes in stiffness were limited, with a maximum increase of 40% near the limits of MCP extension (Fig 2b&c). We expect the clinical significance of these changes is relatively small, given the active strength deficits we measured in the same paretic hands, were as large as 75%.

Neither the single joint structures nor extrinsic finger muscles demonstrated significant changes when analyzed using a linear mixed model analysis (Fig 2d-f). Only the stiffness of the extrinsic muscles in an extended wrist posture demonstrated a trend towards small increases in stiffness (Fig 2e).

## CONCLUSIONS

Potential increases in the stiffness of the hand post stroke could make hand opening and function

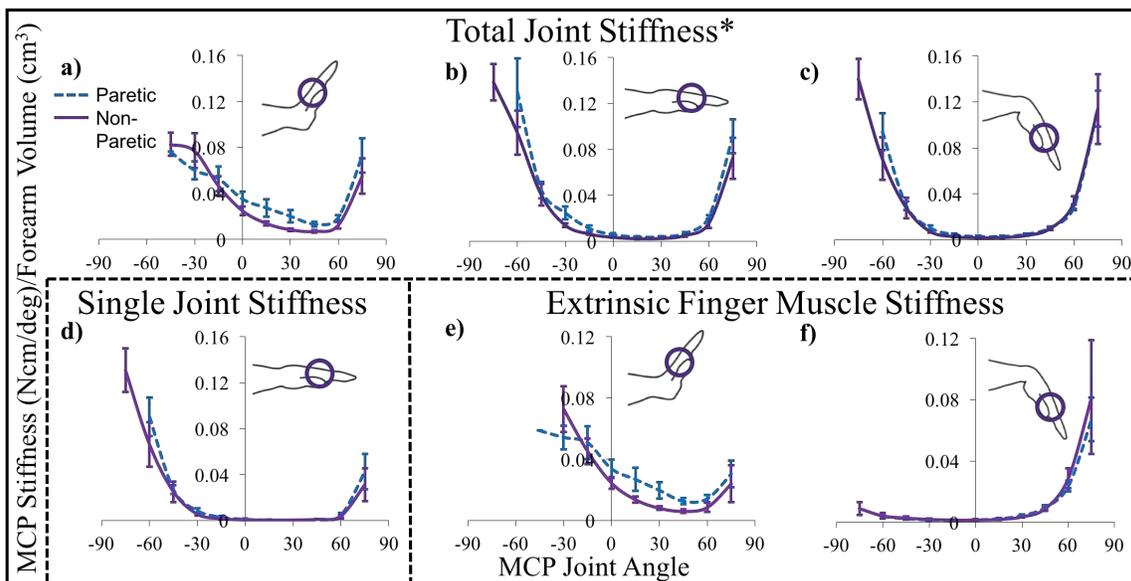

exceedingly difficult. Yet, prior to this study there were no studies showing how passive joint stiffness changes in chronic stroke individuals. We found that there were significant changes in total joint stiffness but these changes were relatively small and most prominent near limits of wrist or MCP ranges of motion. These results indicate that impairments of the hand in individuals with chronic hemiparetic stroke are not likely related to altered passive stiffness of the musculoskeletal structures within the hand. The impairments observed are more possibly due to impaired involuntary neural drive and resulting hypertonicity. These finding indicate that future rehabilitation interventions of the hand should focus on decreasing the effects of hypertonicity while facilitating voluntary neural motor control.

# A NOVEL TEMPERATURE CONTROLLED WHEELCHAIR CUSHION FOR PRESSURE ULCER PREVENTION

Ali Ersen, En-Szu Liao, Linda Adams, Mike Richardson, Myla Quiben and Metin Yavuz

University of North Texas Health Science Center, Fort Worth, TX, USA  
email: [metin.yavuz@unthsc.edu](mailto:metin.yavuz@unthsc.edu) , <https://sites.google.com/site/dryavuzlab/>

## INTRODUCTION

For many wheelchair users, the combination of reduced mobility and impaired sensation, including but not limited to neurological insults, vascular issues, decreased cognition, and morbid obesity, results in a life-time risk of pressure ulcer development. Pressure ulcers are a type of wound that results from a breakdown of tissue over bony prominences due to localized ischemia caused by constant pressure. The compromised blood circulation along with reduced airflow results in an accumulation of heat in the tissue over the bony prominence which accelerates the tissue breakdown. Using an animal model under constant vertical loading, researchers have shown that higher temperatures amplified the tissue damage caused by mechanical strain and limited blood circulation [1]. Contemporary wheelchair cushions usually employ thick foam type materials, which provide a higher quality of pressure distribution [2] but poor heat dissipation.

In this study, we designed and tested a custom-built cushion that circulates chilled water. Effectiveness of the cushion was evaluated by measuring buttocks surface temperatures and peak pressures around the ischial tuberosity, with a targeted maximum temperature and pressure of 28°C and 60mmHg, respectively.

## METHODS

We modified a commercially available non-motorized wheelchair (Drive, 16 Medical Silver Sport 2) and equipped it with a custom built cushion that circulated chilled water (Fig.1A). We used two cooling units attached serially (one's output to other's input). A mini water pump circulated the water through the cooling units into the cushion and back to the cooling units. All elements (two cooling

units and one pump) can be operated separately via control buttons (Fig.1B).

**Figure 1:** The cooling wheelchair A) cushion, B) control buttons

All study procedures were approved by the institutional review board (IRB) prior to recruitment and testing, and informed consent was obtained from subjects prior to testing. In this ongoing proof-of-concept study, we have recruited three healthy male subjects, who did not have any physical disabilities or functional deficits. The average age was 29.7±2.1 (mean ± standard deviation). All subjects' forehead temperature was measured (36.6±0.4°C) prior to testing in order to confirm that the subject did not have an abnormal body temperature. All subjects wore standard spandex tights. The room temperature was measured as 22.9±0.1°C during the test. A thermal image of each subject's buttocks was captured using an Infrared (IR) thermal camera (Flir, T650sc). We placed thermocouple sensors (K-type) at the tissue-cushion interface and at the outlet of the cooling units, which recorded temperatures at various intervals (t=0, 1 min, 10 mins, 20 mins and 30 mins). After obtaining the baseline (t=0) and first temperature (t=1 min) recordings, we asked the subjects to actively propel the wheelchair in the hallway. At the end of active use (t=30 mins), we asked the subjects to stand up and then captured another thermal image of each subject's buttocks (post-activity). Interface pressures were acquired via a pressure mat (Tekscan, CONFORMat® 1 System) that was placed on the top of the cooling cushion.

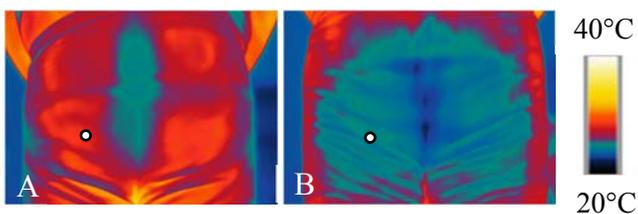

## RESULTS AND DISCUSSION

The recorded tissue-cushion interface and water temperatures from three subjects are provided in Table 1. During the active use, water temperature was maintained around  $21.7 \pm 0.3^\circ\text{C}$ . The interface temperature initially increased to  $27.1 \pm 0.4^\circ\text{C}$  from  $23.0 \pm 0.4^\circ\text{C}$ . Interface temperature dropped down to  $25.1 \pm 1^\circ\text{C}$  at  $t = 30$  minutes.

**Table 1:** Temperature values (mean $\pm$ S.D.) taken with the thermocouple over 30 minutes for  $n=3$

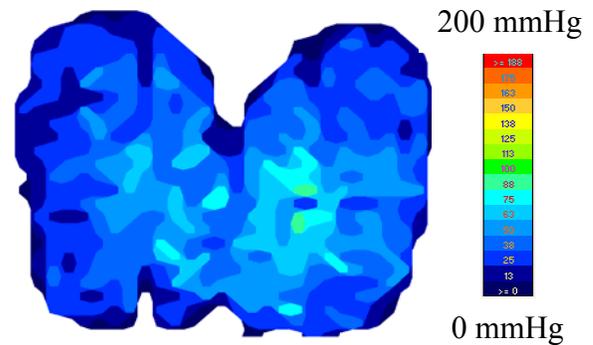

Time (min)	Tissue-cushion Temperature ( $^\circ\text{C}$ )	Water Temperature ( $^\circ\text{C}$ )
0	$23.0 \pm 0.4$	$21.8 \pm 0.4$
1	$27.1 \pm 0.4$	$21.6 \pm 0.1$
10	$26.6 \pm 1$	$21.6 \pm 0.2$
20	$26.0 \pm 1$	$21.7 \pm 0.1$
30	$25.1 \pm 1$	$21.6 \pm 0.5$

These temperature values were confirmed with the IR thermal camera images. Baseline and post activity thermal images of a representative subject are provided in Fig.2. The temperature reduction was calculated as  $4.5^\circ\text{C}$  at the thermocouple location. At this location (white spot in Fig.2) baseline temperature was  $29.5^\circ\text{C}$  whereas post-activity temperature was  $25.0^\circ\text{C}$ . The average temperature reduction at the thermocouple location was  $4.3 \pm 0.3^\circ\text{C}$  in three subjects.

**Figure 2:** Representative thermal images taken by an IR thermal camera, A) baseline (prior to sitting), B) post activity. White spots indicate the location of thermocouple sensors. (Colored scale bar= 20 to  $40^\circ\text{C}$ )

The interface pressure distribution in a representative subject is given in Fig.3. The peak pressure occurred at the right ischial tuberosity and quantified as  $100\text{mmHg}$  while the average pressure was  $39\text{mmHg}$ . The average peak pressure was  $102 \pm 5\text{mmHg}$  for three subjects.

**Figure 3:** Pressure distribution of a representative subject provided by Tekscan ConforMat. The peak pressure is detected as  $100\text{mmHg}$  while the average pressure is  $39\text{mmHg}$ . (Colored scale bar= 0 to  $200\text{mmHg}$ )

## CONCLUSIONS

The custom-built cooling cushion consistently maintained buttocks temperatures below  $28^\circ\text{C}$  in all three subjects. However, the cushion was not able to reduce peak pressures down to the desired value  $60\text{mmHg}$ . Further investigation and modification of the wheelchair cushion design are required to achieve the success criterion for peak pressure.

email: jennybagwell@creighton.edu

## INTRODUCTION

The tibial tuberosity osteotomy (TTO) with antero-medialization is a surgical procedure utilized in persons with persistent patella instability and patellofemoral pain. The surgery involves moving the tibial tuberosity antero-medially which is thought to decrease the laterally directed forces acting on the patella [1]. The anterior translation of the tibial tuberosity also increases the moment arm of the quadriceps muscles, thereby potentially decreasing the knee extensor demand and the patellofemoral joint compressive forces. Although good clinical outcomes have been reported with this surgery [2], the influence of this procedure on patella cartilage loading remains unclear. The purpose of this study was to assess the influence of the TTO procedure on lateral patella and femur cartilage hydrostatic pressure using finite element analysis.

## METHODS

A 3D finite element (FE) model of the knee joint was developed from a healthy female participant (24 years of age). Subject-specific input parameters included 1) patellofemoral joint (PFJ) geometry, 2) weight bearing PFJ kinematics, and 3) quadriceps muscle forces. Subject-specific PFJ geometry and morphology, weight-bearing PFJ alignment, and quadriceps muscle morphology were obtained from magnetic resonance imaging. Lower extremity biomechanics data (kinematics, kinetics, and EMG) were collected during a squatting task (15° of knee flexion).

Detailed descriptions of subject-specific inputs for the FE model have been described in previous publications [3]. The patellar tendon was modeled as

homogeneous elastic and transversely isotropic using tetrahedral continuum elements. Elastic constants for patellar tendon were determined based on the data obtained by Rawson et al [4].

The FE model was modified to simulate the TTO procedure. Specifically, the tibial tuberosity was moved 5 mm medially and 10 mm anteriorly. To account for the change in the quadriceps muscle moment arm associated with the anterior translation of the tibial tuberosity, the new moment arm was estimated and was utilized to determine the modified quadriceps muscle forces used as input in the TTO model. Three models (initial, TTO, and TTO with modified forces) were run using Abaqus software (Fig. 1 and Fig. 2).

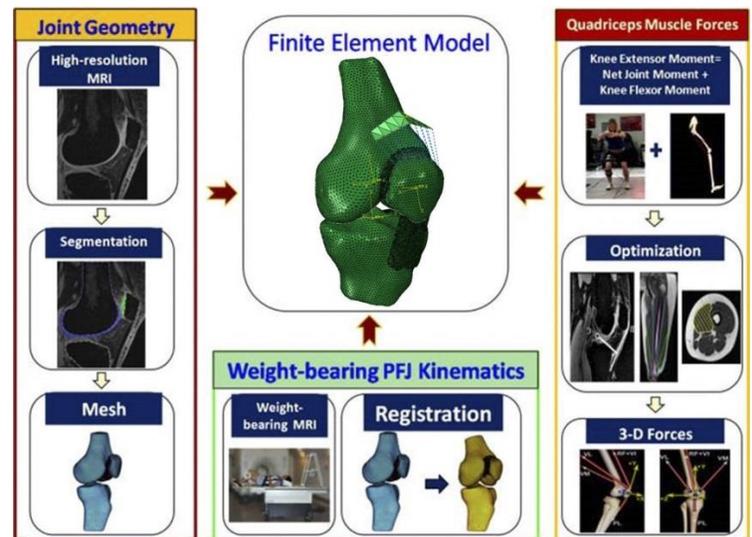

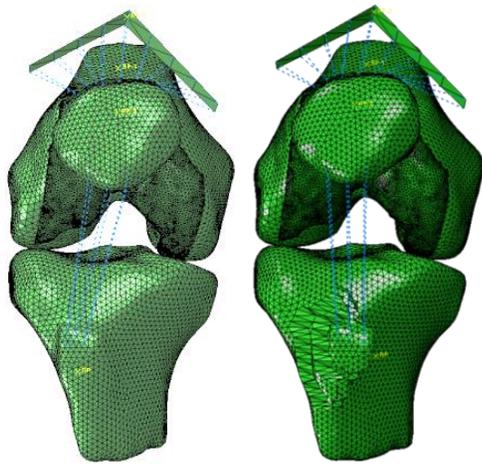

Figure 1: 3D subject-specific finite element model framework.

Mean von Mises stress at the lateral patella and femur chondro-osseous interfaces were the primary variables of interest.

**Figure 2:** Finite element model of the subject specific mesh from the initial model (left) and the tibial tuberosity osteotomy model (right)

## RESULTS AND DISCUSSION

Compared to the initial model, the TTO procedure resulted in a decrease in mean lateral von Mises stress (12% reduction at patella chondro-osseous interface (0.90 MPa vs. 0.79 MPa) and 16% at the femur chondro-osseous interface (0.63 MPa vs. 0.53 MPa) (Fig. 3)). This decrease was even greater when forces were modified to account for the altered quadriceps muscle moment arm (30% reduction at patella chondro-osseous interface (0.90 MPa vs. 0.63

MPa) and 32% reduction at the femur chondro-osseous interface (0.63 MPa vs. 0.43 MPa) (Fig. 3)).

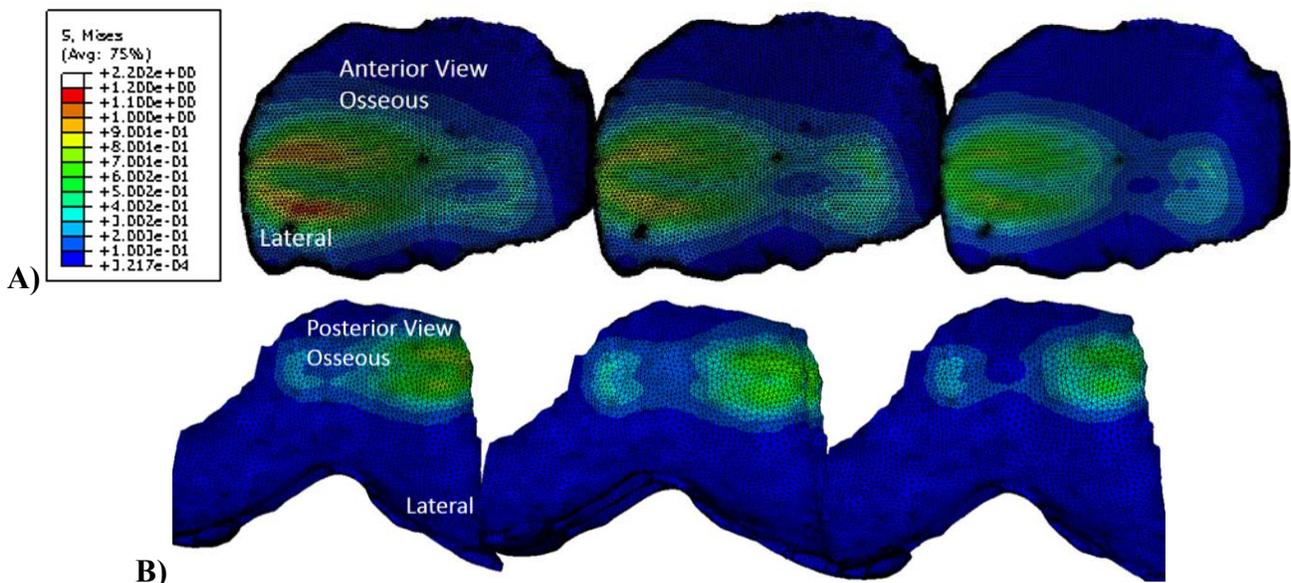

The observed decrease in lateral patella and femur stress with the TTO procedure was the result of an increase in total contact area between the patella and femur. In addition, the decreased quadriceps muscle demand secondary to an increase in the quadriceps muscle moment arm (TTO model with modified forces) contributed to a greater decrease in stress compared to the TTO model.

## CONCLUSIONS

The TTO procedure appears to be effective in reducing lateral patella and femur cartilage stress. The observed changes in cartilage stress may, in part, explain the improved clinical outcomes associated with this surgery.

# Localized Fracture Risk Under Gait Cycle Loading Correlates Poorly with High Mirels' Scores in Metastatic Lesions to the Proximal Femur

Palani Permeswaran, Benjamin J. Miller, Jessica E. Goetz  
Orthopedics Biomechanics Research Laboratory, University of Iowa, Iowa City, IA  
email: palani-permeswaran@uiowa.edu, web: <https://uiowa.edu/uiobl/>

## INTRODUCTION

While primary cancers of the bone are relatively rare and highly variable in presentation, metastatic bone disease is an unfortunate and common complication of many more frequently encountered cancers. It has been estimated that the prevalence of metastatic disease in the United States is approximately 280,000,<sup>1</sup> and treatment of metastatic disease accounts for a substantial portion of the practice of most orthopaedic oncologists. Evaluation of metastatic lesions frequently involves scoring the lesion using the scoring system developed by Mirels. In this system, a lesion is given a score of 1, 2, or 3 in the four different categories of lesion site, size of cortical involvement, lesion type, and pain. Lesions that score >8 are recommended for prophylactic stabilization to prevent pathologic fracture, and lesions scoring 7 or lower are considered unlikely to progress to fracture.<sup>2</sup>

Unfortunately, there are no clear recommendations for patients who score an 8, and the obvious subjectivity of the pain category can lead to challenging decisions to be made about the need to prophylactically stabilize a lesion. The goal of this work was to use patient specific computational modeling to determine if the stresses developing around a metastatic lesion correlated with the Mirels' score.

## METHODS

Under IRB approval, 10 patients with metastatic lesions to the proximal femur, rated >8 on the Mirels' system, were retrospectively identified. Mirels' score distribution among identified patients is as follows: 2-Mirels' 9, 2-Mirels' 10, 4-Mirels' 11, 2-Mirels' 12. Femoral geometry was obtained from the patient's CT scans and the resulting point cloud, converted to a tetrahedral element mesh aligned to the Bergmann coordinate system. CT-based material properties

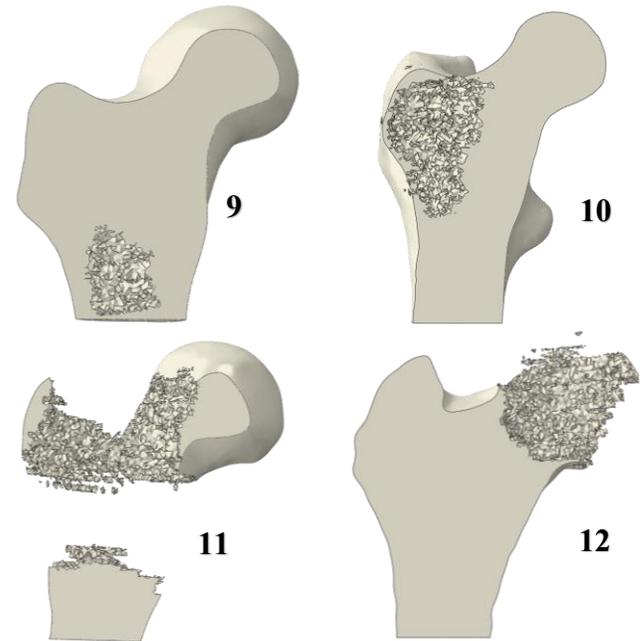

were assigned to each model and a Bergmann walking gait cycle load, applied.<sup>3</sup> Abaqus Standard finite element analysis software was used to solve the stresses for each model. Individual elemental von Mises stresses were exported for analysis at each gait step<sup>4</sup> and the ratio of the CT-based yield stress over the von Mises stress during gait was calculated on an element-by-element basis. This ratio is known as the element's factor of safety (FOS) with a value <1 indicating element failure. To determine the likelihood of localized fracture, contiguous sets of failed elements were analyzed. These sets were obtained by, first, determining the failed element at each step of gait which had the smallest FOS; this indicates the element which yielded the greatest. Adjacent failed elements were then continuously added to the set. The total volume of the contiguous failed element set was divided by the critical volume of failed elements shown to predict fracture.<sup>5</sup> This ratio represents a model's likelihood of localized fracture at each step of the gait cycle. Elements contained within the lesion were excluded from this analysis as they were seen to experience relatively small stresses during loading and fail rarely, if ever. Percentage of contiguous failed elements volume over the critical volume required for fracture was calculated and correlated with the model's Mirels' scores. Scores were assigned by the patient's orthopaedic oncologist.

## RESULTS AND DISCUSSION

Each model's percentage of critical volume failure during gait can be seen in Figures 1-A and 1-B. Several models experienced little to no fracture and are obscured from view. Little correlation is seen at any steps of gait between percentage of critical volume failure and Mirels' (Table 1). The changes in percentage of critical volume failure over the full walking gait cycle were highly variable and dependent upon progression through gait. Localized

fracture seems to occur precipitously; models either experience large amounts of localized fracture or none. This would be expected as the complicated and unpredictable nature of metastases in bone, graphically represented in Figure 3, can cause portions of the femoral head and neck best suited for carrying load during certain times during gait to be compromised in models with lower Mirels' scores but intact in models with higher Mirels' scores.

expanding the range over which the correlation can be made. However, it was clear that high Mirels' scores do not directly relate to specific mechanical risks.

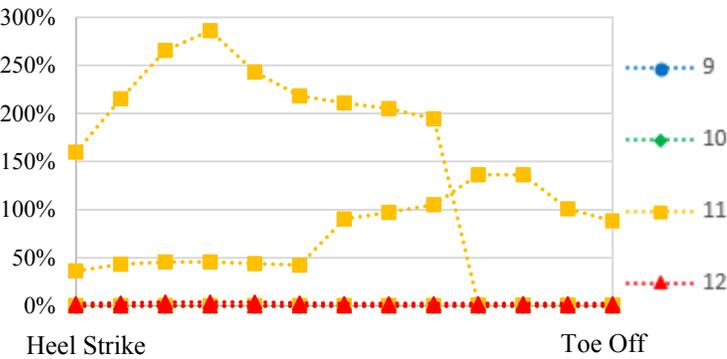

**Figure 3:** Varying Mirels' Scores Less Lesion Elements.

## CONCLUSIONS

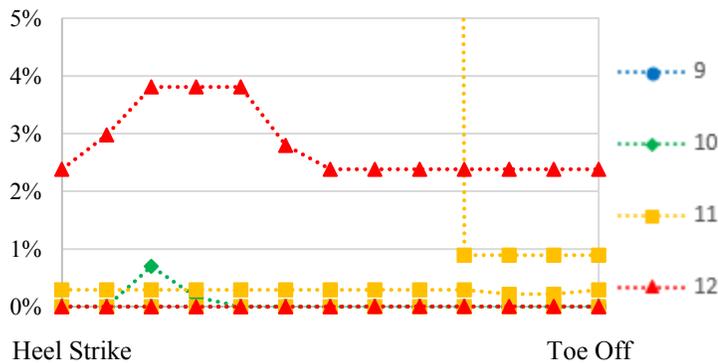

Clinicians should use care when interpreting Mirels' scores, as Mirels' scores in isolation appear not to correlate with direct mechanical compromise of the affected bone. Additionally, in-depth, patient specific mechanical analyses may be of great use in this extremely vulnerable population.

# A TASK PROGRESS-BASED PERFORMANCE MEASURE FOR TRACING

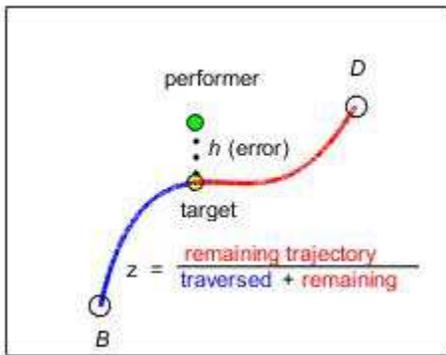

Tim Eakin

The University of Texas at Austin, Austin, TX, USA  
email: eakin@austin.utexas.edu

## INTRODUCTION

A common biomechanical task structure for assessment of motor skills is template tracing in which a performer establishes a position, either from movement of the body or from transduced force production causing movement of an external object such as a cursor on a computer screen, with an objective of matching a target position.

Typically the performer and target positions are recorded in a sequence of data samplings, each with a geometry similar to that shown in Fig.1.

**Figure 1:** Data sampling instance of a tracing task. The target moves from  $B$  to  $D$ , its position being the closest point on the template to the performer's position;  $z$  is the fractional remaining trajectory distance; and the error  $h$  is the distance between the performer and the target.

Performance is evaluated by an error variable constructed from those values, for example the commonly used root mean square error (*RMSE*). Such a measure is a good proxy for accuracy, but does not reflect performance quickness in tasks such as template tracing in which the location of the current target position is determined by the performer position. Conversely, the measurement of task duration is a suitable proxy for average speed in self-paced tasks, but it does not reflect accuracy during performance. It is thus desirable to

construct a quantitative spatiotemporal dependent variable from a sequence of performer and target positions that will reflect both speed and accuracy (or equivalently error and duration) and by which the relative skill levels can be ordered within a set of individual task performances.

## METHODS

The approach to constructing a measure sensitive to task progress as well as geometric error, whose magnitude inversely correlates with accuracy and speed, begins with the generic structure

$$\text{Performance score} = F \left[ \frac{1}{N} \sum_{n=1}^N g(n, z_n) f(h_n) \right]$$

where  $N$  is the total number of data samplings,  $n$  is the index of a particular sampling,  $h$  is the distance error from performer position to target position,  $z$  is the fractional distance yet to be traversed along the target template line,  $f$  is a function of the distance error,  $g$  is a weighting function dependent on the ordinal position of a sampling and the fractional remaining distance for that sampling, and the function  $F$  is the inverse operation of error function  $f$ . If  $g$  is chosen to be 1 for all  $n$  and  $z_n$  and if  $f$  is chosen to be the square of the distance error then the performance score is reduced to the commonly used *RMSE*. However, in order to ensure an increase in the summation magnitude with each additional sampling needed before task completion, the function  $f$  is chosen to be the exponential of the distance error,  $\exp(h_n)$ , rather than its square and thus  $F$  is the operation of taking the natural logarithm of the mean rather than taking the square root. The weighting function  $g$  is chosen such that it amplifies contributions to the score based on the accrued number of data samplings and attenuates contributions to the score based on target position proximity to its end destination. It is of the form

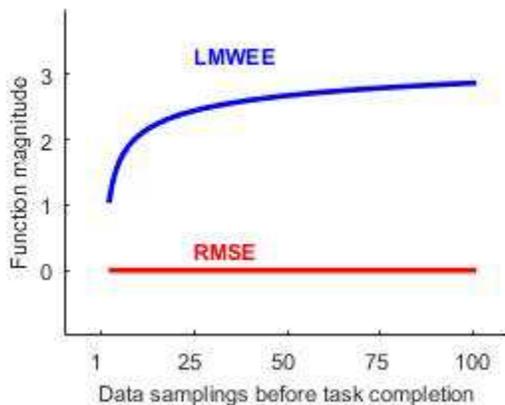

$g(n, z_n) = [a + b \log(n)] \cdot \exp(z_n)$  with the parameters  $a$  and  $b$  chosen to satisfy the desired constraints that every term in the score's summation factor be positive and that the mean of  $N+1$  terms cannot be less than the mean of  $N$  terms. Accordingly the value of  $a$  is chosen to be 1 and the value of  $b$  is chosen to be  $\exp(1)$ . Thus,

$$\text{Performance score} = \log \left\{ \frac{1}{N} \sum_{n=1}^N [1 + e^1 \log(n)] e^{z_n} e^{h_n} \right\}.$$

In analogy with the *RMSE* acronym, this “Logarithm of the Mean Weighted Exponential Error” has the acronym *LMWEE*.

## RESULTS AND DISCUSSION

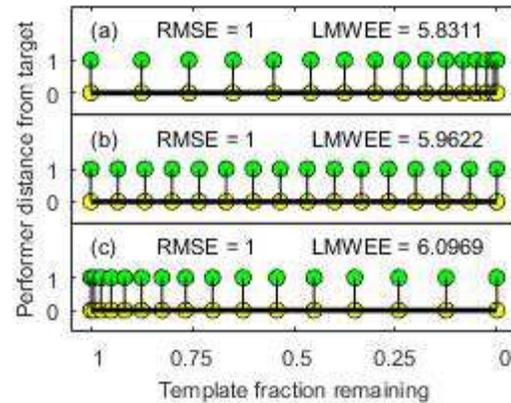

The character of this alternative *LMWEE* metric can be demonstrated by evaluating it for some hypothetical tracing task performances. One example is a tracing task performed with perfect geometric accuracy and with uniform target progress toward its destination. In such a performance the *RMSE* is zero regardless of the number  $N$  of accrued data samplings at task completion, but the *LMWEE* value increases with an increase in  $N$  so that quicker performances will have a lower score. This is shown in Fig 2.

**Figure 2:** *LMWEE* and *RMSE* for a tracing task with perfect geometric accuracy and uniform progress as a function of accrued data sampling number at task completion.

The character of *LMWEE* can be illustrated further with a set of hypothetical tracing task performances

having a constant geometric error and equal samplings  $N$  but in which one performance has a constant acceleration of the target positions toward the destination, one has uniform progress, and one has constant deceleration. This is shown in Fig. 3 where it can be seen that although the *RMSE* remains the same in all cases, the *LMWEE* value decreases as the average position of the target is closer to the destination. The *LMWEE* score is thus attenuated by target proximity to its destination.

**Figure 3:** *LMWEE* and *RMSE* for tracing tasks with a constant error of one unit but with differing progress of target position toward the destination: (a) constant deceleration; (b) uniform velocity/progress; (c) constant acceleration.

An additional objective for this spatiotemporal evaluation metric was that it have a dimensionality the same as that of the performer displacement variable – be it length, force, or some dimensionless scaled or normalized construct. Another objective was to keep the mathematical structure of the measure as simple as possible for conceptual ease, transparency, and tractability in computation. To a large extent the *LMWEE* variable as constructed conforms to these objectives.

## CONCLUSION

The *LMWEE* measure provides a spatiotemporal assessment tool whereby tracing task performances having identical geometric error but differing target position distributions can be ordered in terms of quality or skill level when timeliness of task progress is a goal in addition to accuracy.

# SIMPLIFIED CENTER OF MASS TRACKING IN ANKLE OSTEOARTHRITIS PATIENTS

## INTRODUCTION

Maintaining control of the whole-body center of mass (COM) is paramount in maintaining steady, quiet stance. Lack of stability in COM position may indicate postural control deficits, which have been linked to increased fall risk [1]. While center of pressure measures are often used to evaluate postural stability, calculation of such measures requires a force platform and substantial post-processing of data. Furthermore, it has been suggested that COM may more accurately indicate success of postural control [2].

The location of the human COM is most often calculated using the “segmental method”, which requires full kinematic data collection and intensive post-processing. Double integration of ground reaction force data has been established as a reliable alternative, but still requires an expensive force platform and some data processing. A simplified method characterized by tracking a single point on the lower back has been suggested as an alternative that has been successfully tested in slow walking conditions [3]. If effective in static balance, this would allow clinicians to evaluate postural stability of patients quickly and diagnose balance-related disorders or injuries, such as ankle osteoarthritis. Severe ankle osteoarthritis patients were chosen for this analysis due to the often excessive body sway they experience. Other clinical populations with similarly high sway magnitudes could benefit from the use of this method for clinical assessment of outcomes.

To our knowledge, no previous study has investigated the use of single-marker COM tracking method in a patient population performing static balance tasks. Therefore, the purpose of this study was to evaluate the effectiveness of a simplified method of tracking the whole-body COM in the

assessment of static balance in ankle osteoarthritis patients. We hypothesize that the two methods (double integration and single marker tracking of the COM movement) will produce similar outcome measures and show positive correlation in both anteroposterior and mediolateral directions.

## METHODS

This study was a secondary analysis of previously collected data from 391 ankle osteoarthritis patients. All subjects had end-stage ankle arthritis as diagnosed by a foot and ankle trained orthopedic surgeon and were scheduled for a total ankle replacement within two weeks of initial testing. In order to participate in the study, all subjects had to be capable of independent ambulation without the use of an assistive device and be able to maintain bilateral, quiet, upright stance for 10 seconds. Prior to study initiation, all subjects signed informed consent that was approved by the institutional review board.

Each patient was asked to perform three 10-second, quiet standing trials in two conditions. Trials were conducted with patients standing barefoot on two force plates sampling at 1200 Hz (AMTI, Watertown, MA, USA) with feet together and shoulder-width apart. Lower-body kinematic data were collected using an 8-camera motion capture system sampling at 120 Hz (Motion Analysis, Santa Rosa, CA, USA). COM was calculated for both conditions in two methods: using double integrated force platform data as described by Chan [4], and by tracking the position of a single marker placed on the L4/L5 vertebral joint. Both methods represent center of mass displacement relative to the initial location and not absolute COM locations in the global coordinate system. Coefficients of multiple determination (CMDs) of the mean time series of

each task and intraclass correlation coefficients (ICCs) of the mean COM positions during each task were calculated. Negative CMDs were set equal to 0. Mean COM positions were tested for normality using a Shapiro-Wilks test and found to be not normal. Therefore, the methods were compared for each task with Mann-Whitney tests of the mean anteroposterior (AP) and mediolateral (ML) COM positions ( $p < 0.05$ ).

## RESULTS AND DISCUSSION

Figure 1 is a graphical representation of the mean anteroposterior and mediolateral position of the COM in the feet together (FT) and shoulder width (SW) task as measured by both methods. Mann-Whitney tests revealed significant differences between the location of the two methods in the ML direction only (FT:  $p = 0.0027$ ; SW:  $p < 0.001$ ).

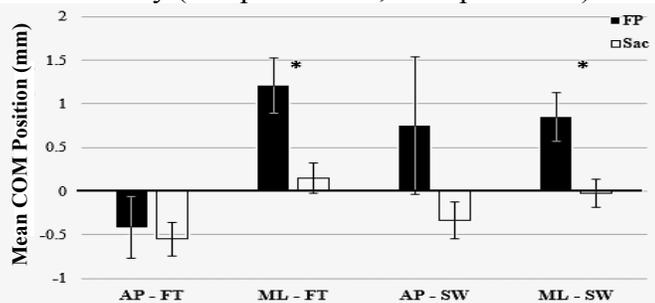

Figure 1: Mean (+/- std. error) COM positions for feet together (FT) and shoulder width (SW) task in AP and ML direction. FP: Force plate integration; Sac: Sacral marker - \* indicates significant difference between methods

Table 1 reports the mean CMD and ICC values for each task and direction. These value indicate that there is limited association between the two measurement methods in the AP and ML directions for the FT and SW tasks.

Taking into account the mostly weak correlations and differences in mean positions, we conclude that the data does not support our hypothesis. These results could indicate that the single-marker method for COM tracking is not suitable for assessing COM

movement during these tasks. However, positive results were achieved in other studies using similar methods in healthy subjects performing more dynamic tasks [3,5]. Other possibilities are that the force platform integration method proposed by Chan is not reliable, or that the tasks in this study have COM movement that cannot be differentiated from signal noise. However, since other studies have employed Chan's method with success [6,7], the former is not a likely explanation. Therefore, calculation of COM from force platform data with this method may not be advisable in patient populations.

## CONCLUSION

The findings of this study suggest that the single-marker sacral method for tracking COM is not reliable in static balance tasks. Due to the lack of whole-body motion capture data in this study, the proposed method was compared to a force-platform double integration method which, while considered an acceptable substitute for the gold-standard segmental method, may not provide reliable data in tasks with lower amplitudes of COM excursion such as those described in this study. Further research is needed to compare this method to the gold standard in patient populations.

# ARE GAIT KINEMATICS SIMILAR BETWEEN ENSEMBLE AVERAGE AND REPRESENTATIVE CYCLE?

Richard Pimentel, Colton Sauer, James Carollo

Center for Gait and Movement Analysis, Children's Hospital Colorado, Aurora, CO  
email: Richard.Pimentel@childrenscolorado.org

## INTRODUCTION

Kinematic data from an instrumented gait analysis (IGA) is typically portrayed in kinematic plots to envision the joint angles and general walking ability of the subject. Given the large amount and complexity of IGA data, these curves typically contain information from either a single representative cycle (RC) or an ensemble average (EA) of the cycles. During an IGA, multiple walking trials are collected and an EA of all the valid gait cycles is computed. Using the EA, a single RC that closely resembles the EA can also be selected for use in clinical interpretation and decision making.

The benefits of using an EA are: 1) it contains summed information of all the gait cycles present during various trials; 2) the gait variability measurements provide additional information about the subject's gait [1]; and 3) the averaged waveform is more reliable than a single cycle [1]. The benefits of using the RC are: 1) it is an intact cycle, coming from one definitive gait cycle; 2) gait features (minima & maxima) are unchanged, these features may be lost during EA; 3) the waveform is not affected by any of the other gait cycles.

These two techniques are mutually exclusive; the benefits of one are the drawbacks of the other. While it has been said that the EA forms the basis of clinical assessments [1], a carefully-selected RC may also serve that purpose. The goal of the study was to compare the RC and EA across the kinematic root mean square (RMS) error between waveforms and how those differences may affect overall quality of gait measured by gait deviation index (GDI) [2]. These were assessed between a group with cerebral palsy (CP) and an age-matched normative group (AMN).

## METHODS

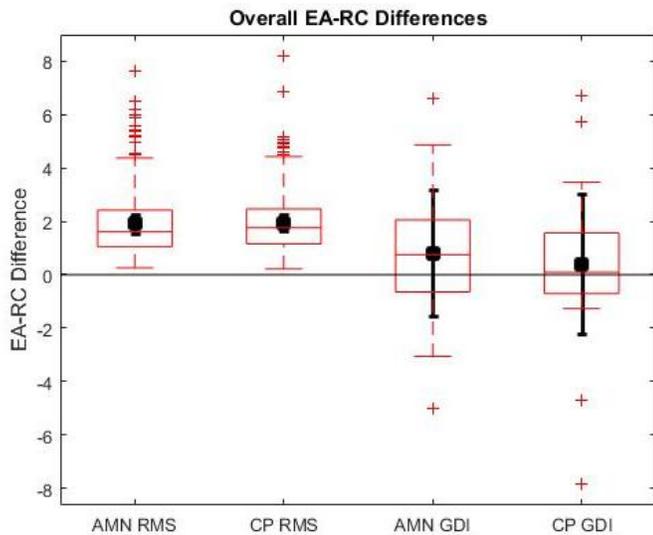

Thirty-two participants were included, 16 with CP and 16 AMNs (16 females and 16 males). Mean characteristics for the groups are shown below.

	N	Age (yr)		Height (cm)		Weight (kg)	
		Mean	SD	Mean	SD	Mean	SD
AMN	16	13.7	4.8	156.9	16.7	49.2	20.5
CP	16	13.8	4.8	152.8	16.1	44.6	14.7
<i>P</i>		0.942		0.482		0.468	

Participants started from standstill and walked through the capture volume at a self-selected pace. The first stride on each side was excluded due to initiation of locomotion. An average of 14 valid strides was collected over at least 4 walking trials for each participant. Kinematics were collected using the Newington-Helen Hayes lower body marker set and captured in Vicon Nexus (Oxford, UK). The Plug-in-Gait model was applied after gap filling and filtering [3]. Using Matlab (v R2015A, Mathworks, Natick, MA, USA), kinematics were parsed from gait events and interpolated to 2% increments of the gait cycle. Lower body kinematics only included those used by GDI [2].

In order for the RC to contain an actual intact gait cycle, RCs were selected primarily on the side with lower GDI and then the contralateral side was chosen from the cycle directly before or after the ipsilateral cycle closest to the EA. Each subject had only one RC and EA across the multiple trials collected.

RMS error was the absolute error between waveforms and GDI difference was calculated as EA minus RC. ANOVAs were used to test for significance in EA-RC difference between the two groups and across body segments/joints. Statistical significance was set at  $\alpha = 0.05$ . All outliers, except for a single extreme outlier, were kept in the sample.

**Figure 1:** EA and RC are similar between groups in terms of RMS error and GDI ( $P \geq 0.500$ ). RMS error is the mean RMS difference in degrees between EA-RC waveforms, averaged across all lower extremity joints. GDI is unit-less (score based). Black represents the mean and SD, while the red box plots represent the median, IQR, bounds, and outliers of the sample (same for Fig 2).

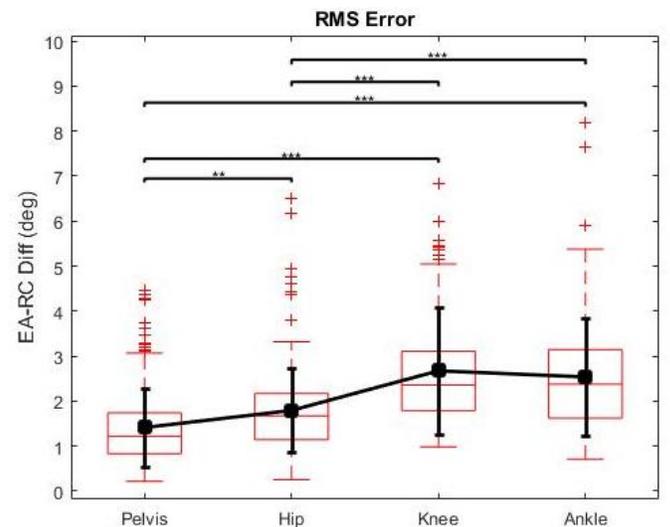

## RESULTS AND DISCUSSION

There were no significant differences between the CP and AMN groups in age, height, or weight ( $P \geq .468$ ). Mean RMS error between EA and RC was similar between AMN and CP groups (Figure 1). GDI scores between EA and RC were similar between groups for both sides (Figure 1). RMS error was not uniform across the various lower body kinematics (Figure 2).

Representative gait cycles or ensemble averages of the gait cycles can be used to portray a person's kinematic curves. While neither version is incorrect, it is important to understand the pros and cons of each data type and how each technique may affect data before making clinical decisions from that technique.

## CONCLUSIONS

The purpose was to determine if there are differences between EA and RC data representation techniques. Overall, EA and RC are similar in accuracy to

**Figure 2:** RMS error between EA and RC by body segment across the whole group. Hip, knee, and ankle RMS error were higher than the pelvis ( $P \leq 0.0027$ ). Knee and ankle RMS error were greater than the hip ( $P < 0.001$ ). \*\* indicates  $P < 0.01$ , \*\*\* indicates  $P < 0.001$ .

approximately  $2^\circ$  on average and gait quality (GDI) is preserved in both techniques. However, distal kinematics (knee and ankle) show greater differences between EA and RC than proximal kinematics. This may be due to attenuation of local maxima and minima, as the distal joints have larger ranges of movement. In summary, gait kinematics can be accurately depicted in either manner but the data may not be as comparable for distal kinematics.

## INTRODUCTION

Patient-reported outcome (PRO) and performance based, functional outcome measures are important parameters to track during rehabilitation of servicemembers (SMs) with lower extremity amputation(s). Presently, little research has looked at the effect of time throughout rehabilitation on PROs and functional outcome measures and whether any potential correlations exist between qualitative and quantitative measures. At the Naval Medical Center San Diego (NMCS D) Gait Analysis Laboratory, quantitative and qualitative measures are collected at multiple time points as part of routine patient care to support the rehabilitation process and document outcomes.

Two qualitative measures are used to evaluate a patient's overall opinion of his or her health: the PROMIS® Global Health, a 10-item instrument scored into two subscales: physical health and mental health [1] and the Short Musculoskeletal Function Assessment (SMFA), a 46-item instrument that measures perceived functional status by two subscales, one a dysfunction index and the other a bother index [2]. The Four Square Step Test (FSST) is a functional outcome measure that is used to quantify the physical balance and agility of patients and is a sensitive and specific test for impaired mobility [3]. Gait velocity is another parameter used in a clinical setting to assess walking ability and is predictive of community ambulation and the ability to perform higher level tasks in the future [4].

The primary purpose of this study was to evaluate the effect of time through rehabilitation on PRO and functional outcome measures for SMs with amputation(s). Correlations between PRO and performance measures were investigated to see if

there are predictable behaviors of good rehabilitation outcomes.

## METHODS

Thirteen male SMs who underwent amputation (one bilateral transfemoral, three unilateral transfemoral and nine unilateral transtibial) after a traumatic injury were identified through an IRB approved retrospective analysis of 2014-2017 clinical records at NMCS D. As part of their clinical rehabilitation process, SMs underwent gait analysis, FSST, and PRO collection at baseline (initiation of unassisted walking), and at six weeks, three months, and six months after baseline. Nine patients successfully completed their six month visit and were included in this study. At baseline, patients were  $28.5 \pm 6.5$  years old and  $3.3 \pm 0.7$  months from amputation (height  $178.7 \pm 6.7$  cm and weight  $89.5 \pm 16.2$  kg). During each visit, patients completed two qualitative PROs: SMFA and PROMIS® Global Health; and two quantitative functional measures: FSST and self-selected walking velocity collected during gait analysis. One way ANOVAs were performed to examine the effect of time on each PRO and functional measure with a  $p < 0.05$ . If a main effect was found, Tukey post hoc tests were used to determine where differences occurred. Additionally, Pearson correlation coefficients were computed for all PRO and functional outcome variables.

## RESULTS AND DISCUSSION

Descriptive statistics are reported in Table 1. There was not a main effect of time through rehabilitation for any of the PRO measures (SMFA Dysfunction  $p = 0.81$ , SMFA Bother  $p = 0.21$ , PROMIS PH  $p = 0.42$ , and PROMIS MH  $p = 0.76$ ). There was a

significant effect of time on the functional measures (FSST  $p < 0.01$  and Velocity  $p < 0.01$ ). Post hoc tests determined a significant improvement in both quantitative measures at the 6 month time point ( $p < .01$  for both). A significant strong correlation was found between FSST and velocity ( $P = -0.65$ ). Additionally, there were significant strong correlations between all PRO measures. Notably, PROMIS mental health score was strongly negatively correlated with SMFA dysfunction ( $P = -0.81$ ).

## CONCLUSIONS

The purpose of this study was to report on PRO and functional outcome measures throughout rehabilitation and to determine how the qualitative and quantitative measures may correlate with each other. Functional outcome measures significantly improved from baseline to the six month time point. None of the PRO measures were significantly improved, however all SMs reported scores were trending toward improvement throughout rehabilitation. It appears that the functional measures have better sensitivity to change compared to the PRO measures in relatively low patient numbers. As more patients are added to this preliminary study, some of the trends toward PRO improvement may become statistically significant. FSST and velocity were correlated which was expected. While no PRO measures were correlated to any functional measures, it was noteworthy that

as PROMIS mental health worsened, the SMFA Dysfunction increased (worsened), indicating that as patient-reported mental health worsens, SMs perception of his or her dysfunction worsens, and vice-versa. In addition to attempting to understand the relationship between PRO measures and functional outcomes, future research could examine more closely the relationship between mental health scores and perceived dysfunction. That in turn may help explain the changes, or lack thereof, in the SMFA across time in rehabilitation in SMs with amputation(s).

## INTRODUCTION

Ultrasound is a non-invasive diagnostic tool commonly used for medical imaging. Most ultrasound imaging is performed freehand where the sonographer holds the probe in contact with the skin, adjusting the probe's orientation until the target region is located. During anatomical imaging, the force exerted by the probe on the tissue must be minimized to view the tissue in a more anatomically correct, undeformed state. During mechanical manipulation, e.g. indentation, quantifying the forces would enable clinicians and researchers to characterize the mechanics of the tissue. Researchers have previously proposed methods to measure force and orientation, and compensate for gravity (weight of the probe) [1,2]. However, these methods lack design modularity and their feasibility for clinical use has not been established. A more automated and adaptable system appears to be an emerging need.

This paper presents a methodology for instrumenting any ultrasound system to measure probe forces and orientation while meeting the previously stated needs by including the following features: 1) automatic association and temporal synchronization of data collected from multiple systems 2) gravity compensation, 3) easily interchangeable probes, and 4) extensibility to include additional instrumentation.

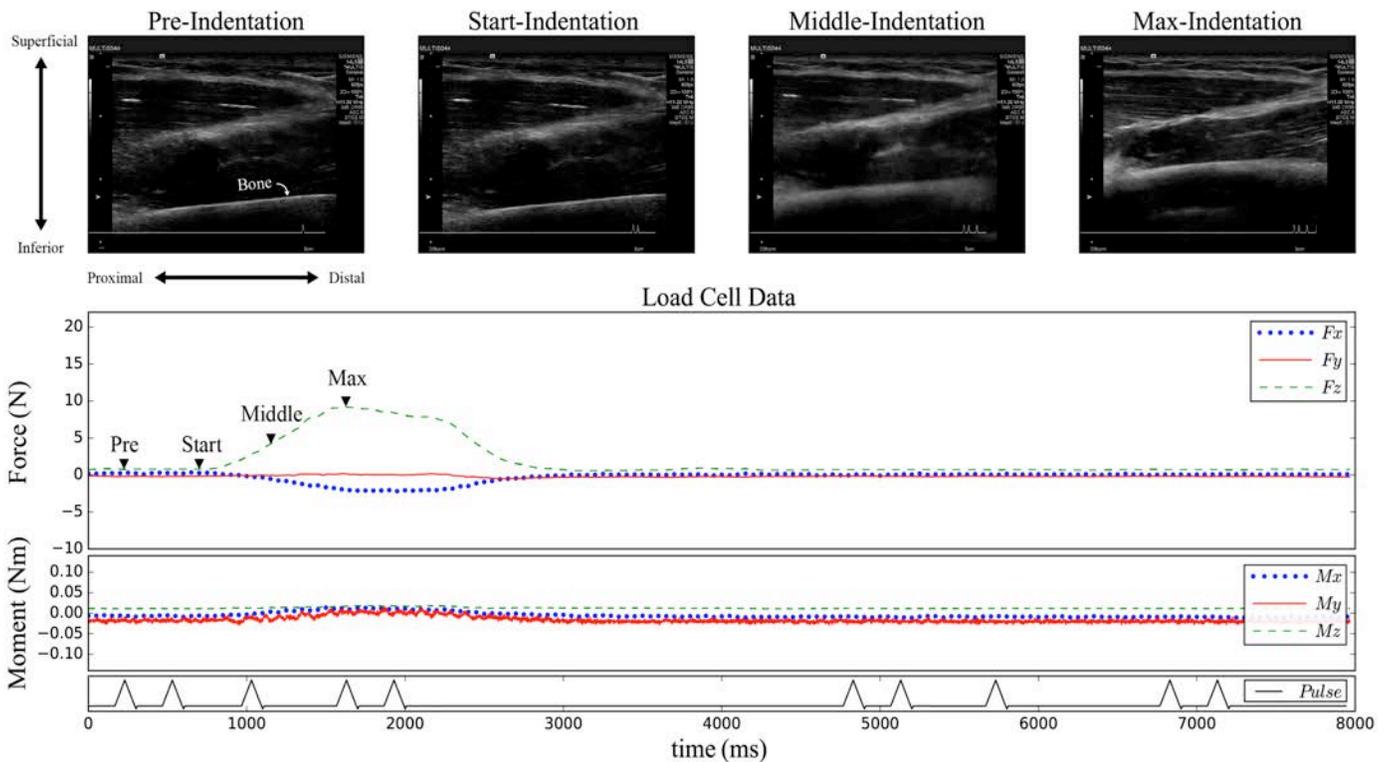

## METHODS

A device (Fig. 1) was designed to measure forces and orientation during freehand ultrasound use (Acuson S3000, Siemens, USA). The device compensates for gravity by using an inertial measurement unit (VN-100, VectorNav, USA) and a 6-axis load cell (Nano25, ATI Industrial Automation, USA), relying on a custom LabVIEW program (LabVIEW, National Instruments, USA) in

**Figure 1.** The instrumented ultrasound system. The Optotrak sensors (NDI, Canada) are an example of additional instrumentation.

conjunction with a mechatronic toolkit (SSCAD Toolkit, Cleveland Clinic, USA). An analog signal unique to a trial supports association and temporal synchronization of data collected by separate systems (ultrasound images, probe forces, and orientation). This signal was similar to an electrocardiogram (EKG) waveform and was sent simultaneously to the force data acquisition system and ultrasound EKG input (Pulse in Fig. 2), where the time instants of signal peaks were stored in the image metadata. A custom Python script was used to associate the ultrasound and force data files based on this information to determine the time difference between data acquisition systems. All force and orientation data were collected using the same custom LabVIEW program on a single computer, making temporal synchronization innate.

**Figure 2.** A time synchronized trial is shown with the corresponding forces, moments, and ultrasound images. All forces and moments were transformed to the ultrasound probe tip after gravity compensation. Location: lower arm, anterior, central.

An experiment was performed for demonstration purposes, where the device was used *in vivo* for anatomical imaging and to collect a series of images during indentation. The experiment was performed freehand by the sonographer on the right extremities of a 26 year old caucasian male subject (height 183 cm, weight 90 kg). A total of 24 locations were imaged on each extremity using either the 14L5 or 9L4 ultrasound probes (Siemens), depending on the depth of bone boundary. For anatomical imaging, each location was imaged with minimal resultant force (<2.2 N). Indentation trials were performed immediately after minimal force trials at 4 of the 24 locations on each extremity. This study was approved by the Cleveland Clinic Institutional Review Board and the Human Research Protection Office of the U.S. Army.

## RESULTS AND DISCUSSION

Data files from all locations were automatically associated and time synchronized. The results from a single trial can be seen in Fig. 2, showing four events throughout an indentation. All forces and moments were transformed to the ultrasound probe tip after gravity compensation. The force  $F_z$  represents the predominant loading axis (perpendicular to the probe tip). Shear loading ( $F_x$  &  $F_y$ ) is expected due to the freehand operation and

the heterogeneous nature of musculoskeletal tissue. Performance of gravity compensation strategy was demonstrated by the near zero-load state before and after indentation.

## CONCLUSIONS

A robust instrumentation system was developed that can fully integrate with any existing ultrasound machine that has an EKG input, increasing the accessibility and adaptability of instrumented ultrasound systems. The device may be equipped with additional instruments, including motion capture sensors to track its orientation and position relative to a specimen and other devices (Fig. 1). This methodology is being utilized in a separate study to measure *in vivo* tissue thicknesses of musculoskeletal extremities for a large group of subjects[3].

# IMPROVED HIP JOINT CENTER PREDICTION

<sup>1</sup> Emily Miller and <sup>1</sup> Kenton Kaufman

<sup>1</sup> Mayo Clinic Motion Analysis Laboratory, Rochester, MN, USA  
email: Kaufman.Kenton@mayo.edu

## INTRODUCTION

In biomechanical modeling for motion analysis, the hip joint center (HJC) is used to define the proximal location of the thigh segment. This is the point about which the hip moments are calculated and the point that defines the orientation of the thigh segment, which determines hip and knee kinematics. The HJC cannot be palpated. For modeling purposes, its location must be calculated. Functional methods for HJC prediction have been shown to be accurate [1], but are difficult to perform for clinical populations with neuromuscular deficits. Therefore, regression based methods are preferred. However, these methods have been shown to yield large degrees of error. Most prediction methods utilize the pelvic landmarks (i.e. the anterior and posterior superior iliac spines) to calculate the location of the HJC [2-4]; Excessive adipose tissue can make these landmarks difficult to locate correctly. A new regression equation utilizing leg length has been shown to improve the accuracy of locating the HJC in cadavers [5]. The Hara regression method has been shown to have considerably less error than the Bell [2] or Davis [3] methods and comparable error to the Harrington method [4]. The purpose of this study was to compare the accuracy of the HJC location calculated with the Harrington method and the Hara method. These two methods were compared to a gold standard digital full-leg coronal radiograph.

## METHODS

Clinical patients (5/8 female;  $23.8 \pm 22.7$  years; BMI =  $20.4 \pm 5.4$ ) visiting the lab for a standard gait analysis and patients (5/8 female;  $69.4 \pm 4.8$  years; BMI =  $29.6 \pm 6$ ) undergoing total knee arthroplasty (TKA) enrolled in a larger post-operative follow-up study were used for this analysis. For the clinical patients both knees were included, while for the

TKA patients only the pre-operative surgical knee was included in the comparison.

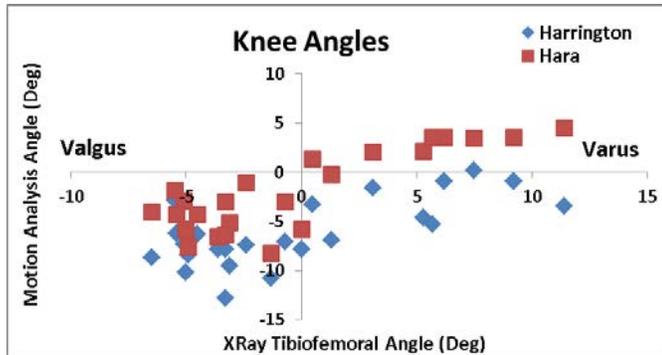

Tibiofemoral angles, calculated using standard digital full-leg coronal radiographs were used as the 'gold standard' for comparison. An angle measurement tool (QREADS: Clinical Image Viewer, Mayo Clinic, Rochester, MN) was used to create vectors from the center of the femoral head to the midpoint of the tibial spines and from the midpoint of the tibial spines to the midpoint of the malleoli. The tibiofemoral angle was calculated as the lateral angle between the femoral and tibial vectors minus 180, where a positive angle was a varus knee and a negative angle was a valgus knee.

The motion analysis knee valgus-varus angles were collected from a static trial. Kinematic parameters were acquired with a motion analysis system utilizing ten infrared cameras (Raptor-12 cameras, Motion Analysis Corporation, Santa Rosa, CA). A set of retro-reflective, 3D markers were placed on the body of each subject as described by Kadaba, et al [6]. The 3D coordinates of the marker data were used as input to a commercial software program (Visual3D 5.02.27, C-Motion, Inc., Germantown, MD) to calculate the joint kinematics. The HJCs were defined using the regression equations developed by Harrington [4] and Hara [5]. The knee center was found on a vector directed medially from the knee marker and at a distance one-half of the measured knee width. Similarly, the ankle center was located by a vector directed medially from the lateral malleolus marker at one half the distance of the measured ankle width.

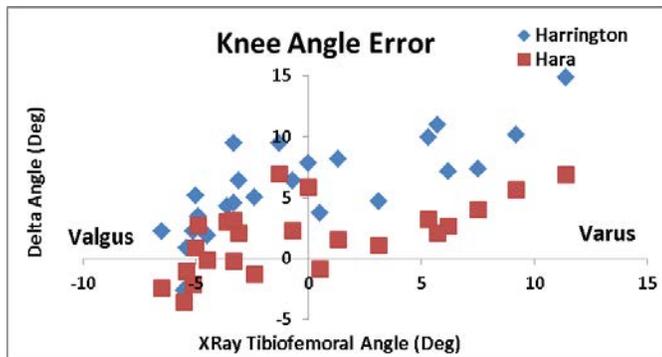

## RESULTS AND DISCUSSION

This study demonstrated that the Hara regression method results in an improved estimate of the HJC

(Fig. 1). The Hara HJC is both more accurate and precise (Fig. 2). The mean error between the gold standard x-ray measurement and the motion analysis calculation for the Harrington HJC regression method was 6.0 degrees (95% CI: 4.4, 7.6) and for the Hara HJC regression method was 1.8 degrees (95% CI: 0.54, 3.0). The mean errors between the two methods were statistically different (P-value = 0.000), however the mean error for the Hara method was still not zero.

**Figure 1:** Harrington and Hara HJC knee valgus-varus angles versus x-ray tibiofemoral angles.

**Figure 2:** Error between motion analysis Harrington HJC and Hara HJC knee valgus-varus angles versus x-ray tibiofemoral angles.

In the findings reported by Hara [5], the Harrington HJC regression model and the Hara HJC regression model had similar error. However, the Harrington method utilizes the pelvic depth distance in the model. This measurement has been shown to have larger errors in a clinical setting compared to medical imaging, which may be contributing to the superior performance of the Hara method to the Harrington method in this in-vivo population.

The Hara method was based upon cadaver estimates. The patients included in this study include children and young adults with neuromuscular pathology and adults with osteoarthritis. This study confirms that the method is reliable and valid in an in-vivo setting.

## CONCLUSIONS

Accurately modeling the HJC is critical for data interpretation and patient care. This study confirms that the Hara HJC regression method is reliable and valid in an in-vivo setting.

## INTRODUCTION

Previous research has shown that data from the whole footprint does not give a complete picture of the forces affecting the foot when walking [1]. Clinically it is more beneficial to examine pressure under specific regions of interest (ROI) instead of the total foot [2]. The justification for having an automated masking technique is that it is standardized [2, 3]. However, previous research has found that automated ROI masking techniques are not as accurate with deformity [2]. Therefore, it may be necessary to either edit the pre-defined mask to eliminate inaccuracies or forgo automated masking techniques altogether and mask the ROI based on visual analysis of the foot print (manual masking). Both manual masking and adjusting a predefined mask are based on the subjective interpretation of the clinician[2]. The purposes of this study were to: 1. Report the common inaccuracies found in masking; 2. Report intra-masker reliability when editing a 10 area mask; 3. Report intra-masker reliability when manually masking a 10 area mask; 4. Report inter-masker reliability between a novice and experienced masker.

## METHODS

Twenty-six children, ages 2.6-12.9 years, diagnosed with unilateral clubfoot underwent pedobarographs. Foot pressure analysis was collected for both the affected and unaffected sides using Novel Emed®X platform and Novel Database Pro M v.23.3.52 (Novel Electronics, Munich Germany). Three trials per side were collected for a total of 156 foot pressure trials. The mask used in this study is a 10 area ROI mask (PRC) mask (Figure 1)[4]. One investigator, with 8 years' experience using Novel software, performed all post processing.

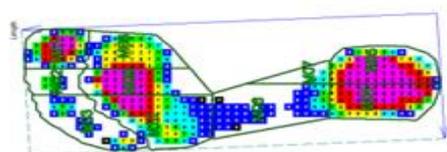

Figure 1. The 10 area PRC mask.

### *Masking Accuracy*

Automated masking of the 156 foot pressure trials was completed using the PRC mask. The 156 foot pressure trials were split into affected and unaffected sides. The foot print was assessed visually for the presence of the four inaccuracies listed in Figure 2. These four inaccuracies are caused by five common foot deformities present in clubfeet. These inaccuracies do not occur in isolation, children with clubfoot can exhibit more than one inaccuracy. The presence of at least one inaccuracy classified a trial as inaccurate.

Figure 2: Common Deformities and Common Inaccuracies when masking clubfeet.

### *Intra-Masker Reliability*

A subset of 10 subjects was chosen at random for the intra-masker reliability. Only one trial for each subject was chosen for a total of 20 foot pressure trials. The PRC mask was applied using automated masking and then edited based on the masker's ability to identify the four common inaccuracies. This was completed for the 20 foot pressure trials on two consecutive days. Values for the contact area (CA) of the 10 ROI were exported for analysis.

The same masker then manually masked the 20 foot pressure trials, using the 10 area PRC mask description as a guide[4]. This was also completed on 2 consecutive days and values for the CA were exported. Interclass correlation coefficients (ICC) were reported.

*Inter-Masker Reliability*

For inter-masker reliability, one investigator, with little to no experience masking, identified inaccuracies and made corrections to the automated masking technique for the 20 foot pressure trials. The investigator was given the description of the PRC mask and was given a tutorial by the experienced investigator. ICC values between the novel masker and the experienced masker were calculated.

**RESULTS AND DISCUSSION**

*Accuracy*

For the unaffected side, 3/78 trials (4%) were identified as inaccurate. Whereas, 19/78 (24%) trials were identified as inaccurate for the affected side. Inaccurate toe mask identification was the most common inaccuracy, where 18/78 had the hallux included in the first metatarsal mask. In addition, 10/78 trials had rotation of the vertical dividing lines.

*Intra- and Inter-Masker Reliability*

ICC values for CA of the 10 regions of interest for intra-masker reliably when editing the automated masking technique, for intra-masker reliability when manually masking, and for inter-masker reliability between a novice and experienced masker are presented in Table 1. Results indicate that the deformities present in clubfoot hinder the automated

masking techniques ability to accurately identify ROI.

Intra- and inter-masker ICC values report excellent reliability (>0.75) for the CA in all regions of the foot except for 2<sup>nd</sup> toe for both inter-masker and intra-masker manual masking and for the 3<sup>rd</sup>-5<sup>th</sup> toes in inter-masker reliability. The low ICC values in the 2<sup>nd</sup> toe and the 3<sup>rd</sup>-5<sup>th</sup> toes can be explained because these are the two smallest areas of the foot print, reliability has been found to be lower in less loaded and smaller areas[5].

**CONCLUSIONS**

This is the first study to report the reliability and accuracy of masking in a pediatric unilateral clubfoot population. The results of this study show that intra- and inter-masking reliability is high for CA in almost all ROI. In addition, automated masking techniques are less accurate for clubfeet than in feet without deformity. Taking into account the excellent reliability for between maskers and between days, it would be safe to conclude that inaccuracies to the automated masking can be reliably corrected by both novice and experienced maskers.

## INTRODUCTION

The ability to recover balance and avoid a fall decreases exponentially with age, falling below one standard deviation (SD) of the mean value of 18-year-olds, above 51.0yrs for forward lean releases [1]. Moreover, in a recent 12-month prospective falls evaluation, while the maximum forward lean angle was shown to significantly predict a future fall in community-dwelling older adults (65-90yrs), postural sway and timed up and go measures were not predictive [2]. Unfortunately, current technologies to measure the maximum forward lean angle are neither simple nor cheap, making it difficult to use in a clinical setting to identify individuals at risk of falls or to evaluate the effectiveness of exercise-based fall prevention programs. Therefore, the purpose of this study was to determine the accuracy of four alternative initial lean angle measurement methods, of various complexity and cost, compared to the current gold standard for forward lean releases.

## METHODS

Twelve healthy adults (mean±SD=27.4±10.1yrs; range=20-48yrs, 50% women) were instructed to recover balance using a single step, after first being leaned forward and then suddenly released from six randomly ordered initial lean angles (5-30deg or 10-35%BW in 5deg or 5%BW increments), using four different measurement methods:

a) The initial lean angle was calculated live in degrees by a **LabVIEW** (National Instruments Corporation, Austin TX) program from 3D marker positions, as captured by four optoelectronic position sensors (Optotrak, NDI, Waterloo ON) at 100Hz [1].

It was measured as the sagittal plane angle between the vertical and the line connecting the midpoints of the two lateral malleoli and the two greater trochanters prior to lean release.

b) The initial lean angle was measured live in percentage of body weight (%BW) by a single degree of freedom **load cell** (FD-2, AMTI, Newton MA) at 1000Hz attached to the lean cable [2,3]. It was then converted to degrees in post-processing by Thelen et al.'s static equilibrium equation using Matlab (Mathworks, Natick MA) and the ground reaction forces under each foot prior to lean release, as captured by two force platforms (OR6-7, AMTI, Newton MA) at 1000Hz [3].

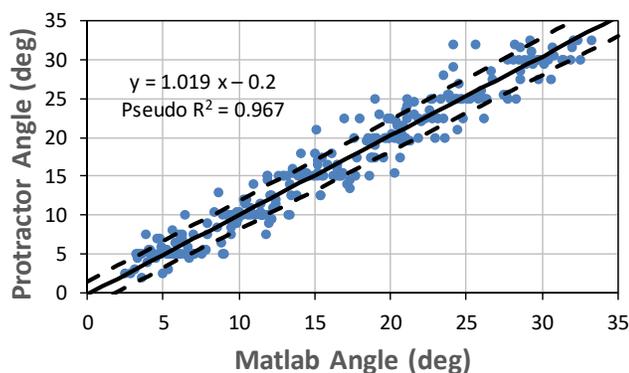

c) The initial lean angle was measured live in degrees by the experimenter leaning the participant, using a digital **inclinometer** (1886-000, Johnson Level & Tool, Mequon WI) attached to the mid-thigh of the step leg of the participant with Velcro elastic straps.

d) The initial lean angle was measured live in degrees by the experimenter acquiring the electronic data, using a giant **protractor** with 5deg increments printed on a poster (60in x 96in) positioned in the sagittal plane 1m "behind" the participant and aligned on the participant's malleoli. This experimenter was blinded to the initial lean angle to be set at each trial to minimize bias.

Finally, the **gold standard** initial lean angle was calculated in degrees in post-processing using Matlab, measuring it as explained in method "a". Furthermore, whichever of the four methods was used by the experimenter leaning the participant to set the initial lean angle, it was then also measured using the other three methods to increase sample size.

## RESULTS AND DISCUSSION

Unconditional growth linear regressions showed that, despite some residual SD ( $p_{\text{ResidualSD}} < 0.001$ , Table 1), the four initial lean angle measurement methods were strongly correlated ( $p_{\text{Slope}} < 0.001$ , Pseudo  $R^2 > 0.966$ ) with the initial lean angle calculated using Matlab (gold standard). As expected, the LabVIEW angle (a) had the smallest residual SD (0.6-0.9deg) and the strongest correlation (99.5%). The load cell angle (b) had the second strongest correlation (97.4%), but the largest residual SD (2.0-4.2deg) as well as significant intercept ( $p_{\text{Intercept}} < 0.001$ ) and inter-individual covariance ( $p_{\sigma_{10}} = 0.030$ ). Surprisingly, the inclinometer (c) and protractor (d, Figure 1) angles had very acceptable residual SD (1.7-2.6deg and 1.6-2.5deg) and correlations (96.6% and 96.7%).

**Figure 1:** Unconditional growth linear regression (mean $\pm$ SD) between the protractor initial lean angle measurement (d) and the initial lean angle calculated using Matlab (gold standard).

The most complex method was the load cell method (b), as the %BW easily fluctuated while setting the initial lean angle, and it required the conversion of the initial lean angle from %BW to degrees in post-processing from ground reaction forces. The second

most complex method was the LabVIEW method (a), as it required calculation of the initial lean angle from 3D marker positions. The inclinometer method (c) was the next one in complexity, as it was slow to display the initial lean angle and required zero resetting at nearly every trial. The protractor method (d) was the easiest but required some training of the experimenter, as he had to position himself perpendicular to the protractor to avoid distortions due to parallax. These distortions could have been reduced by bringing the protractor closer to the participant, but this would have obstructed the optoelectronic position sensors.

Finally, the LabVIEW method is the most expensive one (a $\approx$ 100k\$), followed by the load cell (b $\approx$ 10k\$ in degrees, 1k\$ in %BW), inclinometer (c $\approx$ 100\$) and protractor (d $\approx$ 10\$) methods.

## CONCLUSIONS

Therefore, to measure the maximum forward lean angle accurately in a clinical setting, the protractor method appears to be the simplest and least expensive alternative to current technologies. Lean releases could thus be used to identify individuals at risk of falls or to evaluate the effectiveness of exercise-based fall prevention programs.

## INTRODUCTION

Multiple marker sets and models are currently available for assessing foot and ankle kinematics in gait. The Milwaukee Foot Model (MFM) is one of only two validated models [1, 2]. It is a four-segment model which has been validated for adult and pediatric populations and uses a series of weight-bearing foot/ankle radiographs to index the motion of skin-mounted markers to the underlying bony anatomy, thus quantifying multi-segmental foot kinematics during gait. These radiographs greatly improve the accuracy of the model, particularly when deformities are involved [3]. However, x-rays are not always available in all gait labs. The purpose of this study was to determine the amount of error associated with the MFM when radiographic offset measurements are not available.

## METHODS

A group of 36 healthy subjects (23M, 13F) with no prior surgical treatment to the foot that may have altered its anatomy or function was used for this study. Motion data were collected using Vicon Motion Analysis System (Oxford, UK) at 120 Hz. Data were collected during walking trials at self-selected speed along a 6-meter walkway and processed using the Milwaukee Foot Model (MFM).

During the static trial, a foot position template was made by having the subject stand on a rectangular piece of cardboard and tracing both feet. After the gait analysis, this tracing was used during full weight-bearing radiographs (anterior/posterior, lateral, and modified coronal views) to ensure that the same alignment was achieved. Specific offset measurements were obtained from the radiographs with respect to global reference lines to allow for calculation of the transformation from marker-based to bone-based axis systems. All measurements were

made by the same investigator. The angles were measured for each segment relative to the global reference frame. The average offset of the entire group for each measurement collected was also calculated.

The motion data and radiographic offset measurements were input into a custom software model (MathWorks, Natick, MA). The model calculates a marker-based axis system using marker locations from the static trial and a bone-based axis system using the radiographic offset angles. A transformation matrix is computed to relate the two axis systems. Full details of the model were reported by Long et al [4].

The model was run for each subject with both with the patient-specific offsets and the group average offsets. A paired t-test was used to compare the output (minimum, maximum, and range of motion for each joint) of each simulation.

## RESULTS AND DISCUSSION

Average error in range of motion for each segment analyzed is shown in Table 1. Errors were generally within 1-2 degrees with the exception of the coronal tibia, which showed a 6.1° error on average.

Table 1: Average Range of Motion Error. \* indicates statistically significant differences between the two simulations

<i>Segment</i>	<i>Sagittal Plane</i>	<i>Coronal Plane</i>	<i>Transverse Plane</i>
<i>Tibia</i>	2.2°	6.1°*	1.5°*
<i>Hindfoot</i>	0.5°	0.9°	0.4°
<i>Forefoot</i>	0.7°	0.8°	0.5°
<i>Hallux</i>	1.4°*	1.6°	1.1°*

The joint positions (as measured by maximum and minimum excursions) showed the most error in the coronal plane. Average errors in position were 6.3°,

4.7°, 3.7, and 4.8° for the tibia, hindfoot, forefoot, and hallux segments, respectively. Representative data for a selected subject are shown in Figure 1.

A previous parametric study by our group showed that when the hindfoot orientation angles were perturbed as little as 2° from their true orientation, significant changes to the kinematic output resulted [5]. The effect is most significant in the plane of the perturbation, but significant non-zero effects have also been reported in the transverse plane secondary to perturbations in the coronal plane. This emphasizes the need for repeatable and reliable x-ray measurements in the current model. It also highlights the importance of using bony measurements.

## CONCLUSIONS

This paper illustrated the amount of error that can be expected when using the MFM for analysis of segmental foot kinematics without x-ray offsets. The

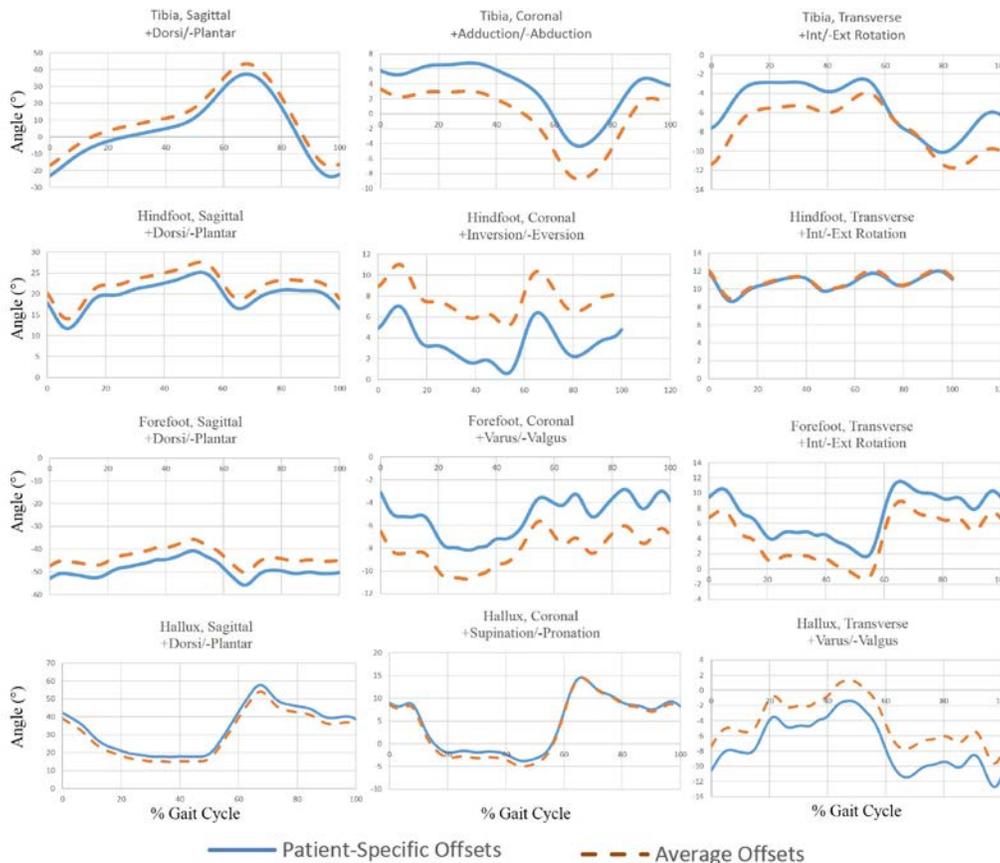

importance of having accurate, subject-specific x-ray offset measurements was demonstrated, particularly in the coronal plane. However, these results can also be used as justification for using the MFM without x-ray offsets for certain applications when x-rays may not be available, such as analyzing sagittal range of motion.

# ERRORS IN MARGINS OF STABILITY ASSOCIATED WITH THE USE OF SIMPLIFIED BODY MODELS DURING WALKING AND TURNING

Kathryn L. Havens, Tatri Mukherjee, James M. Finley

Division of Biokinesiology and Physical Therapy  
University of Southern California, Los Angeles, CA, USA  
Email: khavens@pt.usc.edu, web: [http://pt.usc.edu/Locomotor\\_Control\\_Lab](http://pt.usc.edu/Locomotor_Control_Lab)

## INTRODUCTION

Falls and fall-related injuries are a major public health concern, particularly for older populations and those with neurological disabilities. Prevention of falls relies on an understanding of dynamic balance control. Considering that approximately half of all falls occur during locomotion [1], understanding how stability is controlled and maintained during walking is vital.

During tasks that involve ongoing motion, balance control involves not only control of the position of the center of mass (COM) but also its velocity [2]. To account for both of these factors, Hof et al. proposed a variable, extrapolated center of mass (eCOM) as a metric to characterize dynamic balance. The horizontal distance between the eCOM and the base of support was termed the margin of stability (MoS) [3]. The margin of stability has been used recently to measure dynamic stability during normal walking and during walking with perturbations [4].

Quantification of the MoS requires estimates of the whole body's center of mass. Estimating the whole body center of mass involves quantifying COM locations of all body segments and estimating anthropometrics and distribution of mass. While the gold standard is to use a full body marker set, this method is time-consuming. Studies have therefore used approximations of the COM, such a limited number of pelvic markers [4] or reduced kinematic model of typically available segments when collecting lower extremity kinematics with or without the trunk [5,6]. However, it is unclear whether these methods are appropriate for estimating the COM or how much they affect the margin of stability estimates. Further, the error in

these methods could be exaggerated in certain walking tasks such as turning.

Thus, the purpose of this study was to evaluate the error associated with reduced marker sets in estimating fore-aft and medial-lateral margins of stability during walking and turning tasks.

## METHODS

Thirteen healthy young adults (6 males) participated in this study. Average age, height, and weight were  $26 \pm 3$  yr,  $169 \pm 9$  cm,  $67 \pm 14$  kg, respectively.

Subjects performed straight walking and turning tasks. For straight walking, subjects walked overground for 8 meters. For turning, subjects walked 4 m, performed a 90-degree turn to the right or left and continued walking 4 m. Task order was randomized. Subjects were not constrained to turn type, and performed both step turns (i.e., planting with one foot and turning to the opposite direction of the plant foot) and spin turns (i.e., planting with one foot and turning to the same direction of the plant foot). All trials were conducted at participant's self-selected walking speed.

Three-dimensional kinematics were collected using a 10-camera motion capture system (Qualisys, Inc. Sweden), 250 Hz. Whole body COM was calculated using five methods: 1) as the weighted sum of the COM of all 15 modeled segments using a full body marker set (Visual3D, C-Motion, Inc., Rockville, MD, USA); 2) as the position of a single marker placed on L5-S1 (L5); 3) as the average of four markers on the pelvis (PAM) [4]; 4) as the weighted sum of the COM of the lower extremity (LE); 5) as the weighted sum of the COM of the lower extremity and trunk segments (LETr) [5].

Margins of stability were calculated in the fore-aft and mediolateral directions as described by Hof et al. [3]. The anterior border of the base of support was estimated as the marker placed on the second toe. The lateral border was estimated based on the lateral heel marker. The error between the whole body COM and simplified representations of COM was calculated as the mean difference.

Agreement between whole body COM and simplified methods was quantified using the 95% limits of agreement (LoA) method for repeated measures [7]. The sign test was used to determine whether the error significantly differed from zero. Significance was set at  $\alpha \leq 0.05$ . Upper and lower limits of agreement are shown as mean  $\pm 1.96SD$ .

## RESULTS AND DISCUSSION

In general, the simplified COM models demonstrated a bias for walking and turning tasks. In the mediolateral direction, the bars display bias in different directions (Figure 1), with error bars indicating limits of agreement. For straight walking, only the PAM method exhibited no bias ( $p=0.388$ ). For spin turns, L5 ( $p=0.388$ ) and for step turns, PAM ( $p=0.065$ ) did not demonstrate bias. In the fore-aft direction, all methods tend to overestimate the MoS (positive error) compared to the gold

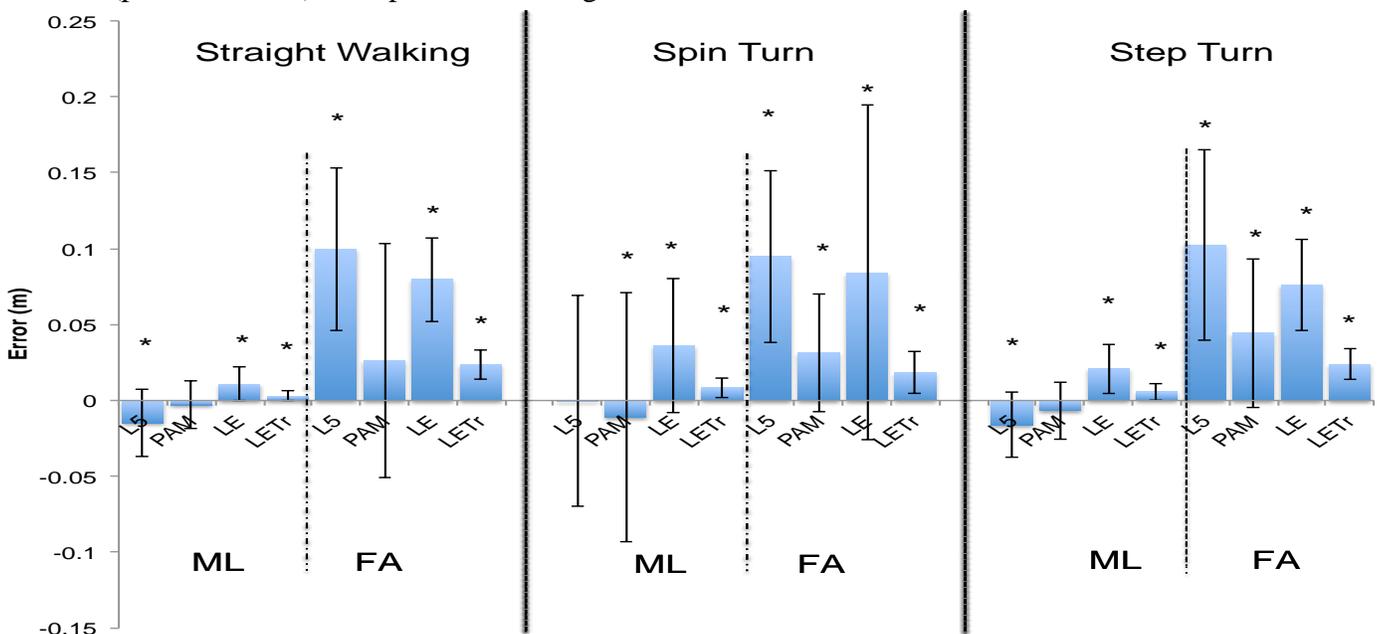

standard. For straight walking, the PAM method did not demonstrate bias ( $p=0.146$ ).

Large limits of agreement (and thus large bias variability) were found in some methods and tasks, but are not compared statistically. However, while some methods may not be biased (i.e., L5 for ML MoS during spin turns), the large variability suggests that the agreement with the gold standard may not be adequate.

This study suggests that simplified marker sets used to estimate the COM often introduce bias and variability in calculations of margins of stability. Small bias was found in LETr model, and consistent bias could theoretically be corrected. However, additional statistical analysis is necessary to compare errors between methods and tasks.

## INTRODUCTION

Out of the top ten occupations in the United States, over half involve prolonged standing [1]. This translates to nearly 3.2 million people whose occupations predispose them to chronic injury due to continual and repeated exposure to blood pooling and muscle fatigue in the lower extremities [2]. Because of this, prolonged standing has been a popular biomechanics research area in the hopes of decreasing injury due to standing.

Prolonged standing causes an increase of blood pooling in the lower extremities due to the decrease in venous return, resulting in volume changes of 3 – 12% [3]. The current “gold standard” for finding anatomical volume measurements is water displacement. However, the water displacement method is subject to a number of inherent issues. Water displacement requires immersing part of the body in water, making it difficult to measure volume while conducting additional tests—especially when using electronics. Furthermore, lifting the leg and transferring it into a bucket of water increases venous return, lending itself to error. Although volume measurements can be taken before and after tests, it is challenging to determine how volume changes over time. In addition, the process is time consuming and unfit for patients in the immediate postoperative period [3]. Because of these challenges, various methods of indirect volume measurements have been proposed, including circumference measurements which are not extremely accurate [3]. As a result, the goal of this study is to validate the use of a 3D

scanner to measure leg volume changes during prolonged standing.

Utilizing a 3D scanner to calculate volume can provide multiple benefits over other methods. Most importantly, using the 3D scanning method requires no subject movement and no potential circulation impedance that may occur by using volume displacement or circumference measurements. Furthermore, a 3D scanner is much cleaner than the water displacement method and allows for the use of EMG’s, force plate, and near infrared technology without the potential of damaging electronic equipment during volume measurements. By using cropping tools in 3D modeling software, it is easy to consistently find limb segment volume in addition to the entire limb. The scanner would also allow for direct volume measurement, which provides a benefit over indirect measurements such as tracking circumference changes.

By comparing volume measurements of objects with known volume with volumes obtained using a 3D scanner, the goal of this study is to validate a novel 3D scanner approach to accurately and precisely measure the volume of known geometric shapes, with the intended goal of calculating volume changes in the limbs, such as leg volume changes during standing.

## METHODS

An EinScan-Pro™ handheld 3D scanner was used to scan a cylinder and hexagonal prism. Three scans of both shapes were taken. The scanner was used to

**Figure 1:** Original picture next to 3D models of the shapes. Bumps on each shape are artifacts left over from adhesive markers the software uses to stitch the image together.

capture the real dimensions of the object and convert it into a digital 3D model. The scanner was accurate to 0.3 mm and can take a full scan of the object in under 3 minutes. The scan was outputted as a “watertight” closed 3D model with real dimensions.

The volume of a scan was found using 3D Computer Aided Design software by modeling it as a solid. The volumes were found 3 times each and averaged. Additionally, the volumes of the blocks were found using their measured dimensions as well as water displacement.

## RESULTS AND DISCUSSION

Volume measurements were first calculated using the 3D scanner. Figure 1 shows each shape next to the final 3D model that was used to calculate the volume. The volume measurements are summarized in Table 1.

The standard deviations for both blocks are small enough for this method to provide adequate repeatability in most cases, specifically in leg volume

changes during standing where changes are on the order of 3% to 12% [2]. The percent error of 1% for the cylinder was also low enough to provide reasonable accuracy for similar applications.

The relatively high percent error of 5.5% for the hexagonal prism could be attributed to the way the scan was taken. The scanner did not pick up the sharp corners of the prism as well as the smooth sides of the cylinder, which could have been a source of error.

## CONCLUSIONS

Using a 3D scanner is a reasonable method to calculate the volume of solid objects. It is best suited for smooth continuous shapes. It may also work as a convenient method to calculate direct anatomical volume changes, although further studies must be done to assure the accuracy of anatomical measurements. Future tests will use a dummy’s leg and a human’s leg to compare the accuracy of the scanner to the other volumetric methods. Applications of this method include quickly finding volume changes in the extremities while performing additional static tests or for patients in the immediate postoperative period [3].

## INTRODUCTION

While several studies have focused on skin motion artifact associated with high impact movements and their inertial effects on activities such as running, little data is available quantifying the influence of soft tissue movement on analyses of high range-of-motion activities [1].

The objective of this study was to compare joint angles and moments at the distal and proximal ends of the pelvis (i.e. hip and lumbosacral joints, respectively) when calculated from anatomical landmarks palpated and digitized in a squat posture versus routine motion analysis techniques where skin markers are affixed to the pelvis in standing.

## METHODS

Data from five female subjects who participated in a related investigation were included in this study (height  $1.66 \pm 0.08$  m, weight  $52.9 \pm 9.5$  kg). Force and motion data were recorded using standard optoelectronic motion capture systems and force platforms. A plug-in-gait marker set was modified by adding tracking markers to the pelvis (iliac crests), thigh, and shank segments; the lumbar spine was tracked via four markers on the L2-L5 vertebral spinous processes.

For each subject, static trials were taken in both standing and deep squat postures. In addition, since tracking markers typically move away from anatomical landmarks as a result of skin motion, anterior superior iliac spine (ASIS) and posterior superior iliac spines (PSIS) landmarks were re-palpated and digitized in the squatting position. Subjects were then asked to perform several deep

squatting dynamic trials in which the squat posture was held for approximately two seconds.

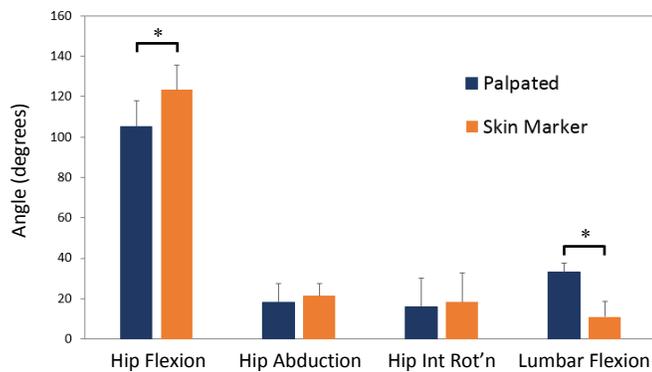

Data were analyzed using Visual3D software (C-Motion Inc., Germantown, MD). The pelvis segment model was based on the CODA algorithm in which hip joint centers are determined from ASIS and PSIS landmarks [2]. Two models were created: one using a pelvis segment defined by the ASIS and PSIS markers in the standing posture, the second defined the pelvis using the ASIS and PSIS landmarks that had been palpated and digitized in the squat position.

Mean three-dimensional hip and sagittal plane lumbosacral joint angles and moments were calculated for the resting position of the same three squat trials for each subject using the two different models; joint angles and moments were averaged across the five subjects, assessed for normal distribution, and compared using a paired samples *t*-test.

## RESULTS AND DISCUSSION

Figure 1 shows the effect of the change in pelvis definition based on palpated anatomical landmarks versus skin markers on three-dimensional hip angles and lumbosacral joint angles.

The decrease in flexion angle at the hip joints for the palpated pelvis model is offset by the increase in lumbosacral flexion when compared to the skin marker model. This exchange in flexion angle at the distal and proximal ends of the pelvis is attributed to the change in orientation of the pelvis segment (modeled as a cylinder) when defined using palpated landmarks instead of skin markers (Fig. 2).

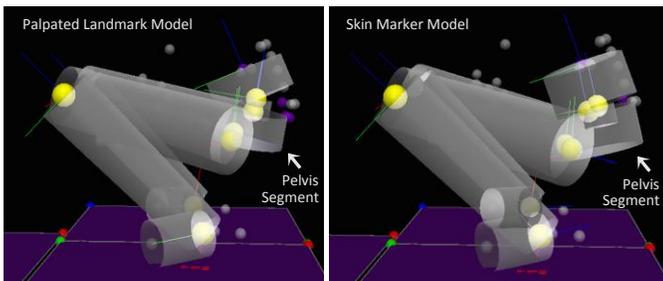

**Figure 1:** Hip and lumbosacral joint angles in the squat position calculated using palpated digitized landmark and skin marker pelvis models (\* $p < 0.05$ ).

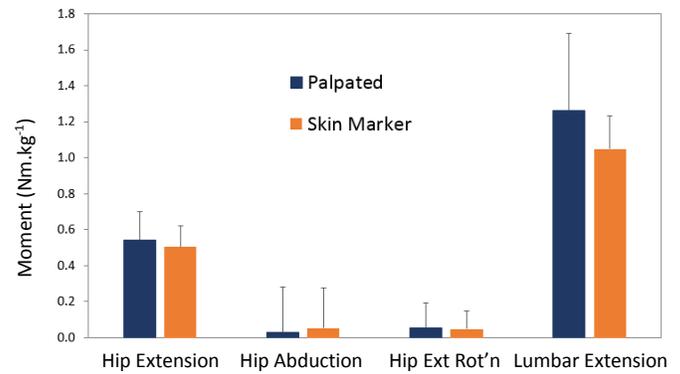

Markers placed on PSIS landmarks in standing move superior to the anatomical landmarks in the squat position, generating an artificial anterior tilt of the pelvis segment. Since the positions of the hip joint centers are determined using the ASIS and PSIS landmarks, they are also affected, in turn (slightly) changing the orientation of the thigh segments.

These results are consistent with the findings by Kuo *et al.* [3] who similarly demonstrated hip and lumbar flexion errors in a high-flexed sitting posture due to a superior shift in PSIS markers.

The significant changes observed when comparing joint angles in the sagittal plane were not replicated in the comparison of moments between the two pelvis segment models (Figure 3).

**Figure 2:** Sagittal plane views of the models defined by palpated landmarks (left) and skin markers (right) clearly demonstrate the different orientations of the pelvis segments that account for changes in hip and L5/S1 flexion angles.

**Figure 3:** Hip and lumbosacral joint moments in the squat position calculated using the palpated digitized landmark and skin marker pelvis models.

This may be due to a relatively consistent center-of-mass position and inertial properties of the pelvis segment between the two models despite its change in orientation.

## CONCLUSIONS

This study has demonstrated how pelvis marker placement is affected by skin motion in a high range-of-motion squatting posture. By comparing two pelvis models generated from standing marker positions and palpated anatomical landmarks in squatting, we can see that hip and lumbosacral angles are significantly altered in the sagittal plane. Although no significant differences were demonstrated in the joint moments, this result should be confirmed with a greater number of subjects. Our findings suggest that skin motion artifact should be taken into consideration primarily during kinematic analysis of high range-of-motion activities.

# Measurement of Interjoint Pressure in the Midfoot using Novel Sensors

<sup>1</sup> Julia Noginova, <sup>1</sup> Emily Hartley, <sup>1</sup> Matthew Hoch, and <sup>1</sup> Stacie I. Ringleb  
<sup>1</sup> Old Dominion University, Norfolk, VA, USA  
email: sringleb@odu.edu

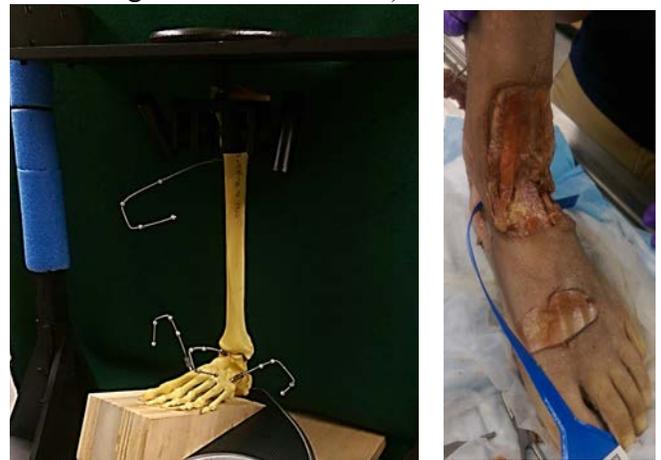

## INTRODUCTION

Contractile and non-contractile structures within the foot such as ligaments and muscles function to support and provide stability to the bones and joints. Injuries and diseases often cause changes to the loading characteristics of the foot and ankle, such as an increase of peak pressure or shifting of loading to major joints of the foot, such as the talocrural and midfoot joints [1-4]. Understanding how the joints are loaded normally and what changes may occur due to injuries may assist with the development of further prevention and treatment strategies to decrease excess pressure on the joints. In healthy intact feet, the contact pressure in the calcaneocuboid and talonavicular joints increased with an increase in dorsiflexion angle when measured with Tekscan (Tekscan Inc., Boston, MA) 6900 I-scan sensors [2]. This dorsiflexion model closely reflects the weight bearing foot positions found during the late stance phase of the gait cycle. The Novel Pliance Sensors (Novel Inc., Munich, Germany) are also made to be placed inside of a joint. Their pressure sensing technology is based on capacitive transducers and calibration occurs with applied pressure in a standard system, while the Tekscan sensors are made out of semiconductors and recommend a variety of calibration methods based on the application. One of the largest differences between the sensors is that Novel Pliance sensors are much thicker than the Tekscan sensors (1.2 mm vs 0.102 mm thickness, respectively).

Due to our interest in understanding the changes in internal joint pressure that occur with injury and/or disease and their treatments, the goal of this study is to determine if Novel's Pliance sensors measure similar changes in pressures in the calcaneocuboid and talonavicular joints during dorsiflexion, as measured previously with the Tekscan sensors.

## METHODS

A below-knee cadaver specimen with no visible deformities (left foot, female, 65 years old) was fixed into a custom-built device capable of loading the foot while in neutral stance. Minimal amounts of skin and tissue were cut so that a Novel strip sensor could be inserted through the midfoot through an incision on the medial side of the foot (Figure 1). One strip sensor was inserted across both the talonavicular and calcaneocuboid joints, simultaneously, as it was not possible to fit a sensor into the talonavicular joint laterally due to its thickness. The contact pressures were measured across the calcaneocuboid and talonavicular joints while different loading conditions (no load, 10 lbs, 20 lbs) were applied to the top of the foot during different stances (neutral and 30 degrees of dorsiflexion).

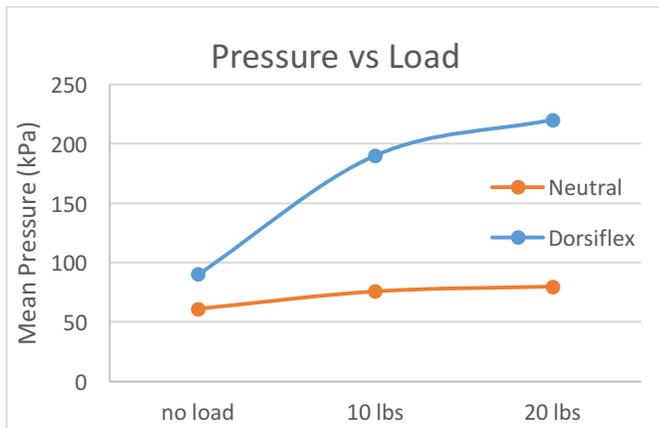

**Figure 1.** a) Custom built ankle positioning and loading device and b) View of Novel strip sensor inserted through the midfoot from the medial side.

The mean and peak pressures of each stance were exported from the Novel Pliance software and plotted for all three load conditions.

## RESULTS AND DISCUSSION

The mean pressure across the calcaneocuboid and talonavicular joints increased minimally when load was applied while the foot was in neutral. However,

while the foot was in dorsiflexion, a greater increase in mean pressure occurred. The largest increase occurred when 10lbs was applied, while a smaller increase occurred at 20 lbs of loading.

**Figure 2:** Mean pressures recorded during neutral and dorsiflexed stance at three different load conditions.

The peak pressures were reported from the talonavicular (n=11) and calcaneocuboid (n=12) joints with Tekscan I-scan sensors when the tibia was axially loaded to 700 N (157.366 lbs), the Achilles tendon was loaded with 400 N (89.92 lbs) and the posterior tibial tendon was loaded with 200 N (44.96 lbs) of force [2] (Table 1). While the exact pressure values cannot be compared due to significantly different loading conditions, both studies observed an increase in peak pressures from neutral to 30 degrees of dorsiflexion.

The greatest amount of mean contact pressure in the present study occurred when the foot was fully loaded in dorsiflexion compared to when in neutral. The substantial pressure during the late stance of gait while the foot is dorsiflexed is thought to cause serious joint deterioration [2]. At 30 degrees of dorsiflexion, the highest ankle angle seen in normal

gait, the mean pressure in the midfoot is over twice that as seen in neutral stance (Fig. 2). These results support the hypothesis that injuries or diseases that increase pressure can cause further break down of the joints, especially when moving through activities of daily living (e.g., walking).

The Novel Pliance strip sensor provided limitations to measuring pressure in the joints. Due to the thickness of the sensor and limited joint space, the sensor could not be inserted laterally into the joint. Another limitation is due to its current design which includes a grommet for suturing it in place. If one sensors was inserted medially and one laterally, the part of the sensors with the grommets would collide and prevent full insertion of the sensors into the joints. Therefore, our current sensors make it impossible to measure talonavicular and calcaneocuboid joint pressures individually. An additional limitation within the study was that joint pressures were measured in neutral and dorsiflexion only. Future studies should consider investigating the joint pressures within a more global range of possible foot positions (i.e., planterflexion, inversion, eversion).

## CONCLUSIONS

The Novel sensors can be used to measure pressure across the talonavicular and calcaneocuboid joints. The limitation being that the calcaneocuboid and talonavicular joint pressures were not isolated. In future work, different degrees of dorsiflexion (0, 10, 20, 30) and additional loading will be investigated.

email: tytsai@sjtu.edu.cn

## INTRODUCTION

Temporomandibular joint (TMJ) is the only joint in the maxillofacial region. It with the surrounding muscles is responsible for various fundamental movements, e.g. chewing, biting, clenching, and yawning<sup>[1, 2]</sup>. Measurement of the TMJ kinematics facilitates diagnoses of TMJ disorder/disease and assessment of treatment effects. However, few studies directly assess in-vivo TMJ kinematics during functional activities. This study aimed to propose a new image-based tracking technique for measurement of in-vivo 6 degrees-of-freedom (6-DOF) TMJ kinematics during maximum mouth opening and closing movement (MOCM) and to evaluate the symmetry of mandibular movement in a typical health subject.

## METHODS

In this Institutional Review Board approved study, a healthy individual (Male, 23 years, BMI 21.5) with no history of any surgical, maxillofacial trauma and orthodontic treatment was recruited. Two custom-made stands for fixation of 6 infrared retro-reflective markers to the upper and lower jaws were 3D printed (Fig. 1A) with Medvance PANGU 4.1 (Meditool, Shanghai, China). The subject with the two 3D printed stands then received a cone-beam computer tomography (CBCT, i-CAT, Imaging Sciences International, Hartsfield, PA, USA) scan for the creation of surface models of temporal bone, mandible and the markers. The local coordinate systems were defined using the mandibular bony landmarks (Fig. 1B)<sup>[3]</sup>. The TMJ motion was tracked via the markers using a portable motion capture system (V120:Trio, Optitrack, NaturalPoint,

Inc., USA) during MOCM (Fig. 2). The 3D TMJ angles and the movement trajectories of the mandibular head centers (MHC), and central incisor (CINC) were calculated in MATLAB (The MathWorks, Natick, USA).

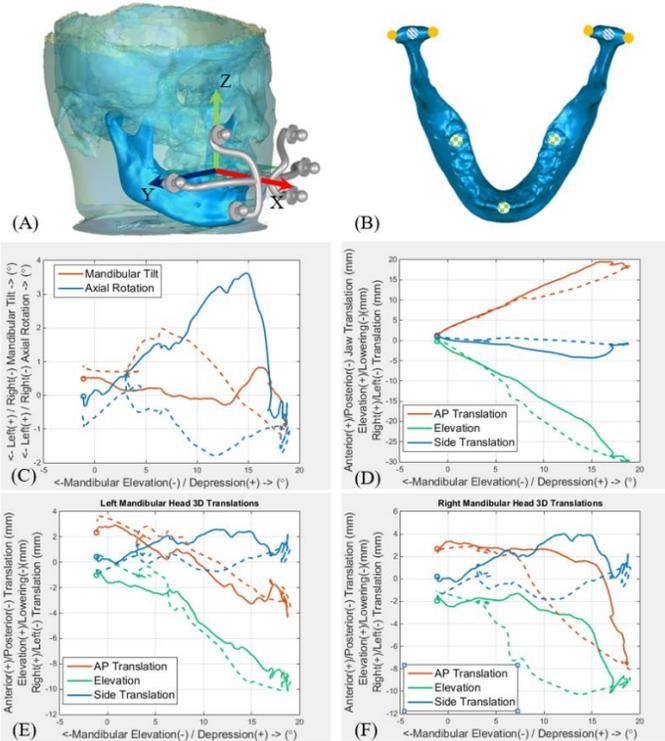

## RESULTS

The TMJ rotations showed an asymmetric pattern between opening and closing paths (Fig. 1C). The maximum mandibular axial rotation angle was up to 4.5°. The maximum mandibular title angles were 3.2° and 1.7° for closing and opening movement, respectively. The translations of CINC were apparently asymmetric between opening and closing paths (Fig. 1D). The trajectories of the bilateral MHC were found to be largely asymmetric during MOCM (Fig. 1E&F). The mouth closing movement did not follow the kinematic path during opening. The return trajectories of the left MHC in anterior/posterior and elevation/depression directions were similar to the opening, while the right MHC differed widely.

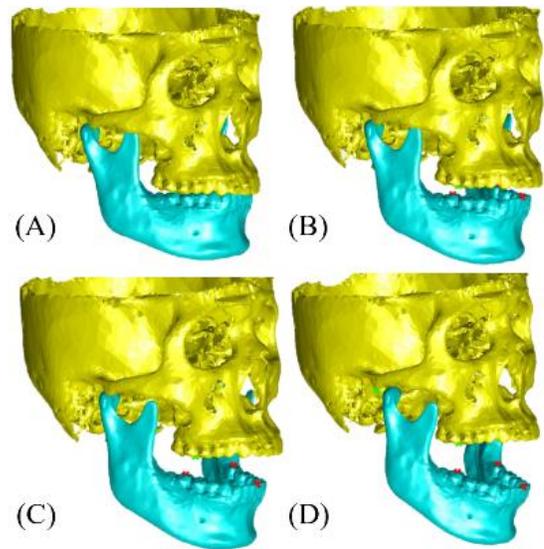

## DISCUSSION

This study successfully demonstrated the feasibility of the novel CBCT-based tracking technique for quantification of the TMJ kinematics. This technique allowed non-invasive determination of in-vivo 6-DOF TMJ motion and provided detailed surface kinematics of the condyles and opposing fossae. The obvious asymmetric mandibular motion was observed between the mouth opening and closing movement, showing complex TMJ motion characteristics and the importance of individualized medicine for TMJ. Further studies are required to

evaluate the accuracy and precision of this technique before extensive clinical applications.

**Figure 1.** (A) CBCT-based 3D models of skull and mandible with anatomical coordinate systems and two 3D printed stands for fixation of 6 infrared reflective markers, (B) Bony landmarks for construction of anatomical coordinate system of the mandible, (C) TMJ rotations and tilts against mandibular elevation/depression, and (D) 3D translations of the central incisor against mandibular elevation/depression. 3D translations of the (E) left and (F) right mandibular head with respect to the mandibular elevation/depression. The obvious asymmetric mandibular motion was observed between the mouth opening (solid lines) and closing (dashed lines) movement.

**Figure 2.** 3D TMJ movement tracked using image-based non-invasive tracking technique during maximum mouth opening movement. (A) 0%, (B) 33%, (C) 66%, and (D) 100% of mouth opening movement.

## INTRODUCTION

A reduction in articular cartilage thickness has been identified as a risk factor for the development of osteoarthritis (OA) (3). Magnetic resonance imaging (MRI) has typically been used to determine cartilage thickness in clinical populations. While MRI scans provide detailed images of cartilage thickness, they are expensive, require specialist equipment and extensive training to administer. Ultrasound imaging has emerged as a less invasive, more cost-effective alternative to MRI that can be used to assess cartilage thickness (2).

While ultrasound has been shown to be reliable in healthy and osteoarthritic populations (1, 4), its efficacy is less certain in other clinical populations. Yet, this tool could be extremely valuable in obese and Type 2 diabetic populations, who have an increased risk for developing OA but may currently be asymptomatic. The reliability of ultrasonography is particularly important in these cohorts, due to the increase in soft tissue surrounding the joints.

Therefore, the purpose of this study is to investigate the reliability of ultrasound scans in determining cartilage thickness in a clinical population. The ability to use ultrasound scans to determine articular cartilage thickness would make this measurement more accessible to researchers thus helping to provide further insight into changes in cartilage thickness in more research. We believe that ultrasound scans will be a reliable method in investigating cartilage thickness in clinical populations.

## METHODS

Six healthy (Age  $37 \pm 14$  yrs;  $78.08 \pm 6.15$ kg) and six Type II diabetics ( $56 \pm 2$  yrs;  $99.84 \pm 13.94$ kg) participated in the reliability assessments, which were conducted in the Sport and Exercise Science

Lab at Massey University, Wellington. Ultrasound assessment techniques were adapted from EULAR guidelines (2). To determine femoral cartilage thickness, participants were required to lay supine with their knee bent as much as possible. While full knee flexion was encouraged, it was not required, as some participants found this position difficult to achieve due to increased thigh circumference. Ultrasound scans were taken using a portable ultrasound system (Sonosite MicroMaxx, USA) equipped with a 13-6 MHz bandwidth transducer. The ultrasound probe was placed transverse to the leg and perpendicular to the bony surface, just superior to the proximal aspect of the patella. Three images were captured on the right leg of each participant during one testing session. The probe remained in the selected spot for each image that was captured. The assessment was repeated within 24-36 hours later.

**Figure 1:** Ultrasound image of femoral articular cartilage: showing medial condyle, intercondylar notch, and lateral condyle.

Cartilage thickness was measured from the thin hyper-echoic line at the cartilage-bone interface using Image J software. Measurements were taken at the medial condyle, intercondylar notch, and the

lateral condyle (Fig 1). The measurements for each of the three trials per site were averaged and intra-class coefficients (ICC) were calculated to assess inter-day reliability (SPSS, Version 24.0. Armonk, NY: IBM Corp). An independent t-test was also performed to compare the mass of each participant group. Statistical significance was set at  $p < 0.05$ .

## RESULTS AND DISCUSSION

ICC values can be found in Table 1. Scans for both populations showed high reliability between days (i.e.,  $ICC > 0.7$ ). The medial condyle in the clinical group had the lowest ICC (i.e., 0.797) but was still above the threshold for high reliability. These findings suggest that measurements of femoral cartilage thickness from images taken from diagnostic ultrasound have high day-to-day reliability in both healthy and diabetic patients. The ICC results found in this study were greater than other reliability studies such as that by Abraham et al (1) where ICC values of 0.42 – 0.68 were reported.

Finally, an independent t-test showed that the clinical group carried more mass than the healthy control group ( $p = 0.015$ ). Where it may have been thought that excessive mass and therefore excessive fatty tissue would inhibit accurate ultrasound measurements, this study provides evidence that ultrasound measurements were of similar reliability in the clinical group when compared to the healthy group. Given that overweight individuals are at greater risk for joint disease such as OA, reliable ultrasound methods could provide a more convenient assessment of OA progression.

Average Measures	ICC		
	Medial	Notch	Lateral
<b>Healthy Control</b>	.989	1.000	.974
<b>Clinical Group</b>	.797	.990	.969

**Table 1:** Intraclass correlation coefficient results for the healthy control and clinical group.

## CONCLUSIONS

The purpose of this study was to determine whether ultrasound imaging is a reliable tool in assessing

cartilage thickness in clinical populations. The current results provide evidence that ultrasound imaging is a reliable assessment tool to measure articular cartilage thickness amongst healthy adults and diabetic patients. Future studies should assess the reliability of ultrasound imaging for cartilage thickness measures in obese adults considering that obesity is a major risk factor for knee osteoarthritis.

## INTRODUCTION

Individuals with spinal cord injury have been reported to have upper limb pain in rates as high as 70% [1]. It is believed that this high prevalence of pain is related to an increased reliance on the upper limbs for mobility. Work is ongoing to understand what specific activities or conditions are most detrimental. This includes an evaluation of both kinematics and forces exerted during tasks.

Activities performed from a wheelchair base, particularly transfers and other weight bearing activities, may be performed with variable hand positioning (e.g. one person may place their hands on the armrest and another on the frame of the wheelchair). This variability in technique necessitates a force sensing approach that can be applied to these various surfaces.

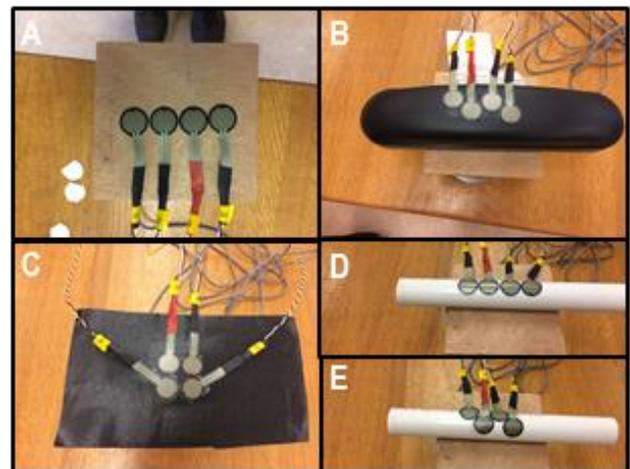

The purpose of this study was to optimize instrumentation of wheelchair components with an array of force sensing resistors (FSR's). We hypothesized that agreement between the FSR array and the gold standard measurements would be dependent on array configuration and the hardness of the surface to which they are applied.

## METHODS

Four circular 12.5-mm diameter FSR's (Interlink 402) were connected to a custom-built signal conditioner (LM358N operational-amplifier with 500  $\Omega$  resistors powered by a 5V regulated power supply). Each FSR was laid on a rigid surface and calibrated with a series of reference masses (500, 1000, 2000, and 7000 grams). FSR's were applied to four different surfaces: a rigid, flat wood plate; a

vinyl-covered wheelchair armrest; and a vinyl-covered cushion foam and a second vinyl covered foam of lower stiffness. Surfaces were selected to replicate components with which wheelchair users may interact during daily activities including manipulating objects and load transfers. FSR's were applied to the surface in three different patterns: straight line (Fig 1A), staggered (Fig 1B), and 4-corners (Fig 1C).

Additionally, FSR's were attached to a 25-mm diameter PVC tube in both straight line and staggered patterns (Fig 1D and 1E, respectively). All materials were mounted on top of a load cell (MLP-150, Transducer Techniques) which was used to capture actual loading applied (Figure 2A).

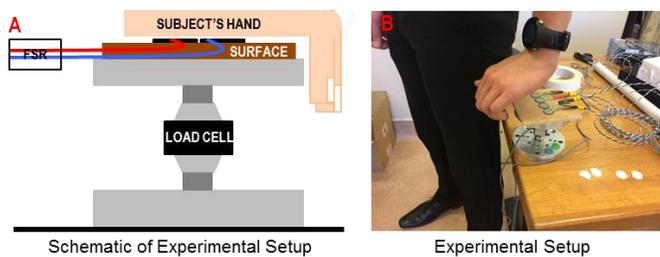

**Figure 1:** Representative FSR configurations: A) straight line on rigid, wood surface, B) staggered on wheelchair armrest, C) 4-corners on cushioned surface, D) straight line on pipe & E) staggered on pipe.

Force measurements were collected from three subjects, each exerting self-directed low, medium,

and high pressures for three trials to each configuration (Fig 2B). Data from each FSR and the load cell were captured simultaneously at a sample rate of 120 Hz.

For each trial, the peak force from the sum of all FSR's was selected, which were compared with the peak load from the gold standard load cell data. For each configuration the Pearson correlation coefficient was assessed, a straight line was fit to the data with linear regression and associated coefficients of determination were calculated, and Bland-Altman plots of agreement were generated [2].

**Figure 2:** A) Schematic of experimental setup B) subjects applying load to instrumented surfaces.

## RESULTS AND DISCUSSION

The Pearson correlation coefficient ranged between 0.63 and 0.98 over all configurations, with the straight line configuration most consistently showing high correlations over the different test surfaces. Slopes of best fit lines ranged between 0.19 and 0.54; with the straight line pattern consistently performing better than other configurations across all test surfaces (Table 1). Bland-Altman plots indicated the best agreement between FSR and load cell data occurred for straight configuration as the smallest range of 95% limits of agreement over different test surfaces was observed.

**Table 1:** Statistical results for all configurations. Data displayed as Pearson correlation coefficient (PCC), slope (m), and coefficient of determination ( $R^2$ ).

	WOOD			WHITE FOAM			BLACK FOAM			ARMREST			PIPE		
	PCC	m	$R^2$	PCC	m	$R^2$	PCC	m	$R^2$	PCC	m	$R^2$	PCC	m	$R^2$
Straight	0.88	0.43	0.77	0.79	0.32	0.62	0.80	0.27	0.64	0.98	0.46	0.97	0.98	0.54	0.95
Stagger	0.90	0.39	0.80	0.63	0.19	0.40	0.82	0.26	0.67	0.98	0.42	0.96	0.96	0.50	0.91
4-corner	0.81	0.42	0.65	0.64	0.19	0.40	0.84	0.35	0.70	0.86	0.35	0.73	<i>not tested</i>		

The analysis shows that, at most, the FSR array is seeing just under 50% of the applied load. One reason for this may be that the FSR arrays were not large enough or dispersed appropriately to capture all contact of the subjects' hands with the surface. The straight line configuration appears to have performed best in this respect, but addition of sensors extending the capture area of this pattern may improve results. When applied to piping, the straight line patterns appear to perform slightly better than the staggered, but only just over 50% of the applied load is captured.

Despite the sensors consistently not capturing the full load applied, correlations for most configurations were quite strong, supporting use of this system as a qualitative, if not quantitative tool.

## CONCLUSIONS

The straight configuration of FSR's consistently correlated well with the applied loading over all surfaces tested, thus we feel it can be used for qualitative assessment of reaction forces of select tasks of wheelchair users.

# 3D SCANNING: AN INNOVATIVE METHOD TO PERSONALIZE BODY SEGMENT PARAMETER CALCULATIONS

Marco Avalos, Mohammad Hasan, Young-Hoo Kwon

Biomechanics Laboratory, Texas Woman's University, Denton, Texas, USA  
email: mavalos1@twu.edu, web: <http://www.twu.edu/kinesiology/biomechanics.asp>

## INTRODUCTION

Motion analysis is commonly used in biomechanics for calculation of various kinematic and kinetic variables. A pre-requisite of an accurate kinetic analysis in motion analysis is an accurate estimation of the body segment parameters (BSP) such as masses, center-of-mass (CM) locations, and principle moments of inertia (MOI) of the segments. [1]. Models to determine these parameters primarily relied on the use of cadavers [2], or technology that results in high costs and the parameters obtained are often not generalizable. Segmentation of the human body into various segments and estimation of the individualized BSPs requires a large number of anthropometric parameters [3]. Modeling of body segments as cascades of simple geometric shapes and use of accompanied equations [4] allows calculation of individualized BSP.

In this study, we propose the use of 3D scanning as a method of measurement for the body segments on a model consisting of 16 segments and a total of 61 geometrical shapes.

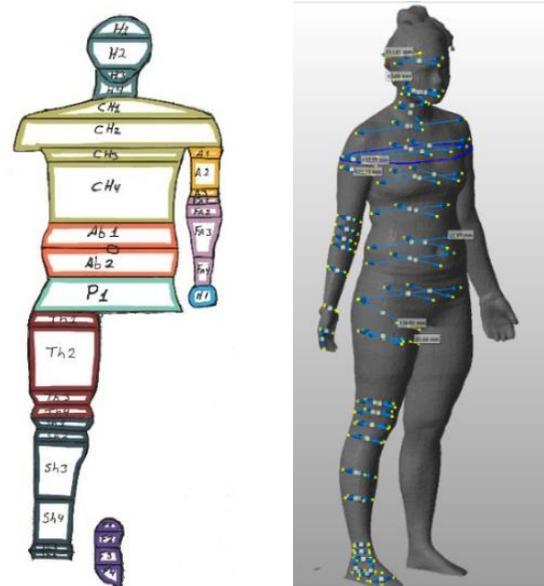

## METHODS

Markers were placed on nine female participants ( $20.88 \pm 1.46$  years old) according to the body model (Figure 1). This model consist is mainly composed by elliptical solid and elliptical columns. Upper and lower body scans were performed using a 360° rotating display stand and a 3D scanner (Kinect, Microsoft Corp., Redmond, WA). The upper and lower scans were merged into one and digitally measured using NetFabb 7.0 (Parsberg, Germany). Assuming symmetry, unilateral manual measurements were also collected. Medirolateral length, circumference and height of segmental shapes were taken 3 times. The segmental BSP's

were calculated using a MatLab code. Intra-class correlation coefficient (ICC) of the total mass of the 3D scan, and manual and real measurement were estimated through SPSS v.22.

## RESULTS

The ICC (0.927) between the two measuring methods and the real total mass were consistent in all the participants. Measurements obtained using 3D scan were consistently higher than the real mass, while measurements obtained using the manual method were consistently lower than the real mass. The upper body measurements show no significant differences ( $p=0.262$ ) when using either the 3D scan method or the manual method. However, both methods show significant differences in the lower body ( $p=0.023$ ) and torso ( $p<0.001$ ) measurements.

**Figure 1:** a) Proposed body model segmentation, b) 3D scan measurements on participant according to proposed body model.

## DISCUSSION

The 3D scan camera used was adapted from first-generation videogame equipment, new technology cameras would allow for better quality imaging. Scanning participants in one swipe would allow better definition and avoid possible distortion created while merging the images. When measuring the circumferences, it was necessary to tighten the measuring tape in order for it not to move from the marker line. This slight compression may explain the reduction in volume and mass of each segment. The

female gynoid body composition may explain why the measurement around the torso and lower extremities resulted in decreased volume when taking circumferential measurements manually.

# DAY-TO-DAY RELIABILITY OF GAIT CHARACTERISTICS AND COORDINATION IN RATS

<sup>1</sup> Peter C. Raffalt, <sup>1</sup> Louise R. Nielsen, <sup>2</sup> Stefan Madsen,  
<sup>2</sup> Laurits Munk Højberg, <sup>2</sup> Jacob Wienecke and <sup>1</sup> Tine Alkjær

email: raffalt@sund.ku.dk

## INTRODUCTION

Animal models (e.g. rodents and cats) are widely used in applied research of various neurological diseases (e.g. cerebral palsy). Such diseases will often cause impaired gait function. Thus, reliable quantification of the animal gait pattern is vital for the assessment of the functional impact of the diseases and the evaluation of rehabilitation protocols. Gait pattern in rodents can be quantified using kinematic analysis of the stride characteristics (e.g. stride/step length, stride/step time, step width) and lower limb joint angles (1). While these measures provide valuable information of the movement pattern, they do not quantify the inter-segment coordination. In human locomotion research, lower limb segment coordination and coordination variability have been quantified using continuous relative phase (CRP) and deviation phase (DP), respectively (2). Applying these measures in gait analysis of rodents could provide additional information of the impact of pathology on the limb coordination during locomotion.

The present study investigated the day-to-day reliability of selected gait parameters in rats during walking at three different speeds. In addition, the CRP and DP were introduced as outcome measures of the lower limb coordination pattern and the coordination variability.

## METHODS

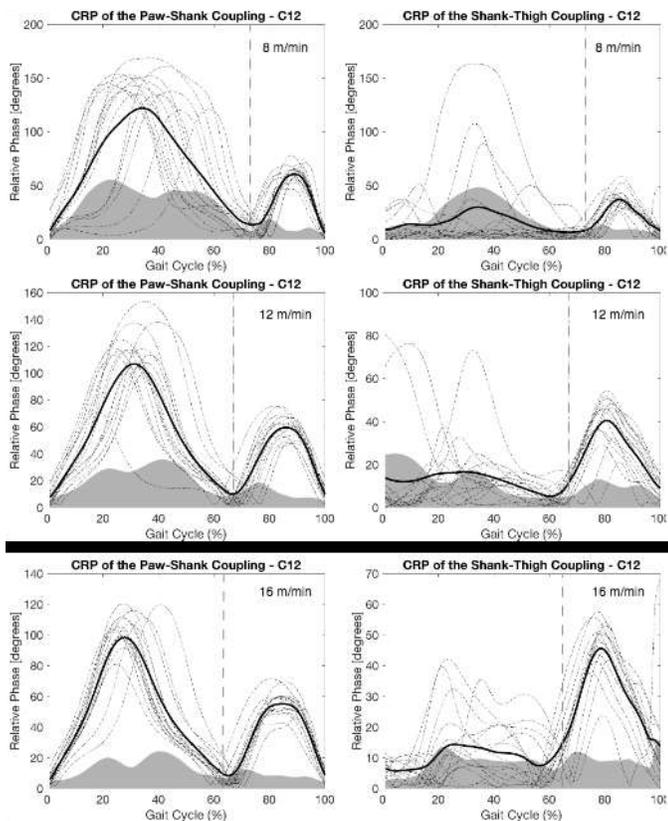

Twenty-six Sprague Dawley rats with a body mass of  $437 \pm 61$ g were included in the present study. Sagittal plane lower limb 2D kinematics were recorded using one infrared camera (Qualisys) operated at 120 Hz. After careful shaving of the left hind limb, four reflecting markers were attached on bone landmarks (ilia crest, greater trochanter, knee

joint center, lateral malleolus and the head of the 5<sup>th</sup> metatarsal bone). On two separate days, each rat walked on a motorized treadmill at three different speeds (8 m/min, 12 m/min and 16 m/min) for at least 45 seconds. Trials were accepted when 15 successful strides were obtained. The following variables were extracted from the kinematic data: stride length, swing phase duration, stance phase duration, hip, knee and ankle joint angle range of motion (ROM), mean CRP and mean DP for the shank-thigh coupling and paw-shank coupling (figure 1).

In order to estimate the day-to-day reliability, intra-class correlation (ICC 1.1) was applied. This ICC assumes that all within subject variability is due to measurement error. In addition, the absolute reliability was quantified by the square root of the mean square error assessed by a two way ANOVA. The statistical analyses were conducted in SPSS. ICC above 0.75 were considered excellent, between 0.60 and 0.74 good, between 0.40 and 0.59 fair and below 0.40 poor.

## RESULTS AND DISCUSSION

The ten investigated variables of the present study included three different stride characteristics (stride length, swing phase duration and stance phase duration), three different joint angle parameters (hip, knee and ankle joint angle ROM) and four coordination measures (shank-thigh mean CRP, paw-shank mean CRP, shank-thigh mean DP and paw-shank mean DP). Across the three walking speeds, joint angle parameters appeared to have good or excellent reliability in more cases (6 out of 9) compared to stride characteristics (4 out of 9) and coordination measures (4 out of 10) (table 1).

**Figure 1:** CRP of the paw-shank and shank-thigh coupling (average CRP curve: solid, each stride: dashed) for one rat (C12) and DP (gray area). Vertical dashed line indicate paw off. Mean CRP was calculated as the mean of the average CRP curve and mean DP was calculated as the mean of the DP across the gait cycle.

Furthermore, across walking speeds stride characteristics appeared to have good reliability in

more cases compared to the coordination measures (table 1).

Based on the measurement error (table 1), speed did not appear to influence the absolute reliability of the investigated parameters.

## CONCLUSIONS

The present study assessed the day-to-day reliability of a number of gait pattern parameters in rats during walking at different speeds. Based on the result, it can be concluded that joint angle parameters in general had good reliability in more cases compared to stride characteristics and coordination measures.

The absolute size of the day-to-day reliability includes both methodological inaccuracies (e.g. skin movements and marker placement) and the inherent biological variation in the rat gait pattern and does not appear to be influenced by walking speed.

Although, the introduced coordination measures CRP and DP potentially provide valuable information of the coordination pattern during walking in rats, interpretation of the measures should be made with caution in light of the reported reliability of the present study.

# RELIABILITY OF BIOMECHANICAL VARIABLES ASSOCIATED WITH KNEE OSTEOARTHRITIS DURING WALKING

Jillian L. Hawkins, Richard A. Brindle, Clare E. Milner

Drexel University, Philadelphia, PA, USA  
email: jh3266@drexel.edu

## INTRODUCTION

Knee osteoarthritis is one of the most prevalent musculoskeletal diseases, affecting 14 million people in the United States [1]. Osteoarthritis is associated with difficulty in physical function and poor quality of life [2]. Specifically, knee osteoarthritis affects walking and daily movement.

Biomechanical variables measured during walking are often studied in individuals with or at risk for knee osteoarthritis and compared to healthy controls. In particular, peak knee flexion and adduction angles and peak knee extension and abduction moments have been measured previously and differences between knee osteoarthritis and control groups were reported [3,4]. However, the measurement errors associated with the dependent variables were not provided.

The purpose of this study was to test within-day and between-day reliability and minimum detectable difference (MDD) of knee variables often associated with knee osteoarthritis. We hypothesized that peak knee flexion angle, peak knee adduction angle, peak internal knee extension moment, and peak internal knee abduction moment during walking would have good or excellent within-day and between-day reliability.

## METHODS

Eighteen healthy adult men between 18 and 50 years old participated in this study. All participants ran at least 10 miles per week for a year or more, were uninjured at the time of testing and did not have a previous severe lower extremity injury. Prior to participating, each participant gave his written informed consent.

An eight-camera motion capture system recorded three-dimensional kinematics at 200 Hz in synchronization with a force plate which recorded ground reaction forces at 1000 Hz. Participants changed into athletic shorts and had their height and weight measured. Retro-reflective markers were attached to the participants' pelvis and lower extremity for defining and tracking segments. Participants wore standard laboratory footwear and a static standing trial was recorded. Following the static trial, anatomical markers were removed and five good walking trials were collected. Walking speed was standardized to  $1.25\text{ms}^{-1}$  ( $\pm 5\%$ ). All participants returned to the laboratory a second time at least 5 days after their first visit, and the walking gait analysis protocol was repeated.

Data were processed using rigid body analysis software. A 20 N vertical ground reaction force threshold indicated the beginning and end of the stance phase. Raw data were filtered at 6 Hz using a low pass 4<sup>th</sup> order Butterworth filter. Knee angles were calculated using the joint coordinate system, and internal joint moments were calculated using inverse dynamics. Peak values during the first 60% of stance were determined using custom software.

Within-day and between-day reliability were analyzed using intra-class correlation coefficients ( $\text{ICC}_{(1,1)}$  and  $\text{ICC}_{(3,5)}$ , respectively). The standard error of measurement (SEM), and MDD values for 95% of a normal distribution were also calculated. Reliability was considered to be excellent if the ICC was greater than 0.90, and good if the ICC was greater than 0.75 [5].

## RESULTS AND DISCUSSION

The purpose of this study was to test within-day and between-day reliability and MDD of variables

associated with knee osteoarthritis. Our hypotheses were supported by the results as all variables had either good or excellent within-day and between-day reliability. (Table 1).

Within-day and between-day MDD values for all variables of interest were about the same. Within-day reliability indicates variability within the individuals measured, such as differences in stride-to-stride movements. Since the data were all collected within the same session, the effect of the rater is minimized. Between-day reliability reflects the reliability of the rater in placing markers between sessions in addition to stride-to-stride and day-to-day differences in the individuals measured. Between-day MDD values can be used to interpret differences in interventional or longitudinal data.

The between-day reliability of several of the variables of interest in healthy young adults was reported recently [6]. The ICCs and MDDs for peak knee flexion angle, extension moment and abduction moment were comparable to our results. Unfortunately, magnitude of these variables were not reported, so we cannot confirm that the peaks are comparable. We have extended the previous findings by reporting the reliability and MDD of peak knee adduction angle, plus the within-day reliability and MDD of all variables of interest. The agreement with existing literature for the common variables is encouraging and suggests that the additional findings we report are also representative of young healthy adults. Thus, we suggest that these findings can be used in future power calculations

for these variables in healthy young men. We anticipate that the findings may be extended to healthy young women as well, because variability during walking is similar in healthy young men and women [7]. Furthermore, the previous reliability study reported on a group of men and women with similar findings to the present study for the common variables [6]. However, these data may not generalize to reliability in other populations, such as older adults and individuals with knee osteoarthritis. We suggest that future studies should determine reliability and MDD using samples representative of these populations.

## CONCLUSIONS

Biomechanical variables often studied in association with knee osteoarthritis during gait have good to excellent within-day and between-day reliability. The MDD values can be used to inform future studies in healthy young men. Caution should be used in extending these data to other populations.

## INTRODUCTION

The measurement of thoracolumbar spine curvature and motion is of interest for study of conditions such as back pain, adolescent idiopathic scoliosis, and age-related spinal deformity. Opto-electronic motion capture systems may allow non-invasive evaluation of spine curvature and dynamic motion with appropriate sets of markers applied to the spine. Such marker sets have been of increasing interest recently, for example with studies of soft tissue artifacts in the back [1] and spine motion in scoliotic and healthy adolescents [2]. However, the between-session reliability of these marker sets for evaluating sagittal spinal curvature has not been evaluated. Thus, the aim of this study was to determine the reliability of the retroreflective marker-based measurements of thoracic kyphosis, lumbar lordosis and pelvic tilt, and compare these measures with corresponding non-radiographic clinical measurements.

## METHODS

A reliability study was conducted on 19 healthy adults (11 men, 8 women) aged between 20 and 74 years. Each subject visited the motion analysis lab and underwent the same set of measurements on two separate occasions an average of 7 days apart (range 2-14 days).

Marker-based measurements were based on a set of 4-marker clusters placed on the skin overlying the T1, T4, T5, T8, T9, T12 and L1 spinous processes, with additional single markers on C7 and the posterior (PSIS) and anterior (ASIS) superior iliac spines (Figure 1). In each session, marker positions were captured using a 10-camera Vicon motion capture system during two static trials in the neutral

upright standing posture (2 sec each). Angle calculations were performed on the mean positions of the markers in the sagittal plane using a custom MATLAB program. For spine curvature, circles were fit to thoracic and lumbar segments [2], then thoracic kyphosis and lumbar lordosis were calculated as angles between T1-T12 and L1 - Sacrum, respectively. Pelvic tilt was defined by the markers placed on the PSIS and ASIS.

**Figure 1:** The set of single and cluster retroreflective markers placed on the back.

Non-radiographic measures were made using established measurement tools reported to have good reliability: the flexicurve for spine curvature [3] and the palpation meter (PALM) for pelvic tilt [4]. A single rater tested each participant in both sessions. Flexicurve angle was calculated for thoracic kyphosis and lumbar lordosis. The PALM measurement was based on the angle between PSIS and ASIS, with a forward tilt defined as negative angle.

Test-retest reliability of each measurement was examined using intraclass correlation coefficients (ICC). Reliability is poor for ICCs < 0.4, fair to good if between 0.4 to 0.75 and excellent if above 0.75. Pearson’s correlation coefficients were calculated to compare marker-based measurements and corresponding flexicurve and PALM measurements. Analyses were performed with Stata/IC 13.1 (StataCorp LP, College Station, TX).

## RESULTS AND DISCUSSION

For thoracic kyphosis, marker-based measurements showed excellent between-session reliability (ICC = 0.95), comparing favorably with the flexicurve measurement (ICC= 0.83) (Table 1). A same-day ICC of 0.94 has been reported for average sagittal thoracic curve during gait cycles in non-scoliotic adolescents [2]. While not directly comparable, this supports the current finding that marker-based measures are highly reliable. We also found a significant positive correlation ( $r = 0.795$ ) between marker-based thoracic kyphosis measurement and flexicurve angle, reflecting good criterion validity of the markers in thoracic curvature measurement (Table 1). This compares well with reported correlations between marker-, and MRI-based measurement of thoracic kyphosis ( $R^2$  of 0.385, [1]), and between flexicurve and radiologic Cobb angle of ( $R^2$  of 0.57, [3]).

For lumbar lordosis, the marker-based ICC value of 0.86 was comparable with the value of 0.84 for flexicurve measurement, both showing excellent between-session reliability (Table 1). Schmid et al. [2] reported the ICC values of 0.90 (CI; 0.80, 0.97) for marker-based sagittal lumbar curve analysis that was averaged during a gait cycle in a same day trial. We also found a significant positive correlation ( $r = 0.643$ ) between marker-based and flexicurve lumbar

lordosis measurement, showing satisfactory criterion validity of markers for lumbar lordosis measurement (Table 1). Again, this compares well with correlations between marker-, and MRI-based measurement of lumbar lordosis ( $R^2$  of 0.552, [1]).

Reliability of marker-based pelvic tilt measurement (ICC; 0.40) was considerably lower than the PALM value (ICC; 0.76). The correlation between marker-based pelvic tilt angle and PALM data was not significant ( $r = 0.345$ ) (Table 1).

## CONCLUSIONS

Marker-based measurements of sagittal spine curvature were very reliable between sessions, and compare quite favorably with frequently used non-radiologic methods. On the other hand, pelvic tilt was not reliably captured, but it may be more sensitive to errors in marker placement as it was based on only four markers. Overall, this study supports opto-electronic motion capture with an appropriate spinal marker set as a reliable non-invasive method for evaluating spine curvature and potentially spinal motion.

## INTRODUCTION

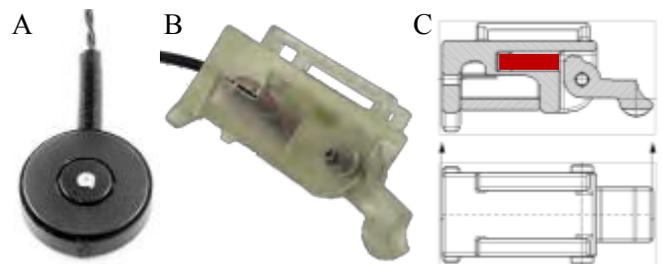

More than a third of older adults fall each year, and the risk of falling drastically reduces an older adult's mobility, independence, and quality of life [1]. Postural control is dependent on proprioceptive feedback of the lower limbs, but this sensation declines with age, and this decline has been identified as a risk factor for falls [2]. Thus, therapeutic technology that can enhance these degrading proprioceptive signals is of great interest to research.

An emerging mode of intervention utilizes the phenomenon of stochastic resonance (SR), whereby a weak or imperceptible stimulus is detected in the presence of an optimal amount of noise. In humans, externally applied vibratory noise increases action potential generation in the mechanoreceptors under the skin, and can enhance perception of tactile and proprioceptive stimuli [3]. Accordingly, SR vibration has been shown to improve postural control when applied to the feet [4] and ankles [5].

Although there is strong potential for this technology, application has been limited because tuning to the proper amount of noise for each subject is challenging. Too much noise will washout the stimulus signal, yet too little will provide no enhancement. The skin mechanoreceptors are sensitive to frequencies between 100–300 Hz [6], and activation of the SR effect requires a consistent level of noise across these frequencies. Potential SR actuators must be able to modulate noise levels without biasing the vibration signal towards any specific frequencies.

Several studies have measured SR postural control using electromechanical C-2 and C-3 tactors (Engineering Acoustics, Winter Park, FL) to produce the mechanical noise signal [5, 7]. These

tactors function like an audio speaker whereby a diaphragm attached to a magnet is situated in an inductor (Fig. 1A). Due to this construction, the diaphragm is easily impeded and its displacement is highly sensitive to the applied pressure of the tactor against the skin. The C-2 and C-3 tactors have also been specifically designed to exhibit resonance behavior between 250–300 Hz, making the production of white noise in the desired frequency band challenging. These characteristics render the tactor problematic for use in SR applications.

**Figure 1:** A) C-3 tactor. B) Our designed piezo lever device. C) Cross sectional view reveals inner cavity where piezoelectric stack (red) resides.

Piezoelectric actuators have also been used in SR research [4, 8], but unlike tactors which can easily be taped to the skin, the geometry of most piezoelectric actuators require some sort of housing to hold the actuator and transfer vibration to the skin. SR studies using piezoelectric actuators have not well described this housing [4, 8]. We have developed a piezoelectric lever device (PLD) which amplifies the displacement of a piezoelectric stack (PK4JQP2, Thor Labs, Newton, NJ) embedded within the housing (Fig. 1B,C). As the piezo will vibrate under an applied load (<144 N) and exhibits resonance at 60 kHz, the PLD should be suitable for producing predictable amplitudes of noise in the required frequency band. The goal of this research was to compare 100–300 Hz vibrational noise when using a C-3 tactor and the PLD.

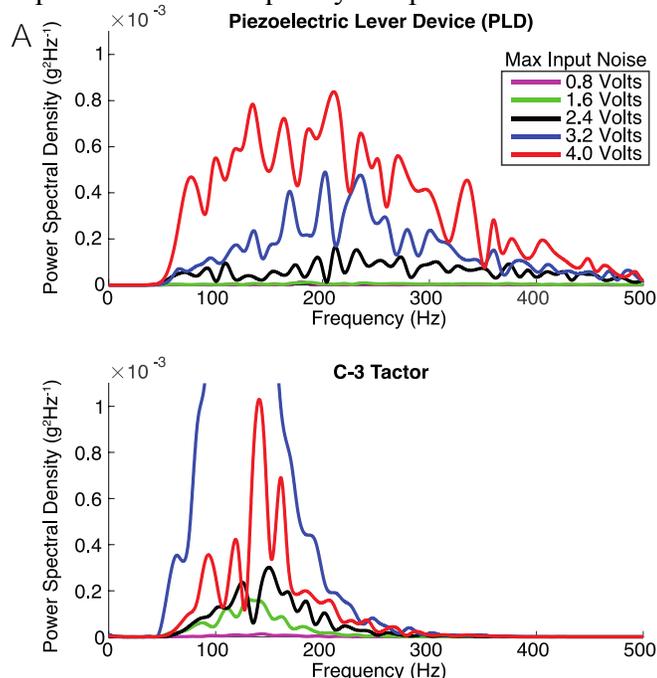

## METHODS

A C-3 tactor and the PLD were secured to a compliant cylinder testbed (simulating skin) using medical tape. An accelerometer (352C23, PCB, Depew, NY) was positioned over the actuators as vibration was driven at 100-300 Hz using a noise signal generated in LabVIEW. Accelerometer data was collected for 10 seconds at 20 discrete levels of input noise, spanning 0.2–4 V in 0.2 V increments, and then analyzed using MATLAB. Each collection was detrended and filtered using a zero-phase digital bandpass filter from 50–500 Hz. The power spectral density was calculated for increasing levels of noise, and the root-mean-squared acceleration was calculated for both 100–200 and 200–300 Hz.

## RESULTS AND DISCUSSION

The PLD demonstrated consistent vibrational noise across 100–300 Hz for all noise levels, but the C-3 tactor exhibited resonance in the 100-200 Hz range (Fig 2A). Analysis of the frequency domain shows that the tactor device did not accurately reproduce a consistent 100–300 Hz noise signal necessary to activate the SR effect across all mechanoreceptors. Attenuation occurred after 200 Hz (Fig 2B).

Comparatively, the PLD responses scaled as expected. The frequency responses were much

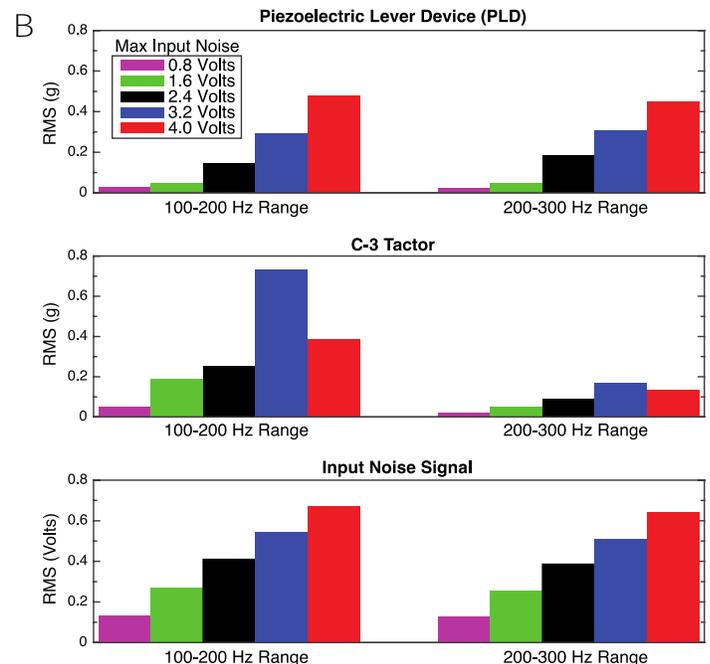

flatter across the 100–300 Hz region, with the frequency response extending out to 500 Hz. The PLD has a more predictable response in the driving frequencies compared to the C-3 tactor device.

## CONCLUSIONS

Vibrational SR devices are a promising technology to enhancing lower limb proprioception and improve postural control in older adults. Due to higher force characteristics and more accurate frequency responses, our findings suggest it may be preferable to use piezoelectric actuators rather than traditional tactor devices for lower limb SR applications. Further development of piezoelectric actuated devices will optimize interfaces for specific musculoskeletal geometries (e.g. Achilles tendon), which will be useful in future gait analysis research.

# FORCE AND CENTER OF PRESSURE ERROR ANALYSIS FOR A FORCE-PLATE MOUNTED STAIR CASE: IMPLICATIONS FOR BIOMECHANICAL ANALYSIS OF STAIR CLIMBING

Joshua D. Roth, Scott C. Brandon, Emily M. Keuler, and Darryl G. Thelen

University of Wisconsin-Madison, Madison, WI, USA

## INTRODUCTION

Stair climbing is a common activity of daily living. It requires greater knee flexion and joint torques than level walking<sup>1</sup>. Thus, biomechanics during stair climbing are especially of interest when studying patient populations with musculoskeletal or neuromuscular impairments. Biomechanical analysis of stair climbing (e.g., inverse dynamics and dynamic multibody musculoskeletal simulations) is important for both clinicians tracking rehabilitation progress and researchers evaluating innovative treatments. However, biomechanical analyses require accurate inputs in terms of ground reaction force (GRF) and center of pressure (CoP) to give meaningful results.

An attractive option to measure ground reaction force and center of pressure during stair climbing is a force-plate-mounted staircase (e.g., FP-Stairs<sup>2</sup>, AMTI, Watertown, MA) (Figure 1). Previous studies have shown that force-plate-mounted staircases do not introduce errors in the vertical component of the GRF or the CoP under purely vertical loads<sup>2-4</sup>. However, the anterior-posterior (A-P) and medial-lateral (M-L) loads present during stair climbing<sup>1</sup> might create errors in the GRF and/or CoP.

Accordingly, the objectives were to (1) characterize the errors in GRF and CoP created by A-P and M-L forces and (2) present and validate a method to reduce these errors.

## METHODS

Forces were applied using an instrumented pole<sup>5</sup> at four locations spanning the width of each of the three steps of a commercially available force-plate-mounted staircase (FP-Stairs<sup>2</sup>, AMTI, Watertown, MA) (Figure 1). Forces were also applied to the surface of each force plate at 8 locations covering the entire surface. The instrumented pole included both an inline load cell (Futek FSH02633, 11 N non-

linearity) and four retroreflective markers. Data were recorded at each location (motion capture at 100 Hz and forces at 2000 Hz) while rotating the instrumented pole about a fixed location to create vertical forces ranging from 150 to 400 N and horizontal (A-P and M-L) forces ranging between  $\pm 100$  N. The motion capture data of the instrumented pole markers were used to determine the applied CoP and orientation of the applied force, and the force data from the instrumented pole load cell determined the magnitude of the applied force. The GRF and CoP were simultaneously estimated from the in-ground force plates (BP400600, AMTI, Watertown, MA) using the sensitivity matrices determined with a previous calibration (surface calibration) using an instrumented pole<sup>5</sup>.

To characterize the errors in GRF and CoP created by the A-P and M-L forces, the difference between

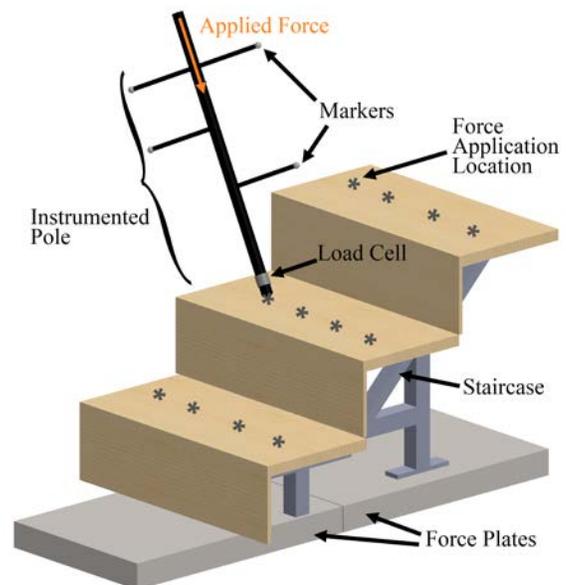

Figure 1. Instrumented pole used to apply a known force at a known location on each stair. The pointed tip of the pole rests in a conical detent in a base plate (not shown) to maintain a fixed force application location (\*) during each trial.

the computed GRF and CoP (force plate) using the surface calibration and the applied GRF and CoP (instrumented pole), respectively was determined for the (1) plate surface (surface calibration): loads applied directly to the surface of the in-ground force plates, and (2) stair surface (surface calibration) loads applied to the surface of the stairs.

To reduce these errors, the data from each stair were used to determine a stair-specific sensitivity matrix that minimized the difference between the applied and computed GRF and CoP for each stair surface (stair-specific calibration). To validate this error reduction method, the errors between the computed GRF and COP and the applied GRF and CoP on each stair surface were recomputed using the stair-specific calibration.

## RESULTS AND DISCUSSION

Errors, mainly bias, in both CoP and GRF were quite large when computed on the stair surface using surface calibration. The bias in the M-L and A-P coordinates of the CoP were one to two orders of magnitude greater than those for the plate surface using the surface calibration (Table 1). When using the stair-specific calibration, the errors in CoP were similar to those for the plate surface using the surface calibration (Table 1). The bias in the M-L, A-P, and inferior-superior (I-S) components of the GRF were about one order of magnitude greater than those for the plate surface using the surface calibration (Table 2). As with the CoP, when using the stair-specific calibration, the errors in GRF were similar to those for the plate surface using the surface calibration (Table 2). The large errors in both CoP and GRF might be due to the stair surfaces being far outside of the region used for the surface calibration. Hence the errors are greatly reduced with the stair-specific calibration because the region of the calibration matches the region where forces are applied.

Table 2. Absolute bias (mean of the magnitude of the bias) and precision (standard deviation) of the errors in the M-L, A-P, and I-S components of the GRF

	M-L GRF Error [N]		A-P GRF Error [N]		I-S GRF Error [N]	
	Absolute Bias	Precision	Absolute Bias	Precision	Absolute Bias	Precision
Plate Surface (Surface Calibration)	0.0	0.5	0.0	0.6	0.1	1.0
Stair Surface (Surface Calibration)	25.6	1.3	7.4	2.2	242.3	1.9
Stair Surface (Stair-Specific Calibration)	0.0	1.2	0.0	2.1	0.1	2.5

Table 1. Absolute bias (mean of the magnitude of the bias) and precision (standard deviation) of the errors in the M-L and A-P coordinates of the CoP

	M-L CoP Error [mm]		A-P COP Error [mm]	
	Absolute Bias	Precision	Absolute Bias	Precision
Plate Surface (Surface Calibration)	0.0	0.6	0.1	0.9
Stair Surface (Surface Calibration)	20.9	5.9	120.5	9.8
Stair Surface (Stair-specific Calibration)	0.2	2.2	0.1	1.1

## CONCLUSIONS

These findings indicate that with a stair-specific calibration, the errors in GRF and CoP using a force-plate-mounted staircase are similar to those when using the in-ground force plates with a surface calibration. Thus, anyone collecting data using force-plate-mounted staircase should perform a stair-specific calibration to minimize the errors in later biomechanical analyses. Errors in the biomechanical analyses might lead to erroneous conclusions about rehabilitation progress and evaluations of innovative treatments<sup>6</sup>.

# ESTIMATING BODY SEGMENT INERTIAL PARAMETERS USING A KINECT V2

Pawel Kudzia, Erika Jackson, Geneviève Dumas

Queen's University, Kingston, ON, Canada

Email: pawel.kudzia@queensu.ca

## INTRODUCTION

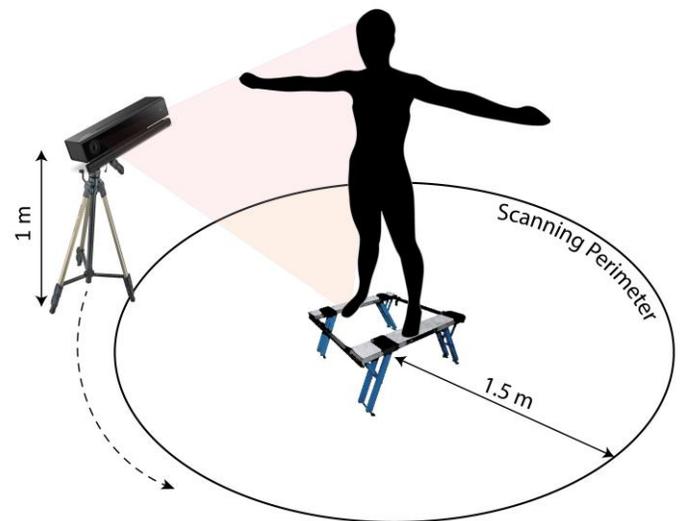

When studying human motion, inverse dynamics is an approach used for the analysis of human movement. Despite being widely used, it is known to have inherent errors [1]. One such error stems from the estimation of body segment inertial parameters (BSIPs) i.e. mass, center-of-mass (CoM) and moments of inertia (MOI). One of the difficulties in approximating BSIP's resides in the quantification of the geometric characteristics of the human body. Current methods in estimating these parameters such as mathematical, medical imaging or cadaver can be time consuming [2], expensive [3], and lack the ability adequately represent the geometric variation of human bodies [4]. Importantly, BSIP estimation is sensitive to how the geometric approximations of the bodily segments represent the true anatomical structures.

In recent years, an inexpensive depth camera the Kinect™ (Microsoft, USA), has shown potential in this application. With 3D imaging capabilities the device has the potential to address some of the limitations associated with current methods [5]. With this in mind, we developed and evaluated a method of employing the Kinect™ (Version 2) to estimate BSIPs. Specifically, the goals of the study were to evaluate the proposed method for scan repeatability, body segmentation repeatability and ease of use. Additionally, we compared the results to a validated approach known as the elliptical cylinder method (ECM) [6] and also to mass estimates obtained from scale values.

## METHODS

Twenty-one subjects (11F, 70±8kg 22±2y; 10M, 73±4kg 23±2y) were recruited for the study. Subjects signed a written consent form approved by the Queen's University Ethics Committee. Subjects

were outfitted into form-fitting attire and weight was taken on a calibrated medical scale. Two-dimensional body markers were placed onto anatomical landmarks to identify individual limb segmentation boundaries [7]. Two scanning protocols were then successively executed. First, following the ECM protocol [6] subject data was collected. Subsequently, subjects were asked to stand as still as possible on an elevated platform with their arms abducted (Fig.1). The Kinect device, tethered via USB 3.0 to a desktop operating system (software: 3D Builder, OS Windows 10; 30Hz) was revolved around the subject following an outlined scanning perimeter (Fig.1). This procedure was repeated until 3 scans were acquired per subject.

**Figure 1:** Kinect experimental setup

In post processing, Kinect scans were exported to open source software MeshLab (64-bit v.1.3.4) where the 3D data files were cleaned of irrelevant data (e.g. floor) and the body was segmented into a 16-segment model using the body markers as segmentation guidelines (Fig 2-B). Following body segmentation, all data was imported into MATLAB (v2016a, Mathworks, Natick, MA) where BSIPs

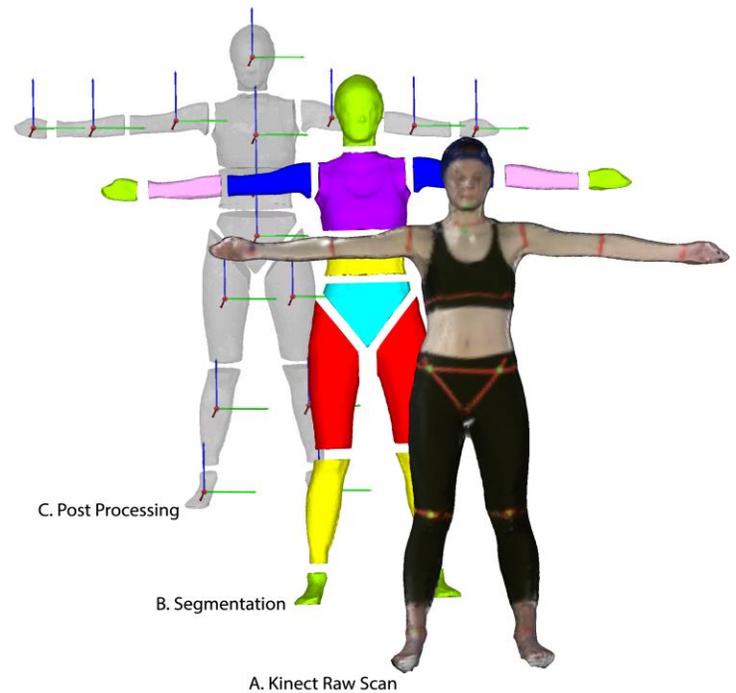

were evaluated using a custom written script. ECM data was processed and evaluated using an available software [8]. For analysis purposes, data was grouped into male and female cohorts.

Two one-way repeated measures ANOVA were used ( $\alpha < 0.05$ ) to evaluate the repeatability of body volume estimates obtained from repeated scans and of limb segmentation volumes obtained from repeated segmentations. To compare the mass values collected from the medical scale to the total body mass estimates obtained with the proposed method and with ECM, each segment volume was multiplied by a corresponding uniform density [9], [10]. A one-way repeated measures ANOVA was then used to evaluate the mass estimates.

## RESULTS AND DISCUSSION

No significant differences were observed ( $p > 0.05$ ) between the repeated scans and between repeated segmentations for both males and females. Similarly, there were no significant differences between the scale, ECM and Kinect scans when comparing body mass estimates for the males. For the females, the Kinect overestimated the total body mass by  $5 \pm 2\%$  ( $p < 0.05$ ) when compared to the scale and ECM results. CoM and MOI data were also computed following the proposed methodology. While full analysis of these parameters is still ongoing the capability of estimating these BSIPs has shown to be efficacious.

These results suggest the potential of the proposed method for subject specific BSIP estimation without gender, age or morphological restrictions. With the ability to acquire consistent volumetric estimates and easily modify density inputs, the possibility of reducing errors in estimating BSIPs exists. Motion artifact during 3D scanning, concave surfaces (e.g. cupping palms or cleavage) or steep edges (e.g. between the arms and thighs) may have contributed to unwanted 3D points, which could result in a discrepancy in the total volume. Although this did not appear to be the case in the male participants, perhaps it may explain some of the overestimations seen in the female participants. Further work understanding and reducing these errors will need to be complete.

**Figure 2:** Sequence of proposed methodology: **A.** Raw scan **B.** Segmentation and **C.** BSIP evaluation.

## CONCLUSIONS

This study demonstrates the potential for using a Kinect sensor as a tool for body segment parameter estimation and also establishes a methodology for post processing 3D scans. With repeatable volume estimates and the ability to estimate a wide range of subject specific parameters, the opportunity for such a system is promising. Ongoing work will focus on evaluating the remainder of the BSIPs which were not fully evaluated (i.e. CoM and MOI).

## INTRODUCTION

Gaze-tracking technology provides a first person point of view of the visual field while measuring direct eye movements, allowing researchers to quantify and describe where an individual is directing their gaze [1]. This has been essential to research in psychology, neurobiology, and animal behavior [2]. Yet, most applications of this technology have been applied to monitoring humans during stationary tasks, with a few exceptions including long jumping and walking [3, 4]. Most of the research on humans has focused on walking, which has indicated obstacle fixations increase as walkers approach obstacles and walkers tend to focus on areas where they eventually will step [4, 6]. These studies have advanced our understanding of visual attention during locomotion in humans; however, methods for tracking gaze during rapid dynamic behaviors have been limited and subjective, and whether these approaches can be used during running and when encountering obstacles is understudied.

The overarching goal of this project was to develop an appropriate method for analyzing gaze while the study subject was in motion, particularly when running and navigating an obstacle in a path [7]. For this, we chose a telemetric gaze-tracker, which provided good spatial and temporal resolution and was lightweight and minimally obstructive for participants. These trackers determine where gaze is directed and collects pupil position data by monitoring the cornea and corneal reflections on a mirror with a small camera. Pupillary movements are then superimposed as a crosshair onto video from a camera mounted on the subject's head [1].

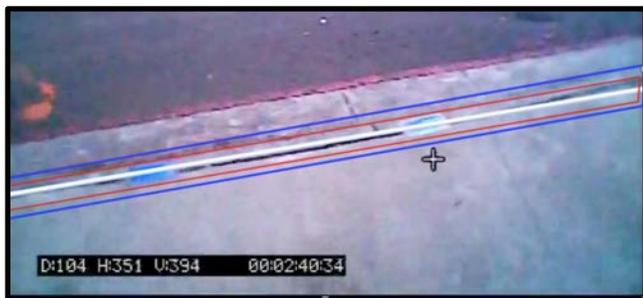

To design an automated and accurate method for identifying gaze fixations, models of error (MoEs) that incorporated the innate spatial error of the gaze tracker and the potential error introduced during digitizing were developed. These MoEs were compared to independent raters scores of the same video to determine the best MoE to analyze gaze-tracker data in a dynamic and complex setting.

## METHODS

The data from 1 male (21 yrs, 1.8 m, 83.9 kg) and 1 female (21 yrs, 1.6 m, 56.7 kg) were used to validate the raters' crosshair tracking method and that of the MoEs. Running participants were recreational runners with no history of injury in the past six months. The gaze tracker (60 Hz, "Omniview," ISCAN Inc., Woburn, MA, USA) was placed on each participant's head, and calibrations from 5.18 m, 3.05 m, and 1.52 m were conducted to confirm the runners' gaze and the crosshair were tracking accurately in the video from the field of view of the runner [8]. Each participant ran on a 20 m sidewalk path, intended to mimic a common urban running environment. After warming up, participants were allowed to run at their self-selected speed for up to 15 laps along the sidewalk path. At about 15 meters into the run, participants encountered and cleared a typical sidewalk curb (0.15 m high). Six trials were chosen from each runner for final analyses. All protocols were approved by Duke University IRB.

To analyze data, the crosshair and curb were digitized in each frame in MATLAB using DLTdv5 [9]. To incorporate the change in relative size of the curb as the runner approached the curb, and to account for error in digitizing and the gaze tracker

itself, an algorithm to create MoEs was developed. The MoEs created polygons around the original curb digitization by adding error rates to the X and Y coordinates of the digitized curb. The result was three scenarios: MoE 0.0 (original digitized curb), MoE 0.75 (added error of 0.99% in the X and 1.44% in the Y direction), and MoE 1.5 (added error of 1.97% in the X and 2.88% in the Y direction; Fig. 1). These rates were chosen based on previous studies [8]. The MoEs were then used to identify if the crosshair was within the area of the different sized polygons in each scenario. An absence/presence tally across the running trials (for each MoE) was used to determine when and how many times the runner looked at the curb.

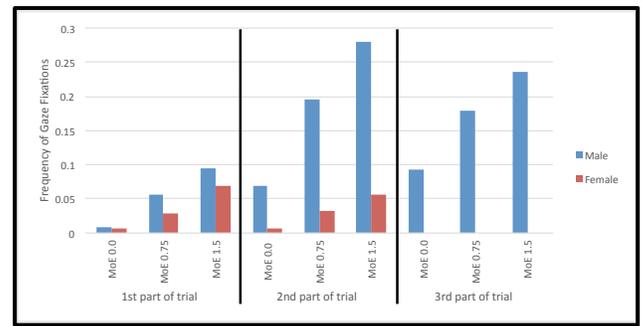

**Figure 1:** Sidewalk curb with superimposed MoEs represented as blue (MoE 1.5), red (MoE 0.75), and white (MoE 0.0) lines. Crosshair indicated by white cross.

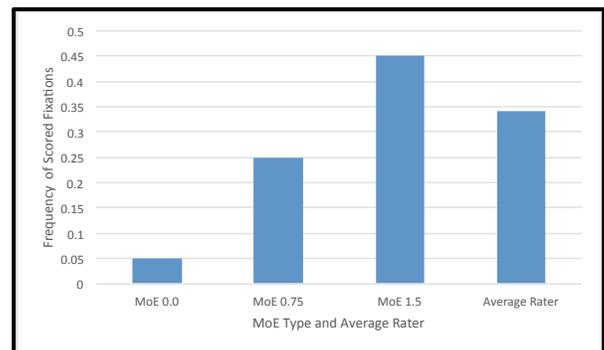

To determine the effectiveness of the different MoEs and to obtain a reliability estimate of them, 10 frames from each of the running participants were chosen and provided to seven independent raters. These raters made decisions of whether the crosshair was on the curb in these 20 frames. Their scores were also tallied as absence/presence. Absence/presence results from the three MoEs and the seven raters were compared.

## RESULTS AND DISCUSSION

As values for MoE increased, so did the frequency of fixations scored at the curb (Fig. 2). The average rater frequency (0.34) fell between MoE 0.75 and 1.5 (Fig. 3) and thus those MoEs best captured the gaze fixation of the runners.

**Figure 2:** Frequency of gaze fixations at the curb over the course of runners' trials (broken into thirds, indicated by vertical lines). Models of error (MoEs) are also represented.

**Figure 3:** Total frequency of gaze fixations at the curb comparing the different MoEs and the average rater.

## CONCLUSIONS

A gaze tracker is an effective means of capturing how individuals observe their environment while running outdoors and navigating obstacles. Using MoEs that scale to a region of interest as a runner moves through the environment allowed us to effectively characterize the gaze fixations of the runner. We were able to determine the best MoE to quickly, efficiently, and reliably analyze gaze-tracker data in a dynamic and complex setting.

# Feasibility of Optical Motion Capture to Compute Head Impact Kinematics

Sean Quisenberry, Mark Jesunathadas, Scott Piland, and Trenton Gould

University of Southern Mississippi, Hattiesburg, MS, USA  
email: trent.gould@usm.edu, web: <https://www.usm.edu/kinesiology>

## INTRODUCTION

The risks of brain injury associated with an impact are often based on measurements of the acceleration of the center of gravity (CG) of an anthropometric test dummy (ATD) headform during a simulated impact. However, translational accelerations experienced by the brain are not confined to the CG and potentially differ vastly from those measured at the CG. Optical motion capture has the potential to measure accelerations of the head at a variety of locations within its volume. However, the accuracy with which optical motion capture can accurately measure accelerations of the head at the CG, much less other locations, is yet to be determined. Thus, the purpose of this study is to confirm the ability of an optical motion capture system to accurately replicate the accelerations of the CG of an ATD headform as measured by an accelerometer during a drop impact.

## METHODS

A National Operating Committee on Standards for Athletic Equipment (NOCSAE) headform was impacted at the top position using a Cadex Inc. (Quebec, Canada) monorail drop impactor. The headform was dropped 10 times each from seven drop heights (20, 30, 40, 50, 60, 70, 80cm) onto a 1-inch modular elastomer programmer (MEP).

Reference acceleration data during the impact was measured with a triaxial accelerometer (PCB Piezotronics, Inc. Depew, NY; sampling rate = 6000 Hz) located at the CG of the ATD headform. Reference acceleration data was processed in accordance with SAE J211a (channel frequency class 1000)<sup>1</sup>. A 10-camera optical motion capture system (Oqus 7+ series, Qualisys, Sweden; sampling rate 3000 Hz) was used to determine acceleration of the ATD from position data of 11 (12.9mm) markers (6 retroreflective tracking, 5 virtual) on the surface of

the ATD headform. Accelerometer data was synchronized with optical motion capture data by an external optical trigger that was activated just prior to the ATD headform impacting the MEP pad.

Marker and accelerometer data were processed and analyzed in MATLAB R2016b (Mathworks Inc., Natick MA). Marker position data from impact events were low-pass filtered with a second-order zero phase lag Butterworth filter. Cut-off frequencies were 20Hz for the perpendicular axis to sagittal and coronal planes, and 200-400Hz for the perpendicular axis to the transverse plane of motion. The filtered position data was numerically differentiated to compute acceleration at the geometric center of the markers corresponding to the CG. Peak translational acceleration from each axis was collected from both the accelerometer and optical motion capture system to calculate resultant peak linear acceleration (peak g).

We performed simple linear regression analysis between the reference and optimal motion capture acceleration peak g values. The strength of the relationship is reported as the coefficient of determination ( $R^2$ ). Additionally, a Bland-Altman plot (difference of the two-paired measurements plotted against the mean of the two measurements) was used to quantify the agreement between the accelerometer and optical motion capture system techniques. Mean absolute percent error (MAPE) was also calculated for each drop height and across all impacts.

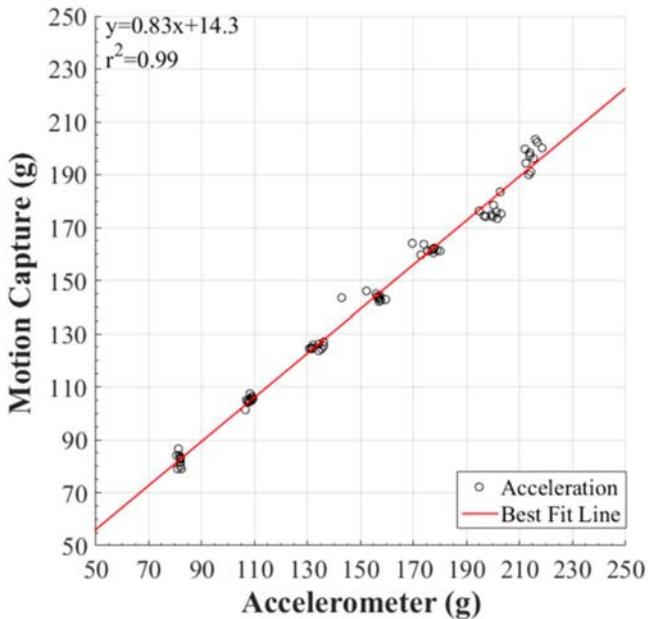

## RESULTS AND DISCUSSION

Linear regression results showed a strong association between optical motion capture acceleration data and reference accelerometer acceleration data for peak g ( $R^2 = 0.99$ ; Figure 1). On average, the optical motion capture system presented a bias of -11g [95% CI:

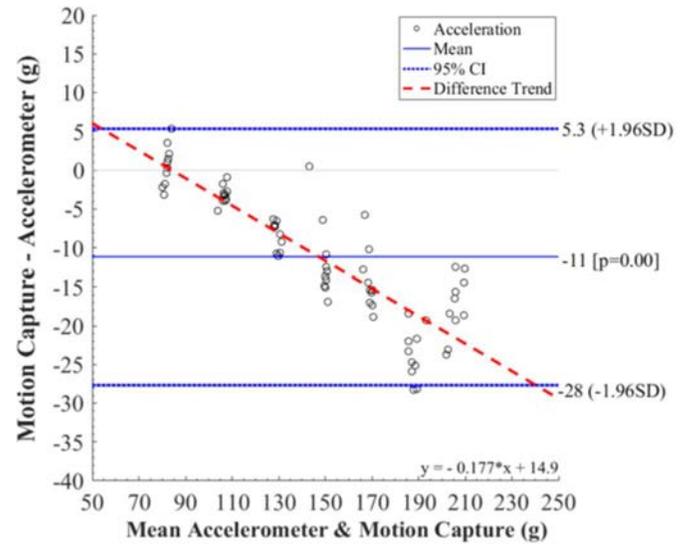

-28 – 5.3 g], and the agreement limit of 17 g (Figure 2). The mean  $\pm$  SD MAPE values ranged from  $2.6 \pm 1.9\%$  at a drop height of 20 cm to  $8.2 \pm 1.8\%$  at a drop height of 80 cm.

Overall there was a high correlation between measures of acceleration between the optical motion capture system and reference accelerometer. However, an observed increase in the variance of peak g values measured with the optical motion capture system as drop height increased (Figure 2). Thus, as impact velocity increases optical motion capture becomes a less precise means to measure peak translational acceleration during impact.

Differences between optical motion capture acceleration measures and those recorded by the reference accelerometer may have been because an appropriate low-pass filter cut-off frequency for the optical motion capture position data was difficult to establish. While a balance had to be made between signal distortion and noise reduction, an optimal cut-off frequency has yet to be determined.

**Figure 1:** Linear regression analysis between accelerometer compared to optical motion capture data for peak linear acceleration. The solid red line corresponds to the ordinary least squares (OLS) best fit line.

**Figure 2:** Bland-Altman plot for peak linear acceleration of the NOCSAE headform. The solid blue line represented the mean peak linear acceleration difference between the two measurement systems, dotted blue lines represent the 95% CI, and dashed red line illustrates the acceleration difference trend.

## CONCLUSIONS

Preliminary findings indicate potential for the utilization of optical motion capture technology as an additional tool to measure the translational acceleration of ATD during impact events. Additional testing is warranted to fully assess, and expand the use of, optical motion capture technology to calculate head impact kinematic variables (e.g., peak linear acceleration, peak rotational acceleration, GSI, HIC).

## INTRODUCTION

Marker-based three-dimensional gait analysis (3DGA) is one of the most common methods for analyzing athletic performance and pathological gait in both clinical and research settings. Recently, it has been shown that errors in marker placement constitute the largest source of error in the repeated measurement of kinematic data [1]. With the increasing popularity of 3DGA, and its wide range of applications, there is a growing need to develop novel methods to improve data quality. However, prior attempts have yielded inconsistent results or clinically impractical protocols.

Osis et al. [2] introduced an expert-based software tool that provides real-time feedback to improve marker placement accuracy in considerably less time than previous marker placement devices, and without the need for initial marker placement to be completed by an expert. Preliminary studies showed the use of the tool lead to a reduction in marker placement deviation for novice users, relative to an expert. These results were encouraging however limited by the small sample size ( $n = 6$ ), and the protocol did not allow for between-day comparisons [3].

Building on the pilot work of Osis et al. [3], the purpose of this investigation was to determine if the real-time feedback tool would improve consistency in gait kinematic data collected by a larger cohort of novice examiners, and whether a similar level of improvement would be observed during a one-week follow-up session. The authors hypothesized that the

real-time feedback tool would decrease the 95% confidence interval (CI) range of mean joint angle data compared to trials without feedback.

## METHODS

All 3DGA trials were conducted on a single runner (male, 24 years, 188 cm, 75 kg). Twelve kinesiology students from a university campus assumed the role of examiner. The novice examiners had completed courses in human anatomy, and introductory biomechanics, however, none had any experience locating anatomical landmarks for the purpose of 3DGA.

Aided by a schematic of the target anatomical landmarks, the novice examiners placed retroreflective markers on the runner. A brief written description of landmark location accompanied the schematic, along with minimal verbal instruction.

Following the first static trial collection, marker data were imported to the real-time feedback software tool, which calculated the inter-quartile range ratio (IQRR) for each marker location relative to a morphometric norm, and displayed a standardized 3D plot. The examiner was instructed to use his/her judgement to adjust the markers, according to the direction and magnitude of deviation observed on the plot. No scale or measurement information were displayed. Next, a second static trial was collected, followed by a 60 second running trial which was processed using both static trial conditions collected prior to and following use of the marker check

feedback program. Set-up and protocol from day one was repeated for day two, resulting in four static trial conditions: PRE feedback day one, POST feedback day one, PRE feedback day two, and POST feedback day two.

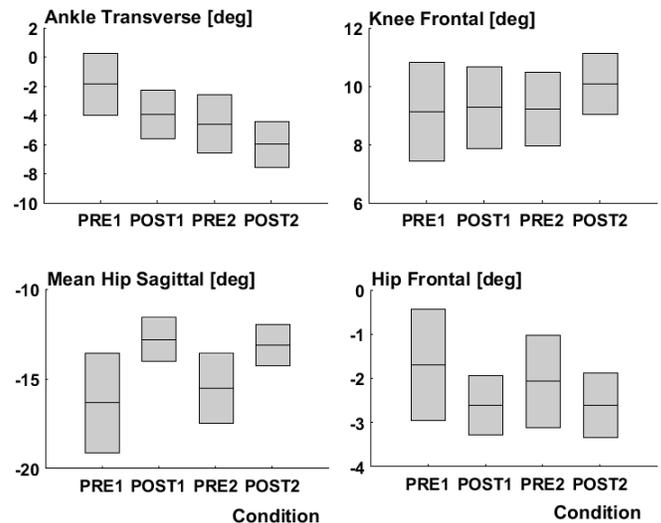

Mean joint angle was reported to be a sensitive indicator of kinematic similarity between conditions that can provide a single representative value of the entire stride [1]. While the mean joint angle was not expected to differ with feedback, it was expected that the 95% CI range of mean joint angle would be reduced as a result of increased marker placement consistency.

## RESULTS AND DISCUSSION

On day one, the use of the real-time feedback tool reduced the 95% CI range for eight out of nine joint angles by an average of 27.45%. The ankle transverse, knee frontal, hip frontal, and hip sagittal planes showed the greatest reduction (Figure 1). On day two, use of the real-time feedback tool reduced the range of the 95% CI for five out of nine joint angles by an average of 24.73%. Consistent with day one, the greatest reductions were seen in the ankle transverse, knee frontal, hip frontal, and hip sagittal planes (Figure 1). Eight out of nine joint angles showed a reduced range of 95% CI in the POST2 condition, relative to PRE1, by an average of 28.36% (Figure 1).

In support of the hypothesis, the use of the feedback tool reduced the 95% CI of mean joint angle data, due to improved marker placement consistency for the group of novice examiners.

The results of this study agree with those of the marker placement simulation by Osis et al. [2], as mean joint kinematics in the ankle transverse, knee frontal, and hip frontal plane were among the variables that were most positively influenced by use of the feedback tool.

**Figure 1:** Visual representation of 95% CI for select joint angles pre- and post- feedback on days one and two. Static trial condition is displayed on x-axis.

## CONCLUSIONS

The feedback tool presented in this study improves upon previous attempts at reducing marker placement deviation by allowing for real-time feedback. It improves upon standardized training protocols by providing continuous monitoring of the examiner's placement consistency, as opposed to an infrequent training session. The findings of the current study indicate that a real-time feedback software tool improves the consistency of marker placement for a group of novice examiners, leading to improved consistency in 3DGA data.

While further refinement of the tool is encouraged, the results of this study demonstrate its benefit as a teaching and training tool in both a clinical and research gait biomechanics laboratory setting.

# RELIABILITY OF ULTRASOUND ELASTOGRAPHY MEASUREMENTS OF THE SEMITENDINOSUS TENDON

<sup>1</sup>Zachary J. Domire, <sup>1</sup>Clara Amat-Fernandez, and <sup>1</sup>Anthony S. Kulas

<sup>1</sup>East Carolina University, Greenville, NC, USA  
email: domiez@ecu.edu

## INTRODUCTION

Measurement of tendon material properties is of interest to determine energy storage capacity, track healing, and possibly determine injury risk. Shear wave elastography (figure 1) is an attractive option to take in vivo measurements. Most studies examining ultrasound elastography as a tool to measure tendon have focused on either the Achilles or patellar tendon, and have often showed questionable reliability.<sup>1,2</sup>

**Figure 1:** Schematic of shear wave elastography. The technique uses a focused ultrasound pulse to generate a shear wave in the tissue of interest and b-mode imaging is used to measure the wave speed, which is inverted to calculate shear modulus.

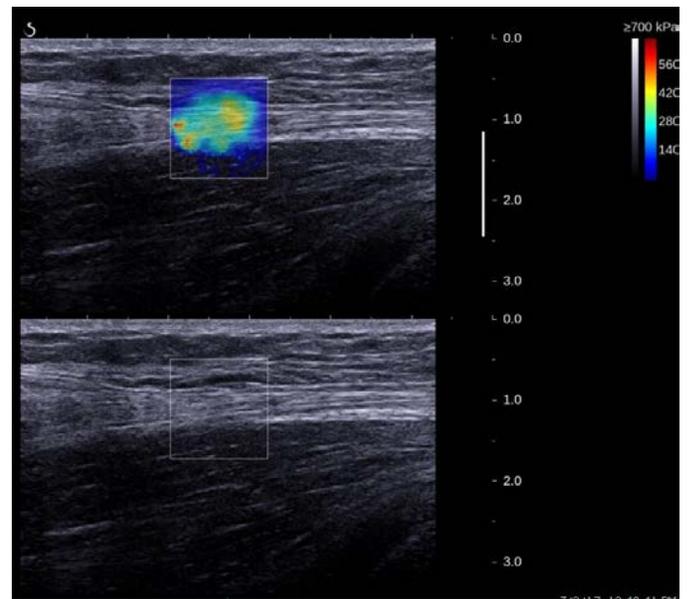

Reliability of typical shear wave elastography measurements of the semitendinosus tendon has not been assessed. The semitendinosus tendon is of particular interest to measure as it is the most used type of graft for ACL reconstructions. Revision rates for semitendinosus graft surgeries are higher than for patellar tendon surgeries.<sup>3</sup> Measurement of material properties of the tendon prior to surgery may be a useful tool to help identify individuals who may have poor outcomes following ACL reconstruction using the semitendinosus tendon and help reduce revision rates.

The purpose of this research is to determine the reliability of shear modulus measurements using ultrasound elastography in healthy individuals.

## METHODS

For this study 7 (mean age=21.9 years; SD±4.5 years) healthy recreationally active individuals with no prior history of hamstring or knee injuries were recruited.

ST tendon shear wave elastography (figure 2) measurements were taken using an ultrasound device (AIXPLORER MultiWave, SuperSonic Imagine S.A., France). Height and weight were also collected during data collection.

**Figure 2:** Ultrasound image of the semitendinosus to the myotendinous junction. Top: Elastogram centered over the tendon. Bottom: B-Mode image with the elastogram region shown.

Measurements were taken with the participant in a prone position with the knee fully extended. ST tendon measurements were taken just at the 50% mark between the medial epicondyle and the myotendinous junction placing the probe

longitudinally across the tissue. Measurements in the ST muscle were taken longitudinally in the middle of the muscle belly. All measurements were taken bilaterally.

Data was recorded as the mean of the values within a 2mm diameter circumference situated in the middle of the tendon. A two-way single measure intraclass correlation (ICC(2,1)) was calculated to establish the reliability of the measurement. Additionally, standard error of the measurement was calculated in absolute and relative to the mean values.

## RESULTS AND DISCUSSION

The difference between mean modulus from trial 1 to trial 2 was approximately 4kPa (Table1). There was high variability in modulus between subjects. However the reliability of the measurement was excellent (ICC=0.96). The standard error of the measurement was approximately 10% of the mean value.

Shear modulus for the current study was determined from a single measurement. It is common to report the value from an average of two or three measurements<sup>4</sup>. Doing so would likely improve the reliability of the measure.

Reliability in the current study is much better than what has been previously reported for the Achilles or patellar tendon.<sup>1,2</sup> A likely reason for questionable reliability in these studies is that the values for modulus were at or possibly above the maximum measurement capacity of the system. While there was considerable inter-subject variability in the value of modulus, even the stiffest tendons were less than 600kPa, and far below the measurement capacity.

The Achilles and patellar tendons are loaded more frequently and with higher loads than most tendons in the body. These tendons may have specialized adaptations that increase their material stiffness beyond other tendons.

## CONCLUSIONS

ICC's for tendon shear modulus were very high indicating good reliability for this measure. There was high inter-subject variability. This wide range of values possibly indicates that some tendons may be better suited as ACL grafts than others.

# PASSIVE IMPLANTED MECHANISM TO IMPROVE FOOT-ARCH RESTORATION FOR ADULT ACQUIRED FLATFOOT DISORDER: VALIDATION THROUGH GAIT ANALYSIS

Hantao Ling, Ravi Balasubramanian

Oregon State University, Corvallis, OR, USA

Email: ravi.balasubramanian@oregonstate.edu. Web: <http://web.engr.oregonstate.edu/~balasubr/>

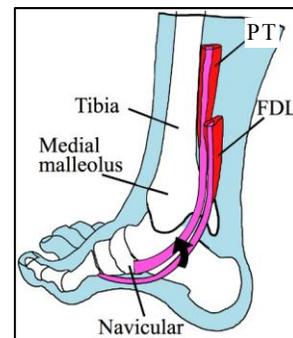

## INTRODUCTION

Adult-acquired flatfoot deformity is commonly treated with a tendon transfer surgery, where the flexor digitorum longus (FDL) tendon is transferred to the attachment point of the posterior tibial (PT) tendon on the inferior side of the navicular bone to restore the forces applied to the foot arch [1] (see Fig. 1). While previous studies have shown that this treatment provides a partial improvement, the current surgery does not restore the foot arch completely. This is evidenced by a medial shift in the foot's ground reaction forces (GRF) when compared with a healthy foot's GRF [2]. This is due to the reduced force capability of the FDL muscle (about one-third of the PT's force capability) [2]. Inspired by a recent approach that surgically implants passive mechanisms in the forearm to improve grasping capability following high median-ulnar nerve palsy [3], this paper explores the use of a passive pulley between the FDL muscle and the foot arch to transfer larger forces to the foot arch. Previously, we have shown using biomechanical simulations that a passive implanted pulley creates a lateral shift of GRF (closer to the force distribution in a healthy foot) in a statically loaded flatfoot [4]. This paper now uses biomechanical simulation to show that the implant also helps shift the center of GRF laterally during the stance phase of gait.

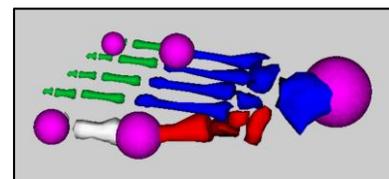

## METHODS

Biomechanical models of a healthy foot and flatfoot with five contact spheres were developed in the OpenSim software platform [5] where the feet were divided into quadrants by the metatarsophalangeal joints and by the sagittal plane (see [6], [7] for comparable models; see Fig. 2). In the healthy foot model, 39.7% of the body weight is distributed to the medial side and 60.3% is distributed to the lateral side [8]. For the flatfoot model, 49.3% is distributed

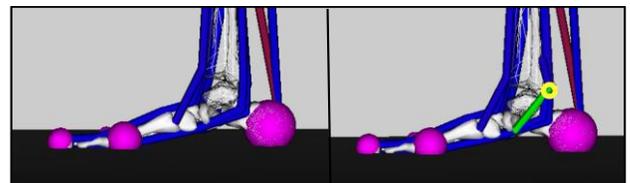

medially and 50.7% is distributed laterally [9]. The models enabled a study of the force distribution between the medial and lateral sides of the foot during the stance phase of gait while also allowing the flexibility needed for the motion. The flatfoot model was modified twice more to represent the foot after the traditional tendon transfer surgery, where the FDL tendon is transferred to the PT tendon, and after the implant-based tendon transfer surgery, which uses a pulley to scale up the FDL muscle force (see Fig. 3).

**Figure 1.** Drawing of a foot showing the relative locations of the PT and FDL tendons, and the navicular bone.

**Figure 2.** Foot model (top view). Showing four quadrants (blue, red, green, white) and five contact spheres (pink).

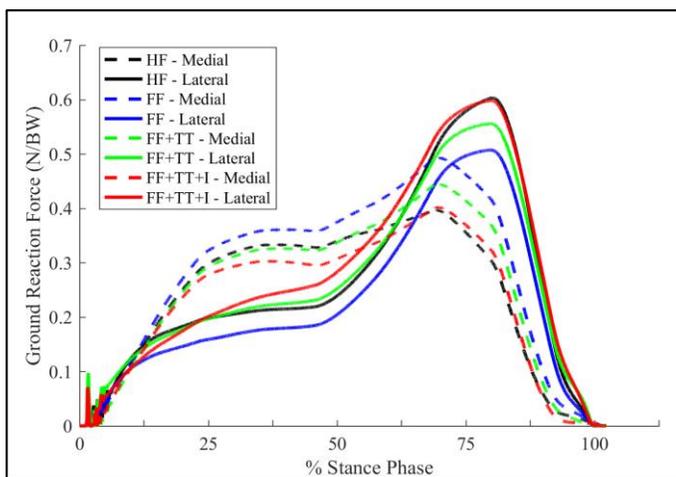

**Figure 3.** Biomechanical models representing (A) a flatfoot or a flatfoot with FDL tendon transfer and (B) a flatfoot with FDL tendon transfer and a passive implanted mechanism.

For each of the four models and simulations, the tibia was held fixed in space while a ground plane moved

relative to it to create the kinematics of a single cycle of the stance phase of gait from heel strike to toe off. While the ground plane moved, nine lower limb muscles were activated based on data generated by the Robotic Gait Simulator [10], and the GRF generated by the five contact spheres was recorded. The force data collected from the spheres on the medial toe and medial mid-foot was compiled into the medial GRF for each model. The same was done for the two spheres on the lateral toe and lateral mid-foot to produce the lateral GRF for each model.

## RESULTS AND DISCUSSION

**Figure 4.** Normalized ground reaction forces of the medial and lateral sides of the foot over the stance phase of gait for a healthy foot (HF), flatfoot (FF), flatfoot with tendon transfer surgery (FF+TT), and flatfoot with tendon transfer surgery and implant (FF+TT+I).

Fig. 4 shows the shift in normalized GRF from the medial to the lateral side of the foot through the entirety of the stance phase of gait in the tendon transfer surgery models. The double peak profiles characteristic of the stance phase of gait and the GRF produced by the heel of the model were identical for each model and were left out of the plot for clarity. While the flatfoot without surgery experienced a large amount of GRF shifted medially (50.7% lateral), the traditional tendon transfer surgery model saw the force distribution shift laterally (55.6%), and

the implant-based tendon transfer surgery model caused a the most drastic lateral shift of the normalized GRF (59.8% lateral). The simulation results are summarized in Table 1. The significant transfer of GRF laterally following the implant-based surgery can be attributed to the force-scaling provided by the implant through the transferred FDL tendon. Specifically, the increase in force transferred by the FDL tendon to the navicular bone results in a lifting force acting on the foot arch that shifts the center of pressure of the foot laterally during the stance phase of gait. This matches what has been observed through cadaveric experiments [11]. Creating accurate biomechanical simulations of the flatfoot condition provides a quicker method of validating implant-based surgery when compared with cadaver studies. Future work will focus on conducting sensitivity studies on how implant location and tendon routing impacts the shifting of the center location of GRF.

# EFFECT OF PROPHYLACTIC KNEE BRACING ON LOWER EXTREMITY KINEMATICS IN RUNNING AND JUMPING

Mitchell L Stephenson and Jason C Gillette

Iowa State University, Ames, IA, USA  
email: mitch.stephenson@gmail.com, web: www.kin.hs.iastate.edu

## INTRODUCTION

Knee braces have become increasingly popular in recreational and professional sport. While many braces are suggested or prescribed as part of rehabilitation post-injury [1], prophylactic use has also become more common [2]. Many recent braces from different manufacturers claim certain levels of effectiveness in preventing non-contact knee (particularly anterior cruciate ligament; ACL) injuries, but do not provide a biomechanical basis for this claim.

The current analysis compares landing biomechanics of a cross-section of recent and popular knee brace designs in two movements chosen to exacerbate non-contact ACL load. It was expected that more structurally-rigid brace designs would limit peak knee angles during ground contact [3].

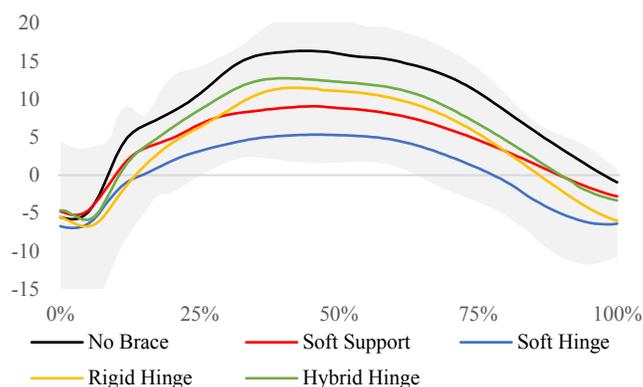

## METHODS

Nine physically-active, uninjured recreational athletes (6 females and 3 males;  $21.4 \pm 1.2$  years;  $1.68 \pm 0.06$  m tall;  $71.4 \pm 8.1$  kg) have volunteered for the ongoing study. Participants provided informed consent, executed a warm-up protocol, and then performed a series of successful practice trials before the series of block-counterbalanced recorded trials.

Kinematics of 28 retroreflective markers placed on the lower extremity, pelvis, and torso were recorded via 8 Vicon cameras at 160Hz through Vicon Nexus 1.8.2 (Vicon Corp, Oxford, UK). Four brace designs were tested: a soft support, a soft hinged, a rigid hinged, and a new hybrid semi-rigid hinged design.

Participants performed a total of three recorded trials for three separate movements in an unbraced and four braced conditions. The brace was worn on the

right leg. The first movement consisted of jumping forward from a 30cm tall block, landing bilaterally with the right foot on an AMTI force platform sampling at 1600Hz, and then fluidly performing a left jump at  $60^\circ$  from anterior for maximum distance. The second movement was identical to the first, but jumped  $60^\circ$  to the right.

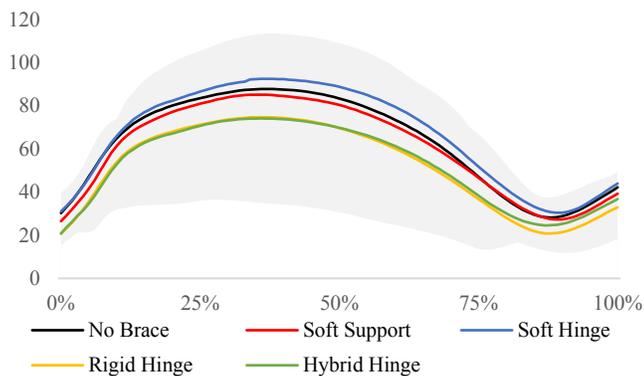

**Figure 1:** Mean knee valgus angle across percentage time in contact with the force platform for each knee brace while jumping left. Gray area represents standard deviation of measures.

The third movement consisted of participants running at a consistent self-selected pace along a 10m path, whereas at the end of the 10m, they placed their right foot on the force platform and sidestepped to the left at  $30^\circ$ . Starting position was manipulated to assure the right foot's strike on the force platform was within normal gait patterns.

Peak knee valgus, varus, and flexion angles during foot contact with the landing force platform were calculated. A repeated-measures analysis of variance was performed to compare the effect of the braces on the knee kinematics for each movement.

## RESULTS AND DISCUSSION

No significant main effects were indicated by the analysis of variance ( $p > 0.15$ ). As demonstrated in Table 1, mean peak knee angles were illustratively different, but moderately variable amongst participants. While some previous research did identify successful reduction in knee valgus angles while wearing prophylactic braces, this change was relatively minor, and the authors concluded little overall prophylactic effect from bracing [4].

**Figure 2:** Mean knee flexion angle across percentage time in contact with the force platform for each knee brace while jumping left. Gray area represents standard deviation of measures.

It is possible that the analyzed sample was not large enough to demonstrate significant differences that may indeed exist. As seen in Figures 1 and 2, a systemic offset in knee angles between the braces is

apparent and may be clinically-relevant. In addition, a more challenging testing protocol might elicit larger differences between the knee braces and no brace.

## CONCLUSIONS

Superficially, it appears that prophylactic bracing, independent of design, may not significantly influence cutting and sidestep kinematics in healthy, active participants. This provides a dichotomy in implications: The preserved peak knee flexion and varus angles may not decrease performance or hinder ACL protective mechanisms, but the braces also did not limit peak valgus angles associated with ACL injury [5]. Further investigation is ongoing to determine effects with a larger sample size.

# EFFECT OF FUNCTIONAL 3D SOCKS ON THE ARCH OF THE FOOT

Misaki Wakamiya, Akinori Nagano

Ritsumeikan University, Kusatsu, Shiga, Japan  
email: [ec0240ps@ed.ritsumei.ac.jp](mailto:ec0240ps@ed.ritsumei.ac.jp)

## INTRODUCTION

The foot is the only body part to contact the ground in normal locomotion. The mechanical interaction between the foot and the ground plays an integral role. In the foot, there are characteristic structures, i.e., the arches of the foot. The arches of the foot have significant roles in the transmission of forces and absorption of shocks [1].

When the arch of the foot falls, the condition is often called “flat foot”. Flat foot is usually associated with excessive subtalar joint pronation; in the case of flat foot, instability of the lower extremity causes hypermobility and passive instability, and more neurological control by the neuromuscular system is required to maintain balance. Thus, the instability resulting from a flat foot could cause pathomechanical problems [2]. As well, the ability of balance control is hampered with flat foot. Previous research has also suggested increased incidences of injury in people with flat foot [3].

Recently, several functional socks to support the foot have been developed. The function of those socks has been studied in terms of comfort, performance enhancement and blister prevention [4, 5]. However, no study has yet clarified the effects of socks on the arch of the foot.

Therefore, the purpose of this study was to examine the effect of functional 3D socks on the arch of the foot.

## METHODS

Five healthy subjects participated in this study. The subjects were  $24 \pm 0.4$  years (mean  $\pm$  SD),  $1.72 \pm 0.03$  m and  $65.6 \pm 3.2$  kg, foot size  $27.2 \pm 1.1$  cm.

The subjects were requested to remain in the natural static standing position for 4 min wearing two types of socks: Normal type Socks (NS) and Functional 3D type Socks (3DS) (Cooma Ltd., Japan) (Fig. 1).

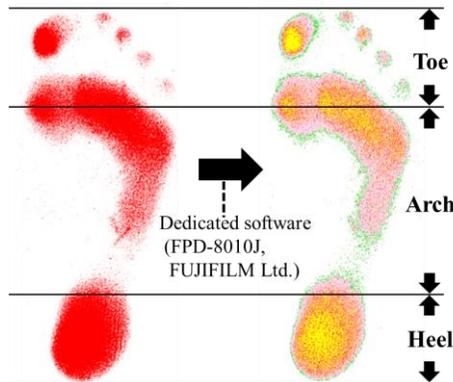

**Figure 1:** Functional 3D type Socks (3DS) used in this study.

Pressure measurement film (PRESCALE, FUJIFILM Ltd., Japan) was used for the measurement, placed under the right foot of the subjects. The color of the area of the film where pressure was applied turned red, and the color depth

was dependent on the intensity of the applied pressure. The image was scanned for further analysis. The scanned image was analyzed by using dedicated analysis software (FPD-8010J, FUJIFILM Ltd.). The regions of analysis were determined by referring to the position of metatarsal phalangeal joint and medial malleolus; from metatarsal phalangeal joint to the tip of the toe (Toe), from metatarsal phalangeal joint to medial malleolus (Arch), from medial malleolus to the tip of the heel (Heel) (Fig. 2).

The size of pressure areas was compared using a paired *t* test between the Normal type Socks (NS) and Functional 3D type Socks (3DS). The level of significance for all statistical analyses was set at  $P = .05$ .

**Figure 2:** Analysis method  
Left side: Scanned image  
Right side: Foot pressure distribution

## RESULTS AND DISCUSSION

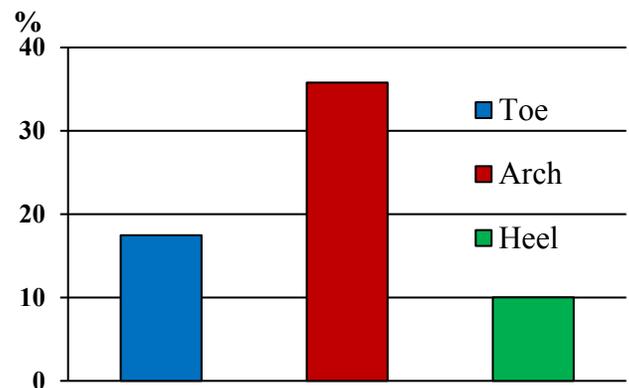

The size of pressure areas was smaller in the 3DS condition compared to the NS condition, in the Arch, Heel, and Total regions of the foot (Fig. 3 and Table 1).

**Table 1:** Summary of the pressure area

	Pressure area (mm <sup>2</sup> )		
	NS	3DS	
Toe	1902.8 ± 329.9	1526.4 ± 309.8	N.S.
Arch	3103.2 ± 563.1	2025.4 ± 665.0	P<0.05
Heel	2335.4 ± 405.4	2094.8 ± 392.5	P<0.05
Total	7341.4 ± 654.5	5603.4 ± 1047.9	P<0.05

**Figure 3:** Foot pressure distribution  
Left side: Normal Socks (NS)  
Right side: Functional 3D type Socks (3DS)

**Figure 4:** Reduction rate of the pressure area

The result suggested that the foot arch was supported by the 3DS. Especially, reduction rate of the pressure area in the 3DS condition was greater than 30% in the Arch of the foot (Fig. 4).

These results suggest that the 3D socks used in this study have a function to support the arches of the foot.

# Effect Of Foot Orthotics On Force Distribution In The Ankle And Subtalar Joint: A Cadaveric Study.

<sup>1</sup> Aron Lechtig, <sup>1,2</sup> Patrick Williamson, <sup>1</sup> Philip Hanna, <sup>1</sup> Stephen Okajima, <sup>1</sup> Peter Biggane, <sup>1</sup> Michael Nasr, <sup>3</sup> Naven Duggal, <sup>1</sup> Ara Nazarian

<sup>1</sup> Center for Advanced Orthopaedic Studies, Beth Israel Deaconess Medical Center, Harvard Medical School. Boston, MA, USA

<sup>2</sup> Department of Mechanical Engineering, Boston University, Boston, MA, USA

<sup>3</sup> Syracuse Orthopaedic Specialists, Department of General Orthopedics and Trauma, Foot and Ankle Division

## INTRODUCTION

Foot orthotics are used to treat a variety of disorders that affect the lower limb and can be purchased as generic over the counter (OTC) or patient-specific products after proper evaluation. The popularity of orthotics has increased over time, and is estimated to reach a market size of \$3.5 Billion by 2020 from \$2.5 Billion in 2014<sup>1</sup>. This allows patients to buy orthotics empirically as a means to alleviate lower limb pain and discomfort. Given the number of orthotic options and anatomical variances, it is unlikely that the patient chooses the correct orthotic.

The foot habitus is the foundation of the lower limb, which depends on its mechanics, orientation and force distribution to maintain a balanced and correlated system. Incorrect modification of the foot habitus can trigger a chain reaction of mechanical events which can cause negative impact on articular cartilage<sup>2</sup>. This study aims to compare the pressure distribution in the ankle and subtalar joint with and without orthotics.

## METHODS

Five fresh-frozen lower limb cadaveric specimens without known skeletal conditions were used. The femoral head was potted with poly (methyl methacrylate) (PMMA) for positioning it against the loading apparatus. Two TekScan pressure sensors (model 6900; TekScan, South Boston, MA, USA) were inserted into the ankle and subtalar joint. Specimens were placed on a custom jig composed of a steel scissor jack equipped with a load cell (model LTH400 rated for 1000 lb, Futek, Irvine, CA, USA) mounted on the in-house made metal box frame to apply Cranio-caudal force on the femoral head of a supine leg. This allowed for modulated

loading of the leg; 75lb load (half-body-weight)<sup>3</sup> applied at the femoral head while the foot was supported against a fixed-plate keeping the ankle in neutral position.

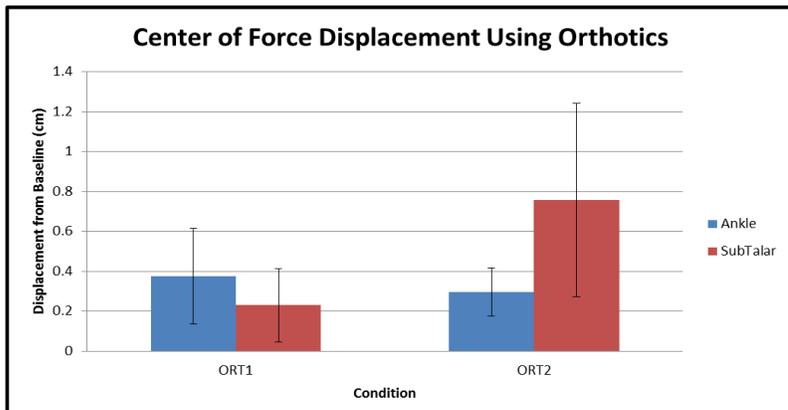

Testing was conducted by placing orthotics underneath the medial half of the sole at the level of the Talo-navicular joint. Mean pressure (MP), peak pressure (PP), contact area (CA), and center of force (COF) were measured in the previously mentioned 2 joints under three conditions; barefoot (BASE), with 1.5cm (ORT1) and 3cm (ORT2) height orthotics.

Each condition was tested three times per specimen; the results were averaged per specimen and used for final analysis. Displacement of the COF was calculated relative to its location at baseline. The absolute vector displacement, medial/lateral and anterior/posterior displacement values were also calculated.

## RESULTS AND DISCUSSION

With ORT1 and ORT2, the COF was significantly displaced from its location at BASE as can be seen in **Table 1** at the ankle by  $0.38 \pm 0.24\text{cm}$  and  $0.30 \pm 0.12\text{cm}$  (Mean  $\pm$  SD) respectively ( $p < 0.05$ ) and at the subtalar joint by  $0.23 \pm 0.18\text{cm}$  and  $0.76 \pm 0.48\text{cm}$  (Mean  $\pm$  SD) respectively ( $p < 0.05$ ), shown in **Figure 1** below.

There was no significant difference among BASE, ORT1 and ORT2 regarding the MP, PP and CA ( $p > 0.05$ ).

**Figure 1.** Mean and SD of the absolute displacement values from baseline (0) of the center of force in the Ankle and Subtalar joint under ORT1 and ORT2 conditions.

The mechanical impact of orthotics depends on the shape, material and height; which are highly variable parameters among the commercially available orthotics.

Based on our findings, the placement of a solid material between the foot and the ground could modify the location of the COF within the lower limb joints. We believe that this is the result of the alteration on the foot habitus and joint orientation.

Further, *Krause et al.* shows that changes in joint orientation and non-physiological location of the COF are related to the development of articular degenerative changes<sup>4</sup>. We argue that improper use of orthotics has the potential to lead to similar adverse effects, due to their ability to change COF.

Many studies have shown the improvement on biomechanics and quality of life after the proper use of orthotics, nonetheless the high variability between subjects, conditions and available orthotics require a careful evaluation for each patient to achieve positive results with orthotics<sup>5,6</sup>.

We encourage further investigation of the effect of foot orthotics in a larger sample size as well as their potential adverse effect on joints within the lower limb.

## CONCLUSIONS

Based on our findings, previous studies and the accepted mechanism of articular degenerative conditions development, we believe that the unsupervised use of orthotics can lead to negative articular consequences with prolonged use. We recommend the use of foot orthotics under supervision after a rigorous evaluation of the patient.

# EFFECTS OF WATER IMMERSION ON PLANTAR SKIN PROPERTIES AND SENSITIVITY

Daniel Schmidt\*, Andresa M.C. Germano, Tina Drechsel, Thomas L. Milani

Chemnitz University of Technology, Department of Human Locomotion, Chemnitz, Saxony, Germany

\*email: daniel.schmidt@hsw.tu-chemnitz.de, web: <https://www.tu-chemnitz.de/index.html.en>

## INTRODUCTION

Skin is the largest organ in the human body, and has many important functions like protecting from dehydration and preventing the intrusion of microorganisms or chemicals [1]. Recent studies showed that certain external factors negatively influence the protective skin function and increase the likelihood of (plantar) ulcer formation [2, 3], affecting quality of life. One of these factors is long-term water exposure. To our knowledge, effects of a shorter duration of water exposure (<1h) have not been reported. Furthermore, assessing plantar skin sensitivity (e.g. vibration perception thresholds, VPTs) may be desirable, since decreased sensitivity is known to facilitate ulcers formation. Decreased sensitivity could also result from water immersion, since water softens the skin [3] and may damp vibration stimuli. Therefore, the present study investigated the effects of short-term water immersion (45min) on various plantar skin properties and sensitivity. We hypothesized increased elasticity and softness, as well as decreased deformation resistance and sensitivity.

## METHODS

18 healthy subjects (mean±SD: 23.8±2.7yrs, 176.1±9.4cm, 69.5±9.5kg) participated in this study. Subjects were informed about the aim of this study and gave written informed consent. If subjects experienced any discomfort, they were free to withdraw from this study at any time. Furthermore, all measurements were conducted according to the recommendations of the Declaration of Helsinki.

First, subjects acclimatized to room temperature (23±2°C) for 10min (barefoot). Then, various plantar skin properties were measured at the Hallux of both feet prior to the intervention (pre): a) skin temperature using an infrared thermometer

(UT301C, Uni-T, China); b) the logarithmic decrement (log D) of the natural oscillation to characterize the tissue's elasticity using the MyotonPRO device (Myoton AS, Estonia); c) the tissue's deformation resistance using a durometer (AD-100-OO, Checkline Europe, Germany) and stiffness (S) readings using the MyotonPRO; and d) skin sensitivity (VPTs) using a TiraVib vibration exciter (Model TV51075, Germany, 200Hz).

The participants' right or left foot was randomly assigned as either control (CF) or intervention foot (IF). During the intervention, subjects sat in a chair and the IF was immersed completely in water (45min, adjusted according to initial Hallux temperature). Meanwhile, the CF remained untreated resting on an insulating foam surface. After the water intervention (post), all of the above-mentioned skin properties were measured again in the same manner. A standardized protocol for all measurements was applied.

Three trials were collected for all analyzed skin properties (except skin temperature), respectively. The mean from those trials was calculated for further analysis (performed R, The R Foundation for Statistical Computing, Austria). The Shapiro-Wilk-Test was used to test for normality of data ( $\alpha=0.05$ ). Pairwise comparisons of each of the skin properties were performed using a dependent t-test and Wilcoxon test for normally and not normally distributed data, respectively ( $\alpha=0.05$ ).

## RESULTS AND DISCUSSION

Although we tried to maintain all temperatures at constant levels, post water temperatures were slightly decreased resulting in slightly decreased post skin temperatures: 1.5°C (CF) and 1.8°C (IF). However, such differences are not expected to influence skin sensitivity [4].

Water immersion significantly reduced both log D and durometer readings (Fig. 1), confirming our hypothesis. The other skin properties (VPTs; S), however, remained unaffected by the intervention (Table 1), contradicting our hypothesis. Since log D is inversely proportional to the tissue's elasticity [5], water immersion increased the skin's elasticity. This was also evident by decreased durometer readings, suggesting a softening of the skin.

The softening effect of water on skin was already confirmed in an earlier study [3]. Mayrovitz et al. [3] also found that the vulnerability of blood vessels to pressure-induced blood flow reductions was increased, hence facilitating ulcer formation after long-term (5.5h) water exposure [3]. Additionally, another study showed that skin wetting increased abrasion damage, skin permeability, and microbial growth [2]. Although skin sensitivity did not decrease in this study, some of the other developments found in previous examinations were

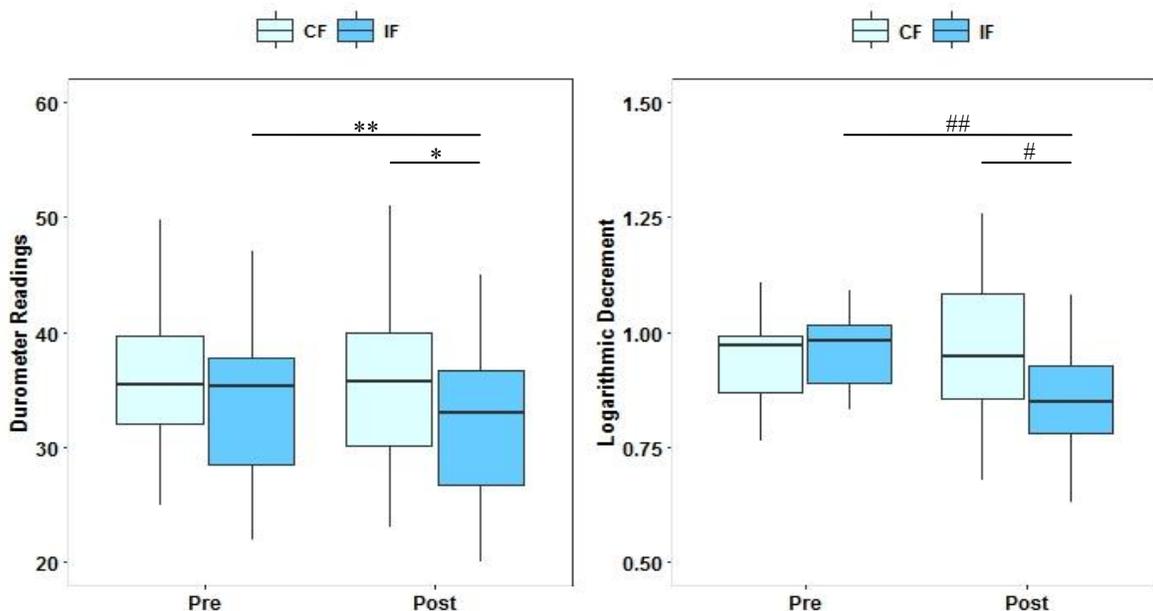

already present after our short-term exposure (45min), e.g. skin softening. As reported above, this could have similar detrimental effects regarding ulcer formation, and might especially be the case in subjects with impaired skin recovery capabilities.

# THIGH-CALF CONTACT DURING SIX HIGH KNEE FLEXION MOVEMENTS: ONSET, RANGE OF MOTION, MAGNITUDE, AND CONTACT AREA

David C Kingston, Stacey M Acker

University of Waterloo, ON, Canada

E-mail: [stacey.acker@uwaterloo.ca](mailto:stacey.acker@uwaterloo.ca) Web: <https://uwaterloo.ca/biomechanics-of-human-mobility-lab/>

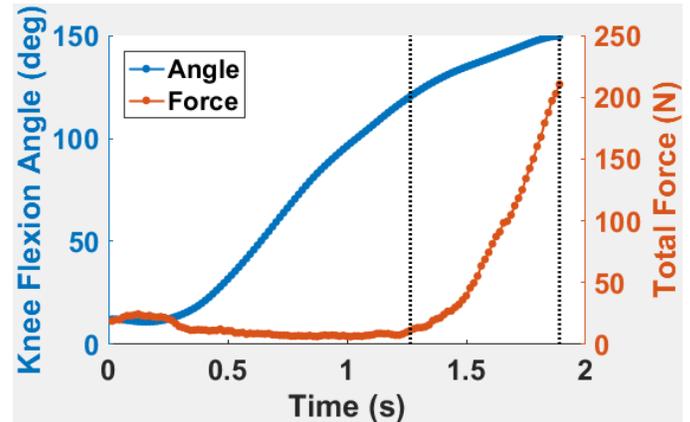

## INTRODUCTION

Limited data are available to define parameters of contact force between the thigh and calf during high knee flexion ( $>120^\circ$ ) postures [1]. Given the elevated incidence of degenerative knee diseases in populations that regularly assume these postures, further insight to refine injury mechanisms is needed [2]. Currently, no known three-dimensional musculoskeletal models incorporate thigh-calf contact parameters when estimating knee joint contact loads. Therefore, the purpose of this study was to quantify contact force, area, onset, and maximum angle between the thigh and calf during six high knee flexion postures.

## METHODS

Twenty-eight males ( $23.7 \pm 3.8$  yrs,  $1.77 \pm 0.1$  m,  $77.2 \pm 15.6$  kg) and 30 females ( $21.0 \pm 3.8$  yrs,  $1.63 \pm 0.1$  m,  $61.7 \pm 10.3$  kg) performed five repetitions of transitions to six high knee flexion postures. Postures were heels-up squat, flatfoot squat, dorsiflexed kneel, plantarflexed kneel, dorsiflexed asymmetric kneel, and plantarflexed asymmetric kneel. Trial order was fully randomized. Kinematics were recorded at 64 Hz (3020/Certus, NDI, Waterloo, ON) for the right foot, shank, thigh, and the pelvis. Thigh-calf contact total force and area were recorded simultaneously at 64 Hz with a sensor (3005E, Tekscan, South Boston, MA) attached to the posterior right thigh.

At the frame where  $110^\circ$  of knee flexion angle occurred, the average of force data from a 10-frame window ('baseline') and SD were calculated. Onset (Figure 1 – left black vertical line) was defined as the frame where force data exceeded baseline by two SD. Max angle was manually selected for each trial where the knee flexion angle plateaued (Figure 1 – right black vertical line).

**Figure 1:** Thigh-calf contact onset (left black vertical line) and max angle (right black vertical line) during a heels-up squat.

A linear mixed-model, with a-priori alpha set to 0.05, was used with fixed variables of sex and posture to assess differences between postures for onset, max angle, force, and area. Bonferroni corrections were made on pairwise post-hoc tests to adjust  $\alpha$  levels.

## RESULTS AND DISCUSSION

Mean values from all participants are reported in Table 1. Of the 58 participants, only 23 (11M/12F) were able to achieve thigh-calf contact in the flatfoot squat posture. A main effect of posture ( $p < 0.001$ ) occurred for onset with post-hoc comparisons indicating differences only in the pair of asymmetric kneeling tasks; plantarflexed asymmetric kneel onset being  $4.4^\circ$  earlier than dorsiflexed asymmetric kneel ( $p = 0.001$ ). A main effect of sex ( $p = 0.011$ ) also occurred in onset with females ( $124.1^\circ$ ) achieving thigh-calf contact  $3.1^\circ$  later than males ( $121.0^\circ$ ).

A main effect of posture ( $p < 0.001$ ) occurred in max angle with plantarflexed kneeling being  $3.2^\circ$  higher than flatfoot squat. A main effect of sex ( $p = 0.001$ ) also occurred in max angle with females

(154.4°) having 7.0° higher flexion than males (147.4°).

The only main effect in force was posture ( $p < 0.001$ ). The posture with the highest total contact force (DAK) was 139.08N higher than FS.

Finally, there was an interaction of posture by sex for contact area ( $p = 0.013$ ). Simple main effects indicated that, when performing plantarflexed kneel, females (155.6 cm<sup>2</sup>) had 18.3 cm<sup>2</sup> larger contact area than males (137.3 cm<sup>2</sup>).

These results indicate that there is considerable force transfer between the thigh and calf during high knee flexion postures. Therefore, incorporating these parameters in a model of the knee would decrease compressive joint contact force estimates. Given that females achieved higher knee flexion angles, and no effect of sex was found in force, it would suggest that females would experience more unloading than males when normalizing force estimates to percentage body mass. In addition, these findings suggest that future predictive efforts need only focus on a single posture, from each of the three postural pairs (e.g. squatting, kneeling, asymmetric kneeling), since the effect of ankle position appears to be minimal for these outcome measures.

Experimental findings of onset differ from previously reported data (heels-up squat and dorsiflexed kneeling postures from 10 participants) [1]. Onset occurred approximately 10° and 15° earlier

in squatting and kneeling respectively. This discrepancy is likely because previous work used a pressure sensor designed for seating applications (Conformat #5330, Tekscan, South Boston, MA) which has a non-sensing border around the sensor. Similarly, previous work did not use standardized anatomical coordinate systems to define knee flexion angles as only three markers were used; the greater trochanter, lateral epicondyle, and lateral malleolus.

Only ≈40% of participants achieved thigh-calf contact during the flatfoot squat posture. For many North American populations, this posture is not commonly practiced [3]. Therefore, applicability of these data to groups who assume these postures regularly (e.g. East Asian or Middle Eastern) should be done with caution.

Future work will investigate the feasibility of predicting these parameters using anthropometric based regression and incorporation into a three dimensional musculoskeletal joint contact model of the knee to account for unloading effects. Fluoroscopic data are needed to verify joint angle findings and better estimate tibiofemoral translation when assuming maximal range of motion postures.

## INTRODUCTION

With the development of the society, leisure activities and exercises, especially jogging, are becoming more popular. More and more females participate in sports, virtually evolving into a trend. However, many people are busy and warm up exercises can be ignored easily, which may result in sports injuries. Achilles tendon (AT), commonly known as the calcaneus tendon, is located in the back of the calf. At the end of the gastrocnemius, it tapers off and becomes tendon tissue connecting to the calcaneus, serving as the connection between muscle and bone. AT is the body's thickest, largest, and strongest tendon, with an average length of 15 centimeters. Its flexibility is critical during exercise, as it can withstand 8 times the body's weight while running and jumping. Repeated stretching causes the AT to become fatigued, leading to rupture [1]. This study focuses on the effects of two different warm up routines on the AT of females who exercise regularly. We utilize jogging and hot compresses as the two warm up methods and then analyze the risk of injury posed to the AT.

## METHODS

Ten untrained female amateurs, who regularly participated in recreational running and were able to comfortably run 2 kilometers, volunteered to participate in this study. Candidates with any history of AT injuries or other major injuries to the lower limbs that impeded normal gait were excluded from the study.

During the two-week period of the experiment, we conducted trials on the first, the fourth, and the eleventh day. The baseline test was performed on the first day. We marked Soles muscle-tendon junction (Soles MTJ) as point A and Gastrocnemius muscle-

tendon junction (Gastrocnemius MTJ) as point B. A mechanical properties test and ultrasound scan were performed immediately. On the fourth day, we set the treadmills in Taipei Medical University's recreational center to 11.3-14.5 kilometers per hour (adjusted in accordance with each participant's height). After participants ran for 15 minutes, we immediately performed a mechanical properties test and ultrasound scan. On the eleventh day, we used heat padding on the participants. We set electric blankets (iLove, New Taipei City, Taiwan) to 45 degrees Celsius and covered participants' legs from the knees down until the calcaneus. Then we let participants ran for 15 minutes, after that the same tests were performed.

We built spring pedals to perform the mechanical properties tests. The ankle torque was set at 27N-m (50% MVC, maximal voluntary contraction), and the spring pedal board was placed flat on the ground. Participants sat with their knees bent at 90 degrees and used their dominant foot to step on the board, affixed with a girdle, at 50% MVC in the plantar flexion position. To ensure accuracy, the two points underwent three isometric contractions and simultaneous ultrasound scans. Throughout the process, the probe remained at the same position for two seconds at a time.

We used the GE Vivid I ultrasonography machine, coupled with the GE linear probe 12L-RS to perform 2D ultrasonography manually, followed by tissue speckle tracking using the Echopac software in order to determine movement of the MTJ, strain rate, mechanical parameters, etc. A two-way ANOVA and post hoc analyses were conducted by SPSS at  $p=0.05$ .

## RESULTS AND DISCUSSION

The displacement of two points (A and B) were measured and represented lengthening of three tissues (free tendon, soleus tendon and Gastrocnemius tendon) in three warm-up conditions (Table 1). The strain rate of three tissues were measured and compared among three warm-up conditions (Table 2). The two-way ANOVA test revealed that there were differences in lengthening and strain rate of tendon tissues for different tissue types. The post hoc test showed there were differences between lengthening of Gastrocnemius tendon and Soleus tendon in the control group and the hot-compress treatment group. It was also found that the strain rate of the single tendon and the Gastrocnemius tendon were significantly different in the control group and the hot-compress group. The strain rates of the single tendon and the Soleus tendon were significantly different in the control group and the hot-compress group.

The results indicate that elasticities of tissues were significantly different in the situations without warm-up and with hot-compress treatment. There was no significant difference between tissues after warm-up by jogging. Different mechanical behavior between tissues might induce injury during being stretched.

## CONCLUSIONS

**Table 1. The displacement (mm) of three tendon tissues were compared among three warm-up conditions**

	Free tendon			Gastrocnemius tendon			Soleus tendon (between two MTJs)		
	Control	Warm	Jogging	Control	Warm	Jogging	Control	Warm	Jogging
Mean( $\pm$ SD)	0.27 $\pm$ 0.31	0.22 $\pm$ 0.18	0.33 $\pm$ 0.28	0.37 $\pm$ 0.21	0.37 $\pm$ 0.21	0.49 $\pm$ 0.45	0.16 $\pm$ 0.29	0.15 $\pm$ 0.31	0.21 $\pm$ 0.51

**Table 2. The strain rate (1/sec) of three tendon tissues were compared among three warm-up conditions**

	Free tendon			Gastrocnemius tendon			Soleus tendon (between two MTJs)		
	Control	Warm	Jogging	Control	Warm	Jogging	Control	Warm	Jogging
Mean( $\pm$ SD)	0.02 $\pm$ 0.01	0.03 $\pm$ 0.04	0.10 $\pm$ 0.21	0.11 $\pm$ 0.07	0.07 $\pm$ 0.05	0.11 $\pm$ 0.11	0.08 $\pm$ 0.07	0.04 $\pm$ 0.07	0.00 $\pm$ 0.26

The present study found that Achilles tendon tissues after treatment with hot-compress were similar to tendon tissues without any warmup. However, jogging caused no difference between tendon tissues. The contribution of warming up towards performance is still controversy. Numerous authors have attributed the protective benefits of warming up in increasing range of motion or body temperature to causing a decrease in AT flexibility [2]. However, there is no literature which can specify that muscle and tendon contractions lead AT to Stretch-Shortening-Cycle (SSC) during warmup exercises. If athletes could know more about this phenomenon, they will be able to better protect their AT and improve their performances.

## INTRODUCTION

Wear particles of ultra-high-molecular-weight-polyethylene (UHMWPE) are a cause of implant loosening in total joint arthroplasty [1]. A previous ankle simulator wear study demonstrated no reduction in wear rate for a vitamin E-stabilized, crosslinked UHMWPE when compared to conventional UHMWPE when using an anterior/posterior motion of +/- 0.3mm. When the anterior/posterior motion was increased to +/- 1.5 mm (with all other parameters unchanged), the wear rate increased by 121% for conventional polyethylene but only by 43% for the crosslinked material [2]. In this study, the surface wear scarring and wear debris are analyzed and discussed.

## METHODS

Six TAR wear couples were mounted in a Shore Western Knee Wear Simulator modified for ankle wear. Three control tibial inserts were manufactured from Ticona GUR1020 UHMWPE (INBONE® II, Wright Medical, Memphis, TN). Three inserts, geometrically identical to the controls, were manufactured from Ticona GUR1020-E, a UHMWPE resin blended with 0.1%  $\alpha$ -tocopherol (w/w), which had been crosslinked with 65 kGy e-beam radiation. The insert with conventional UHMWPE is marketed for sale internationally. The crosslinked insert is not an approved medical device and was manufactured for research purposes only. All samples were sterilized with ethylene oxide gas.

Wear was conducted in 25% bovine serum, with EDTA and sodium azide. All samples were preconditioned in the lubricant for 48 hours prior to initial weighing.

The kinematic profiles used for wear testing was previously described [2]. The initial 2 million cycles had an anterior/posterior motion that varied from

0.3mm anterior to 0.3mm posterior ("Low A/P"). From 2M to 4M cycles, this motion was increased to 1.5mm anterior to 1.5mm posterior ("High A/P"). Inserts were rotated to a different wear station every million cycles. Mass loss and dimensional change have been previously presented.

At 2M, 3M, and 4M cycles, the surface of the inserts were marked with different colors of ink based on the appearance of the surface. Four surface textures were marked: pitting, scratching, polishing, and undamaged (visible machine marks). Marking was conducted with the aid of a stereo microscope (6.5x–8x). Photographs of the wear scars were taken with a ruler visible in the image. ImageJ (National Institutes of Health, United States) was used to measure the area of each wear scar type, using the ruler for calibration of the area measurement. Two-sample t-tests were used to determine statistical significance between groups ( $p \leq 0.05$ ).

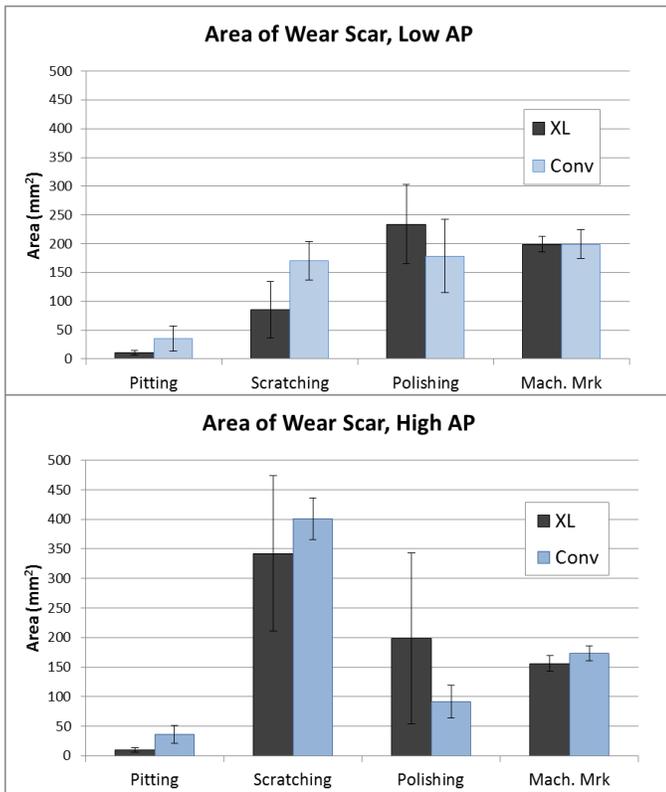

Wear particles were characterized using the method outlined in [3]. Serum samples from the fluid changes at 0.5M cycles and 2.5M cycles were analyzed. One sample (2.5M cycle, conventional UHMWPE) out of the three collected was discarded due to a wear simulator station failure mid-test.

## RESULTS AND DISCUSSION

The wear scarring summary is shown in Figure 1. With conventional UHMWPE inserts, the increase in the A/P motion increased the area of scratching on the surface of the insert by 135% ( $p = 0.004$ ). This trend was also present in the crosslinked inserts, although not significant ( $p=0.086$ ).

Pitting in the crosslinked inserts at the high A/P was less than pitting observed in the conventional inserts, although this did not reach the level of significance chosen for this test ( $p = 0.094$ ).

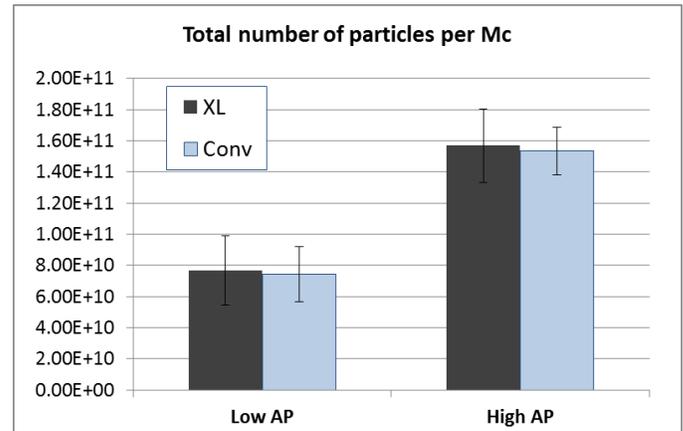

Similarly, the area of the insert that showed scratching scars in the crosslinked inserts was less than that of the conventional inserts ( $p = 0.089$ ).

**Figure 1:** Area of wear scarring types. Low AP wear scarring was measured at 2M cycles, High AP at 4M cycles.

Although the gravimetric wear rate in the crosslinked group was 32% less than the conventional group for the high AP condition, this difference was not observed in the total number of particles generated. Figure 2 shows the number of particles measured (normalized per million cycles).

The average maximum dimension of wear particles, and equivalent circular diameter (the diameter at which the area of a circle is equal to that of the 2D representation of the particle image) showed no significant differences between groups. Results are shown in Table 1 and Figure 1.

**Figure 2:** Particles measured from 0M to 0.5M (low A/P) and 2M to 2.5M cycles (high A/P). The crosslinked, high AP sample had 2 specimens, due to wear simulator station malfunction.

This study has demonstrated that increasing the anterior/posterior motion during wear simulation will increase the amount of scratching on total ankle insert surfaces, and will generate more particles compared to a gait cycle with lower A/P motion. This study has also shown that with this implant geometry, there is no significant difference between conventional vs a vitamin E-stabilized crosslinked UHMWPE insert in wear scarring or number of particles generated.

## INTRODUCTION

In the United States of America, more than half of all high school students participate in some form of athletics each year, making up a population of over 7 million adolescent student-athletes.<sup>1</sup> High school athletes sustain an estimated 1.5 million injuries each year with the ankle and knee being the most common sites of injury.<sup>2-5</sup>

Acute non-contact lower extremity injuries result in impairments in balance, power of the single limb, and jump-landing mechanics. Evidence supports that it is important to assess neuromuscular impairments following injury and for safe return to sport after injury rehabilitation. Currently, no brief comprehensive clinical tool exists for this purpose.

The purpose of this study was to describe and provide the initial data for the establishing age-specific scores of a novel, brief clinical lower extremity grading system (LEGS) of neuromuscular components as a baseline pre-season assessment for United States' high school-aged sports participants to assess risk of injury and performance potential. Additionally, the LEGS may also add utility as an additional measure to help clinicians identify neuromuscular status of the lower extremity following injury rehabilitation.

Baseline assessments with LEGS may also offer a practical clinical data tool which would allow for comparison during the rehabilitation phases of injury management of lower extremity acute non-contact injuries and for return to sport decision making.

## METHODS

Two hundred and fourteen male (n=91) and female (n=123) athletes between the ages of 12 and 17 years were recruited from San Francisco bay area public schools. Sample size was determined by performing a *priori* power analysis using G\*Power statistical software (Version 3.1.9.2) with power set at 0.8. As participants in high school athletics, all subjects played at least one of three sports: soccer (n=101), cheerleading (n=29), or basketball (n=84). These specific sports were selected based upon the common occurrence of noncontact acute lower extremity injuries involved with sport participation and high-risk maneuvers.<sup>2</sup>

The LEGS employed in this study consisted of brief assessments in the following three domains: (1) dynamic balance, (2) jump-landing mechanics, and (3) lower limb power as measured by the Y-balance test (YBT), drop-jump video test (DJVT), and triple crossover hop for distance test (TXHD), respectively.

All subjects completed pre-participation health history questionnaires to rule out current pathological conditions (any condition that would prohibit clearance to participate in athletics). Exclusionary criteria included incomplete pre-participation physical exam, and/or inability to physically perform any of the required assessments. Prior to study participation all procedures were explained to each subject. Subjects and their parents/guardians read and signed assent and consent forms and video assent and consent forms that were approved by the Stanford University institutional review board for human subjects.

Standard normal distribution was calculated for all scores to enable percentile rankings to be established for all participants. Each participant's score was also averaged to present an overall LEGS percentage score. Scores were also used in analysis and correlated to sex, gender, body mass index, age, and sport.

## RESULTS AND DISCUSSION

The three directions from the YBT were averaged for each limb, normalized for limb length, then an average was taken between limbs to describe dynamic stability of the stance leg. The highest score for boys and girls was 114 and 119 cm, respectively.

From the DJVT, the highest possible score (knee separation distance/hip separation distance) from the DJVT was 100 for both boys and girls. Highest averaged scores for boys' and girls' TXHD test were 683 and 538 cm, respectively.

Overall mean YBT value was 94.6 cm with a standard deviation of 9.1 cm. Overall mean DJVT value was 80.2 cm with a standard deviation of 15.2 cm. Overall mean TXHD value was 453.4 cm with

a standard deviation of 88.7 cm.

Percentile rankings for all participants were calculated for each test score and overall averages of percentile rankings ranged from 8% to 89%. This method provides initial data for age and sports specific values for future comparison and further scientific analyses.

## CONCLUSIONS

The Lower Extremity Grading System (LEGS) is presented as a clinical tool used for evaluating neuromuscular control analytics for use during baseline or return to play decision making process in adolescent athletes.

## INTRODUCTION

The foot is a complex structure that endures ongoing development throughout life. Its purpose is to support, stabilize and diminish the impact of forces on the lower limb during locomotion. During the developing stages, internal and external factors can influence the formation of specific foot architecture. The morphological processes of specific architectural components of the foot, such as the medial longitudinal arch, are vital for adequate function. While medial architectural characteristics of height and stiffness serve as important indicators of healthy and pathological function of the lower extremity, limited research regarding the developmental processes remain limited. Specifically, literature regarding foot morphology using the arch height index measurement system among African-American school aged children in K-12 is lacking. The aim of this study was to assess changes in foot morphology for school aged children in a developmental research school, to determine when the foot components of foot girth (FG), arch height index (AHI) and arch height stiffness (AHS) stabilize and become more consistent.

## METHODS

Seventy-eight participants (52 females, 26 males in grade levels (1<sup>st</sup> – 9<sup>th</sup>) volunteered to participate in this study. Prior to conducting any measurements, parents/guardians provided informed consent and the participants provided assent. Foot anthropometric measurements of total foot length, truncated foot length, and maximal dorsal height were taken with the Arch Height Index Measurement System to achieve the arch height and arch height stiffness measures. Arch height was computed by dividing the maximal dorsal height by truncated foot length.

Further, arch height stiffness was computed by dividing the change of arch height by body mass. An additional anthropometric assessment of foot girth was taken using a measuring tape while the participant was seated. The foot girth was defined as the circumferential distance between the first metatarsophalangeal head and the fifth metatarsophalangeal head.

## RESULTS AND DISCUSSION

A one way mixed model ANOVA was employed to determine if significant differences existed in these measures across grades. Significant differences were noted for the following comparisons: Left foot girth (LFG) (Figure 1) in the following grade levels: First grade vs 5<sup>th</sup> ( $p=.005$ ), 6<sup>th</sup> ( $p=.002$ ), 7<sup>th</sup> ( $p<.001$ ), 8<sup>th</sup> ( $p<.001$ ), 9<sup>th</sup> ( $p<.001$ ). Second grade vs 5<sup>th</sup> ( $p=.001$ ), 6<sup>th</sup> ( $p=.015$ ), 7<sup>th</sup> ( $p=.005$ ), 8<sup>th</sup> ( $p=.001$ ), 9<sup>th</sup> ( $p<.001$ ). Third grade vs 5<sup>th</sup> ( $p=.024$ ), and 9<sup>th</sup> ( $p=.001$ ). Fifth grade vs 2<sup>nd</sup> ( $p=.001$ ) and 3<sup>rd</sup> ( $p=.024$ ).

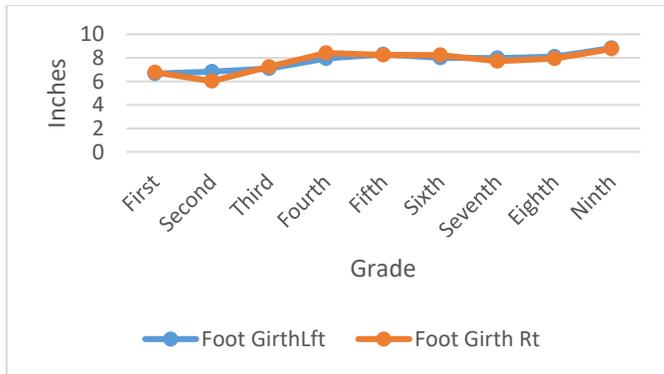

Right foot girth (RFG) (Figure 1): first grade vs 5<sup>th</sup> ( $p=.035$ ), 6<sup>th</sup> ( $p=.037$ ), and 9<sup>th</sup> ( $p=.006$ ). Second grade vs 4<sup>th</sup> ( $p=.007$ ), 5<sup>th</sup> ( $p<.001$ ), 6<sup>th</sup> ( $p<.001$ ), 7<sup>th</sup> ( $p=.002$ ), 8<sup>th</sup> ( $p<.001$ ) and 9<sup>th</sup> ( $p<.001$ ).

Left arch height stiffness (LAHS) (Figure 2) in first vs 6<sup>th</sup> ( $p=.026$ ) and 7<sup>th</sup> ( $p=.017$ ).

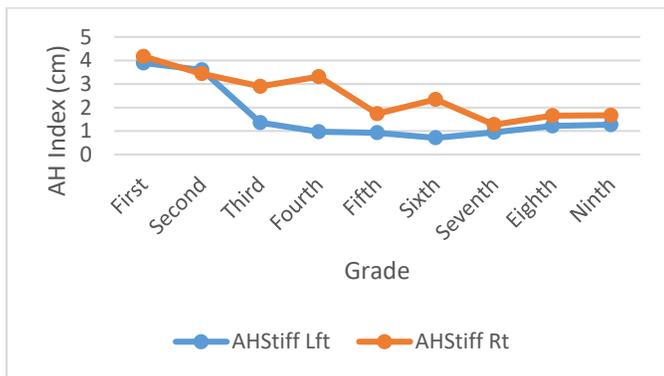

Right arch height stiffness (RAHS) (Figure 2) in first vs 5<sup>th</sup> ( $p=.029$ ), 7<sup>th</sup> ( $p=.001$ ) and 8<sup>th</sup> ( $p=.005$ ); second vs 7<sup>th</sup> ( $p=.040$ ).

No significant differences were noted between arch height index (AHI) (Figure 3) for either foot in any grade. Neither was there a difference in the measures of LFG, RFG before the fifth grade and after the ninth. While LAHS and RAHS seem to

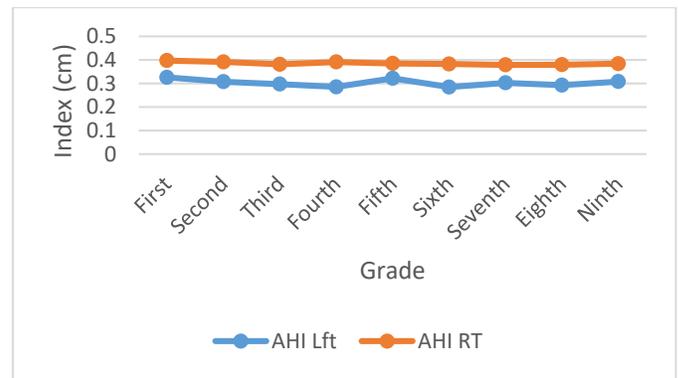

stabilize in the late middle to early high school years.

**Figure 1:** Left & Right Foot Girth

**Figure 2:** Left & Right Arch Height Stiffness

**Figure 3:** Left & Right Arch Height Index

## CONCLUSIONS

In the current study, the foot morphology characteristics of arch height index, arch height stiffness and foot girth, can experience dramatic changes from early childhood to fifth grade and throughout the middle school years until early high school grade levels. The lack of a significant finding for AHI suggests that the proportional relationship between foot components does not change significantly as the child grows and develops. Further research is needed to determine how maturation; weight or gender may influence arch development.

# ACTIVITY RELATED PLANTAR TEMPERATURE INCREASE IN HEALTHY SUBJECTS

Linda S. Adams, Ali Ersen and Metin Yavuz

University of North Texas Health Science Center, Fort Worth, TX, USA  
email: Metin.Yavuz@unthsc.edu, web: [www.sites.google.com/site/dryavuzlab/](http://www.sites.google.com/site/dryavuzlab/)

## INTRODUCTION

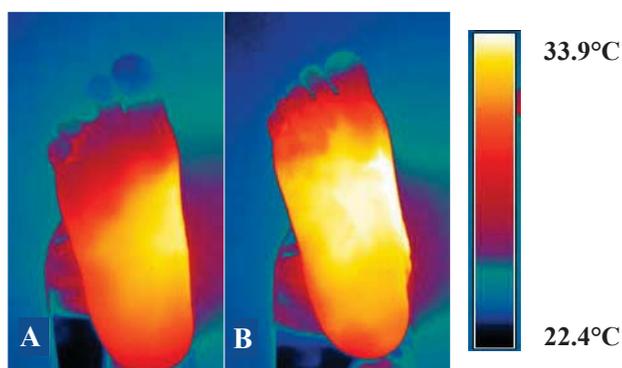

Skin temperature has long been studied as a causative factor in formation of pressure ulcers (i.e., decubitus ulcers). For example, in a swine model, Kokate et al applied constant pressure of 13.3 kPa for 5 hours with constant temperatures of 25°C, 35°C, 40°C and 45°C [1]. The results indicated that no tissue damage was observed at the 25°C sites, but substantial deep tissue damage and necrosis was observed at the sites of 35°C and above. Investigators studying diabetic foot ulcers have hypothesized that prolonged application of mechanical stresses, not only plantar pressure but also shear, leads to an inflammatory response, increased temperature, and ultimately tissue necrosis [2]: as Brand suggests, “the foot would heat up before breaking down” [3]. A study by Armstrong et al demonstrated that monitoring skin temperatures and limiting physical activity in the event of a bilateral temperature difference of  $> 2.2^{\circ}\text{C}$  could prevent ulceration [4]. Several researchers including, recently, Yavuz et al [5] reported a significant increase in the mean foot temperatures of diabetic neuropathic patients compared to control subjects. Moreover, based on studies in healthy adults, we believe that the plantar temperatures in diabetic subjects could be even greater after activity; Yavuz and associates reported a  $5.3^{\circ}\text{C}$  temperature increase on the foot sole in healthy individuals as a result of walking only for 10 minutes at 3.2km/h [6]. The purpose of this study was to quantify temperature increase in healthy subjects after 20 minutes of treadmill activity and after 70% of typical daily activity, as measured by steps. Further advancements in the treatment and prevention of diabetic ulcers demands a more comprehensive understanding of the multifactorial nature of ulcer development that will only result from a study of the following interrelated factors: plantar stresses, activity and acute and chronic plantar temperature increases.

## METHODS

This is an ongoing observational case-control study that involves analysis of temperature, shear and activity in healthy and both neuropathic and non-neuropathic diabetic subjects. Temperature data from both feet of the first 5 healthy subjects was analyzed. Subjects visited the research lab in the morning and were fitted with a FitBit®. After walking a minimum of 2400 steps, subjects returned to the laboratory. In the afternoon, subjects engaged in two bouts of treadmill walking, each lasting 10 minutes. The total estimated steps including study activities such as treadmill walking was 4800 steps or about 70% of typical daily activity in healthy individuals. Plantar temperatures were measured in the morning and twice in the afternoon, before and after treadmill activity, using a FLIR T650sc infrared thermal camera. Average temperatures were determined for the whole plantar foot, excluding lesser toes. Final maximum temperatures were obtained.

## RESULTS AND DISCUSSION

Three males and two females, three subjects between the ages of 24 and 27 and one aged 41, were tested. Average and maximum temperatures are shown in Table 1 and a representative subject’s thermal image is shown in Figure 1. Combining results from both left and right feet, the difference between morning and post-treadmill plantar temperatures ranged from  $2.6^{\circ}\text{C}$  to  $7.8^{\circ}\text{C}$  with a mean difference of  $6.0^{\circ}\text{C}$  and a standard deviation (SD) of  $1.7^{\circ}\text{C}$ . The difference between pre-treadmill and post-treadmill plantar temperatures ranged from  $0.0^{\circ}\text{C}$  to  $7.7^{\circ}\text{C}$  with a mean difference of  $2.8^{\circ}\text{C}$  (SD  $2.7^{\circ}\text{C}$ ). Maximum plantar temperatures after completion of the 2<sup>nd</sup> treadmill bout averaged  $35.2^{\circ}\text{C}$  (SD  $1.1^{\circ}\text{C}$ ) with 60% of subjects having plantar temperatures above  $35^{\circ}\text{C}$ , the critical value for tissue breakdown as demonstrated by Kokate et al.

**Figure 1.** Representative thermal profile. Average plantar temperature excluding lesser toes was 28.4°C prior to treadmill activity (A) and 31.7°C after (B).

While the change in temperature resulting from the in-lab treadmill exercise doesn't confirm the 5.3°C increase after 10 minutes of treadmill walking, as previously reported by Yavuz et al., 60% of the final resulting temperatures are above 35°C, the threshold temperature established by Brand for the increased risk of tissue breakdown. Also there is evidence that the pre-tread plantar temperatures were already elevated from activity between the morning and afternoon sessions. The pre-tread plantar temperatures were taken after subjects had completed the required FitBit® steps and several subjects returned to the lab sweaty, suggesting recent physical activity and elevated core temperature. Current results are limited by the small sample size and lack of age diversity. This ongoing study involving about 30 subjects in each subject group will look at temperature increases as a result of both daily activity, as simulated by the overall number of steps taken during the study, and acute activity associated with the treadmill walking. Furthermore, temperature data will be analyzed in relationship to plantar stresses (pressure and shear), which will be taken barefoot and

in-shoe during treadmill walking. In a recent article by Yavuz et al, the relationship between plantar stress and temperature is explored and a distinction is made between chronically elevated plantar temperatures resulting from prolonged activity and an inflammatory response in the body and acute elevated temperatures that result from activity such as walking [5]. The authors state that chronic thermal response results from prolonged exposure to repetitive stresses and is characterized by inflammation. In the case of the diabetic, it is believed that both this chronic and acute temperature increase contributes to tissue breakdown. As seen in this study, the effect of daily and acute activity combined may lead to temperatures in the plantar foot of healthy individuals that is above a critical threshold for tissue breakdown. In the diabetic, these final temperatures may be even higher due to higher resting temperatures, increased inflammation, higher plantar stresses and the highly insulating properties of diabetic footwear. Such information about the diabetic foot may lead to improved ulcer prediction and prevention methods.

# NET ENERGY TRANSFER VIA BIARTICULAR MUSCLES DURING PEDALING FLOWS DISTAL-TO-PROXIMAL DUE TO HAMSTRINGS ACTIVITY

<sup>1</sup> Alexis (Lex) D. Gidley and <sup>2</sup> Brian R. Umberger

<sup>1</sup> Brigham Young University – Idaho, Rexburg, Idaho, USA

<sup>2</sup> University of Massachusetts, Amherst, MA, USA

email: gidleya@byui.edu

## INTRODUCTION

The unique actions of biarticular muscles have been scrutinized for years. While all muscles contribute to the flow of segmental energy, biarticular muscles have the unique ability to transfer mechanical energy generated at one joint to a neighboring joint [1,2]. For example, when the knee and hip are both extending, the rectus femoris is lengthening at the hip and shortening at the knee, which may cause work generated by uniarticular hip extensor muscles to appear as joint work at the knee.

From this joint-level perspective, during the push-off phase of running and jumping net energy transferred via biarticular muscles flows from proximal-to-distal joints [2]. Specifically, rectus femoris (RECT) and gastrocnemius (GAST) dominate the energy flow in the proximal-to-distal direction, while the hamstrings (HAMS) transfer a small amount of energy from the knee to the hip [2]. While the coordination of biarticular muscles has been shown to be critical to performance in running and jumping, similar analyses have not been performed in a wide range of other activities.

In pedaling, there is a similar power generation phase to running and jumping when the hip and knee extend simultaneously. However, in contrast to running and jumping, during seated pedaling the trunk is relatively fixed and the path of the foot is constrained, which could influence biarticular muscle contributions to energy transfer. Therefore, the purpose of this study was to examine the transfer of energy via biarticular muscles during pedaling.

## METHODS

A musculoskeletal model with 9 muscles per leg (3 biarticular: HAMS, RECT and GAST), a fixed hip and 3-degrees of freedom was used to generate

forward-dynamics planar simulations of pedaling (200W, 80 RPM) using simulated annealing. Each muscle was modeled as a two-element Hill-type muscle tendon unit (MTU) with a contractile element parameterized by fiber type distribution, optimal length, maximal force, and force-length-velocity properties, and a series elastic element parameterized by the tendon slack length.

Power transferred by a biarticular muscle was calculated from the product of the torque produced by the muscle (muscle force  $\times$  moment arm) at the joints it crosses and the angular velocities of those joints [1]. Work was determined by integrating power with respect to time. Note that in calculating the energy transferred by biarticular muscles, the work at the two joints, while opposite in sign, may not be equal in magnitude because the instantaneous moment arms and angular velocities at the two joints will usually be different.

## RESULTS AND DISCUSSION

RECT, HAMS and GAST each transferred energy between the joints they cross during the pedal cycle, with the greatest amount transferred during the downstroke. (Figure 1a-c). During the downstroke, net energy was transferred in the distal-to-proximal direction (8.12 J) (Figure 1a & b). RECT transferred a small amount of energy from the hip to the knee (2.27 J) (Figures 1d & e), which is in the same direction as the push-off phase of running and jumping [2], but of a considerably smaller magnitude. This energy transfer to the knee coincides with the critical knee extension during the transition phase near top dead center and into the downstroke [4]. Very little energy (0.39 J) was transferred from the knee to the ankle by GAST during the downstroke. This energy flow through GAST plays a

crucial role in running and jumping [2], but contributes little to pedaling.

The dominant energy transfer was due to HAMS, which transferred substantial energy (10.78 J) from the knee to the hip, mostly during the second half of the downstroke (Figure 1d & e). This distal-to-proximal energy transfer by HAMS in pedaling is the same in running and jumping [2], but of a much greater magnitude. This flow of energy through HAMS enhanced hip and reduced knee extension joint powers mostly when the foot moved back under the hip to follow the pedal trajectory. Thus, HAMS dominated energy flow primarily during the second half of the leg extension phase, which is likely related to its role in controlling the direction the force on the pedal [5].

During the upstroke, GAST transfers a modest amount of energy (3.32 J) from the ankle to the knee, contributing to knee flexion (Figure 1e & f). There is also some energy transferred from the knee to the hip via RECT (2.50 J), contributing to hip flexion (Figure 1d & e). This direction of energy flow through RECT is similar to the swing phase of running when the knee and hip are also flexing [6]. HAMS transfers only a small amount of energy (1.01 J) from the hip to the knee, resulting in a net distal-to-proximal energy flow during the upstroke (4.81 J). Thus, pedaling differs from running in that net

energy transfer via biarticular muscles is distal-to-proximal in both the propulsive *and* recovery phases.

Finally, we note that while joint power flows proximal-to-distal in activities like jumping, segment power flows distal-to-proximal [3]. Interestingly, we find just the opposite in pedaling, with joint power flowing distal-to-proximal, while segment power flows proximal-to-distal [7].

## CONCLUSIONS

We conclude that net energy transferred via biarticular muscles during pedaling flows distal-to-proximal, but individual muscle flow directions are identical to that of running and jumping. The net distal-to-proximal energy flow during pedaling is due to the dominance of HAMS during the downstroke, which reflects the unique task constraints of pedaling associated with the fixed hip and the need for directing force on the moving pedal.

# BICEPS FEMORIS AND RECTUS FEMORIS ACTIVATION DURING FOUR POSTURES OF HIGH KNEE FLEXION

<sup>1</sup> Annemarie F. Laudanski, <sup>1</sup>Helen C. Chong, <sup>1</sup> Stacey M. Acker

<sup>1</sup> University of Waterloo, ON, Canada

Email: [alaudanski@uwaterloo.ca](mailto:alaudanski@uwaterloo.ca) <https://uwaterloo.ca/biomechanics-of-human-mobility-lab/>

## INTRODUCTION

In North America, postures involving high knee flexion, such as kneeling and squatting (with a knee flexion angle of  $>120^\circ$ ) are most commonly adopted in occupational settings (e.g. tiling, roofing, childcare). In contrast, East Asian cultures, including Chinese, Japanese, Korean, and Vietnamese nationalities, tend to use these postures frequently during activities of daily living for socializing, eating, rest, and religious practices [1]. These high flexion postures have been associated with increased prevalence of knee osteoarthritis (OA) [2, 3].

While it has been theorized that the risk associated with high knee flexion postures results from high moments about the knee during these postures [4, 5], a comparison of muscle contributions associated with high flexion moments has yet to be explored. Therefore the primary objective of this study was to compare rectus femoris and biceps femoris muscle activity coincident with peak flexion moments in kneeling and squatting postures. Additionally, a comparison between ethnicities and sexes was conducted to determine whether any group might adopt different muscle recruitment strategies in these postures.

## METHODS

Thirty-one participants were studied in this retrospective cohort study: twenty-one (eleven males) of European descent (Caucasian group) and ten (seven males) of East Asian (Chinese, Japanese, Korean, or Vietnamese) descent (East Asian group). All were raised in Canada. The study was approved by the university's ethics board and all participants provided informed consent prior to participation.

Four postures were studied: flat foot squatting (FS), heels raised squatting (FxS), dorsiflexed kneeling (FK), and plantarflexed kneeling (FxK). Participants completed randomized trials until 5 trials of each posture were obtained. Participants transitioned from standing into each pose (descent phase), then held the fully flexed pose for 8 seconds (static phase), then transitioned back to standing (ascent phase). Kneeling transitions were performed asymmetrically so that one knee (the "trail" leg) made contact with the force platform before the other (the "lead" leg).

An 18-camera motion capture system (Optotrak, Northern Digital Inc., Waterloo, ON, Canada) was used to collect kinematic data at 64 Hz. Infrared markers were secured to the foot, shank, and thigh of participants' lead leg, as well as to their sacrum. Two AMTI force platforms (Advanced Mechanical Technology Inc. Watertown, MA, USA) were used to collect ground reaction data at 2048 Hz. Wireless EMG electrodes (Wave Plus EMG, Cometa, Cisliano, Italy) were placed on the rectus femoris and biceps femoris of the lead leg, and sampled at 2048 Hz in order to record muscle activity. Two trials of maximum voluntary contractions (MVC) were collected per muscle group and used for EMG normalization purposes [6].

Knee joint moments were expressed in the tibial coordinate system [7]. During the descent and ascent phases for each trial, the EMG activations during peak flexion moment were calculated and then averaged across trials; while for the static phase, the mean EMG activations were calculated and again averaged across trials. Statistics were run using 3-way mixed model (pose (4) x ethnicity (2) x sex (2)) ANOVAs on the descending, ascending, and static phases for the biceps femoris and rectus femoris activations (a total of 6 ANOVAs). In cases where a significant main effect was detected, a post-hoc

Tukey test was performed in order to determine significant differences. A critical value of 0.05 was used in all tests to determine statistical significance.

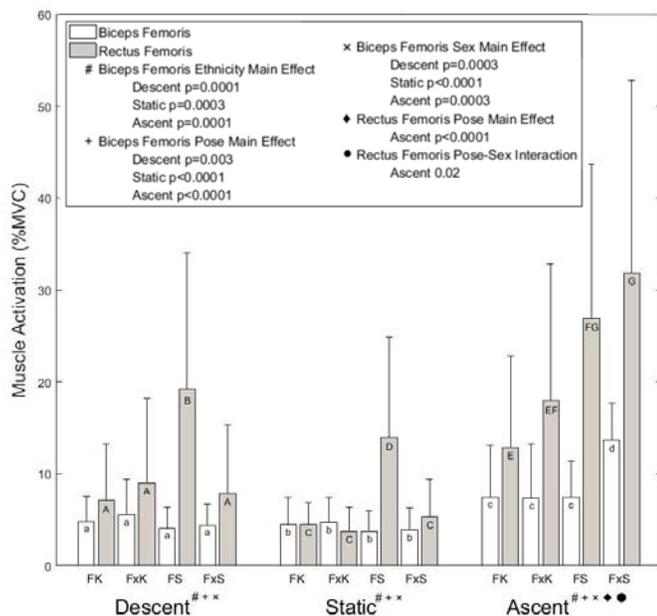

## RESULTS AND DISCUSSION

Results for biceps femoris and rectus femoris activation during descent, static, and ascent phases for all postures can be found in Figure 1. Rectus femoris activation was found to be most elevated in all three phases of flat foot squatting. Through post-hoc analysis, East-Asian males were found to have the lowest biceps femoris activations across all postures while females were found to have significantly higher muscle activation than males during the heels raised squat (43.1 ( $\pm$ 20) %MVC in comparison to 23.1 ( $\pm$ 20) %MVC for males).

The highest levels of both biceps femoris and rectus femoris activations were found to occur during squatting. Biceps femoris activity, while ascending from a heels raised squat, nearly doubled the activation recorded during any other posture (13.7 ( $\pm$ 3.8) %MVC compared to an average of 7.2 ( $\pm$ 5.1). Ascending from a heels raised squat also required the

highest recruitment of rectus femoris activation (31.8 ( $\pm$ 21) %MVC). Muscle recruitment was not found to be statistically different during any phases for plantarflexed kneeling and dorsiflexed kneeling.

This retrospective cohort study sought to analyze a subgroup of participants from a larger currently unpublished study in which flat foot squatting was found to elicit significantly lower peak knee flexion moments in comparison to the three alternative high knee flexion postures. However, results from this study suggest that during descent and static phases of flat foot squatting, rectus femoris activation is highest, as the quadriceps are recruited in order to regulate knee flexion angles. The results of the current study therefore suggest that while squatting activities could prove beneficial for building strength in the rectus femoris, for individuals who suffer from OA leading to pain during compression of the knee or individuals with quadriceps weakness or injury [8], a kneeling posture, rather than a squat, should be recommended in order to minimize rectus femoris activity. Further consideration of additional exposure measures and person-specific factors will therefore be required in order to best protect the knee from the risks associated with high knee flexion postures.

**Figure 1:** Biceps femoris and rectus femoris activation during flat foot squat, heels raised squat, dorsiflexed knee, and plantarflexed knee. Pose main effects have been marked in lower-case for biceps femoris and in upper-case for rectus femoris.

## INTRODUCTION

The metatarsophalangeal joint (MTP) has been reported to absorb large amounts of energy while generating very little during running [1]. Multiple studies have assessed the effects of the longitudinal bending stiffness of footwear on MTP mechanics and energetics [1,2]. However, these studies reported only the material bending stiffness of the shoe, and did not report MTP joint stiffness during running.

Joint stiffness affects the neuromuscular control of movement, injury risk, and performance. During gait it is commonly calculated as the change in moment divided by the change in angle during the energy absorption phase of stance [3]. The MTP joint does not follow a similar energy absorption and generation pattern as the ankle and knee that are commonly modeled as a spring-mass system. The MTP dorsiflexes throughout most of stance phase peaking during late stance, instead of mid-stance [4]. Despite eliciting a phase dependent stiffness curve, only one portion of the angular load-displacement relationship has been quantified for the MTP joint [5]. There is not currently a common methodology for reporting MTP stiffness. This study investigates MTP stiffness properties during running, and presents initial interpretation of what function each portion of the MTP load-displacement curve represents.

## METHODS

To date, three male runners (average 20yr, 175cm, 58.5kg, 15:20min 5000m best, 67mi/wk) have been enrolled in this ongoing study. Written informed consent was given by the subjects prior to the IRB-approved protocol. Running trials were conducted at 3.89, 4.44, 5.00, 5.56, and 6.11 m/s on an instrumented split-belt treadmill (Bertec, Inc., Columbus, OH). These velocities were chosen as

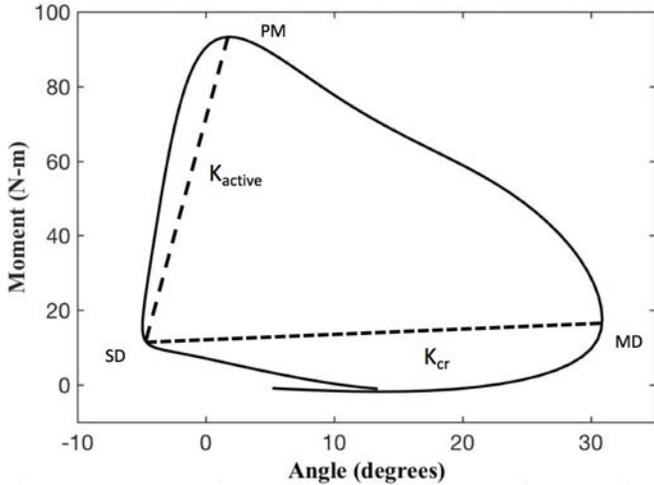

they are representative of relevant training and racing paces for competitive distance runners. Rest between conditions was self-selected, with subjects instructed to start the next condition when they felt no effects of fatigue. Subjects all wore the same footwear (Brooks Launch 4) to control for the effects of varied longitudinal bending stiffness among shoe types. Windows were cut in the shoes at the hallux, first and fifth metatarsals, and the medial, lateral and posterior calcaneus, to allow for direct application of retro-reflective markers to the skin. Marker coordinate data were collected at 200Hz using an 8-camera motion capture system (Motion Analysis Corp., Santa Rosa, CA). Ground reaction force data were collected at 2000Hz using the force-instrumented treadmill and then imported from Cortex to Visual3D for kinematic and kinetic analysis. A two-segment foot model was defined, with an MTP pin joint defined by a vector between the 1<sup>st</sup> and 5<sup>th</sup> metatarsal markers.

Two separate measures of MTP joint stiffness were defined by plotting the change in angle against the change in moment of the MTP joint. Active stiffness ( $K_{active}$ ), was calculated as the change in moment divided by the change in angle within a phase defined from initial dorsiflexion to peak plantar flexor moment. Critical stiffness ( $K_{cr}$ ) was calculated as the change in moment over the change in angle within the prolonged phase from initial dorsiflexion to peak dorsiflexion, similar to [5].

## RESULTS AND DISCUSSION

Data presented from three of the five running speeds are preliminary and part of an ongoing study. Joint stiffness values represent the combined effects of the foot-shoe complex. The defined stiffness quantities from two portions of the MTP load-displacement curve are discussed with respect to functions related to injury or performance.

The active stiffness ( $K_{active}$ ) was much higher at the fastest running speed, but did not consistently trend upward (Table 1). The active stiffness is representative of when the musculotendinous structures crossing the plantar surface of the MTP joint are storing elastic energy from initial dorsiflexion to the time of peak plantar flexor moment and is the portion of stance when the maximum elastic energy is stored. From an injury perspective,  $K_{active}$  indicates how the MTP joint is attenuating the ground reaction force.

**Figure 1:** Representation of joint stiffness calculations. SD: initial dorsiflexion, PM: peak plantar flexor moment, MD: max dorsiflexion.

The critical stiffness ( $K_{cr}$ ) showed a decreasing trend as running speed increases (Table 1). Previous research defines  $K_{cr}$  as representing the threshold of the elastic benefit of shoe stiffness [5]. We propose that  $K_{cr}$  is also an indicator of the ability of the MTP joint to utilize stored elastic energy. The large hysteresis response suggests that while the initial energy storage ( $K_{active}$ ) is substantial, the hysteresis portion of the curve (PM to MD) indicates dissipation of a large amount of that energy while the MTP joint continues to dorsiflex, reducing the amount of elastic energy for the MTP to utilize

during plantar flexion at terminal stance to assist in forward propulsion. Thus, critical stiffness may be an important performance metric to consider.

The ratio between  $K_{active}$  and  $K_{cr}$  could be used as an indicator of the effectiveness of the stretch shortening cycle of the toe-flexor muscles. Effective stretch-shortening response requires quick loading and release. In a standard spring-mass model, a stiffer joint effectively stores and returns more elastic energy than a compliant joint. Though the toe-flexor muscles continue to experience strain while dorsiflexing, the moment value is decreasing, effectively dissipating the stored energy during the active stiffness phase.

## CONCLUSIONS

Initial examination of these preliminary findings indicates that MTP joint stiffness may be analyzed by two separate functions; active attenuation and utilization of stored energy. Continued analysis of the results from this ongoing study may help to identify injury mechanisms and performance enhancement.

# ARCH STRUCTURE AND LOADING PATTERN MAY PREDICT RUNNING FOOT MECHANICS

<sup>1</sup> Adrienne D. Henderson, <sup>2</sup> Joaquin A. Barrios, <sup>1</sup> Dustin A. Bruening,

## INTRODUCTION

Foot structure has long been implicated as a factor in running related injuries and used as a predictor in functional interventions, such as footwear and orthotic prescriptions. While arch height has been associated with passive foot mobility (i.e. higher arch corresponding to higher passive midfoot stiffness) [1], a relationship between foot structure and dynamic foot function has proved elusive. Studies exploring static to dynamic relationships have focused almost exclusively on ankle and midfoot joint kinematics. Positive findings, such as low arched runners landing in a more everted ankle position [2] reflect a relationship between structure and posture as opposed to structure and function. On the other hand, functional range of motion (ROM) measures appear to be similar between foot types [2].

One reason that a true static/dynamic relationship has been so elusive is that foot kinematics may be greatly influenced by variations in foot loading. For example, passive mobility is generally assessed by comparing foot posture between sitting and standing. However, in standing, the center of pressure is generally posterior to the midfoot, while during running, the center of mass travels the length of the foot, creating a much larger torque on the midfoot joints. Additionally, the combination of frontal plane hindfoot position and midfoot torque can affect midfoot motion via the midtarsal locking theory, which postulates that hindfoot inversion reduces flexibility across the joints of the midfoot.

The purposes of this study were to explore relationships between static foot structure and foot mechanics in running by incorporating loading variables into the analysis. We first controlled foot strike pattern, evaluating both rearfoot strike (RFS) and forefoot strike (FFS) patterns. In a FFS, the hindfoot is less everted throughout stance, and midtarsal loading occurs much earlier [3]. We also included several novel kinetic measures of foot

function, hypothesizing that midfoot stiffness and midfoot power absorption would be correlated with measures of foot structure.

## METHODS

Eighteen female runners (25±4 yrs., 1.65±0.06 m, 61±7 kg) were tested. Static structure was assessed using the Foot Posture Index (FPI) [4] as well as standing arch height and arch stiffness from the Arch Height Index Measurement System (AHI) [5]. Dynamic function was assessed as subjects ran over ground at 3.7 m/s with both rearfoot (RFS) and forefoot (FFS) strike patterns. Subjects wore minimalist shoes with cut-outs and reflective markers were placed directly on the skin according to a modified kinetic multi-segment foot model [6]. Marker trajectories and force plate data were collected at 150 and 1,500 Hz respectively.

The ankle and midtarsal joints were modeled in Visual 3D software [6]. Joint angles were extracted using a typical Euler sequence. Joint moments and powers were calculated by first partitioning the ground reaction force to each segment sequentially using the center of pressure [7]. Analysis focused on loading phase only, which was defined from initial contact to peak midtarsal dorsiflexion. Extracted metrics consisted of: ankle eversion ROM, tri-planar midtarsal ROM, peak midtarsal angular velocity magnitude, midtarsal negative work (integral of power), and midtarsal stiffness (slope of the linear portion of the sagittal plane moment / angle graph). Each of these seven functional metrics was then correlated ( $\alpha = 0.05$ ) to the three structure metrics (FPI, standing AHI, and AHI stiffness).

## RESULTS AND DISCUSSION

Of the 42 tested relationships, only 5 were significantly correlated, with four of these five confined to the FFS pattern. It is possible that a FFS increases the ability to detect a static/dynamic relationship for several possible reasons. First,

Barnes et al. [1] hypothesized that low arched feet do not show increased ROMs because they are naturally already approaching an end-range. A FFS position, where the hindfoot is not on the ground, may influence this end-range effect. In addition, the reduced hindfoot eversion accompanying FFS [3] may stiffen the midfoot, potentially also reducing this end-range effect, or reducing the inter-subject variability in midtarsal mechanics.

Arch height index was negatively correlated with midtarsal dorsiflexion ROM in FFS. This supports findings relating arch structure to passive arch stiffness [1], but has not been shown before. Encouragingly, RFS may have also been significant if a larger sample size had been used ( $p=0.0683$ ). A correlation was found with FPI and the traditionally assumed frontal plane ankle motion (e.g. increased eversion in flatfeet), however, our results suggest that midfoot dorsiflexion may be a more sensitive measure, regardless of loading pattern.

AHI was also negatively correlated with sagittal plane midtarsal stiffness. Previous studies have used ROM as a surrogate for stiffness, assuming that a more compliant joint would result in more motion. However, this ignores the effects of loading. The stiffness calculated in this study comprises both motion and loading into one variable, and results suggest that this variable should be employed in future studies.

There were no significant correlations found with the AHI stiffness measurement. AHI stiffness measures the statically loaded foot, but may not replicate dynamic loading conditions.

FPI was negatively correlated to both ankle eversion ROM and midtarsal inversion/ eversion ROM. These two variables are coupled (i.e. with the forefoot on the ground, ankle eversion should result in midtarsal inversion). The only RFS correlation, that of midtarsal ab/adduction ROM, was also found with FPI. The differences between FPI and AHI correlations demonstrate that these measurements reflect different aspects of foot structure.

Our subject sample was fairly homogenous. Sixteen of 18 subjects had normal arches, the other 2 qualifying as low arches according to Zifchock et al's AHI criteria [8]. Future study should investigate these same variables in a larger sample that includes both high and low arch subjects.

## CONCLUSIONS

Despite the homogenous sample, several variables show promise in connecting static and dynamic foot stiffness. These variables showed up primarily in FFS suggesting that loading pattern affects this relationship. Future studies should expand the sample size and scope to better assess these relationships.

# EFFECTIVE AVERAGE ANKLE MOMENT ARM AT VARIOUS SPEEDS

<sup>1</sup> Luke Steinbach, <sup>2</sup> Peter G. Adamczyk

<sup>1</sup>Department of Mechanical Engineering, University of Wisconsin, Madison, WI, USA  
Email: [lsteinbach@wisc.edu](mailto:lsteinbach@wisc.edu)

## INTRODUCTION

Control of the ankle-foot complex in walking is dominated by a heel-to-toe rolling motion, whereas in running at high speeds, the ankle and foot are part of the spring like behavior of the leg. These differences represent a shift toward more forefoot-dominated ground interaction at the higher speeds. This shift has been shown through changes in the center of pressure (COP) at initial ground contact [1]. However, instantaneous COP location at a specific time may not capture the full effect of changes in overall ankle control. An understanding of such changes is important for efforts to design and analyze biomimetic assistive devices such as foot-ankle prostheses, which may not adapt appropriately to different speeds.

This study investigates ankle control across a range of speeds including both walking and running. We hypothesize that ground reaction forces will show an overall forward shift as speed increases, representing a more forefoot-dominated strategy. We use a new metric to evaluate this overall shift, which incorporates a weighted average of center of pressure throughout the stance phase. We term this metric the “effective average ankle moment arm” (EAAMA). This parameter estimates the average sagittal moment arm of ground reaction forces about the ankle joint, across an entire stance phase of walking or running. EAAMA is designed to identify kinematic aspects of ankle control related to dorsiflexion/plantarflexion posture and hindfoot vs. forefoot-dominated ground interaction. Results across different speeds are intended to identify the average change in pressure distribution over the plantar surface as locomotive speed changes. We

also compare and contrast this metric to a simple initial-contact COP measurement. *We hypothesize that as locomotive speed increases, both EAAMA and initial COP will translate anteriorly.* The results of this study may influence biomimetic design and control of lower limb assistive devices.

## METHODS

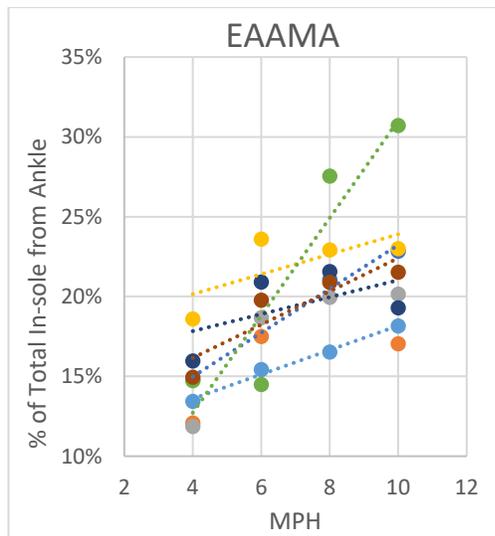

Pressure insoles (Novel GmbH) were placed in the shoes of 8 subjects. Each insole has 99 transducers to measure localized pressure data across the foot. Data were recorded at 4, 6, 8, and 10 mph for each subject on a treadmill, for 20 seconds at each speed. Data processing to find the EAAMA used following steps:

- Assign ankle position to 30% of total in-sole length from the rear of the in-sole.
- Calculate instantaneous COP and total normal ground reaction force at each sample time.
- Integrate the total force impulse and total ankle moment impulse within each trial.
- Calculate EAAMA, defined as moment impulse divided by force impulse.

Take the average of both feet if acceptable cycles were present.

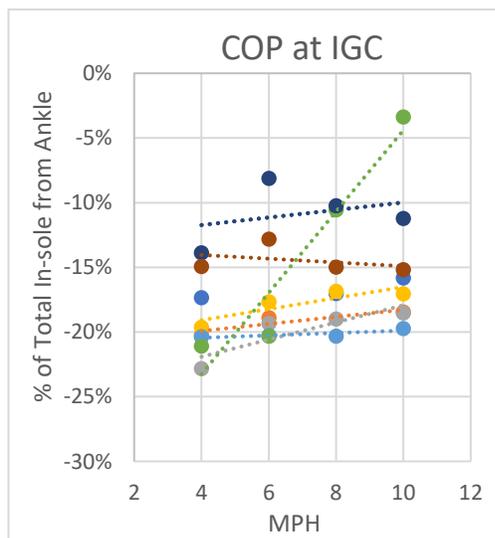

## RESULTS AND DISCUSSION

The EAAMA for each subject resulted in an anterior translation in the sagittal plane on the plantar surface, with an average translation across all subjects of 38% (Fig. 1). All subjects had a walking speed moment arm of 10% to 20% of the in-sole size forward of the ankle. This corresponds to the mean plantar moment found by Winter (reported in [2]) thus offering validation of our results for walking speeds.

**FIG. 1:** The EAAMA of 8 subjects (different color dots). The ordinate represents how far forward of the ankle the EAAMA is, normalized by in-sole size.

Instantaneous COP at initial ground contact (IGC) was also examined for comparison against results from the EAAMA. If the COP at IGC shows anterior translation, then the EAAMA at the same speed cannot show a posterior, or no, translation since more force is being applied away from the heel.

**FIG. 2:** The COP at IGC for 8 subjects (different color dots). The ordinate represents how far behind the ankle the COP is, normalized by in-sole size.

Fig. 1 and Fig. 2 share different ordinate ranges because the COP in Fig. 2 is only at initial ground contact at the beginning of the stance phase. The negative ordinate represents ground reaction forces behind the ankle (heel contact). There is not a direct correlation between Fig. 1 and Fig. 2 as a few of the subjects show a posterior, or insignificant, translation of the COP at IGC, yet a definitive anterior translation for the EAAMA. This could mean that those subjects are exerting much more force on toe-off at running speeds in order to bias the EAAMA anteriorly, while still maintaining, or translating posteriorly, the initial ground contact. These results support the hypothesis that ground interaction forces move forward to become more forefoot-dominated as speed increases, even if initial ground contact location does not change. Future testing with stricter protocols will discern the details of the discrepancy between these measures.

## CONCLUSIONS

The effective average ankle moment arm across different speeds appears to capture a new aspect of ankle-foot control across changes in speed. The slight discrepancy between the EAAMA and the COP at IGC may yield interesting information after further testing. Technical improvements in future testing will be focused on improving robustness to sensor noise in the pressure insoles, which was a significant challenge in this pilot study. Future work will include a higher number of subjects, the same type of running shoe for all subjects, and an instrumented split-belt treadmill to verify in-sole data.

## INTRODUCTION

Osteoarthritis (OA) of the first metatarsophalangeal (1<sup>st</sup> MTP) joint is the most common form of degenerative disease in the foot. Increased joint loading and concomitant stress are considered important factors in OA onset and progression. Radiographically-confirmed OA has been quantitatively associated with a lower-arch (planus) alignment [1]. Presence of 1<sup>st</sup> MTP joint OA has been reported in 27% and 34% of men and women over 50 years of age, respectively [2].

Degeneration of the 1<sup>st</sup> MTP joint presents as a reduction in dorsiflexion from >60° for healthy; >40° for hallux limitus; [3] and <20° for end-stage, hallux rigidus [2]. Outcomes for end-of-stage salvage procedures are either unpredictable or limit normal biomechanical function. Joint sparing procedures for mild to moderate disease are favorable to delay OA progression and reduce the economic cost and biomechanical concessions associated with current end-of-stage-treatments. First MTP joint cheilectomy combined with proximal phalangeal dorsiflexion osteotomy (Moberg) is one such treatment. However, postoperative contact mechanics are not fully understood.

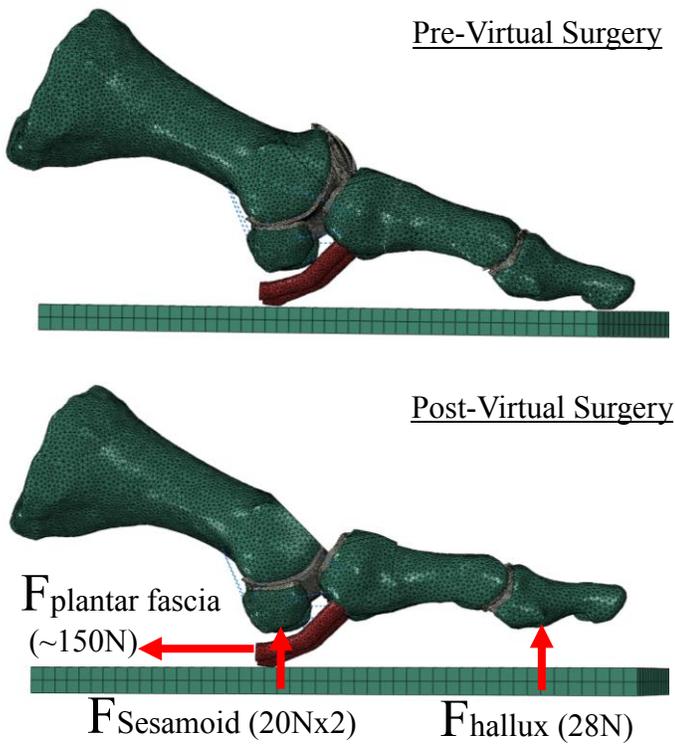

The aim of the combined surgery is to remove osteophytes at the dorsal aspect of the 1<sup>st</sup> MTP joint and to dorsiflex the hallux, thereby, freeing up space for the joint to recover range of motion. The goal of this study is to compare the effect of cheilectomy with different Moberg osteotomy geometries on 1<sup>st</sup> MTP joint contact mechanics.

## METHODS

Six cadaveric-specific finite-element (FE) models of the first ray (including metatarsal, sesamoids, proximal phalanx and distal phalanx, as well as associated cartilage and plantar fascia) were developed. All specimens were free of cartilage defects.

Each specimen was imaged, using a 3T MRI-scanner. Three-dimensional (3D) geometrical models were created, where each tissue was segmented in Mimics (Materialise, Belgium), assembled in CATIA (Dassault Systèmes, France) and meshed in Abaqus (Dassault Systèmes, France). The Bones (E=7.3GPa,  $\nu$ =0.4) and cartilage (E=25MPa,  $\nu$ =0.4) were modelled as linear elastic parts for explicit, dynamic analysis. Fourteen ligaments (tension-only ‘wires’; E=260MPa,  $\nu$ =0.4) and the plantar fascia (E=350MPa,  $\nu$ =0.4) were also modelled.

Model geometry was then modified (Fig. 1) to simulate a cheilectomy only, and a cheilectomy combined with 1-mm and 3-mm Moberg osteotomy. The metatarsal bone of each model was rotated in a physiological manner to simulate a planus arch-alignment. Loading conditions were determined during prior cadaveric testing for experimental validation of the computational models. Loads of 28 N, 20 N and 20 N were applied beneath the hallux, lateral sesamoid and medial sesamoid, respectively, to represent one quarter scale of the ground reaction forces during gait. The plantar fascia was loaded with ~150 N to balance moments created by the ground reactions forces.

**Figure 1.** FE model of a first ray (with loading conditions) pre- and post-virtual cheilectomy and 3-mm Moberg osteotomy titration.

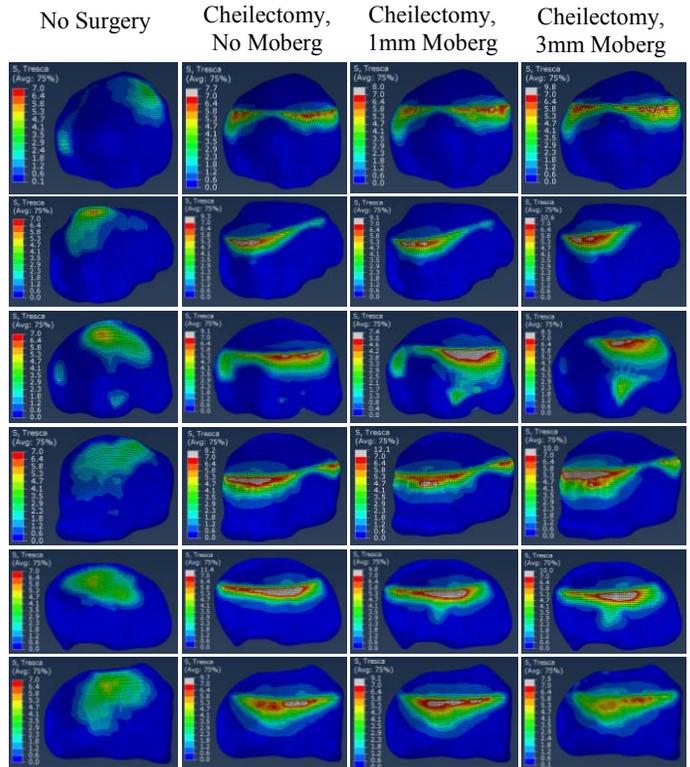

## RESULTS AND DISCUSSION

Six cadaveric-specific FE models of the first ray were developed to compare 1<sup>st</sup> MTP joint peak shear stress and location of peak shear stress. Stress analyses were performed pre- and post-cheilectomy, without and with Moberg osteotomies, titrated to 1-mm and 3-mm. The computationally-predicted peak shear stress at the 1<sup>st</sup> MTP joint phalangeal base cartilage is shown in Fig. 2. FE analyses demonstrated plantar shifting and increased magnitude of peak shear stress post-cheilectomy.

## CONCLUSIONS

The ability to calculate unique stress distributions before and after virtual surgery suggests that FE model-based analysis is sensitive to the effect of different size and shape specimens. This series of models can be used to develop insight into current

and future surgical techniques at a subject-specific level.

**Figure 2:** Shear stress distributions in the proximal phalanx base cartilage for each first ray specimen presenting with no surgery; cheilectomy and no Moberg osteotomy; cheilectomy and 1-mm Moberg osteotomy and; cheilectomy and 3-mm Moberg osteotomy.

The next phase of this research will be to increase the loading conditions applied to each FE model to represent the full scale ground reaction forces experienced beneath the 1<sup>st</sup> ray during gait.

## INTRODUCTION

Primary (idiopathic) osteoarthritis (OA) of the knee and hip are considerably more prevalent (approximately 20-30% of adults across numerous populations) [1] than the ankle's (less than 1% among adults) [2-3]. Despite suggested links between mechanical loading, articular tissue degeneration, and the risk of OA, it is unclear whether loading asymmetry differences between lower extremity joints is consistent with reported differences in OA incidence between these joints. This study investigated the effect of physical activity rigor on loading asymmetry between lower extremity joints.

## METHODS

13 young adults (7 males and 6 females) (21.7±2.3 years; 170.6±6.9 cm; 65.2±7.9 kg) participated in this study.

Horizontal drop jumps from 41 (low), 56 (moderate), and 71 (intense) cm were implemented as proxies for varying levels of physical activity rigor. Participants were instructed to stand on a box, drop vertically, and jump as far forward as they could upon contacting the force plate below. A 12-camera VICON motion capture system and AMTI force plate acquired joint kinetics and kinematics.

Sagittal joint moments at the hip, knee, and ankle were calculated using inverse dynamics. Moments were averaged across five trials per condition. Cross-correlation coefficients were calculated to estimate loading (moment) symmetry between bilateral homologous joints (equation 1).

$$\text{Corr} - \text{norm } x, y = \frac{\sum_{n=0}^{N-1} x[n] y[n]}{\sqrt{\sum_{n=0}^{N-1} x^2[n] \sum_{n=0}^{N-1} y^2[n]}} \quad (1)$$

Where N is the length of the signal, and x and y are independent in-phase signals. Vector outputs from cross-correlation calculations were normalized to the signal energy (denominator in equation 1).

Movement initiation was delineated as the first non-zero vertical center of mass velocity (vCOM). Touchdown and takeoff from the force plate were defined as the instants vertical ground reaction force exceeded and fell below 40N, respectively.

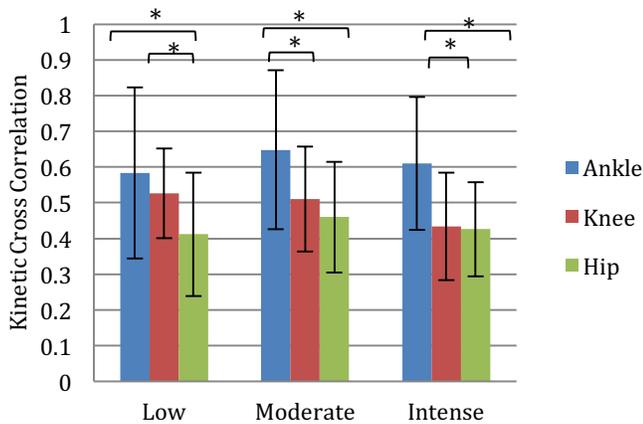

Movement termination was delineated as the last zero vCoM velocity. A 3 (drop height) x 3 (joint) ANOVA with repeated measures was calculated to determine the effects of both factors on loading symmetry. Alpha level was  $p \leq .05$ .

## RESULTS AND DISCUSSION

The knee ( $p = 0.020$ ), ( $p = 0.001$ ), and hip ( $p = 0.002$ ), ( $p = 0.001$ ), showed greater loading asymmetry than the ankle with increased physical activity rigor, i.e., when subjects dropped from 56 cm and 71 cm, respectively.

The hip showed greater kinetic asymmetry than both the ankle ( $p = 0.003$ ) and knee ( $p = 0.004$ ) with decreased physical activity rigor, i.e., when subjects dropped from 41 cm.

Previously, young adult females showed greater loading asymmetry at the knee and hip compared to the ankle during the sit-to-stand task [2].

3. Forczek W, et al. *J Hum Kinet.* **35**, 47-57. 2012.

**Figure 1:** Loading asymmetry between the ankle, hip, and knee joints during low, moderate, and intense physical activity. \* Indicates significant difference between joints.

Despite differences in methodology, this finding is consistent with the observation that greater joint structural stability, which likely imposes greater kinematic constraint, may necessitate more bilaterally uneven moment contributions (increased asymmetry) at the hip and knee compared to the ankle [3].

## CONCLUSIONS

The risk for excessive loading and associated articular tissue degeneration may be greater at the hip than the ankle irrespective of physical activity rigor. Conversely, this risk seems greater at the knee than the ankle only with increased physical activity rigor.

These findings are consistent with previous reports of higher primary OA incidence at the hip and knee compared to the ankle in general adult populations. Therefore, the relationship between physical activity rigor and primary osteoarthritis incidence needs to be further researched, particularly at the knee.

# DECREASED PLANTAR SENSATION IS ASSOCIATED WITH INCREASED LOADING

<sup>1</sup>Toyin Ajisafe, <sup>1</sup>Ferdinand Delgado, <sup>2</sup>Hsin-Chen Fanchiang

## INTRODUCTION

Decreased plantar cutaneous sensation is associated with a number of conditions, including obesity [1]. Individuals with obesity have greater plantar pressure than those with healthy weight [1].

Interestingly, individuals with overweight and obesity are thought to experience increased ground reaction forces solely due to increased body weight. It is unclear whether decreased plantar cutaneous sensation might engender any compensatory changes to vertical ground reaction forces and impulse during a dynamic non-locomotor task (standing calf raise).

## METHODS

Eleven young adults (four females and seven males) ( $24.18 \pm 4.35$  years;  $171.58 \pm 8.21$  cm;  $76.64 \pm 18.25$  kg) participated in this study.

There were two conditions: no icing and icing.

In the no icing condition, subjects stood barefoot in the middle of an AMTI force plate and performed standing calf raises at a cadence of 48 beats per minute for 90 seconds. The force plate acquired vertical ground reaction forces. Participants were asked to maximally push up and stand on their toes, then lower back down at each audible beat of a metronome.

In the icing condition, participants' forefeet were cooled on bagged ice (while seated) until their forefoot plantar temperature read  $6^{\circ}\text{C}$  on an infrared thermometer. Icing was immediately intervened by the foregoing movement task on the force plate. The order of conditions was randomized. Participants returned to the lab after 24

hours to complete the second condition. Vertical ground reaction force peaks were estimated and averaged across 90 seconds. In addition, we estimated vertical ground reaction force impulse ( $J$ ) by integrating vertical ground reaction force time series ( $F$ ) data over time ( $t$ ), using MATLAB (equation 1).

$$J = \int_{t_0}^{t_{90}} F(t) dt \quad (1)$$

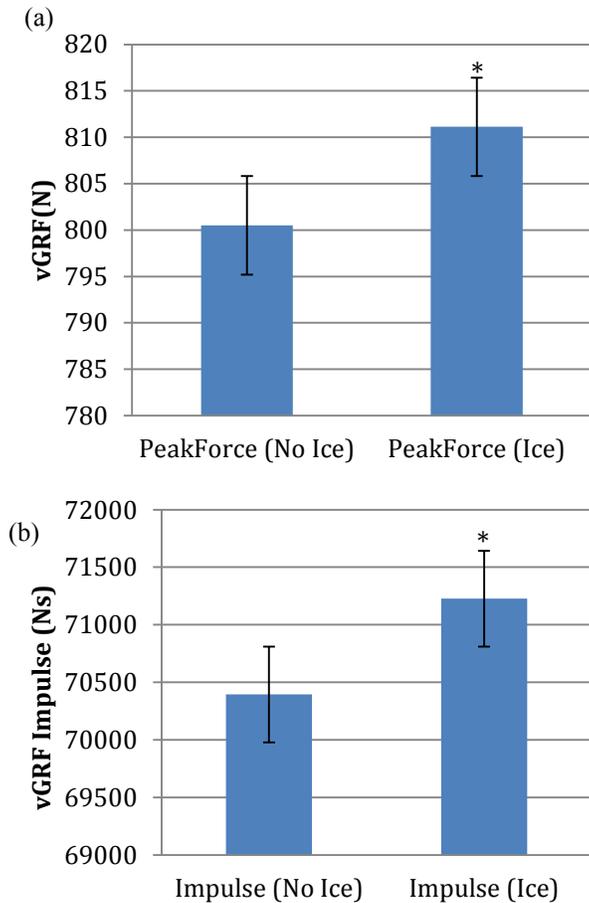

We calculated a paired-samples t-test to determine the effect of forefoot cooling on vertical ground reaction force and impulse. Statistical significance was set at  $p < .05$ .

## RESULTS AND DISCUSSION

A set of paired-samples t-tests, showed significant differences in vertical ground reaction force ( $t(10) = -2.563, p = .028$ ) and impulse ( $t(7) = -2.806, p = .019$ ) between the conditions (Fig. 1).

To our knowledge, there has not been any previous research on the influence of decreased plantar cutaneous sensation on ground reaction force and impulse.

Intact young adults increased vertical ground reaction force and impulse following forefoot cooling (Fig. 1a and 1b) in this study. It is plausible that the observed increase in loading is compensation engendered by deficits in plantar sensation.

**Fig. 1:** (a) mean vertical ground reaction force (vGRF), (b) mean vertical ground reaction force impulse. \* indicates significant difference between conditions.

## CONCLUSION

The finding of increased loading and its temporal properties following forefoot cooling suggests that decreased plantar sensation may cause increased loading. This may have implications in conditions that are associated with decreased plantar sensation, including obesity.

The association between increased loading and decreased plantar sensation warrants further investigation, especially considering that obesity has been linked with greater plantar pressure and incidence of foot-related injuries/discomfort.

## INTRODUCTION

Mild traumatic brain injury (mTBI) is a global health concern with an estimated 42 million individuals worldwide receiving an mTBI each year [1]. Recent work has demonstrated that a 3 minute visuomotor tracking (VMT) test can classify mTBI with comparable to or better accuracy than several standard clinical scales, in less time [2]. This may be a result of the VMT test simultaneously evaluating several processes which are often impaired after mTBI such as fine motor performance, reaction time, and spatial processing.

Understanding normal variability in VMT performance can help improve mTBI classification. The goals of this study were to: 1) quantify normative performance on the VMT task, 2) determine if there are human factors associated with differences in task performance and 3) quantify the relationship between VMT performance and standard assessments of fine motor control, reaction time, and spatial processing.

## METHODS

### Visuomotor tracking task

VMT performance was quantified using a novel device [2], adapted to run on an iPad (Fig. 1).

Participants were asked to squeeze a hand dynamometer, and vary their grip force to match an unpredictably-changing target force for 3 minutes. Target force was scaled to their age and sex-based maximum grip force [3]. Previous work demonstrated a model of participants' feedback response (Eq. 1) – how participants changed their grip force in response to errors in force and force velocity – could classify mTBI with a sensitivity of 87% and a specificity of 93% [2].

$$\dot{x}_{(t)} - \dot{x}_{T(t-\tau)} = -K_p(x_{(t-\tau)} - x_{T(t-\tau)}) - K_d(\dot{x}_{(t-\tau)} - \dot{x}_{T(t-\tau)}) \quad \text{Eq. 1}$$

In Eq. 1,  $x$  equals a participant's grip force (given by the position of the vertical bar in Fig. 1).  $x_T$  represents the target grip force (given by the position of the horizontal bar in Fig. 1).  $\tau$  captures

sensorimotor processing delays, and is quantified as the time difference which minimizes the root-mean-square (RMS) error between a participant's grip force and the target grip force.  $K_p$  and  $K_d$  act as a gain on errors in force and force velocity respectively, similar to stiffness and viscosity in a mechanical system, quantifying how each participant responded to error at time  $t$  to update grip force at time  $t + \tau$ .

### Participant recruitment and study design

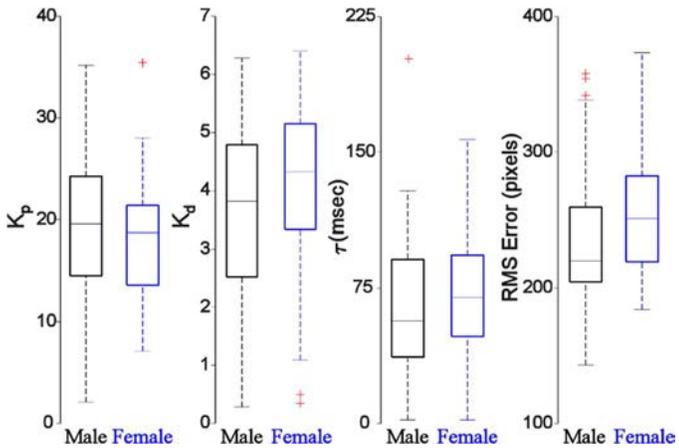

A total of 125 participants were recruited from the attendees of the 2016 American Society of Biomechanics Meeting (70M 30.2±8.9 years; 55F; 27.3±6.3 years). The study was approved by the MITRE IRB and the ASB executive committee. Demographic information, including history of head injury, were recorded. Participants completed the VMT task followed by standard assessments of cognitive and motor function: Trail Making Test A (TMA) to assess spatial processing [3]; nine-hole peg (NHP) test [4] to assess fine motor performance; and a mouse-click reaction time (RT) test to assess simple RT [5]. VMT data was collected at 240Hz and filtered using a 2<sup>nd</sup> order Butterworth filter with a 2Hz cutoff. Time to completion was measured for both TMA and NHP tests. RT was quantified as the average across 50 trials. VMT parameters  $K_p$ ,  $K_d$ , and  $\tau$  were calculated for each participant (Eq. 1). Three statistical models were constructed to determine if variability in each clinical measure (TMA, NHP, and RT) could be explained by the independent variables  $K_p$ ,  $K_d$ , and  $\tau$ ; sex was also included as an independent variable. Student's t-tests were used to determine if human factors affect performance.

## RESULTS AND DISCUSSION

### Visuomotor tracking performance

Normative VMT performance is shown in Fig. 2. RMS error is represented in pixels to account for differences in the ratio of pixels to lbs for each participant, due to age and sex differences in maximum grip force. The variability in healthy performance is likely indicative that a baseline assessment would be beneficial when evaluating an individual for mTBI. Females had significantly higher  $K_d$  ( $p=0.046$ ) and RMS error ( $p=0.010$ ).  $K_p$

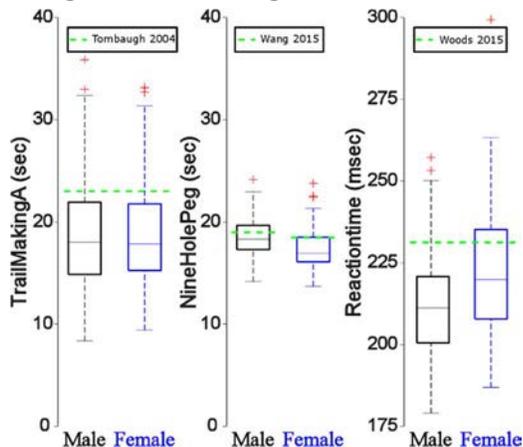

( $p=0.090$ ) and  $\tau$  ( $p=0.055$ ) were not significantly different. The results suggest that men and women respond differently to the VMT task and adding sex to the mTBI classifier [2], should be considered.

**Fig 2:** Box and whisker plots of the VMT parameters

### Clinical assessments

Regarding the conventional clinical assessments, in general, our population was faster, had smaller inter-subject variability, and reduced overall range relative to the previously reported age- and population-based norms (Fig. 3) [4,5,6]. Females were significantly faster than males at completing the NHP test ( $p<0.001$ ) but had slower RT ( $p<0.001$ ). Since RT has been used to evaluate mTBI, our data supports considering sex when using these tools.

**Fig 3:** Box and whisker plots of the clinical parameters with previous measured norms in green

### Statistical models

Although all statistical models were significant, the VMT parameters only captured a small portion of the variability in spatial processing, fine motor performance, and reaction time: TMA (adjusted  $r^2 = 0.121$ ;  $p<0.001$ ); NHP (adjusted  $r^2 = 0.073$ ;  $p=0.011$ ); RT (adjusted  $r^2 = 0.281$ ;  $p<0.001$ ). This

implies that VMT parameters are capturing more of the variability in participants' reaction time than the variability in participants' spatial processing or fine motor control abilities, quantified by these assessments. In addition, the weak correlation between VMT parameters and performance on the NHP test suggests that fine motor performance in prehensile tasks is significantly distinct from fine motor grasp modulation.

### Effect of history of head injury

Other factors may also affect VMT performance. Individuals with a self-reported history of head injury ( $N=36$ ) performed significantly slower on the NHP test compared to individuals without a history of head injury ( $N=88$ ,  $p=0.023$ ). A self-reported loss of consciousness (LOC) ( $N=9$ ) in the last injury further increased population differences. Participants with LOC were slower on the NHP test ( $p=0.016$ ), and trended higher on  $K_d$  ( $p = 0.051$ ), [2], than those without a self-reported history of head injury. Higher  $K_d$  has previously been shown to indicate more mTBI like VMT performance [2].

## CONCLUSIONS

This study revealed substantial variability in normative VMT performance, suggesting a baseline assessment and the inclusion of sex would improve mTBI classification. VMT parameters marginally explained variation in the clinical assessment signifying the VMT model may not be capturing the cognitive and motor processes explored within this study. Our finding that previous head injuries alters task performance suggests that medical history may also need to be considered by a mTBI classifier. Future studies should explore a larger age-range and consider other human factors that could potentially affect mTBI diagnosis and monitoring with VMT such as age and education.

## INTRODUCTION

Bipedal walking requires the active control of lateral stability [1]. Neurologically uninjured humans accomplish this goal largely through step-by-step adjustments in step width. Briefly, step width is actively controlled based on the mechanical state of the pelvis or center of mass [2-3].

The apparent ease of ensuring lateral stability in healthy controls does not extend to many clinical populations, as lateral losses of balance are often a challenge to mobility. For example, the typical stabilization strategy of actively modulating foot placement is disrupted in a subpopulation of chronic stroke survivors classified as at an increased risk for falls [4]. Unfortunately, no rehabilitation methods currently exist to retrain appropriate step-by-step adjustments in mediolateral foot placement.

In the long term, our goal is to develop a device able to retrain the typical stabilization strategy using either assistive or perturbing methods. The purpose of the present study was to test whether our elastic force-field [5] can influence this strategy in healthy controls. We hypothesized that assistive methods would strengthen the relationship between pelvis mechanics and step width, but only while the force-field was active. We also hypothesized that perturbing methods would produce after-effects in which step width was more tightly controlled.

## METHODS

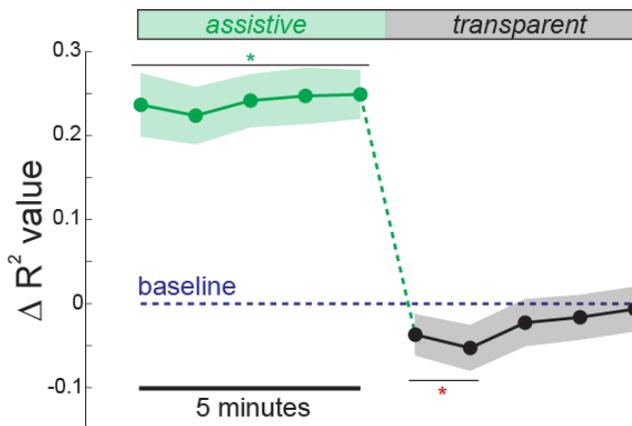

This work involved a custom-built elastic force-field [5]. This novel device can exert controllable mediolateral forces on the swing leg during walking, without interfering with forward progression. The device is interfaced with a motion capture system,

allowing near real-time control based on participant kinematics (measured using active LED markers). Based on prior studies of sensorimotor adaptation using split-belt walking [6] or other force-fields [7], several control modes were applied:

- 1) *Transparent*. The force-field remained aligned with the leg, minimizing mediolateral forces.
- 2) *Assistive*. At the start of each step, we predicted the upcoming step width based on pelvis mechanics. The force-field pushed the swing leg toward this location.
- 3) *Perturbing*. We predicted step width at the start of each step, but the force-field pushed the swing leg away from this location (e.g. encouraging a narrow step when a wide step was predicted).

24 healthy controls (16F/8 M; age=24±2 yrs; height=172±11 cm; mass=74±13 kg) participated in this experiment, and were randomly assigned to *assistive* or *perturbing* groups (n=12). Participants performed seven random-order treadmill walking trials at 1.2 m/s: no force-field (5-min); *transparent* (5-min); five 10-minute trials in which the force-field switched from *assistive/perturbing* to *transparent* mode at the 5-minute mark. These five trials differed only in the pelvis mechanics parameters used to predict the upcoming step width. As no significant differences were observed between these trials, they were combined for the purpose of the present analyses.

Our primary analysis focused on the strength of the relationship between pelvis mechanics at the start of a step and subsequent step width. To quantify this relationship, we performed multiple regressions to predict step width from mediolateral pelvis velocity and displacement from the stance foot (for each minute of walking). Higher R<sup>2</sup> values would indicate a stronger relationship. We used ANOVAs to detect significant changes in R<sup>2</sup> magnitude from baseline.

**Figure 1:** Effects of *assistive*-mode force-field on mechanics-dependent control of step width. Shaded regions indicate 95% confidence intervals, and asterisks indicate a significant ( $p < 0.05$ ) post-hoc differences from baseline.

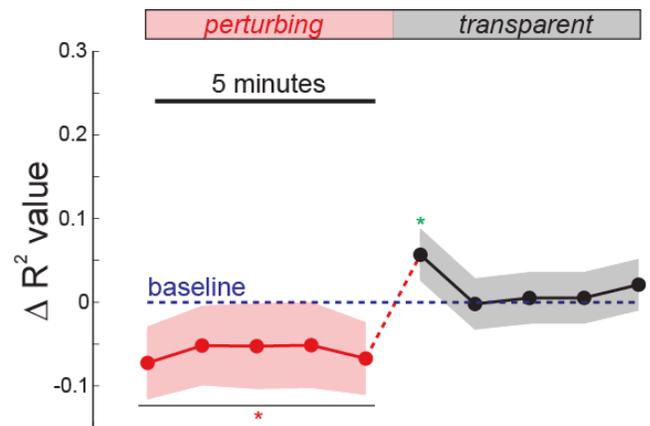

## RESULTS AND DISCUSSION

Our metric of gait stabilization strategy ( $R^2$  value) was nearly identical between normal ( $0.50 \pm 0.09$ ) and *transparent* ( $0.49 \pm 0.08$ ) walking conditions ( $p = 0.40$ ). This result indicates that our force-field does not interfere with the step-by-step control of step width when in *transparent* mode.

With the force-field in *assistive* mode, the relationship between pelvis mechanics and step width was clearly strengthened (Fig. 1). However, the switch to transparent mode caused short-lived after-effects, as the  $R^2$  magnitude was significantly reduced for the next 2-minutes of walking.

With the force-field in *perturbing* mode, the relationship between pelvis mechanics and step width was slightly weakened (Fig. 2). The switch to transparent mode elicited tighter control over step width (evidenced by an increased  $R^2$ ) for the next minute of walking.

The present results demonstrate that our force-field can influence the step width control strategy used by uninjured adults. *Assistive* methods appear to promote “slacking” [8], transiently reducing active control over the assisted gait behavior. In contrast, *perturbing* methods appear to produce beneficial after-effects, likely due to sustained use of the greater active control required to prevent a loss of balance.

**Figure 2:** Effects of *perturbing*-mode force-field on mechanics-dependent control of step width.

Future work will investigate whether similar methods can be used to retrain the typical lateral stabilization strategy in chronic stroke survivors. The relative effectiveness of our control methods may be influenced by participants’ baseline functional level, with more limited individuals benefiting more from *assistance* [7]. As with split-belt walking, multiple exposures may be needed to affect gait behavior [6].

## CONCLUSIONS

Our novel elastic force-field can influence the lateral stabilization strategy during gait. The device may have potential to serve as a rehabilitation tool for patients with reduced mobility due to gait instability.

# Muscle Synergy Extraction from EMG (Electro Myogram) data: A comparison of algorithms (PCA, NMF, pICA)

<sup>1</sup> Rajat Emanuel Singh, <sup>2</sup> Kamran Iqbal, <sup>2</sup> Ghulam Rasool, <sup>2</sup> Gannon White <sup>3</sup> Shelby Wingate <sup>3</sup> Hazel Hutchinson  
<sup>1</sup> University of Arkansas at Little Rock, Ar, USA.  
email: resingh@ualr.edu, kxiqbal@ualr.edu

## INTRODUCTION

Muscle Synergies is defined as the pattern of co activation of muscles recruited by a single neural command [1]. The concept of Muscle Synergy has been effectively utilized in myoelectric control for prosthesis [2]. The mathematical model of muscle synergies is in two forms a) time variant b) time invariant [3].

The Synergies are extracted in the form of matrix from the (Electro Myogram) EMG data using different blind source separation algorithm. The Matrix extracted can reconstruct the EMG signal by linearly recombining several time invariant synergies, each activated by a time dependent activation coefficient [1]. It has been hypothesized, if the reconstructed muscle activation pattern for specific task is produced with an artificial limb it is more likely to produce similar biomechanical movement for the specific subtask since muscle synergies represent motor modules recruited by the nervous systems [5], which will allow an amputee with prosthetic limbs to make task specific movements. In this study, we will compare different algorithmic approach to extract muscle synergies for myoelectric prosthesis.

## METHODS

For Muscle Synergy extraction, raw EMG data from Rasool *et al* is used. The data were collected from 12 participants with height  $171.4 \pm 8.8$  cm and age  $28.2 \pm 6.5$  years (mean  $\pm$  std. dev) from wrist muscles. Preprocessing on raw EMG data included removal of the transient part of EMG signal with a ctp (contraction time percentage) of 50%-70% followed by segmentation of the signal into non-overlapping 250ms windows [2]. It has been shown that 200-300ms windows are optimal to retain maximum information, and taking greater than

300ms windows segmentation decreases the amount of information. Root mean square (RMS) values of the EMG signal were obtained and the data were separated into n bins based on the number of stimulus (movement tasks) [2]. After preprocessing, extraction of Muscle Synergies with different blind source separation (BSS) algorithms was performed. A muscle activation pattern is mathematically deduced in the following form represented below, where  $C$  represents activation coefficient, n represent number of muscles, m represent length of activation pattern and  $W$  represent Synergy matrix.

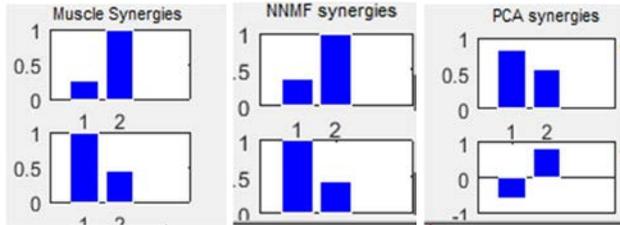

$$M^{n \times m} = W^{n \times s} \times C^{s \times m}$$

$$M = \begin{bmatrix} M_1(t) \\ \vdots \\ M_m(t) \end{bmatrix}, \quad W = \begin{bmatrix} W_{11} & \dots & W_{s1} \\ \vdots & \ddots & \vdots \\ W_{1m} & \dots & W_{sm} \end{bmatrix},$$
$$C = \begin{bmatrix} C_1(t) \\ \vdots \\ C_s(t) \end{bmatrix},$$

MATLAB 2014a is used for extraction of muscle synergies. The separation scheme involves extracting a synergy matrix  $W$  from the EMG data, on running PCA on the processed data, there was a reduction in the dimensionality of output matrix. Similarly, with NMF the dimensional reduction can be achieved. We used MATLAB toolbox for Principle Component Analysis (PCA), Probabilistic Independent Component Analysis (pICA), Non-Negative Matrix Factorization Algorithm (NNMF/NMF). updating the code to run our data model. The EMG data matrix is  $n \times m$  where  $n$  is the number of sensors and  $m$  is the samples. The output Synergy Matrix ( $W$ ) has a reduced dimension for NMF and PCA ie. ( $n \times d$ ) where  $d$  is the number of components selected, i.e., the number of synergies (we selected only 2 synergies). But for pICA, the output Synergy Matrix ( $W$  matrix) is in the form  $d \times m$ , so a PCA algorithm on the MATLAB code is

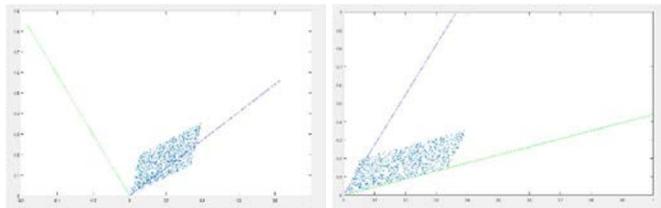

run first, followed by pICA which changes the dimensionality to the form of  $n \times d$ . In order to find the performance of each algorithm a simulated data set is used. A MATLAB code for NNMF, PCA and pICA is run. The following results are produced that has been discussed below.

## RESULTS AND DISCUSSIONS

**Fig 2:** Reconstructed Synergies compared with actual Synergies using NNMF and PCA.

The reconstruction of the muscle synergies with NNMF approach is done on MATLAB on the simulated data set, which showed that NNMF was more precise as compared to PCA. On the other hand, the pICA performs better than the NNMF [2]. The result also provides us the understanding of the orthogonality of both PCA and NNMF. In particular, the result shows that the PCA is orthogonal where as NNMF is not.

**Fig 3:** Vectors of the PCA (Left) and NMF (Right) for the reconstructed muscle Synergies.

## CONCLUSIONS

The extraction of Muscle Synergy is very important in myoelectric prosthesis. The solutions we obtain from extraction of muscle Synergy are not unique because of the non-convexity. From the above results and discussion, it can be assumed that the performance of pICA for the extraction of muscle Synergy is highest among the three algorithms followed by NNMF and PCA. For the agonistic and antagonistic relationship in the simulated data set PCA shows the relationship but does not allow proper reconstruction [3]. Researching further for the

proper reconstruction of agonistic-antagonistic relationship between muscles autoencoder algorithm has been evaluated which gave better result when compared to other algorithms [4]. There is an another alternate to NNMF which is FA (Factor Analysis). The FA algorithms performs better than the NNMF but not superior to pICA [4].

# CENTER OF MASS CONTROL AND MULTI-SEGMENT COORDINATION IN CHILDREN DURING AND AFTER WHOLE BODY VIBRATION

Huaqing Liang and Jianhua Wu

Georgia State University, Atlanta, Georgia, USA. Email: hliang2@gsu.edu

## INTRODUCTION

Maintaining upright posture under external perturbations requires the coordination between the nervous system and the musculoskeletal system, and it is a milestone of motor development in early childhood [1]. Whole-body vibration (WBV) has acute effect on postural control and muscular activation during standing, resulting in an increased sway velocity and sway area of center-of-mass (COM), and the residual effect usually vanish within 20 minutes after the vibration exposure [2]. In quiet standing, a human body can be considered as a multi-segment linked system, and the uncontrolled manifold (UCM) approach has been used to examine how this multi-joint motor redundancy is utilized to achieve postural control of the body [3]. The aim of study was to compare the joint variance partitioning pattern between children and adults while controlling the COM before, during, and after WBV disturbance.

## METHODS

*Subjects:* Fifteen children (6M/9F) and fourteen young adults (6M/8F) participated in the study. Mean (SD) age of the children (TD group) was 8.1 (1.8) years, height 1.32 (0.10) m, and mass 30.2 (6.7) kg. Mean (SD) age of the adults (YA group) was 24.5 (3.9) years, height 1.68 (0.12) m, and mass 70.6 (13.4) kg.

*Experimental design:* An 8-camera Vicon motion capture system and the Vicon full-body PSIS model were used for data collection. A Soloflex platform was used to provide WBV with the frequency of 28 Hz and the amplitude of <1mm, resulting in a vertical acceleration of 0.5g ( $g=9.81\text{m/s}^2$ ). Subjects were asked to stand upright with feet hip width apart 4 times: before vibration (phase *Pre*), during vibration (phase *Vib*), immediately after vibration (phase *Post\_0*), and 5 minutes after vibration (phase

*Post\_5*). Each standing trial lasted for 40 seconds. There were also 2 visual conditions: eyes open (EO) and eyes closed (EC). The order of the conditions was randomized and at least 5 minutes of rest was provided between conditions.

*Data analysis:* The COM data was obtained based on the position of all the markers. The root-mean-square (RMS) of COM in the anterior-posterior (AP) direction was calculated and normalized by each subject's height. Markers on the right side of the body were used for the UCM approach and a geometric model was built that associated the COM movement with the following 8 segment angles: foot, shank, thigh, pelvis, trunk, head, upper-arm, and forearm [1]. The movement on the sagittal plane was examined and all the angles were defined as the segmental angle with respect to the horizontal. The variability of the segment angles can be partitioned into two subspaces: the UCM subspace within which the variability helps maintain the mean COM position, and the orthogonal (ORT) subspace within which the variability causes the deviation of the COM [3, 4]. For a coordinated postural control, the variability in the UCM subspace is larger than that in the ORT subspace [1, 3]. Customized MATLAB program was used to calculate the variance in the UCM ( $V_{UCM}$ ) and ORT subspace ( $V_{ORT}$ ) separately. The UCM ratio was further defined as:

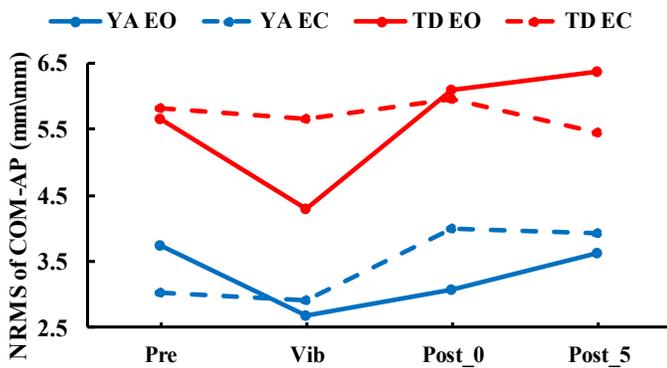

$$UCM\ ratio = \ln(V_{UCM} / V_{ORT})$$

*Statistical analysis:* A 4-way (2 group x 2 visual x 4 phase x 2 component) ANOVA with repeated measures were conducted on variance in the two subspaces. A series of 3-way (2 group x 2 visual x 4 phase) ANOVA with repeated measures were conducted on RMS of COM-AP and UCM ratio. Post-hoc pairwise comparisons with Bonferroni adjustments were conducted when appropriate. Statistical significance was set at  $\alpha = 0.05$ .

## RESULTS AND DISCUSSION

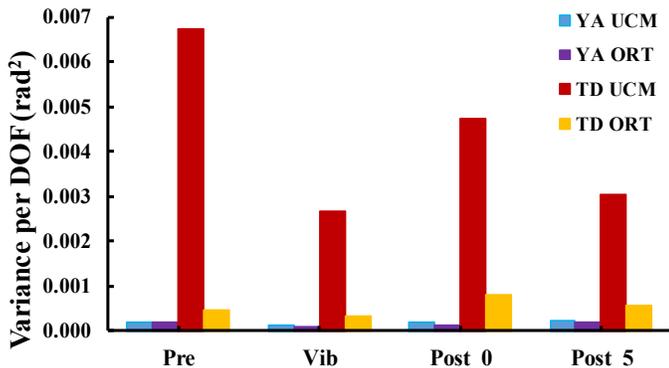

The TD group showed a larger RMS of COM-AP than the YA group. Both groups also displayed a decrease of RMS from *Pre* to *Vib* phase, but increased to *Pre*-level immediately after vibration (Fig. 1). There was a group effect ( $p<0.001$ ) and a phase effect ( $p=0.014$ ). When there was vibration disturbance, both groups constrained their COM sway within a narrower range to adapt to the mechanical vibration, which was more prominent in the TD group.

**Fig. 1** Normalized RMS of COM-AP

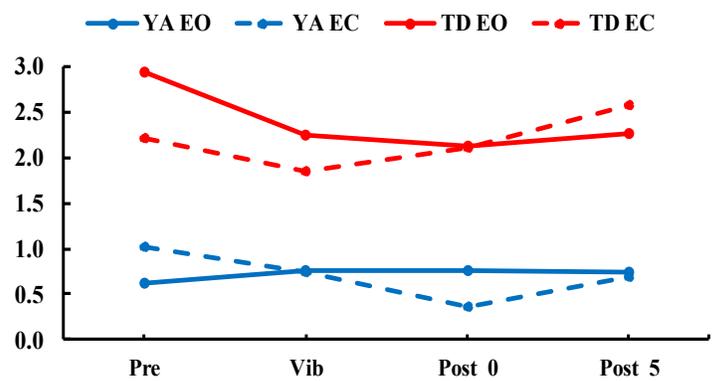

The TD group displayed a larger variance than YA group in both UCM and ORT subspaces. For both groups, a larger variance was generated in the UCM compared to the ORT subspace (Fig. 2). There was a group by component interaction ( $p<0.001$ ). Post-hoc analysis revealed that the difference in variance between two subspaces was greater in the TD group than in the YA group. No visual or phase effect was found for either group.

**Fig. 2** Eyes Open

The TD group exhibited a larger UCM ratio than the YA group across all phases at both visual conditions (group effect,  $p<0.001$ ) (Fig. 3). Both groups displayed a UCM ratio greater than zero, suggesting that more variance was partitioned into the UCM subspace to assist the control of COM for the standing task before, during, and after WBV. The greater UCM ratios observed in the TD group were majorly resulted from the larger difference in variance between two subspaces compared to the YA group. No phase effect was found for both groups, suggesting that even though total variance decreased and increased at different phases, the structure of variance partition remained the same for YA and TD.

**Fig. 3** UCM Ratio

## CONCLUSIONS

Both groups displayed a decrease in overall COM-AP sway variance during WBV, but returned to baseline level immediately after the cessation of vibration. In terms of the structure of variance partition, both groups distributed more variability in the UCM than ORT subspace across all phases although the TD group had a greater variance. This suggests that the TD group may have developed a postural control strategy similar to that observed in YA to regulate variance partition.

## INTRODUCTION

One of the interesting problems in motor control is the redundancy of motor action across a single joint. This allows for an array of complex motions with many possible solutions. While this topic has been well studied with respect to biomechanical solutions the relationship of muscle activity to central processing is not yet understood. With the rise of high-yield decomposition it has now become possible to analyze motor activity not as just a simple gain but as a summation of neural inputs.

The purpose of this study was to determine motor unit (MU) characteristics within agonist muscles to determine recruitment differences during contraction. In addition this study aimed to determine specific relationships between MU behavior that would provide a better understanding of the redundancies of the neuromuscular system.

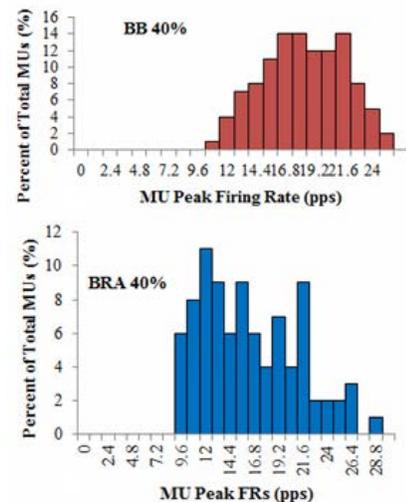

## METHODS

Eleven subjects (5 male, 6 female, 22-31yrs) participated in an isometric elbow flexion force tracking task, during which surface electromyography (EMG) was collected on the right biceps brachii (BB) and right brachioradialis (BRA). Their arms were restrained horizontally at 90 degrees elbow flexion. A force matching task was performed for three low force levels: 20, 30, and 40 percent of their maximal trials (MVIC).

The surface EMG was decomposed using specialized software (Delsys Inc., Boston MA) into individual MU spike trains [1]. Recruitment and rate coding characteristics were extracted from these spike trains and compared across force levels. Only spike trains whose accuracy was reported as 90% by the software was used for analysis.

## RESULTS AND DISCUSSION

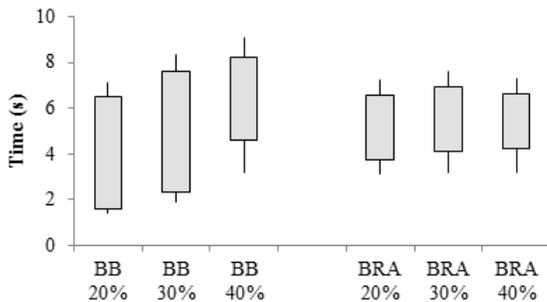

Recruitment and rate coding were defined by specific parameters obtained from the force trace in combination with the decomposed MU trains. Recruitment was defined by recruitment threshold (force level at recruitment, %MVC), the initial firing rate (firing rate at recruitment), and recruitment time. Rate coding was defined by the average peak firing rate (defined hereafter as 'peak firing rate').

**Figure 1:** Sample MU distributions for a subject at 40% MVC.

All subjects showed an expected increase in BB MU peak firing rate with a corresponding increase in force contraction ( $p < 0.05$ ). This trend was not seen in the BRA peak firing rates. In addition BB and BRA peak firing rate distributions were quite different as well (Fig 1). The BB distribution followed a more standard 'bell shaped', while the BRA distribution is better described as a 'lop sided hill'. This was mostly consistent across all subjects and the distribution for both muscles did not significantly change shape across force levels.

To get a broader perspective of the firing rate behavior of the pool related to recruitment we compared the initial firing rate and peak firing rate for each MU. For both BB and BRA there was an expected increase in firing rate with the increase in initial firing rate. Linear fits were calculated for each force level. Earlier recruited MUs with higher peak firing rates had greater initial firing rates [2,3]. An increase in force was accompanied by an increase in the slope of the linear fit for both muscles. This was expected with the BB due to its increased peak firing rates with an increase in force, but was unexpected in the BRA. Even more confounding was that the linear fits for the BB were much worse than for the BRA ( $R^2_{BB}=.213$ ,  $R^2_{BRA}=.633$ ). This indicates that the BRA MUs have more regulated rate coding than those of the BB.

**Figure 2:** MU Firing Times for a single subject. Bottom of the box represents recruitment time, top represents when MU reached peak firing rate.

BB and BRA data for all subjects also showed a difference in motor unit recruitment timings. For all force levels BB MUs were recruited earlier than BRA MUs (Fig 2). In addition it seems as though the time from recruitment to peak firing rate corresponded with the relationship between peak firing rate and force for the BB. BRA MUs, which had no relative change in peak firing rate across force levels, reached their peak at about the same time. Both of these concepts are observed in Figure 2. Because each force contraction was performed at a consistent rate (10% MVC/sec) this may suggest a relationship between rate coding and force rate.

The recruitment threshold distribution mean was positively correlated with force contraction level for both BB and BRA ( $p<0.05$ ,  $p<0.05$ ). This is not unexpected; it is assumed that at lower force levels

not all MUs have been recruited, and muscles will recruit MUs gradually with force until a specific force level [3,4]. Coupling MU's recruitment thresholds with their corresponding initial firing rates should be a more accurate representation of recruitment assuming the muscle is fairly homogenous in firing behavior. A negative relationship exists between initial firing rate and the recruitment threshold within subjects across all force levels and both muscles ( $R^2_{BB}=.35$ ,  $R^2_{BRA}=.41$ : average fits for all subjects). This being said, there was no global relationship across all subjects in recruitment threshold mean, linear fit slope or intercept.

All data presented here define two very different control schemes for both the BB and BRA. One possible explanation is that the BB acts as a force producer while the BRA acts as a force regulator. Precise control is not required if the goal is to produce force, and is represented by the early recruitment times and less organized methods of rate coding seen in the BB. Meanwhile the BRA has much more organized rate coding and does not change its firing rate behavior with respect to force, implying that the force is not its goal.

This recruitment data indicates that each subject has their own specific MU force-firing rate characteristics, most likely represented in physiological differences between subject's muscles. All previous firing rate relationships and data have been true across and hold their significance throughout the population. This may mean that recruitment is a function of subject-specific muscle parameters while rate coding is a function of a common neural drive across the population.

## INTRODUCTION

Trunk motor control has been studied using a traditional hemisphere-balance seat [1]. However, such a task has no deterministic input signal to the subject. To improve upon methods of assessing trunk motor control, we recently developed a novel seated balance task (**Figure 1**) that applies known torque perturbations (input) to the subject's pelvis while balancing on a robotic-controlled seat. While this setup improves the signal-to-noise ratio compared to the traditional setup, experimental measurements must be deemed reliable before future implementation. Therefore, this study investigated the reliability of the nonparametric descriptors of the seated balance task depicted in **Figure 1**.

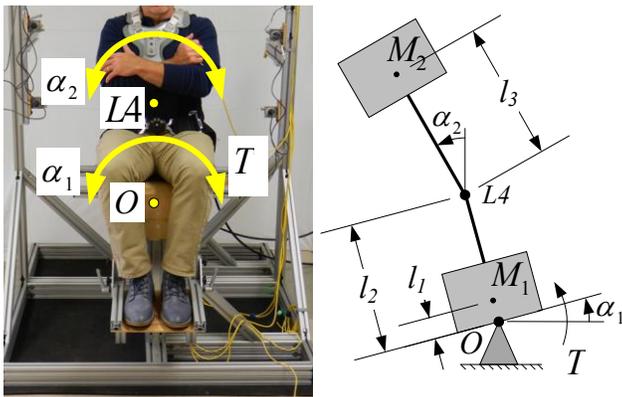

balance task in three visits separated by at least 23 hours. Each visit included three testing conditions: eyes open (EO), eyes closed (EC), and eyes closed with vibration to the lumbar region (VIB). Each testing condition consisted of four practice trials (30s each) and three full trials (30s each).

**Table 1:** Subjects' demographic characteristics.

	Females (n=19)	Males (n=11)
<b>Height (m)</b>	1.63±0.05	1.78±0.07
<b>Weight (kg)</b>	70.6±12.8	86.1±11.5
<b>Age (years)</b>	34.7±12.0	30.7±12.3

The data collected was the input perturbation torque ( $T$ ), and the output lower and upper body angles ( $\alpha_1, \alpha_2$ ).  $T$  was a pseudorandom ternary sequence generated from a motor.  $\alpha_1$  was recorded by an encoder in the motor, while  $\alpha_2$  was recorded using string potentiometers. The motor also provided stiffness and damping response according to the measurement of  $\alpha_1$ . Both the amplitude of  $T$  and the seat stiffness were calibrated for each subject before the trials to make the level of task difficulty similar between subjects.

To assess trunk motor control accuracy in the time and frequency domains, root mean square error (RMSE) and mean bandpass error energy ( $E_{mb}$ ) [2] were computed. The frequency passband region (for  $E_{mb}$ ) was 0.1-1.6 Hz. The subjects were assumed to minimize the error  $e = w_1\alpha_1 + w_2\alpha_2$ , where  $w_1$  and  $w_2$  are scalar weights. The weights were estimated from the static equilibrium, of the system shown in **Figure 1**, given by  $M_1l_1\sin(\alpha_1) + M_2[l_2\sin(\alpha_1) + l_3\sin(\alpha_2)] + T = 0$ . By approximation, we have  $\text{mean}(T) \cong 0$  and  $\sin(\alpha) \cong \alpha$ . Therefore,  $[M_1l_1 + M_2l_2]\alpha_1 + [M_2l_3]\alpha_2 \cong 0$ . The error was then estimated to be  $e = 0.89\alpha_1 + 0.45\alpha_2$ .

**Figure 1:** The novel seated balance task utilizes a perturbation torque ( $T$ ). The physical model has two degrees of freedom ( $\alpha_1, \alpha_2$ ).

## METHODS

30 healthy subjects (**Table 1**) participated in the study. They had no history of back pain lasting more than three days or a neurological condition affecting motor control. The subjects performed the seated

Intra-class correlation coefficients ICC(3,k) along with 95% confidence intervals (CI) were computed for both RMSE and  $E_{mb}$  to assess between-day reliability. Coefficient of multiple correlations (CMC) of  $E_{mb}$  were calculated to assess both within-day and between-day reliability. The CMCs were computed from the empirical transfer function estimate (ETF) [3] of a single trial., The ETFs were computed from  $T$  to  $\alpha_1$  and from  $T$  to  $\alpha_2$ , and so were the CMCs.

## RESULTS AND DISCUSSION

The between-day ICCs, listed in **Table 2**, show excellent reliability ( $ICC \geq 0.94$ ) and narrow confidence intervals. The CMCs are listed in **Table 3**. Both within-day and between-day reliability are excellent with  $CMC \geq 0.93$  and  $CMC \geq 0.89$ , respectively.

**Table 2:** Between-day reliability as ICC(3,k) and 95% CI.

Task	ICC of RMSE	ICC of $E_{mb}$
EO	0.95 (CI 0.92-0.98)	0.95 (CI 0.91-0.97)
EC	0.96 (CI 0.92-0.98)	0.95 (CI 0.91-0.98)
VIB	0.95 (CI 0.91-0.98)	0.94 (CI 0.90-0.97)

The results agree with the excellent reliability reported in previous studies [1], [4] of unstable seated balance. In [1], RMS of the distance travelled by the center of pressure was used, and reliability was assessed using correlation coefficient ( $R=0.90$ ). In [4], RMS of the seat angle (the error) was used to assess reliability in the form of dependability coefficient ( $\phi=0.77$ ).

On the other hand, another study [5] reported poor to fair ICCs (0.29–0.56). It might be due to (1) low signal-to-noise ratio since there is no deterministic perturbation signal, or (2) the coupled dynamics of

the anterior-posterior and the lateral directions in [5]. In our experiment, the perturbations were applied solely in the lateral direction. Moreover, it was reported that the ICCs increased with the task difficulty level [5]. So, the differences in the results might be due to the different task difficulty.

The limitations of the reported results are as follows. The ETFE uses averaging which improves the precision (less variance), but increases the bias (more deviation from the true mean). The  $E_{mb}$  calculation used the same averaging technique in frequency-domain.

## CONCLUSIONS

The novel seated balance task (**Figure 1**) is reliable and the resulting measurements are reproducible. Therefore, it can be used to assess trunk motor control.

# MUSCULAR FATIGUE INFLUENCES MOTOR SYNERGIES DURING PUSH-UPS

Elizabeth M. Bell, Kyung Koh, Ross H. Miller and Jae Kun Shim

University of Maryland, College Park, MD, USA

email: lizbell@terpmail.umd.edu, web: <https://sph.umd.edu/neuromechanics>

## INTRODUCTION

The conventional push-up is a popular exercise used by the American College of Sports Medicine to test muscular endurance [1] and is required in the Army Physical Fitness Test [2]. The push-up is an effective way to improve muscle performance of the shoulder, arm and trunk<sup>3</sup>, is a popular, easy-to-learn exercise that normally requires no equipment [3]. Despite the popularity and importance of push-ups in exercise programs and return-to-duty military requirements, motor control mechanisms of this motion are relatively unknown. Push-ups require changes in the ground reaction forces generated at each point of contact with the ground (all four extremities) which are achieved through muscular contractions.

Research focusing on uninjured push-up performance exists [3] but it is unknown how muscular fatigue influences synergistic actions between the forces produced by hands and feet. It is important to look at the synergistic mechanisms used by the whole body to produce movements of the center of mass.

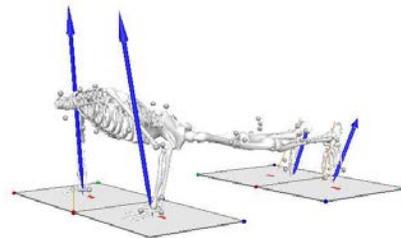

This work aims to investigate the neuromechanical adaptations that occur, and to determine if performing push-ups to volitional fatigue induces common synergistic changes between extremities.

## METHODS

Volunteers participated in a single motion capture data collection after completing informed consent procedures approved by the local Institutional Review Board. Each participant was instructed on how to complete conventional push-ups<sup>3</sup> with their hands shoulder width apart (Fig. 1). Participants were instructed on how to arrange themselves in a plank position with each extremity within the bounds of an embedded force platform (Kistler Instrument Corp., NY, USA). Audio feedback via metronome

(50bpm) and pre-trial instructions were provided to participants in order to establish the controlled, three-beat tempo of 24 push-ups per minute. On the first beat participants started downward movement, on the second they pushed upward and on the third they held a plank position.

Analog data was collected from four force plates at a rate of 1000Hz as participants completed one trial where they performed as many push-ups as possible, stopping at self-determined failure.

**Figure 1:** 3D representation of participant orientation on force plates.

The start of each push-up cycle was defined as the point at which the whole-body center of mass began to move downward from the plank position and the cycle ended when the center of mass returned to the start position. The push-up cycle was broken into the following phases: downward motion (DOWN) upward motion (UP) and plank (PLANK). Phase determinations were based on movement of the center of mass. Force signals were processed using a Butterworth low-pass filter with a cut off frequency of 50Hz.

An index of synergy ( $SYN_i$ ) was calculated for every DOWN, UP, and PLANK motion for each push-up repetition within a trial:

$$SYN_i = \frac{\sum_{j \neq i}^n \text{corr}(vGRF_i, vGRF_j)}{n} [1]$$

where  $i = \{\text{left hand, right hand, left foot, right foot}\}$  and  $vGRF_i$  is the vertical ground reaction force normalized to bodyweight (BW) at  $i^{th}$  limb and  $n=3$ , or the number of limbs not equal to  $i$ .

Since participants completed a different number of push-ups within the trial,  $SYN_i$  from all repetitions for all 14 participants were plotted with respect to the % of trial completion. A Pearson correlation test with significance at  $p \leq 0.05$  (MatLab 2016A, Natick, MA, USA) was used to determine if the slope of the line of best fit ( $\Delta SYN_i / \Delta \% Trial$ ) was different than zero.

Data was collected from 14 participants (9F, 5M; Table 1).

**Table 1.** Participant demographics

	Mean	(SD)
Age (yr.)	22.0	(3.8)
Body mass (kg)	72.3	(13.4)
Height (m)	171.7	(9.1)
Number of pushups or repetitions completed (#)	22.7	(6.4)

## RESULTS AND DISCUSSION

The slope each line of best fit can be seen in table 2.

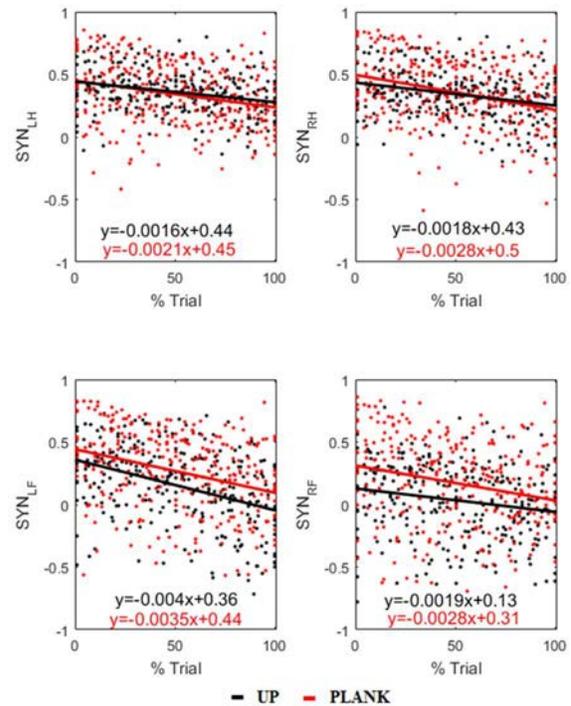

**Table 2.** Average rate of change of  $SYN_i$  normalized to trial time

	$\frac{\Delta SYN_{LH}}{\Delta \% Trial}$	$\frac{\Delta SYN_{RH}}{\Delta \% Trial}$	$\frac{\Delta SYN_{LF}}{\Delta \% Trial}$	$\frac{\Delta SYN_{RF}}{\Delta \% Trial}$
DOWN	8.1E-04	-9.3E-05	-2.4E-03	-1.4E-03
UP	-1.6E-03*	-1.8E-03*	-4.0E-03*	-1.9E-03*
PLANK	-2.1E-03*	-2.8E-03*	-3.5E-03*	-2.8E-03*

\* indicates  $\Delta SYN_i / \Delta \% Trial$  was significantly different than zero ( $*p \leq 0.05$ ). LH: left hand, RH: right hand, LF: left foot, RF: right foot.

During DOWN motion  $SYN_i$  did not significantly change (all  $p \geq 0.21$ ). In DOWN the main muscles involved in this action (triceps brachii, pectoralis major) were lengthening.

Initial measures of  $SYN_i$  during UP and PLANK phases were positive indicating that vGRF forces of all limbs were co-varied in order to increase whole body force. In other words, limbs were working together to produce increases or decreased in vGRF needed for COM movement. Significant changes in  $SYN_i$  over the trial were seen during UP (all  $*p \leq 0.01$ ) and PLANK (all  $*p \leq 0.01$ ) phases (Fig. 2).

**Figure 2.** Index of synergy ( $SYN_i$ ) measures and linear best fit for data from all participants during upward motion (UP) (black) and PLANK (red) phases of each push-up.

## CONCLUSIONS

We investigated the effect of fatigue on synergistic actions as participants performed push-ups to volitional fatigue. We found that muscular fatigue affected the synergistic actions between limbs in upward motion and plank while not in downward motion. This result indicates that after muscular fatigue the limbs were not working together to produce movement of the COM.

# TALES FROM THE UNINVOLVED LIMB: MOTOR CONTROL IN UNILATERAL ACHILLES TENDINOPATHY

Abigail L Fietzer and Kornelia Kulig

University of Southern California, Los Angeles, CA, USA  
email: fietzer@usc.edu, web: <http://pt.usc.edu/labs/mbrl/>

## INTRODUCTION

Variability is not simply noise or the failure of an imperfect human movement system; it is present even in elite athletes [1]. The magnitude of movement variability shifts with changing skill level, and a certain degree of variability is required in order to be adaptable to small changes in the task or within the performer [1-2]. Movement variability is altered in cases of pathology; some studies indicate greater variability is associated with pathology while others indicate a decrement [3-6].

Uncontrolled manifold (UCM) analysis divides variability into destabilizing ( $V_{ORT}$ ) and stabilizing ( $V_{UCM}$ ) subspaces, testing contributions of variance in elemental variables to variance in a task level variable [2]. Where  $V_{UCM} > V_{ORT}$ , the elemental variables are controlled to inter-compensate and stabilize the task level variable.

Unipedal hopping is a tightly-controlled ankle-drive task useful in modeling aspects of other ecologically relevant bouncing gaits such as running, which is an activity commonly associated with Achilles tendinopathy. While numerous studies have been conducted seeking risk factors for Achilles tendinopathy development, the motor control aspects of this pathology have been grossly ignored in the literature. The purpose of this study was to investigate potential differences in hopping control strategy between the involved and uninvolved limb in persons with unilateral Achilles tendinopathy and healthy controls.

## METHODS

Twenty-five healthy adults (age 23-55, 15 female) and nine otherwise healthy adults (age 24-60, 4 female) with unilateral Achilles tendinopathy participated. Participants with Achilles tendinopathy

had been fully participating in their recreational activity of choice symptom-free for  $\geq 1$ mo at the time of testing, and remained symptom-free during testing. Motion capture was conducted for  $\geq 25$  unipedal hops per leg, with arms constrained by holding a dowel across the shoulders. Testing was performed at 1.7Hz, which is slower than typical self-selected hopping rate (2.0-2.3Hz). Hopping at this rate remains an ankle-driven task but highlights supraspinal control [7].

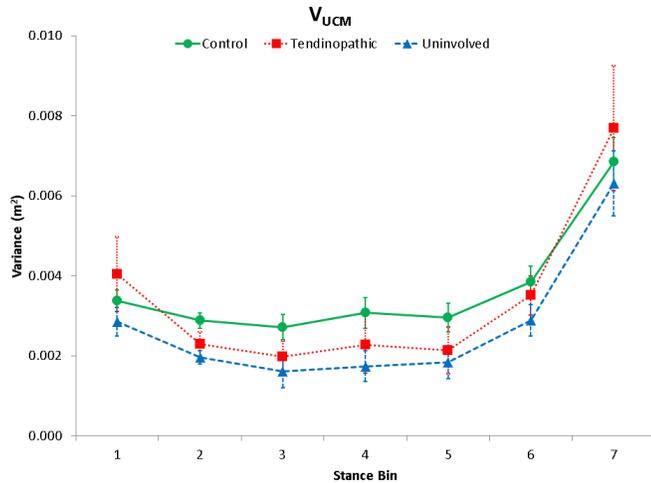

We sought to discover if differences in the control of elemental variables (individual foot, shank and thigh positions) to stabilize the task level variable of overall vertical leg length were apparent between the different limb types (tendinopathic, uninvolved and control). UCM analysis was performed for every 1% of time-normalized stance phase. Stance was divided into 7 equal bins, with bins 1-3 representing early, mid-, and late impact absorption, bin 4 the most crouched position, and bins 5-7 early, mid-, and late propulsion toward flight. Control limbs were pooled bilaterally. Due to the small sample size of tendinopathic subjects, T-tests were run between control and tendinopathic limbs at each bin, and between control and uninvolved limbs at each bin ( $\alpha=0.05$ ).

## RESULTS AND DISCUSSION

Tendinopathic limbs demonstrated a trend toward lesser  $V_{UCM}$  than control limbs during mid- ( $p=0.13$ ) and late ( $p=0.15$ ) impact absorption (Fig. 1). There was no difference between tendinopathic and control limbs in  $V_{ORT}$  throughout stance.

Uninvolved limbs demonstrated lesser or lesser-trending  $V_{UCM}$  than control limbs during mid- ( $p<0.01$ ) and late- ( $p=0.04$ ) impact absorption, the most crouched position ( $p=0.02$ ), and early- ( $p=0.06$ ) and mid- ( $p=0.11$ ) propulsion (Fig. 2).

Uninvolved limbs also demonstrated lesser or lesser-trending  $V_{ORT}$  than control limbs during early- ( $p=0.03$ ), mid- ( $p<0.01$ ) and late- ( $p=0.02$ ) impact absorption, the most crouched position ( $p=0.02$ ), and early- ( $p=0.14$ ) propulsion.

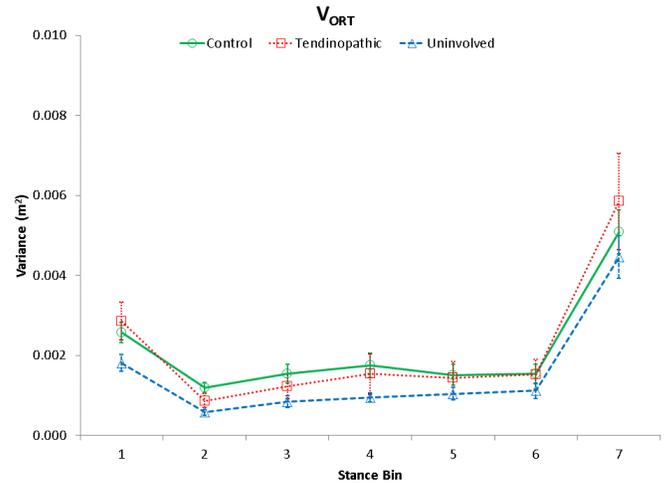

**Figure 1:** Average stabilizing variability ( $V_{UCM}$ ) for the control (green circles), tendinopathic (red squares) & uninvolved (blue triangles) limbs across 7 stance bins. Whiskers represent standard error.

Uninvolved limbs express less of both types of variability (stabilizing  $V_{UCM}$  and destabilizing  $V_{ORT}$ ), thereby likely maintaining a similar  $V_{UCM}$  to  $V_{ORT}$  ratio and thus a similar overall degree of vertical leg length stabilization during single-legged hopping as healthy controls. Tendinopathic limbs express less stabilizing ( $V_{UCM}$ ) variability, but similar levels of destabilizing ( $V_{ORT}$ ) variability as control limbs. This likely corresponds to a lesser  $V_{UCM}$  to  $V_{ORT}$  ratio and thus a decreased overall degree of vertical leg length stabilization during single-legged hopping compared to healthy controls.

## CONCLUSIONS

Results of this study indicate that both the tendinopathic and uninvolved limbs of participants with currently-asymptomatic unilateral Achilles tendinopathy demonstrate a different control

strategy than healthy controls during slow-paced single-legged hopping. Future studies to test whether these control strategies are mutable within this population are warranted with an eye toward the development of interventions directed at the prevention of Achilles tendinopathy development or progression.

**Figure 2:** Average destabilizing variability ( $V_{ORT}$ ) for the control (green circles), tendinopathic (red squares) & uninvolved (blue triangles) limbs across 7 stance bins. Whiskers represent standard error.

# GENERALIZATION OF SPLIT-BELT LOCOMOTOR ADAPTATION: MOTORIZED TREADMILL AFTEREFFECTS ARE PRESERVED AFTER WASHOUT ON A NON-MOTORIZED TREADMILL

<sup>1</sup> Daniel L. Gregory, <sup>2</sup> Frank C. Sup, <sup>1</sup> Julia T. Choi

<sup>1</sup> Department of Kinesiology and <sup>2</sup> Department of Mechanical and Industrial Engineering, University of Massachusetts Amherst, Amherst, MA, USA

email: dgregory@umass.edu, web: <http://blogs.umass.edu/jtchoi/>

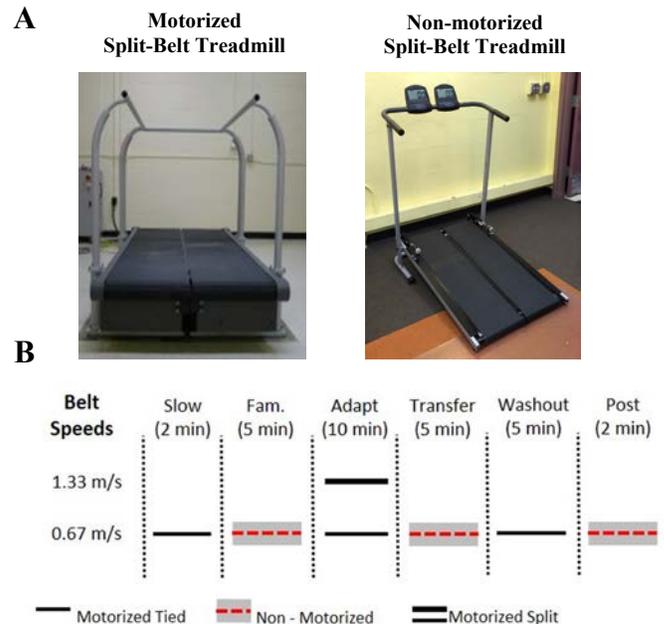

## INTRODUCTION

The locomotor system is constantly adapting to environmental changes. Once a locomotor pattern is adapted, the changes (after-effects) are stored until they are actively washed out. To what extent can a newly adapted locomotor pattern be transferred between different contexts? Here we used a motorized split-belt treadmill to independently control the speed of each leg, causing spatial and temporal perturbations that must be adapted to improve walking symmetry [1]. The specific objective of this study is to determine whether adaptations to walking symmetry on a motorized split-belt treadmill (MT) are generalizable to walking on a self-regulated non-motorized split-belt treadmill (NMT). If so, it may be possible to utilize a low-cost non-motorized split-belt treadmill for long-term training in a home-based setting to improve transfer of adaptive locomotor training to other relevant contexts (e.g. over ground walking).

## METHODS

Six subjects participated (5 female, 1 male; age  $26.6 \pm 5.5$  years). For this study, we designed and built a self-regulated non-motorized split-belt treadmill (**Fig. 1a**) that utilizes gravity ( $13^\circ$  incline) to assist subjects driving the symmetrically resisted but independently controlled belt speed. The training paradigm (**Fig. 1b**) consisted of walking in both MT and NMT conditions. To drive adaptation of inter-limb coordination, subjects walked on the MT at a 2:1 speed perturbation (0.67 and 1.33 m/s) for 10 minutes. To assess transfer and washout of after-effects, subjects walked at their preferred speed on the NMT and the slow speed (0.67 m/s) on the MT during the Transfer and Washout periods. Finally, subjects walked at preferred speed on the NMT (Post) to assess any residual after-effects.

Step-length and double support symmetry were calculated for each stride [1]. Step length and double

**Figure 1:** A) Motorized (MT) and non-motorized (NMT) split-belt treadmills. B) Study design required subjects to switch between MT and NMT conditions without stepping.

support adaptation magnitudes were calculated as the difference between early (strides 3-5) and late (final three) adaptation. Transfer and washout indexes were defined as the ratio of the magnitude of after-effects to the magnitude of split-belt learning. To determine the relationship between after-effect size and belt speed [2], mean NMT belt speed was calculated as the mean speed of the ankle marker during single-leg stance for strides 3-5 during transfer. The after-effect magnitude is the mean of after-effects during the same period. EMG data were collected at 2000 Hz (Trigno, Delsys Inc.) from bilateral medial gastrocnemius (MG) muscles. EMG data was high-pass filtered at 45 Hz (3<sup>rd</sup> order Butterworth), demeaned, rectified, and low-pass filtered at 35 Hz (3<sup>rd</sup> order). Stride time was normalized to 100% of the gait cycle. EMG amplitude was normalized to the peak averaged EMG during baseline walking. Subject 1 EMG was

not included in the analysis due to poor recording quality.

## RESULTS AND DISCUSSION

**Fig. 2a** shows that subjects adapted inter-limb coordination on the MT. During transfer, subjects showed pronounced after-effects on the NMT (transfer index: double support =  $0.87 \pm 0.65$ , step-length =  $0.9 \pm 0.7$ ), that gradually faded. Similarly, upon returning to the MT during washout, after-effects persisted (washout index: double support =  $1.32 \pm 0.68$ , step length =  $1.38 \pm 0.93$ ) and gradually washed out. There were no after-effects on the return to the NMT.

Transfer index was larger in this study relative to over-ground transfer for both double support (0.87 vs 0.3) and step length (0.9 vs 0.3) [1]. After-effect size is an indication of neural network sharing between contexts, where large aftereffects are expected [1, 2]. Here we show that MT adaptations are generalizable to NMT walking, indicating a potential use in gait rehabilitation.

After-effect magnitude has been shown to be greatest at speeds matched to the slow belt during adaptation, with abating aftereffects in either direction [2]. **Fig. 2b** shows diminishing aftereffects size as slow NMT belt speed moves further from the MT slow belt speed (0.67 m/s; vertical dashed line) for each subject, indicating that belt speed represents an important contextual relationship for transfer that needs further investigation.

Group average MG EMG traces in **Fig. 2c** shows after-effects during transfer and washout. During the transfer period, the slow MG activity increased while the fast MG activity decreased around mid-stance (20% - 40% stride cycle) compared to baseline NMT walking. The MG EMG after-effects were washed out by the end of the transfer period. During the washout period, the after-effects were expressed as additional MG EMG bursts during early stance in the slow leg (10% - 20% stride cycle) and fast leg (0% - 10% stride cycle). The after-effects washed out after 5 minutes of MT walking.

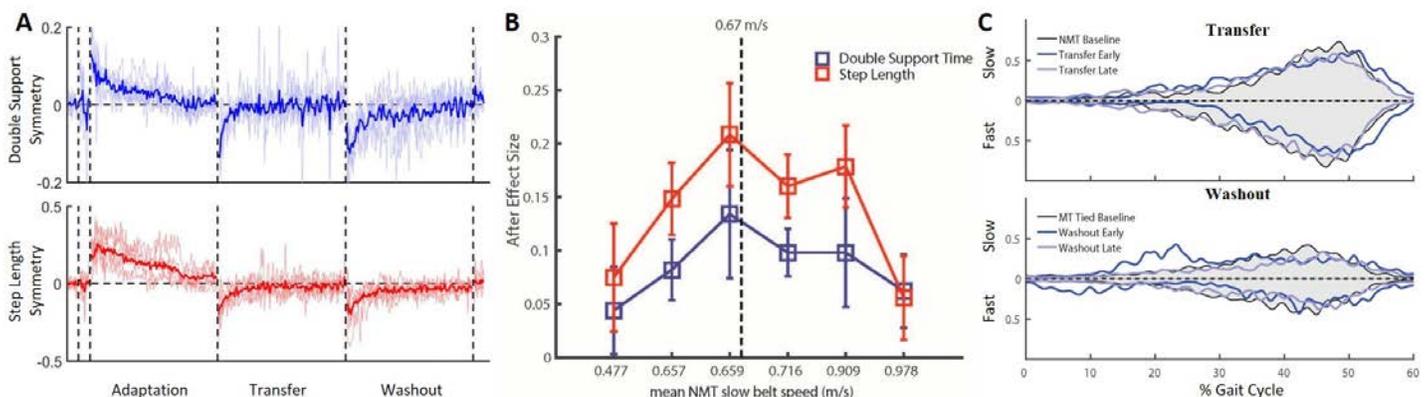

In summary, robust kinematics and EMG after-effects during NMT walking demonstrates that a low-cost split-belt NMT can be used as part of a gait re-training protocol. To promote optimal locomotor learning and generalization, future studies will explore treadmill design, slow belt-speed matching, learning style and changes in muscle activity related to changes in kinematics.

## INTRODUCTION

Studies of motor unit firing behavior have begun to improve our understanding of the strategies employed by the central nervous system to coordinate groups of muscles and generate force. For example, findings of the fundamental property of “common drive” to the motoneuron pool have revealed that motor unit firing rates within and across muscles are regulated with varying degrees of correlation depending on whether the muscles are acting as synergists or antagonists during different contraction tasks [1]. But such work has been limited to studies of isometric contractions or to the use of intramuscular sensors that are not practical for studying motor control during normal human movement. Consequently, the mechanisms used by the central nervous system to control non-isometric movements remain unknown. Therefore, we developed a non-invasive system of surface electromyographic (sEMG) sensors and software algorithms for measuring motor unit firing behavior during dynamic activities and used this system to investigate the activation of motor units in groups of muscles during movements of the upper-limb.

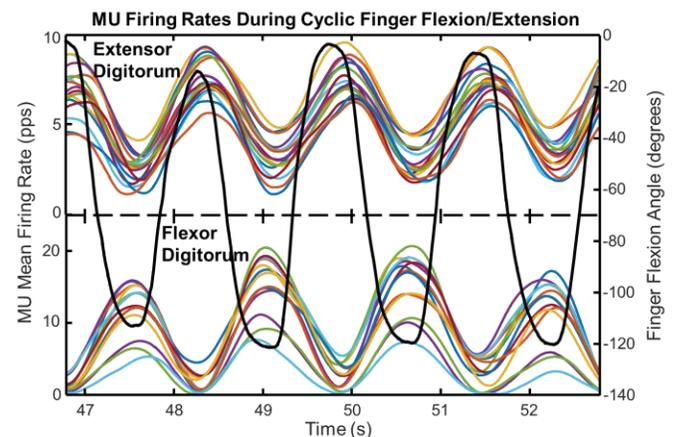

## METHODS

Experiments were conducted on 6 subjects (3 male and 3 female; 40±16 yrs.) with no known history of neuromuscular health conditions. Non-invasive dEMG sensors (Delsys Inc, Natick, MA) were placed on the extensor digitorum, flexor digitorum profundus, pronator teres and biceps brachii muscles to record high-fidelity sEMG signals produced during voluntary dynamic activities including: flexion/extension of the fingers, pronation/supination of the forearm and object grasping. The finger force, the finger joint angle and the inertial measurements of the wrist were measured

during the execution of each task using Trigno™ auxiliary sensors (Delsys, Inc. Natick, MA). Data recorded during the different movements were processed by the dEMG dynamic decomposition algorithms to extract action potentials and firing times of the active motor units [2]. The motor unit data were validated for accuracy and analyzed to investigate the firing behavior during voluntary movement activity.

## RESULTS AND DISCUSSION

Throughout cyclic dynamic movements in the upper-limb, the firing behavior of all motor units was governed by the same underlying control mechanisms: 1) the firing rates were ordered in an inverse hierarchical relationship relative to the motor unit action potential amplitude as previously described by the “onion-skin” phenomenon; and 2) the firing rates of motor units within each muscle were correlated with respect to one-another and with the output movement in accordance with the

**Figure 1:** Motor unit (MU) mean firing rates (colored lines) measured from the finger extensor and flexor muscles during four cycles of opening and closing of the hand (black line).

common drive [2]. When comparing the motor unit firing behavior across muscles, we observed that the firing rates maintained a relatively high correlation but the latency of the correlation shifted depending on the activity being performed. Specifically, when two muscles acted as antagonists, the correlation of the motor unit firing rates across muscles manifested a relatively greater latency (Figure 1) compared to when the muscles were coactivated during more synergistic tasks.

## CONCLUSIONS

Our data indicate that motor units within each muscle studied under dynamic conditions are governed by the same underlying control properties of the onion-skin and common drive that have been well documented and established in the literature for isometric tasks [2]. Depending on the movement activity, motor units across muscles acting as synergists have positively correlated firing rates, whereas those across muscles acting as antagonists

have negatively correlated firing rates. This would indicate that the central nervous system drives the motor units in a manner that utilizes that same underlying control scheme by shifting the latency between the motor unit firing rates across the two muscles.

# STABILIZATION OF LEG LENGTH AND ORIENTATION ACROSS DIFFERENT HOPPING FREQUENCIES IN CHILDREN AND ADULTS: A UCM ANALYSIS

Matthew Beerse and Jianhua Wu

Georgia State University, Atlanta, GA, USA. Email: [mbeersel@student.gsu.edu](mailto:mbeersel@student.gsu.edu)

## INTRODUCTION

Adults coordinate their lower limb joints to stabilize leg length and leg orientation during single-leg hopping in-place with a pattern that is maintained across different frequencies [1]. Children modulate whole-body vertical stiffness and horizontal center-of-mass movement similarly to adults when increasing hopping frequency, but not as effectively [2]. It is unknown if children accomplish hopping at different frequencies with a similar pattern of joint coordination as adults. This study aimed to compare the interjoint coordination strategies during single-leg hopping at different frequencies between children and young adults.

## METHODS

*Participants:* 16 young adults, 8F/8M, aged 24.56 (SD 3.45) years with height of 1.68 (0.10) m and body mass of 73.75 (15.17) kg and fourteen children, 5F/9M aged 8.70 (1.81) years with height of 1.34 (0.08) m and body mass of 32.97 (7.95) kg participated in this study.

*Experimental design:* Subjects completed four frequency conditions established by the subject's preferred frequency. We calculated the subject's preferred frequency as the average self-selected frequency during three 20-second trials. A metronome was used to guide the frequency conditions and was set to the subject's *preferred* frequency, a 20% increase (*moderate*), a 40% increase (*fast*), and a 20% decrease (*slow*).

*Data collection:* Subjects hopped on their dominant leg in-place on an AMTI force for 20-second trials. We used an 8-camera Vicon motion capture system and a full-body PSIS marker set to collect kinematic data at 100Hz. Three child subjects were unable to complete the *fast* condition.

*Data analysis:* We calculated four joint segment angles, foot, shank, thigh, and pelvis, in relation to the horizontal using the kinematic marker position. These joint segment angles were used to create geometric models of a leg length vector (the anterior/posterior and vertical distance between the toe and anterior superior iliac spine), and leg orientation with respect to the ground [1]. The geometric models allowed for the assessment of the variability of the joint configurations related to task variables, leg length and leg orientation, within an uncontrolled manifold (UCM) analysis. We normalized each hopping cycle to 100% and completed UCM analyses for each 1%.

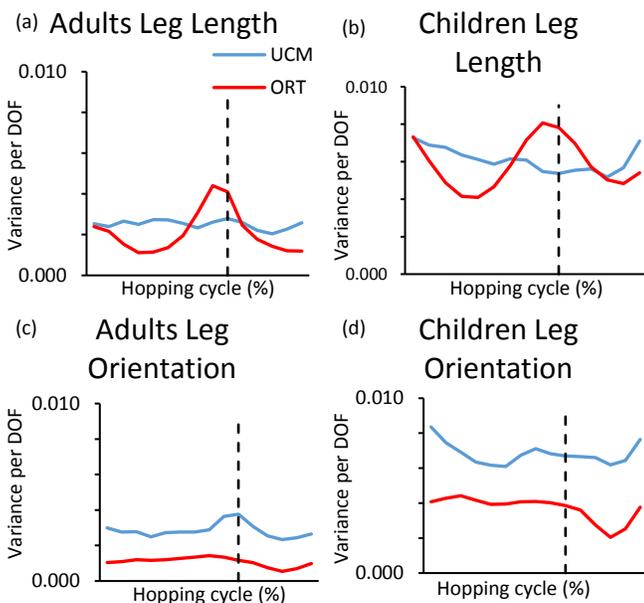

The average joint configuration at each percentage were used as the reference configuration. The two geometrical models were linearized into Jacobian matrices and used to find the null space [3]. Variance of joint configuration was partitioned into two subspaces: a UCM subspace that maintains the mean of a task variable, and an ORT subspace that deviates a task variable from its mean. We calculated the amount of variance per degree of freedom for each subspace. We then calculated an index of motor abundance (IMA) by dividing the difference of the UCM and ORT variances by the total variance [4]. The total variance was calculated as the diagonal sum of the covariance matrix per degree of freedom of the four joint segment angles. We averaged IMA across the entire hopping cycle at each frequency condition. A positive IMA value (UCM>ORT) indicated a stabilization of the task variable. A negative IMA values (UCM<ORT) indicated destabilization.

*Statistical analysis:* Repeated measures two-way ANOVAs (2 group x 4 frequency) were conducted on average IMA values for both leg length and leg orientation. Post-hoc pairwise comparisons with Bonferroni adjustment were completed when necessary. A significance level was set at  $\alpha=0.05$ .

## RESULTS AND DISCUSSION

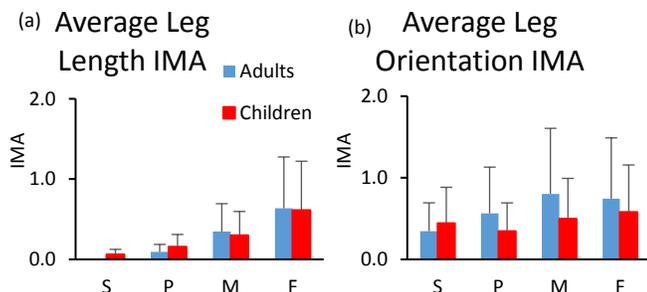

Figure 1 presents average pattern of variance across the hopping cycle for the *preferred* frequency condition. For leg length, both children and adults illustrate a pattern of stabilization around mid-stance and destabilization around take-off (dashed line) (Fig. 1a-b). For leg orientation, both groups stabilized throughout the hopping cycle with greater stabilization around take-off, and less stabilization around mid-stance (Fig. 1c-d). Children demonstrated a greater amount of total variance compared to adults.

Fig.1

Note: Charts for preferred frequency. Vertical dashed line indicates take-off.

Fig.2

Note: S for *slow*, P for *preferred*, M for *moderate*, and F for *fast* frequency condition.

Average leg length IMA across the hopping cycle increased with hopping frequency in both groups (condition effect,  $p < 0.001$ ; Fig. 2a). Post-hoc

analysis demonstrated increases from *slow* to *moderate*, *slow* to *fast*, *preferred* to *fast*, and *moderate* to *fast*. No group difference was found in average leg length IMA. Average leg orientation IMA demonstrated a group by frequency interaction ( $p = 0.035$ ) (Fig. 2b). Children did not change their average leg orientation IMA values across frequencies, however, adults increased with hopping frequency.

During single-leg hopping in-place, children demonstrate similar patterns of interjoint coordination when modulating hopping frequency. However, children do not decrease leg orientation stabilization when hopping 20% slower than preferred (*slow*), as found in adults. Hopping slower than preferred challenges the balance control of children [2]. Therefore, our results may indicate a necessity to maintain leg orientation stabilization to support balance during the *slow* frequency condition.

While children demonstrate greater total variance during single-leg hopping, UCM analysis allows for the classification of the variance into subspaces affecting and not affecting performance. Our results indicate that children single-leg hop with a similar interjoint coordination strategy throughout the entire hopping cycle compared to adults. Specifically, leg length and leg orientation are out of phase during the hopping cycle with peak leg length around mid-stance and leg orientation around take-off.

## CONCLUSIONS

While having greater total variance, children use a similar interjoint coordination strategy to stabilize leg length and leg orientation for single-leg hopping in-place.

## INTRODUCTION

Using functional near-infrared spectroscopy (fNIRS), previous research by Kurz et al. [1] has shown that there is greater hemodynamic activation in motor areas of the cortex while walking backward compared to walking forward. Additionally, stride time variability during forward walking was found to positively correlate with sensorimotor cortical activation [1]. Previous research has also shown that motion artifacts in fNIRS data correlates to the magnitude of head movement [2]. If fNIRS is used to examine cortical activation during walking, it may be necessary to account for differences in head movement between conditions.

The purpose of our study was to extend the work of Kurz et al. [1] by examining sensorimotor cortical activation during forward and backward walking conditions, while also quantifying head movement. We hypothesized that our results would be consistent with previous findings, and greater hemodynamic response during backward walking would be concurrent with increased head movement.

## METHODS

Ten healthy participants (age  $22.1 \pm 1.4$  y, 6 males and 4 females) performed a forward and backward walking trial. Each trial consisted of 30 seconds of walking followed by 30 seconds of rest, repeated 5 times continuously.

The fNIRS was placed over regions of interest (supplementary motor area: SMA, pre-central gyrus: PreCG, post-central gyrus: PostCG, and superior parietal lobule: SPL) based on the International 10/20 System for EEG [1, 3]. Average maximum oxygenated (oxyHb) and average minimum

deoxygenated (deoxyHb) hemoglobin concentrations were compared relative to condition specific baselines. Maximum oxyHb and minimum deoxyHb are associated with cortical activation and have been used in previous walking studies [1].

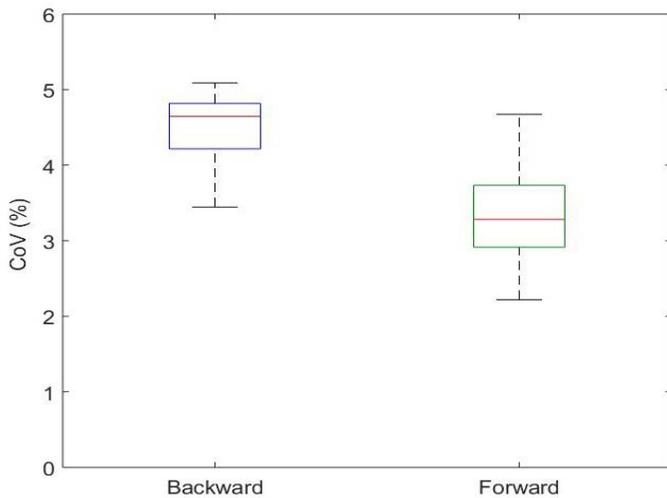

Heel strikes and toe offs were recorded using pressure sensors. This data was used to calculate inter-stride interval (ISI) during walking, which was defined as the time in between heel-strikes for the same foot. Mean, standard deviation, and coefficient of variation (CoV) were calculated for ISI.

Motion capture markers were placed on head, neck, and sternum to quantify head movement during walking conditions. Range of motion and line path were calculated for the anterior-posterior, medial-lateral, and vertical directions for each head marker.

Wilcoxon sign-ranked tests were performed to determine if there was a difference in oxyHb, deoxyHb, ISI, range of marker movement, and marker line path between walking conditions. Spearman's rank correlations were used to determine if average maximum oxyHb correlated with ISI coefficient of variation, mean, or standard deviation for walking conditions.

## RESULTS AND DISCUSSION

ISI coefficient of variation was significantly greater during backward walking compared to forward walking ( $P = 0.004$ ). Mean ISI was significantly greater during forward walking ( $P = 0.004$ ) and there was no significant difference in ISI standard deviation ( $P = 0.113$ ) (Fig. 1). These results suggest that the greater ISI coefficient of variation during backward walking was due to shorter stride time intervals, not significantly greater variability.

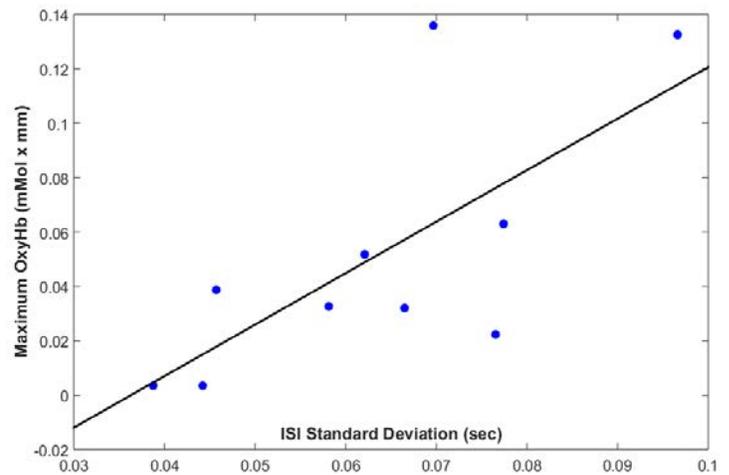

**Figure 1:** ISI coefficient of variation for forward and backward walking ( $P = 0.004$ ).

Range of movement and line path were calculated for the marker on the left temple. Anterior-posterior range of head movement was significantly greater during backward walking ( $P = 0.004$ ). There was no significant difference in range of movement in the medial-lateral ( $P = 0.432$ ) or vertical ( $P = 0.322$ ) directions. The total line path of the head marker (line integral) was not significantly different between walking trials ( $P = 0.233$ ). This indicates that the increased head movement during backward walking was due to slow anterior-posterior drift, which would not influence fNIRS results.

For all four regions of interest, there were no significant differences in maximum oxyHb concentration between backward and forward walking ( $P > 0.05$ ). Minimum deoxyHb concentration in the SMA was significantly lower during backward walking ( $P = 0.020$ ). There were no significant differences in minimum deoxyHb concentrations for the PreCG ( $P = 0.375$ ), PostCG ( $P = 0.846$ ), or SPL ( $P = 0.375$ ).

For forward walking, there was a significant positive correlation between maximum oxyHb in the PreCG and ISI standard deviation ( $r = 0.66$ ,  $P = 0.044$ ) (Fig. 2). There was also a significant correlation between maximum oxyHb in the SPL and ISI mean for forward walking ( $r = 0.66$ ,  $P = 0.044$ ).

**Figure 2:** Correlation between PreCG activation and ISI standard deviation during forward walking ( $r = 0.66$ ,  $P = 0.044$ ).

## CONCLUSIONS

Based on the measures of this experiment, stride time variability and sensorimotor cortical activation did not differ between forward and backward walking. Differences in hemodynamic activation may be more apparent in subcortical regions [4]. Head movement did not affect the results of this study, but should be taken into account for future fNIRS studies examining walking. The positive correlation between stride time variation and cortical activation suggests that the primary motor cortex (PreCG) may be implicated in forward walking variability.

## INTRODUCTION

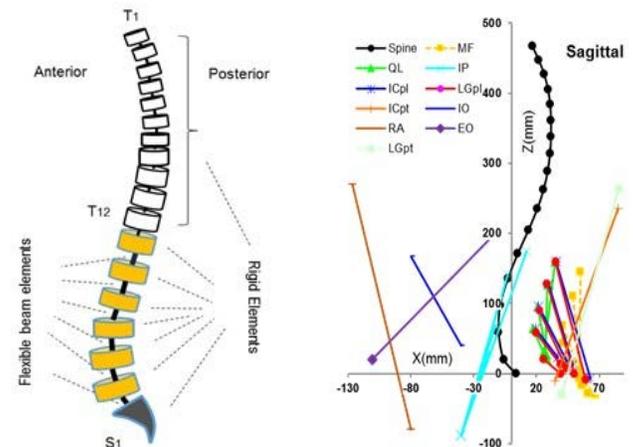

With regard to the low back pain problem, imaging is used to detect potential structural and geometrical abnormalities in the lumbar spine. The geometrical information from imaging, if combined with proper mechanical models, may provide a unique platform for the personalized assessment of trunk neuromuscular abnormalities in patients with LBP. Particularly, if changes in lumbar spine kinematics due to abnormalities in trunk neuromuscular behavior can be captured by the current imaging techniques, it may be possible to use image-based kinematics in kinematics-driven computational models to detect potential abnormalities in trunk neuromuscular behavior through personalized estimation of trunk muscle forces.

Recently, we have used a kinematics-driven finite element (FE) model of the spine (Fig. 1) within a heuristic optimization procedure to estimate lumbar kinematics under a trunk neuromuscular strategy that minimized sum of squared stress across all trunk muscles [1, 2]. The resultant kinematics of lumbar spine for a trunk forward bending task were consistent with image-based reports of lumbar spine kinematics of asymptomatic individuals. Using the same approach, estimation of lumbar segmental kinematics for various neuromuscular strategy assumptions is possible. Therefore, the objective of this feasibility study is to determine changes in lumbar segmental kinematics due to alterations in trunk neuromuscular strategy and to verify if such changes are within the reported precision of current imaging techniques.

## METHODS

Five different trunk neuromuscular strategies, each represented by a distinct cost function for the above mentioned heuristic optimization procedure, were selected to either represent the trunk neuromuscular

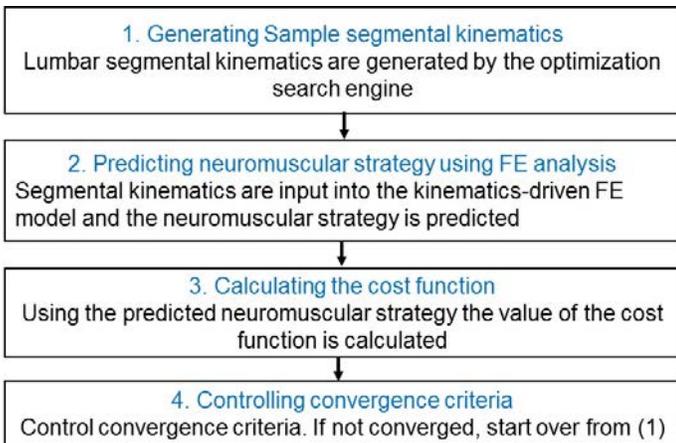

strategy of asymptomatic persons or a neuromuscular abnormality that minimizes loading on a specific aspect of lower back tissues (i.e., muscles, ligaments, intervertebral discs, and facet joints).

**Figure 1:** A schematic FE model of the spine and its components (left), the musculatures in the sagittal (right) plane in upright posture, and the dimensions (mm) were presented.

A neuromuscular strategy associated with the minimum value of sum of squared muscle stresses across the entire trunk muscles has been reported to be consistent with the electromyography measures of trunk muscles and disc pressure in asymptomatic persons, hence, was regarded to represent a normal neuromuscular strategy. On the other hand, abnormal neuromuscular strategies that minimize loads in muscles, ligaments, intervertebral discs, and facet joints were represented by strategies that respectively minimize sum of muscle forces across the entire trunk muscles, passive moment, compression, and shearing force at the L5-S1 intervertebral disc. For each neuromuscular strategy, kinematics of the lumbar spine (i.e., the axial and angular deformations of each motion segment) were obtained for a static trunk flexed posture involving, respectively, 40° and 10° of thoracic and pelvic

rotations in the sagittal plane. Details of the computational methods for the estimation of lumbar segmental kinematics associated with a given neuromuscular strategy can be found elsewhere [1, 2]. In summary, however, the heuristic optimization procedure searches for a set of lumbar segmental kinematics that when prescribed into the kinematics-driven FE model results in prediction of a neuromuscular strategy that minimizes the associated cost function (Fig. 2).

**Figure 2:** The algorithm used for the estimation of lumbar segmental kinematics associated with a given neuromuscular strategy.

## RESULTS AND DISCUSSION

The estimated angular and axial deformations of lumbar motion segments for the five neuromuscular strategies studied here are presented in the Table 1. Minimum changes in the angular and axial deformations of a motion segment with alterations in

neuromuscular strategy ranged from 0° (L2-L3 segment) to 0.5° (L4-L5 segment) and 0 mm (L1-L2 and L2-L3) to 0.04 mm (L4-L5), respectively (Table 1). Similarly, maximum changes in the angular and axial deformations of a motion segment with alterations in neuromuscular strategy ranged from 2.4° (L2-L3 segment) to 7.5° (L5-S1 segment) and 0.11 mm (L2-L3) to 0.39 mm (L3-L4), respectively (Table 1). The differences in kinematics of at least five (out of twelve) cases between each two neuromuscular strategies are detectable by current imaging techniques whose precision have been reported to be ~ 0.1 mm and ~ 0.1° [3]. Particularly, the differences in kinematics of lumbar segments between each combination of two neuromuscular strategies (10 possible combinations) are detectable in 97% of cases for angular deformation and 55% of cases for axial deformation. Therefore, combined imaging and computational modeling appears to have potentials for predicting abnormalities in neuromuscular strategies. Specifically, a geometrically and materially subject-specified model of the spine can be used in future to obtain the neuromuscular strategy that generates the closest lumbar kinematics to those measured from imaging. The accuracy of such assessment strategy can further be improved by implementing dynamic rather than static assessment tasks.

# EXPLORING HAPTIC FEEDBACK ON KINESTHETIC AWARENESS: A CASE STUDY

Jo Shattuck, Jack Ransone,  
University of Nebraska and the Nebraska Athletic Performance Laboratory, NE, USA  
Email: [joshattuck@huskers.unl](mailto:joshattuck@huskers.unl), website: <http://www.huskers.com>

## INTRODUCTION

Proprioception (kinesthetic awareness), of the precise joint angles of the effector is especially critical in the cognitive and associative stages of motor learning [1]. The ability to replicate an effector angle in any skill involving a ball and target is crucial for successful ball control. In order to replicate and correct a movement, the subject must have accurate and consistent knowledge of the body's position. Kinesthetic awareness training (KAT) provides the addition of haptic feedback in real time, to introduce secondary discriminatory system information into kinesthetic processing to improve kinesthetic awareness. We propose that haptic feedback through KAT will improve the ability to replicate a joint angle in multi-joint movements [2]. We tested this hypothesis on multiple movements. This dataset refers only to forearm angle replication during shot preparation movement in basketball.

## METHODS

We assessed peripheral limb control, specifically the vertical angle of the right forearm during a basketball shot measured with and without real-time haptic feedback. Four participants, (3 males, 1 female, each was either 20 or 21 years old), wore a miniature motion-capture and feedback device with internal sensors that recorded continual position data in 8 axes at approximately 16Hz. The target angle was determined by the subject, who held the basketball in their desired shot preparation position for 2 full seconds. The precise angle was then captured into the KAT tool through the smartphone app. A researcher then bounce-passed the basketball to the subject from 12 feet away; the subject was asked catch the ball, then return to the shot preparation pose as quickly and accurately as possible, as if preparing to shoot. The device was programmed to automatically provide haptic vibrations while the forearm angle was replicated.

To maintain a 'real-world' basketball environment, the subject could choose to whether or not to shoot the ball. Our outcome measures were:

- 1) Time-to-target: samples needed to replicate shot preparation forearm angle after catching the ball. A beginning reference point began when the angle was within 40 degrees of the target. Angle was considered IN when within 4 degrees of the target.
- 2) HIT/MISS rate: For each trial, a HIT was recorded if the subject held the angle for 2 consecutive samples. A MISS was recorded if the target angle was not reached for 2 consecutive samples. MISSES/HITS is the MISS rate.

**Figure 1:** Forearm at target angle.

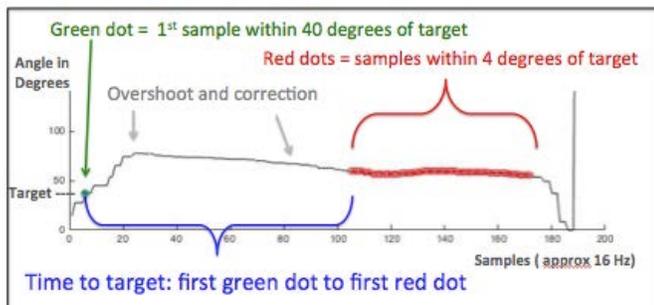

**Figure 2:** KAT placement.

The subject wore the KAT on the forearm continually as we collected three sets of five trials: a pre-training baseline set, a KAT condition set with haptic feedback, and a post-test set without-feedback, for a total of 15 trials per person. It is important to note that the goal was not to achieve any *particular* forearm angle across subjects, nor to test the effectiveness of any *particular* angle on shooting success, but instead, to test each subject's ability to replicate their chosen effector angle, that they determined for themselves before the task.

## RESULTS AND DISCUSSION

Single-tail paired T-tests of pre and post KAT in within-subject comparisons showed significant differences in time-to-target, in 2 of the 4 subjects. ( $p = 0.02$  and  $p = 0.03$  for subjects 3 and 4). One notable effect was the HIT/MISS ratio across all subjects in both conditions. The MISS rate in the KAT conditions was lower than in non-KAT sets (5% misses in KAT sets and % 26 misses in non-KAT sets).

**Figure 3:** Outcome measure in a single trial.

This data is part of an ongoing study testing motor performance simple and complex movements. In this subset of data two of the within-person comparisons showed significant improvement in time needed to replicate the target angle with KAT. Also, the total MISS rate was 5 times lower in the non-KAT sets when compared to the KAT sets.

Our sample size is not large enough to show meaningful differences in angle replication, however, this case study reports on the findings regarding motor behavior when haptic feedback is implemented in a motor task. Visible overshoots and undershoots of the target angle happened more frequently in the KAT conditions, presumably the reflecting the kinesthetic awareness as the subject 'explored' the effector position and felt the haptic feedback. Logically, subjects spent more time in the target angle in the KAT conditions, although this was not part of the instructions to the subject. In future studies, improvements to the methods will include a larger sample size, more trials per set, and two groups design, one with feedback, and one without, instead of alternating conditions, to better control the practice effect.

Further experiments are warranted to determine if KAT training can improve kinesthetic awareness, and more importantly, if the improvement translates to increased performance of a motor skill.

## CONCLUSIONS

This effort was the first use of a novel feedback/monitoring device. The study was not intended to determine the *optimal forearm angle of a basketball shot*, but instead to test angle replication skill, reflecting our measure of kinesthetic awareness. The results show that a miniature motion capture device could be used to test biomechanical techniques in motor skill in real-life situations, without the restraints of in-laboratory multi-camera marker systems.

It is logical that a device that offers vibratory corrective feedback, at the exact instant the correct angle is replicated, would lead to that angle indeed, being replicated, during a movement. The larger purpose is to investigate haptic feedback as an intervention in human movement. Real-world applications include basic motor skill acquisition [2], clinical rehabilitation, post-trauma physical therapy, movement disorders, neurosensory motor dysfunction, and/or other rehabilitative populations with kinesthetic awareness deficits.

## INTRODUCTION

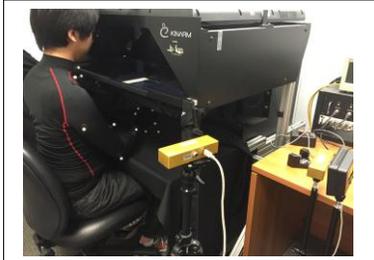

The human motor system is capable of a range of actions that are modified through experience. Motor learning has been actively studied to examine exactly how humans learn a motor skill by building sensorimotor maps that transform the sensory inputs into the motor output [1]. One of the crucial problems involved in this transformation is the “degrees of freedom problem”, a problem of effectively eliminating the redundancy of transforming high-dimensional joint space motor commands to the three-dimensional operational (endpoint) space movement [2]. However, in many studies on computational motor control, this degree of freedom problem has been substantially simplified or overlooked, and the primary focus has been put on the behavior in the operational space only. For instance, to examine the error-based mechanisms underlying motor learning, researchers have been using robotic manipulators [3, 4] to conduct human behavior studies on arm reaching movements. Typically, the only kinematic information provided and measured by these manipulators is the position and velocity of the manipulandum's handle, while the variability in the joint space induced by the coordinated movement of trunk, limb, and the wrist is purposely eliminated using restraint devices such as harness seat belt, air sled and arm casts. Likewise, the biomechanical models of the arm incorporated in the studies also have been drastically simplified as a planar two-link system of the elbow and the shoulder only, or simply as a linear point-mass system. Although these studies are successful in revealing the mechanisms of skill acquisition, an important component concerning how this adaptation is achieved within the kinematic redundancy is currently missing.

Due to the reasons discussed above, we believe the redundant kinematic factors should be concurrently and systematically assessed, rather than constrained, in motor learning studies. In addition to the endpoint trajectory (hand position and velocity in arm reaching experiments), analyzing kinematic changes in the joint space can provide useful information on brain's coordination strategy, such as the coordinate system used by the motor system during learning, the mechanical aspect of the motor cost function, and the control preference in multiple muscle coordination. To accomplish this goal, we incorporated 3D motion capture and musculoskeletal models with standard motor learning studies. Collectively, through the development of motion capture and modeling methods, our long-term goal is to perform biomechanical simulation of musculoskeletal models of the upper limb in order to provide a comprehensive representation of how the neural and motor systems synergistically accomplish the learning of new motor behaviors.

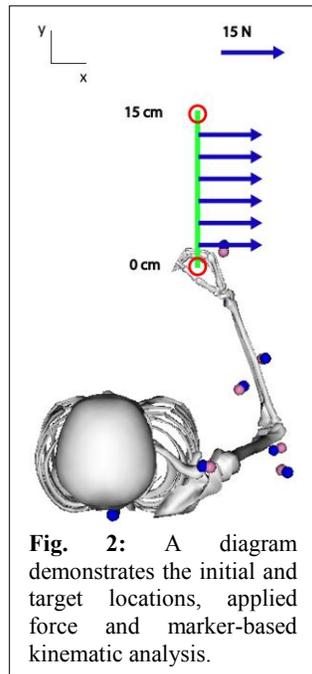

In this short report we describe our preliminary study that examined the kinematic factors in an arm reaching motor learning task. We hypothesized that the motor system exploits the redundant degrees of freedom to fine-tune the secondary factors of the motor cost, such as manipulability and dexterity. Specifically, we hypothesized that during a two-dimensional force adaptation task, subjects would systematically alter the elbow elevation over the course of motor learning, which is the only redundant degree of freedom when the hand is constrained to move within the horizontal plane. In addition, we expected to determine the mechanical implication of this change through biomechanical analysis, and to further elucidate the brain's strategy to solve the degrees of freedom problem.

## MATERIALS AND METHODS

Fig. 1 shows our system setup. We integrated two Bumblebee2 Stereo Vision Camera Systems (Point Grey Research) with the KINARM robotic manipulandum (Bkin Technologies) to track the arm motion from the lateral side of the subject. Four videos (640 X 480) were acquired at 48 frames per second from the four cameras and streamed to a desktop through firewire. Twelve infrared reflective markers (1cm diameter) fixed to 3D-printed bases were taped to the upper torso, upper arm, lower arm and hand of subject. Markers were also attached to the robot handle whose motion data was used to temporally synchronize the cameras to KINARM. We developed programs to calibrate the two stereo cameras and calculate 3D positions of the markers from the video data.

**Fig. 1:** The user manipulates the KINARM robotic handle while performing a motor learning task. We used two stereo cameras to concurrently measure upper limb kinematics.

**Fig. 2:** A diagram demonstrates the initial and target locations, applied force and marker-based kinematic analysis.

Each subject performed five blocks of reaching movements. The first and the last blocks consisted of null trials with no force perturbation. In the other blocks, a constant force of 15N perpendicular to the

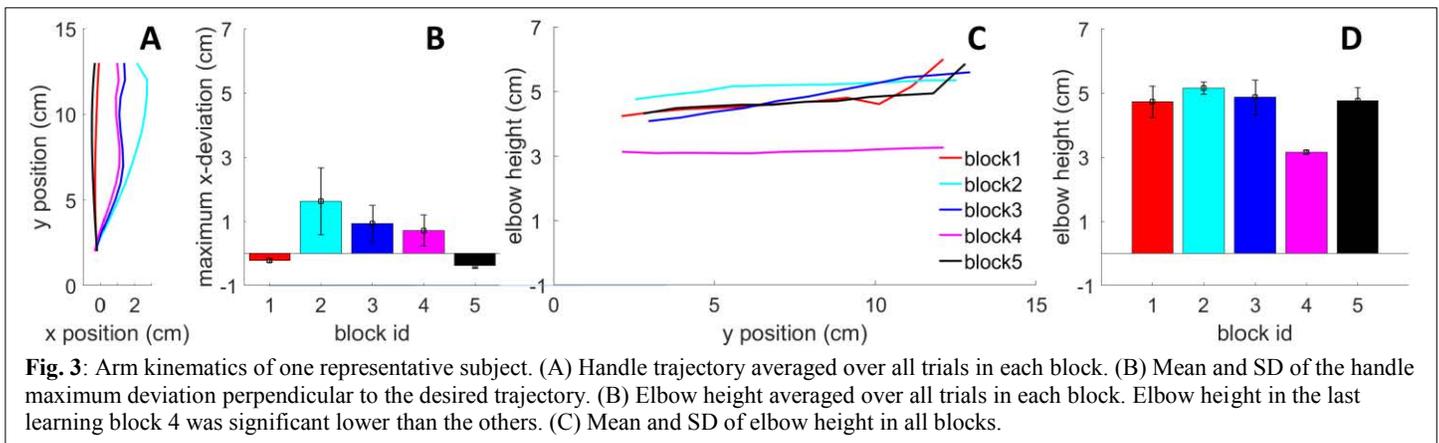

desired handle trajectory (x-direction in Fig. 2) was applied to the handle. More details on similar experiments can be found in [4]. An OpenSim arm model [5] was used to carry out subject-specific kinematic analysis. The pink markers in Fig. 2 are the template markers and the blue markers are the experimentally measured markers. Inverse kinematics was performed in OpenSim and arm kinematics of all reaching movement were examined.

## RESULTS AND DISCUSSION

Four subjects were recruited for the study. Fig. 3 showed analysis of one subject to describe the analysis. The subject was able to gradually learn the task, shown by the decreasing maximum trajectory deviation in blocks 2-4 (Fig. 3B). The subject first elevated his elbow at the beginning of learning (in block 2) then lowered his elbow during subsequent learning (in blocks 3 and 4). Other subjects also showed variable elbow height during learning trials that was significantly different from the elbow height in the null trials. Our preliminary analysis showed the feasibility of the proposed framework in studying the kinematic factors in motor learning. In the future, we plan to carry out more data collection and analysis to systematically test our hypothesis that changes in elbow angle correlates with the motor adaptation throughout the test session.

# Anticipatory Behaviors in Lateral Weight Shifting

Jackson Fox, Kevin O'Brien and James P. Schmiedeler

Aerospace and Mechanical Engineering, University of Notre Dame, Notre Dame, IN, USA

E-mail: [jfox10@nd.edu](mailto:jfox10@nd.edu), [kobrie23@nd.edu](mailto:kobrie23@nd.edu), [schmiedeler.4@nd.edu](mailto:schmiedeler.4@nd.edu)

## INTRODUCTION

Research on human postural control has typically emphasized quiet standing, but standing balance also requires the ability to dynamically shift ones weight in order to modulate center of pressure (CoP) position in performing functional activities [1]. Prior to voluntary balance adjustments or the initiation of walking, the human body exhibits anticipatory actions to maintain stability throughout the dynamic motion [2]. Implications of the anticipatory actions include improved resistance to falls during these voluntary movements. The present study investigates how shift strategy and CoP positioning during a lateral weight-shifting task are affected by shift direction and prior knowledge of an upcoming shift that enables anticipation.

## METHODS

Eighteen healthy subjects, 5 male and 13 female, ages 18-21 participated in this study. All subjects gave their informed consent prior to the study, which was approved by the appropriate Institutional Review Board. Using the Nintendo Wii Balance Board and the WeHab software [3] to provide visual feedback at approximately 60 Hz on a large computer monitor positioned at eye level, each subject was instructed to shift his/her CoP such that the small circle displaying its position overlaid on a background image of a Balance Board was within a target region. See Figure 1. Subjects completed nine 3-minute tasks and were instructed to shift into as many displayed targets as possible in the allotted time. The shaded rectangular targets (width equal to twice the CoP indicator's diameter) appeared at the center, on the right side, and on the left side of the board, with each lateral shift followed by a return shift to center. The lateral targets were positioned at a distance from neutral such that the subject had to support 70% of her/his weight on the corresponding

foot. The location of the target following a central target was randomized. As a result, subjects were able to anticipate the direction of shifts to the center, but not the direction of lateral shifts. Once the subject had shifted his/her CoP into the target, the CoP had to remain continuously in the target for three seconds before the target disappeared and the next appeared. Subjects were able to see the three-second numeric countdown on the visual display.

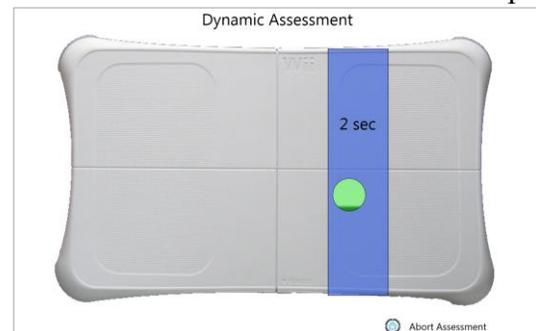

Figure 1: Visual feedback with CoP and target.

For each shift, the mean position of the subject's CoP in the lateral direction relative to the center of the target was computed for the 100 milliseconds prior to the target changing location. (The mean position in the anterior-posterior direction was also computed, but analysis revealed no significant trends.) Negative mean values indicate the side of the target closest to the location of the next target. A multi-factor ANOVA tested the effect of the subject number, the shift number for each subject, and the shift type on the mean position of the CoP prior to the shift. Shift type was defined by the starting and ending locations as type 1: left-to-center; type 2: right-to-center; type 3: center-to-right; and type 4: center-to-left.

## RESULTS AND DISCUSSION

Figure 2 plots the mean CoP positions relative to the target centers across all subjects for each of the four shift types. The ANOVA results indicated that

shift type was a significant main effect. A linear regression between shift type and mean CoP position revealed no statistically significant difference between the type 1 and type 2 shifts ( $p > 0.05$ ) back to center, while all other comparisons indicated statistically significant differences ( $p < 0.001$ ). This similarity in pre-shift behavior for type 1 and type 2 shifts was further investigated.

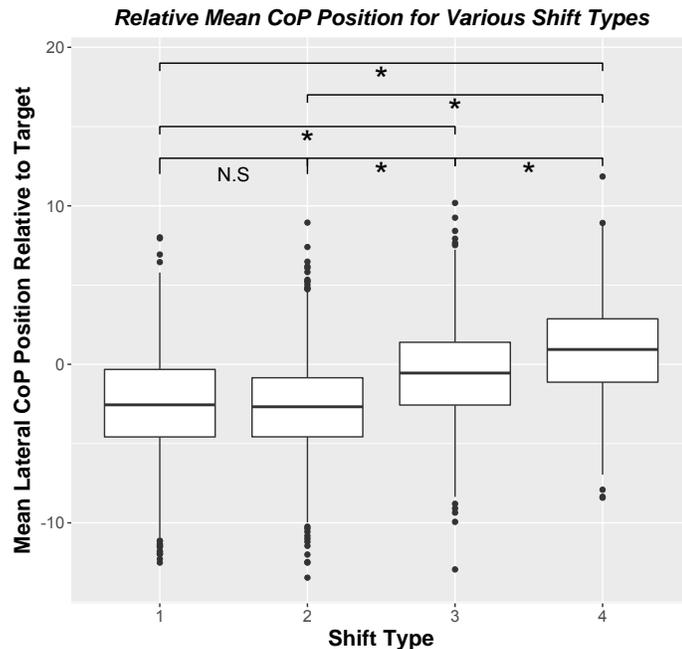

Figure 2: Mean lateral CoP position prior to shift initiation across all subjects for shift types: 1 left-to-center; 2 right-to-center; 3 center-to-right; and 4 center-to-left. (\* indicates  $p < 0.001$ ).

All subjects demonstrated a preference for a mean location in the “inside” half of the offset targets (closer to center). Of the 18 subjects, 13 had at least 75% of their shifts begin from the inside half of the target, with a minimum of 62% of the shifts, a maximum of 98%, and an average of 81.3%. While some subjects exhibited clear preferences for one side in type 3 and type 4 shifts out from center, there was no consistency among the group as a whole, and not all showed a clear pattern, as they did for the type 1 and type 2 shifts.

The subjects’ uniform preference for maintaining the CoP in the inside half of the target prior to shifting from an offset target inward could result from a number of factors. As the offset targets require the subject to support more weight on one

foot to even enter the target, the inside position could simply be preferred for comfort – it reduces the load on the outside leg within the task constraints. As the shifts from center involve moving from a neutral position, no comfort bias would be expected there. Alternatively, the difference could result from the anticipatory effects of shifting from offset targets to center that are not present in the shifts from center out because of the randomized offset target locations. The inside position should modestly reduce the time required to shift back to neutral, consistent with the instructions to complete as many shifts as possible. Furthermore, a shift to any target requires the CoP to first move opposite the target direction as the subjects pushes off [4]. Positioning the CoP closer to the inside target boundary provides a larger buffer to prevent the CoP from moving outside the target during its initial movement. This could be important if subjects started shifting prior to the new target appearing because moving the CoP out of the target too soon would reset the 3-second counter. This characteristic was not found for shifts away from center, perhaps because subjects were unable to anticipate the location of the next target.

## CONCLUSIONS

Young, healthy subjects consistently preferred to maintain an inside mean CoP position within an offset target prior to a visually guided, anticipated weight shift to neutral, which may be explained by maximizing comfort and/or shift speed within the task constraints. Future studies could further examine the role of anticipation by removing the visible timer and randomizing the required time spent in a target. Additionally, more target locations could be included to examine the effects of the subject knowing the direction but not the magnitude of an upcoming shift.

# MUSCLE RECRUITMENT AND COORDINATION DURING COMMON CLINICAL UPPER-EXTREMITY FUNCTIONAL TESTS

<sup>1</sup> Keshia M. Peters, <sup>1</sup> Valerie E. Kelly, <sup>1</sup> Tasha Chang, <sup>1</sup> Madeline C. Weismann, <sup>1</sup> Sarah Westcott-McCoy, and <sup>1</sup> Katherine M. Steele

## INTRODUCTION

Electromyography (EMG) can provide quantification of muscle recruitment and coordination during dynamic tasks. In research, EMG data are often used to evaluate muscle coordination during highly constrained tasks [1]. Conversely, in rehabilitation settings, clinical tests involving unconstrained movements are commonly used to simulate tasks of daily living and evaluate function [2]. However, EMG data are seldom used during these tasks to quantify patient-specific deficits. A need exists to evaluate unconstrained movements to facilitate the translation of experimental research to clinical practice.

The aim of this study was to evaluate how unimpaired individuals recruit and coordinate their muscles during clinical tests. Specifically, we sought to identify which muscles are used to execute common upper-extremity tasks and whether co-contraction levels are similar across muscle groups and tasks. Establishing normative patterns of recruitment and coordination may assist in identifying patient-specific deficits and opportunities for intervention.

## METHODS

The Jebsen-Taylor Hand Function Test (JTT) was performed by 20 unimpaired participants, 12 males, 8 females (avg  $\pm$  std) age  $27 \pm 5.7$ , height  $174.4 \pm 9.1$  cm, weight  $72.6 \pm 11.0$  kg. The JTT is a timed test that evaluates unilateral movement during simulated tasks in the following order: 1. writing, 2. card turning, 3. picking up small objects, 4. feeding, 5. stacking checkers, 6. moving light cans, and 7. moving heavy cans.

Surface EMG data were recorded from 8 upper-limb muscles for the dominant side: biceps brachii, triceps lateral head, extensor carpi radialis longus (ECRL), flexor carpi ulnaris (FCU), extensor digitorum (ExtD), brachioradialis, anterior deltoid, and posterior deltoid (Trigno Wireless EMG Systems; Delsys, Boston, MA, USA). Maximum voluntary isometric contractions (MVICs) were collected for normalization. EMG data were processed in MATLAB (MathWorks, Inc., Natick, MA, USA) and included high-pass filtering (40Hz), rectification, and low-pass filtering (40Hz) each muscle to calculate a linear envelope.

Percent co-contraction (%COCON) was calculated by comparing the over-lapping integrated areas of the linear envelopes relative to the total integrated area of both muscles [3]. We evaluated %COCON for four muscle pairings: anterior and posterior deltoid (AP), biceps and triceps (BT), brachioradialis and triceps (BrT), and flexor carpi ulnaris and extensor carpi radialis longus (FE). A one-way ANOVA with post-hoc t-tests, with Bonferroni correction for multiple comparisons were conducted to compare %COCON of each muscle pairing, as well as average MVIC of individual muscles across tasks ( $\alpha = 0.002$ ).

## RESULTS AND DISCUSSION

Two distal arm muscles, ExtD and FCU, exhibited greater recruitment than other muscles across most JTT tasks, demonstrating that the JTT places a greater demand on forearm muscles (Fig. 1, Left). The ExtD had significantly greater recruitment (relative to %MVIC) than shoulder and elbow muscles for tasks 1, 2, and 3, and all muscles for tasks 4, 5, 6, and 7. The high activation level of the ExtD demonstrates the relative demand placed on

this smaller muscle and the necessity of finger extension during tasks of daily living, an ability often impaired after stroke. Other muscles that span the wrist may also serve as wrist stabilizers. For example, in the heavy cans task, the ExtD may function as the primary mover, and the remaining wrist movers, FCU and ECRL, may function to stabilize the wrist.

No differences were found in %COCON of muscle pairings across tasks. Average %COCON across tasks were  $35.8 \pm 3.3\%$ ,  $44.0 \pm 3.3\%$ ,  $55.1 \pm 4.5\%$ , and  $49.1 \pm 3.3\%$  for the AP, BT, BrT, and FE, respectively. BrT had significantly greater %COCON than the shoulder (AP) and forearm (EF) during tasks 3 – 7, suggesting the importance of stabilizing the elbow during these tasks. Recent research found a positive correlation between BT and BrT co-contraction levels and speed during the deceleration phase of elbow extension [3], which may also indicate elbow co-contraction is important during timed and targeted tasks like the JTT.

Muscle recruitment during tasks was independent of the time required to complete the task for unimpaired individuals (Fig. 1, Right). For example, the writing task took the longest to complete and had low levels of recruitment in the proximal arm muscles. However, the ExtD and FCU had a significantly higher mean recruitment level than the shoulder and elbow flexors ( $p < 0.0002$ ). Conversely,

the checkers task was completed in  $4.3 \pm 0.8$  seconds and had the lowest mean recruitment level across tasks and most muscles, likely due to the relatively small working space. There was greater inter-subject variability in muscle recruitment than time to complete each task.

## CONCLUSIONS

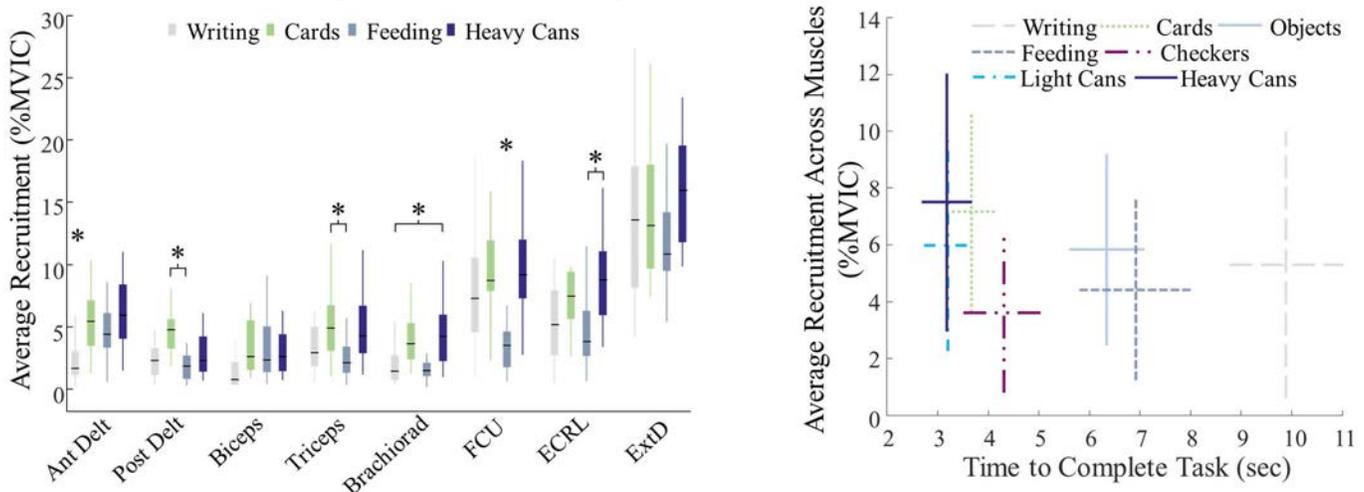

Quantifying muscle recruitment and coordination during unconstrained clinical assessments in unimpaired individuals provides a set of baseline measurements that can be used to evaluate muscle-specific deficits for individuals with neurologic impairments, such as stroke or cerebral palsy. Such assessments may be used to track recovery, inform therapy, and accelerate rehabilitation.

# REDUCTION IN STABILITY OF MANUAL BEHAVIOR IN UNCERTAIN CONDITIONS

Mitchell A. Tillman and Satyajit S. Ambike

Purdue University, West Lafayette, IN, USA

email: [sambike@purdue.edu](mailto:sambike@purdue.edu). web: [www.purdue.edu/hhs/hk/Biomechanics-MotorBehavior/](http://www.purdue.edu/hhs/hk/Biomechanics-MotorBehavior/)

## INTRODUCTION

Ensuring the stability of motor action is critical for executing successful movements. However, maximizing stability is not always desirable [1]. For example, a transition between motor states must be preceded by the destabilization of the prior state. *Anticipatory synergy adjustments* describe the destabilization of a motor state that begins ~300 ms before the intended change in that state is observed [2]. Similarly, when rapid movement is expected in the near future, the motor system must manage two contrasting objectives: (1) ensure the stability of the current state, and (2) achieve rapid transitions to new states, if required. We argue that the stability of the current motor state is modulated to lower values to account for uncertain task requirements and to achieve dexterous task switching.

Here, we verify if stability reduction enables the dexterous use of the fingers. Subjects performed four-finger, isometric, constant force production tasks in two conditions. In the first (stable) condition, subjects produced one constant target force and had a-priori knowledge of the target's invariance. In the other (dexterous) condition, subjects tracked a longer, unknown, randomly varying trajectory that included the constant-force target as an integral part. We hypothesize that the stability computed during the constant force-production phases in the two conditions (1) will be maximal for the stable condition, and (2) will be progressively lower as the task demands increase.

## METHODS

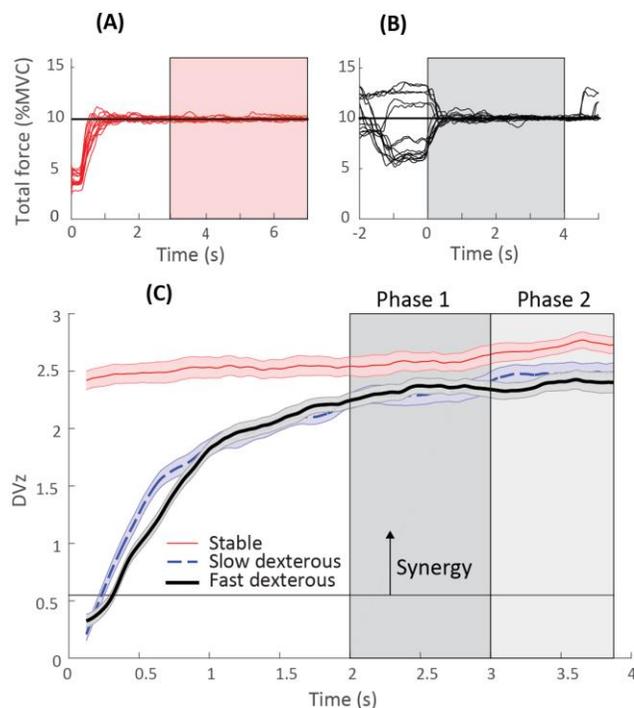

Twenty-five healthy subjects (6 male, 20.4±2.5 yrs) participated in the study after providing informed consent. Subjects were seated comfortably in a chair with their forearms resting on top of a table. They placed the distal phalanx of each finger of their dominant hand on one force transducer (Nano-17;

ATI Automation). The transducers recorded each finger's downward vertical force at 1000 Hz. Visual feedback on the total force,  $F_T$ , was provided for all trials via a computer screen placed in front of the subject.  $F_T$  was computed as the sum of the vertical downward forces of all fingers ( $F_T = \sum F_i$ ;  $i=1$  to 4).

For the stable condition (Task 1), subjects produced a constant  $F_T$  value (10% of maximum voluntary contraction - MVC) for 7 s with the knowledge of the target's invariant location. This task was repeated 16 times [2]. For the dexterous condition (Tasks 2 and 3), the subjects modulated their total finger force and tracked an  $F_T$  target that randomly changed its vertical position on the screen. The target  $F_T$  profiles lasted for 30 s and consisted of smooth transitions between varying durations and magnitudes of constant  $F_T$ , including one instance of 10% MVC which lasted for at least 4 s. There were 8 distinct target  $F_T$  profiles for Tasks 2 and 3 each, which were repeated once to obtain a set of 16 trials for each task type. The target moved faster for Task 3 compared to Task 2, making Task 3 harder. The trials were randomized within each task, and the tasks were block randomized across subjects.

The last 4 s of Task 1 (Fig. 1A), and the first 4 s of Tasks 2 and 3 were used for further analysis, after the data were time aligned to match the start of the 10% MVC portion (Fig. 1B). The individual finger forces ( $F_i$ ) were filtered using a zero-lag, 4<sup>th</sup>-order, low-pass Butterworth filter (10-Hz cut-off). The stability of behavior was quantified using the uncontrolled manifold (UCM) analysis [3]. The UCM analysis partitions the variability in the input finger forces into a component along the UCM which does not affect the output force (*good* variance:  $V_U$ ), and variability orthogonal to the UCM that affects  $F_T$  (*bad* variance:  $V_O$ ). The relative amount of good variance, normalized by the total variance  $V_T$ , computed per degree of freedom, yields the synergy index:  $\Delta V = (V_U/3 - V_O)/(V_T/4)$ .  $\Delta V$  is z-transformed

to yield  $\Delta V_z$  for statistical analysis.  $\Delta V_z > 0.549$  indicates that the fingers covary to stabilize  $F_T$ , i.e., if one finger force increases, others compensate by reducing their force to maintain  $F_T$ . A *synergy* exists between the fingers, and a greater  $\Delta V_z$  indicates a stronger synergy and higher stability. Conversely,  $\Delta V_z < 0.549$  implies covariation between the fingers that destabilizes  $F_T$ .  $\Delta V_z$  was computed within each trial using a 250 ms sliding window.  $\Delta V_z$  values for two Phases (Phase 1: 2-3 seconds and Phase 2: 3 to 3.875 seconds) were averaged within those time bins for each subject and subjected 2-way, repeated-measures ANOVAs with factors *Phase* (2 levels) and *Task Type* (3 levels). Bonferroni corrections were used for pair-wise comparisons.

**Figure 1:** Representative data for Task 1 (A) and Task 2 (B). Data in the shaded rectangles is used for computing the synergy index. Across-subject and trial mean $\pm$ SE of the synergy index (C).

## RESULTS AND DISCUSSION

The total force,  $F_T$ , in the 4 s window for Task 1 (Fig. 1A) shows fluctuations about the 10% MVC target. In contrast,  $F_T$  in the 4 s window for Tasks 2 and 3 (Fig. 1B) contain an initial period when force trajectories converge to the 10% MVC target from different previous states. So  $\Delta V_z$  for Task 1 displays a near-constant value, but  $\Delta V_z$  for Tasks 2 and 3

show a period (up to  $\sim 0.3$  s) of covariation that achieves  $F_T$  convergence to 10% MVC ( $\Delta V_z < 0.549$ ; Fig. 1C). Then,  $\Delta V_z$  gradually increases reflecting an increasing tendency to stabilize  $F_T$ . The key observation is that  $\Delta V_z$  values for the slow and fast dexterous tasks (Tasks 2 and 3) always remain lower than those for the stable task (Task 1).

The ANOVA revealed a significant effect of *Task Type* [ $F_{(2,48)}=10.721$ ;  $p < 0.01$ ]. Pair-wise comparisons revealed  $\Delta V_{z\text{stable}} (2.63 \pm 0.07) > \Delta V_{z\text{slow-dexterous}} (2.37 \pm 0.07)$ , and  $\Delta V_{z\text{stable}} > \Delta V_{z\text{fast-dexterous}} (2.35 \pm 0.07)$ . There was also a significant *Phase* effect [ $F_{(1,24)}=39.403$ ;  $p < 0.01$ ]. Pair-wise comparisons revealed  $\Delta V_{z\text{Phase-1}} (2.39 \pm 0.06) < \Delta V_{z\text{Phase-2}} (2.51 \pm 0.06)$ . The interaction was close to significant [ $F_{(2,48)} = 3.041$ ;  $p = 0.058$ ], and it suggested that the increase in  $\Delta V_z$  across the phases tends to be slower for fast dexterous task compared to the other two tasks.

Our first hypothesis was supported by the data. The stability associated with the constant  $F_T$  is reduced ( $\sim 10\%$ ) when subjects expect to produce force changes of unknown direction and magnitude at an unknown time in the near future. Although the drop in  $\Delta V_z$  was similar for Tasks 2 and 3, it tended to last longer for Task 3 (near-significant *Task*  $\times$  *Phase* interaction). These  $\Delta V_z$  changes are anticipatory synergy adjustments, but with two prominent differences: (1) they lasts over 8 times longer than the previously reported ( $\sim 300$  ms), and (2) we show limited destabilization that facilitates movement if and when required. In contrast, earlier work reports progressive destabilization of the current state that is necessarily followed by a state change in *self-paced actions* that do not involve uncertainty [2]. The relation between stability modulation and task performance remains to be established in our study. However, this is the first demonstration of task-specific stability reduction in hand function, and our results have implications for the understanding and the clinical assessment of manual dexterity.

## INTRODUCTION

Kinematics of many of our most common movements such as saccades and reaching have historically been explained exclusively through the minimization of implicit motor costs [1, 2]. Surprisingly, these sensorimotor control models do not consider important external variables such as the amount of reward available in the environment. If we assume that the purpose of a movement is to acquire a more rewarding state, and that time discounts the value of that reward, then movements are affected by a cost of time. More recent models propose that kinematics may be modulated according to the overall expected utility of the movement, with motor costs being discounted by the rewards associated with the movement outcome [3]. According to this framework, the speed of a movement is optimized according to competing effort and reward costs (slower=less effort, faster=more reward). These predictions are supported experimentally with humans and other animals making faster saccades to targets paired with an increased reward [4,5]. The current study investigated how kinematics in a *reaching* task can be modulated by reward. Furthermore, we probed the specificity of these effects both within a movement and across subsequent non-rewarding movements. We hypothesized that when reward is at stake, individuals would exert more effort. We found that expectation of reward coincided with greater peak velocity and reach extent, and shorter reaction time.

## METHODS

Twenty naïve participants (27.5 years, 11M, 9F) used a robotic handle to control an invisible cursor that interacted with a virtual environment displayed on an LCD monitor. The task consisted of moving the cursor from a middle home circle towards

different quadrants with the direction indicated by a marker displayed in one of four locations (Figure 1A, 45, 135, 225, or 315 degrees from the home circle). For each out-then-return reaching movement, we measured reaction time, peak outward velocity, movement duration, maximum excursion, distance to target, and peak return velocity (Figure 1B). The protocol consisted of a 40 trial baseline block followed by 4 experimental blocks of 100 trials. During baseline, participants reached to the four quadrants at self-selected speeds. This behavior continued during each experimental block, but with one of the quadrants now being paired with a reward (audible beep, exploding target, 4 arbitrary points). At the end of the block, the reward location was changed to a new quadrant so that a unique location was rewarded for each block (Figure 1C, 4 quadrants, 4 blocks).

**Figure 1:** Experimental design. A) Set-up: Participants sat in a chair while grasping the handle of a robotic arm that controlled a cursor on a monitor located at eye level. B) Schematic of movement kinematics measured each trial. Distance to marker was calculated as absolute angle between marker and where cursor crossed outer ring. C) Protocol timeline: The order of rewarded blocks was identical for six participants and pseudo-randomized for the remaining fourteen.

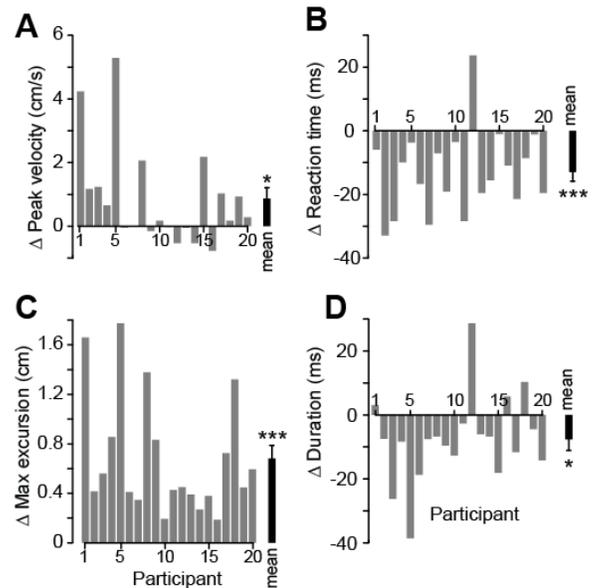

Participants were neither aware of the total number of trials remaining in a block nor when a new block began. The only information they received regarding the progress of the experiment was that the experiment would end after an undisclosed amount of points were acquired. Using paired t-tests, we measured the changes in kinematics due to increased reward. To test for specificity in the effects of reward, we compared average kinematics for rewarded trials against non-rewarded trials preceding (two trials) and following (three) reward. Finally, we measured whether the effect of reward persisted through the return component of a reaching movement by comparing return velocity between rewarded and non-rewarded trials.

## RESULTS AND DISCUSSION

Individuals moved with higher outward peak velocity, greater maximum excursion, faster reaction time, and shorter duration when reaching towards targets associated with reward (Figure 2). Peak velocity increased by 2% ( $p=0.023$ ), maximum excursion increased 4% ( $p<0.001$ ), reaction time decreased by 5% ( $p<0.001$ ) and duration decreased by 2% ( $p=0.023$ ). There was no change in distance to marker ( $p=0.220$ ). This suggests, that similar to saccades, as the value of the movement outcome increased (more reward), people exerted more effort in those movements. When looking at the specificity of reward's effects on kinematics, we found that peak velocity and maximum excursion returned to pre-reward levels immediately following the rewarded trial. Duration and reaction time however, had a slightly exaggerated slowing in the trial immediately following reward, when compared to pre-rewarded trials and later post-rewarded trials ( $p's<0.05$ ). This suggests that reward may delay movement initiation and execution in non-rewarded movements immediately following reward.

Reward was attained as the hand crossed the outer ring. However, the movement continued as the hand returned the cursor to the center location. We found that expectation of reward affected only the center-out velocity of the movement, but not the velocity of the return phase back to center. This finding

demonstrates that expectation of reward discounts the effort that is expended before reward is attained, and not the effort that may be expended afterwards.

**Figure 2:** Changes in A) peak velocity, B) reaction time, C) maximum excursion, and D) duration as a result of heightened reward ( $*p<0.05$ ,  $***p<0.001$ ). Grey bars represent individual participants and black bars represent group means and SE.

## CONCLUSIONS

We found that humans altered the kinematics of their reaching movements under the expectation of reward. Expectation of reward appeared to discount the effort that the brain was willing to expend in performing a reaching movement.

## INTRODUCTION

Quiet stance (QS) is typically used to examine postural control through assessment of the center of pressure (CoP). However, weight bearing asymmetries (WBAs) may also be of value and have relationships to postural alignment and low back pain [1], although it's not fully understood how WBAs relate to the muscle activity and asymmetries at the trunk level. If WBAs do correlate back to the musculature at the hip and lumbar area, it may provide support for use of this measure, as WBAs are easier to collect than muscle activation asymmetries (MAAs). A previous study has indicated sex differences in muscle activation strategies, with women having more motion originate from the hip rather than the trunk during trunk flexion-extension movements [2]. These differences could potentially be related to the differences in core muscle use, size, and fiber type percentage between men and women [2,3,4]. Throughout a typical day, most individuals are on their feet, with prolonged standing (PS) becoming more highly recommended in the work place [5]. Most PS studies are 1-2 hours in length [6,7], however, a more brief 30 minute study may be more representative of the short bursts of time that individuals are on their feet throughout the day. The goal of this study was to examine the relationship between WBAs and MAAs during QS both immediately prior to and post 30 minutes of PS, the effects of PS on this correlation, and sex related differences within healthy young adults during QS.

## METHODS

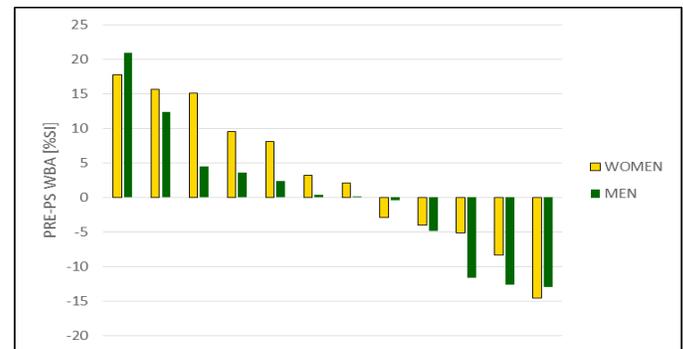

Twenty-four healthy, pain-free subjects (12 male, 12 female) voluntarily participated in the study (age =  $22.3 \pm 2.4$  years, height =  $1.70 \pm 0.09$  m, mass =  $69.89 \pm 11.31$  kg, BMI =  $24.1 \pm 2.5$  kg/m<sup>2</sup> [mean  $\pm$  SD]). All subjects verified that they could stand comfortably for 30 minutes. Subjects performed two 60 sec. QS trials (pre-PS & post-PS) separated by one 30 min. free-standing trial. For the QS trial,

each subject had a set stance width of 10% of their standing height and were instructed to have a quiet, relaxed stance. For the 30 min. free-standing trial, subjects could shift their feet and sway to keep comfortable, as long as their feet didn't cross over onto the opposite force platform. Bilateral ground reaction forces under each foot were measured during each trial. Surface electromyography of each lumbar erector spinae (ES), gluteus medius (GM), internal obliquus, and external obliquus were also measured each trial. Muscle activity was normalized to a reference contraction (%ref) conducted at the start of the study [6,8]. WBAs and MAAs were calculated by subtracting the non-dominant limb (ND) from their dominant limb (D) using the %SI equation (Equation 1)[9].

$$\%SI = \frac{D-ND}{\frac{1}{2}(D+ND)} * 100 \quad (\text{Equation 1})$$

## RESULTS AND DISCUSSION

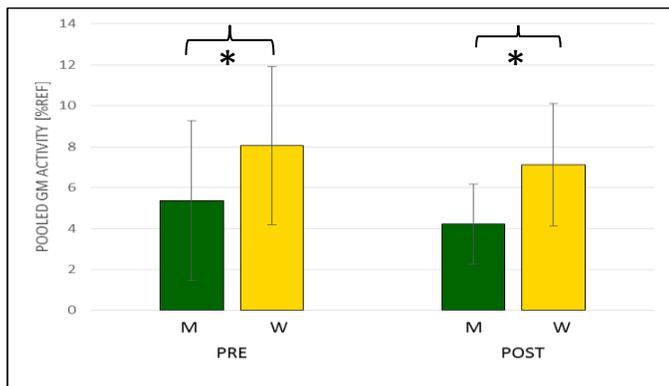

There were no differences in WBA or MAA between the pre-PS and post-PS trials, nor between the men and the women ( $p > 0.05$ ) (Figure 1). In both of the QS trials, there were no significant differences between the D and ND limbs ( $p > 0.05$ ).

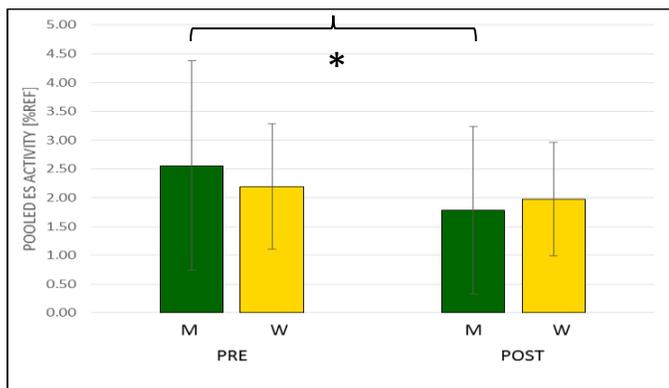

**Figure 1:** Individual subject WBA during the pre-PS trial ranked from highest (most weight on D limb) to lowest (most weight on ND limb). Post-PS WBAs behaved similarly.

Typically, the direction of the WBA stayed similar between the pre-PS and post-PS trials, and were significantly correlated (women  $p=0.016$  &  $r=0.676$ ; men  $p=0.002$  &  $r=0.807$ ).

The women had overall higher GM activity than the men (women =  $7.58 \pm 3.44$  %ref, men =  $4.79 \pm 2.93$  %ref;  $p=0.041$ ) (Figure 2). Overall ES activity decreased from the pre to the post-PS trial for the men, but not the women (women =  $2.08 \pm 1.03$  %ref, pre-PS men =  $2.56 \pm 1.82$  %ref, post-PS men  $1.79 \pm 1.46$  %ref;  $p=0.002$ ) (Figure 3).

**Figure 2:** Glutes Medius (GM) activity levels with the D and ND sides pooled. Error bars indicate first SD. \*main effect  $p<0.05$  between men and women.

**Figure 3:** Erector Spinae (ES) activity levels with the D and ND sides pooled. Error bars indicate first SD. \*interaction  $p<0.05$  with men dropping pre-post.

During the pre-PS trial, there was a significant, although weak, correlation between the WBA and the GM asymmetry for the women ( $r = 0.615$ ,  $p = 0.044$ ) but not the men ( $r = 0.354$ ,  $p = 0.259$ ). This correlation was not significant in women during the post-PS trial ( $p=0.903$ ). The majority of the MAAs

were significantly correlated between the pre-PS and post-PS trials (women  $p\leq 0.001$  &  $r\geq 0.836$ , men  $p\leq 0.002$  &  $r\geq 0.802$ ), with the only exception being the ES asymmetry for the men ( $p=0.211$  &  $r=0.433$ ).

## CONCLUSIONS

While these results suggest that PS does not have an effect on WBA or MAAs during QS, a small amount of individual variation does exist. There also appears to be sex related differences in both muscle activity and possible changes in muscle use. Previous studies have also indicated sex related differences at the hip and trunk level, with woman activating hip muscles prior to trunk muscles during flexion-extension exercises [2]. These sex related findings could be related to the musculoskeletal differences between men and women [2,3,4]. The relationship between WBAs and GM MAAs changing from pre-PS to post-PS shows that a subject being rested versus unrested does matter for collecting these measurements. Furthermore, these results may potentially relate to what is occurring during the 30 minutes of PS, since the subjects could shift their weight and move around somewhat naturally during the trial. The 30 min data is currently being processed and analyzed.

## INTRODUCTION

The mechanical impedance of human joints is fundamental to our ability to interact with the world. These properties describe the stiffness and damping characteristics of a joint and are actively regulated by the nervous system for adaptation to unexpected changes in task dynamics [1]. However, mechanical and analytical challenges have hindered the study of joint impedance during dynamic tasks, such as walking. Characterizing ankle impedance is critical to our understanding of how the nervous system regulates the mechanics of locomotion, and is needed to provide a basis for the development of biomimetic assistive technologies and their control systems.

Methods have recently been developed to overcome the challenges in estimation of ankle impedance during walking. Rouse *et al.* accurately estimated ankle impedance during the controlled dorsiflexion region of the stance phase of walking [1], while Lee *et al.* have characterized ankle impedance during swing phase and early loading response [3]. However, a gap remains in our knowledge of ankle impedance in late stance phase—or *push off*—when the calf muscle contracts to propel the body forward. This is a particularly important region of the gait cycle, when the majority of mechanical work is provided by the legs [4]. Estimating ankle impedance during late stance phase is challenging because quantifying ankle torque is more sophisticated due to motion and deformation of the midfoot segments following heel rise. Fortunately, motion capture studies have analyzed how the fore-foot, midfoot, and rear-foot segments move relative to each other, the shank, and the ground [5]; but these data have not previously been used in conjunction with joint impedance identification.

The ankle is essential to the energetics of human locomotion, producing the majority of mechanical power [4]. By separating total ankle work into the contributions due to elastic energy storage or return, and displacement of the virtual equilibrium position

of the biological controller, we can improve our understanding of how energy is stored, added, or removed during gait. Understanding energetic contributions to joint dynamics is essential for emulating natural gait in biomimetic assistive technologies.

This study quantifies ankle impedance during this crucial portion of stance phase, and evaluates energy transfer within an impedance framework that may represent aspects of the neuromotor control system. Analysis during late stance provides insight into how active power generation in locomotion affects joint mechanics and neuromotor control modalities.

## METHODS

The purpose of this study is to determine the mechanical impedance of the ankle during the late stance phase of walking using mechanical perturbations and measuring the joint's torque response. To this end, ten healthy subjects participated (6 male, 4 female, age  $25 \pm 4$  years, weight  $73 \pm 13$  kg), with no history of neurological impairments. Two degree angular perturbations in both the plantarflexion and dorsiflexion direction were applied to the ankle at two distinct time points in late stance phase, using a single degree of freedom platform robot [1]. Relevant force data were measured using a force platform included within the robot. The perturbation-induced changes in ankle angle were related to the resulting joint torque response by a second-order parametric model comprised of stiffness, damping and inertia components. Least-squares system identification was used to estimate impedance. Using data from aforementioned motion capture studies, a novel time varying, subject specific transformation was developed to resolve the ground reaction force to the ankle, allowing for accurate and robust torque measurements during mid-foot deformation.

Using an impedance control framework, parameterized by (1), we represented the instantaneous kinetic, kinematic and impedance aspects of human walking [1]. The equilibrium position ( $\theta_0$ ) of the stiffness element governing ankle torque was calculated for each subject by solving (1) using the non-perturbed ankle angle and torque information.

$$T_w = b_a \dot{\theta}_w + k_a (\theta_w - \theta_0) \quad (1)$$

The mechanical energetics of the ankle can be represented as a combination of energy storage and return ( $W_S$ ), and work due to displacement of the equilibrium position ( $W_D$ ). These contributions are estimated using numerical integration of (2) and (3) respectively, and their sum defines total ankle work.

$$W_S = \int k_a (\theta_w) d(\theta_w - \theta_0) \quad (2)$$

$$W_D = \int T d\theta_0 \quad (3)$$

## RESULTS

The second-order model comprised of stiffness, damping, and inertia accurately characterized ankle mechanics during late stance phase (variance accounted for =  $90 \pm 7.7\%$ ).

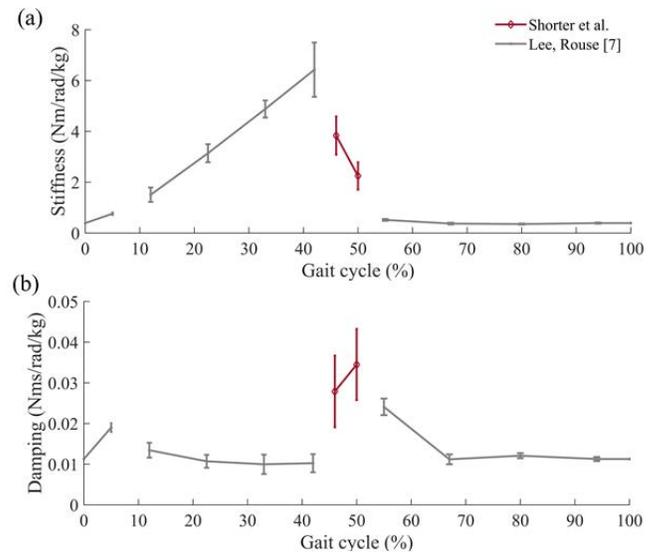

The stiffness component of impedance decreased linearly throughout late stance from  $3.84 \text{ Nm/rad/kg}$  to  $2.25 \text{ Nm/rad/kg}$ . Mean damping estimates during late stance were found to be relatively constant around  $0.03 \text{ Nms/rad/kg}$ . Mean ankle-foot inertia values were consistent across time points and matched previously reported values during gait [7].

The results of the equilibrium position analysis show equilibrium position to increase linearly from  $0.2$  to  $0.4 \pm 0.06$  radians in late stance. Using (2) and (3), spring work and displacement of equilibrium position contributions were found to be  $45 \pm 4\%$  and  $17 \pm 1\%$  of total work respectively.

## DISCUSSION

Stiffness decreased from values reported pre-heel rise to the relatively low stiffness found during swing phase [7] (Fig. 1). Furthermore, damping estimates increased during late stance when compared to damping values found in early and mid-stance (Fig 1). These findings are in agreement with previously reported work showing increased damping in preparation for toe-off [5].

Comparing ankle work throughout the gait cycle, there are observable differences in system energy.

**Fig. 1:** Body weight normalized ankle stiffness (a) and damping (b) reported across the gait cycle modified from [7]. Red indicates average results across perturbation direction during late stance.

In early-mid stance equilibrium position has been shown to be constant, indicating ankle work is entirely due to spring energy [1]. Work in early-mid stance was determined using reported stiffness and equilibrium angle estimates made previously using the platform robot [1]. Less than  $2.3 \pm 0.7\%$  of work done in early-mid stance is attributed to equilibrium angle position. These results contrast results of work done in late stance, wherespring work and work due to equilibrium angle displacement both added to total work ( $45\%$  and  $17\%$  respectively). The method by which energy is been added or removed changes throughout the gait cycle. Subsequent research is required to discern the neural control strategy behind changes in energetics.

## INTRODUCTION

Tracking tasks are commonly used in biomechanics and motor control research. Quantitative measures of these tasks often include tracking accuracy (e.g., error) and steadiness (e.g., variability). Such measures aid in determining task performance, which may aid in classifying or differentiating groups, but understanding where differences in control manifests is not possible. Applying control systems engineering and system identification techniques to understand the biomechanics and control of human systems is a possible solution. Such an approach typically involves a response (output) to an external stimulus (input), such as visual targets or external perturbations. These responses can then be modeled in a closed-loop system that incorporates biomechanical and neurophysiological parameters. Implementing such modeling techniques can be used to non-invasively estimate biomechanical and neurophysiological factors governing human movement.

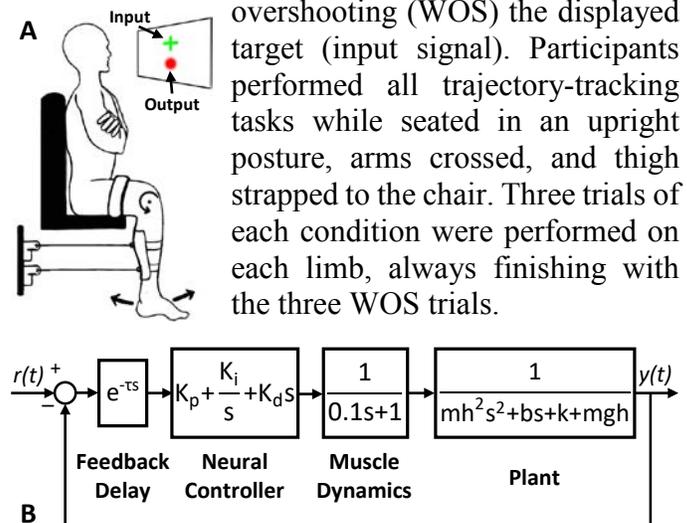

While trajectory-tracking tasks have been used to study impairments related to the lower extremity [1], [2], most studies do not employ a control systems approach. Therefore, the purpose of this study was to determine if changes in neurophysiological control parameters are identifiable during a knee trajectory-tracking task when given two distinct instructions. We hypothesized that differences in control parameters would exist between the two conditions, which would provide insight into the neurophysiological mechanisms associated with control of the knee.

## METHODS

Twenty-seven individuals (n=11 women, n=16 men) participated in this study. Michigan State

University's Biomedical and Health Institutional Review Board approved the research protocol. All participants signed an informed consent form.

For the knee trajectory-tracking tasks, participants were seated upright in a chair, with their knee positioned at 90 degrees. Their shank was instrumented with a lightweight bracket that allowed the attachment of two string potentiometers (model SM2, Measurement Specialties, Inc., Chatsworth, CA) to record angular position of the knee joint (**Figure 1A**). The knee trajectory-tracking input signal was comprised of 4 step inputs with amplitudes of either 2 degrees or 4 degrees and duration of 5 seconds each. The input signal was displayed on a computer monitor and participants were to respond to the step input by flexing and extending their knee joint. Two sets of instructions were provided: 1) perform the task as fast and accurate as possible (FAP), and 2) perform the task as fast and accurate as possible, but without overshooting (WOS) the displayed target (input signal). Participants performed all trajectory-tracking tasks while seated in an upright posture, arms crossed, and thigh strapped to the chair. Three trials of each condition were performed on each limb, always finishing with the three WOS trials.

**Figure 1:** A) Experimental setup. B) Block diagram representation of a closed-loop system where  $r(t)$  and  $y(t)$  are the input and output, respectively.

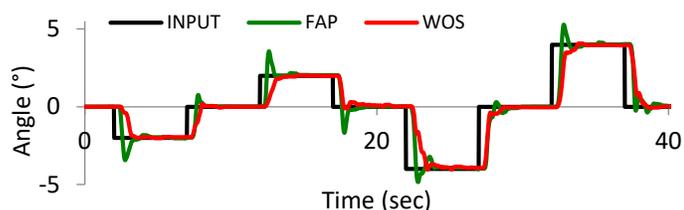

To determine differences in control parameters between the two conditions, the experiment was modeled as presented in **Figure 1B**. This model included a PID-controller to represent a neural controller [3], [4], muscle dynamics [4], [5], plant (simple pendulum with stiffness and damping [5], [6]), and feedback delay. PID-controller gains ( $K_p$ ,  $K_i$ ,  $K_d$ ) and feedback delay ( $\tau$ ) were estimated for each condition by nonlinear least squares. Each trial was divided into eight sections such that a section contained 1s before a step and 4s after that step. Thus, eight different parameter sets were estimated per trial and then averaged across trials and limbs.

Variance accounted for (VAF) was used to determine the quality of the modeled time-domain data fit to the experimental data (0-100%; where higher VAF indicates better model fit). Additional non-parametric variables (i.e., RMS error, delay time, rise time, % overshoot, and settling time) were calculated to characterize the recorded response (across trials and limbs). Paired t-tests were used to determine differences between conditions for both non-parametric and parametric variables. Statistical analyses were performed in SPSS (V.23, Armonk, NY) with a significance level set at  $p < 0.05$ .

## RESULTS AND DISCUSSION

The response of both tasks demonstrated second order behavior, where the FAP response exhibited characteristics of an underdamped second order system and the WOS response was similar to being critically damped or overdamped (**Figure 2**). The overall mean VAF for both conditions was 98.9% ( $\pm 1.2\%$ ), indicating excellent model fits.

All non-parametric variables were significantly different between FAP and WOS (**Table 1**). The neural controller gains and feedback delay were also significantly different between conditions (**Table 2**).

**Figure 2:** An example of the experimental time-series data for both FAP and WOS conditions.

**Table 1:** Calculated non-parametric variables.

	FAP	WOS	% Diff.	$p$ value
<b>RMSE (deg)</b>	0.019	0.020	4.35	<0.001
<b>Delay Time (s)</b>	0.387	0.412	6.70	<0.001
<b>Rise Time (s)</b>	0.375	0.571	52.5	<0.001
<b>Overshoot (%)</b>	30.9	11.2	-63.8	<0.001
<b>Settling Time (s)</b>	3.017	2.900	-3.89	0.025

**Table 2:** Parametric estimates of gains and delay.

	FAP	WOS	% Diff.	$p$ value
<b><math>K_p</math></b>	7.94	5.33	-32.7	<0.001
<b><math>K_i</math></b>	43.49	31.38	-27.8	<0.001
<b><math>K_d</math></b>	0.459	0.211	-53.9	<0.001
<b><math>\tau</math> (s)</b>	0.352	0.366	3.84	<0.001

It is clear from both non-parametric and parametric analyses that individuals were able to alter the control of their knee for the two conditions. In particular, FAP showed improved performance (i.e., shorter delay and rise times) by an aggressive controller (i.e., higher  $K_p$  and  $K_i$ ), while WOS provides improved relative stability (i.e., smaller overshoot) by a less aggressive controller (i.e., lower  $K_p$  and  $K_i$ ). Identifying changes in gains and feedback delays of knee control is consistent with modeling of other body regions, though research considering the response to other inputs is needed.

## CONCLUSIONS

Control of the knee is influenced by task instruction. Neural controller parameters (gains, delays) can be identified using a control systems approach.

## INTRODUCTION

Implanted neuroprostheses utilizing functional neuromuscular stimulation can restore standing function after paralysis due to spinal cord injury (SCI) by supplying constant open-loop (OL) stimulation to the trunk, hip, and knee extensors [1]. With these systems, users are unable to set a task-specific posture to prepare for a functional activity. To address this issue, we developed the posture follower controller (PFC). It is a closed-loop control system that continuously modulates muscle activation according to changes in the projection of whole-body center of mass (CoM) on the base of support. The objective of this study was to implement and assess the performance of the PFC experimentally with one recipient of an implanted neuroprosthesis. For proof-of-concept, center of pressure (CoP), which can be readily obtained from force plate data in the laboratory, was used as a surrogate for CoM as the feedback signal. We hypothesize that the UE load exerted as the user moves from one posture to another with the PFC will be the same as the UE load exerted with OL stimulation.

## METHODS

A 60 year-old male with T4 paraplegia (AIS B) participated in the experiments. At the time of testing, he was approximately 216 cm tall and weighed 63.5 kg. He was well conditioned and actively using a 24 channel surgically implanted neuroprosthesis for standing and exercise at home at the time of data collection. The muscles targeted by the implanted system for standing included: gluteus maximus, semimembranosus, and vastus lateralis. Prior to participating in the experiments, the subject signed informed consent forms approved by the

Institutional Review Board of the Louis Stokes Cleveland Veterans Affairs Medical Center.

As the user adjusted from a nominal erect posture, the controller continuously tracked CoP location and proportionately modulated stimulation, according to the change in CoP location, to the bilateral gluteus medius, posterior portion of the adductor magnus, and gastrocnemius. Activation to the muscles the subject required for standing was not modulated. The controller was tuned over the course of several sessions in the laboratory, prior to experimental evaluation with the subject.

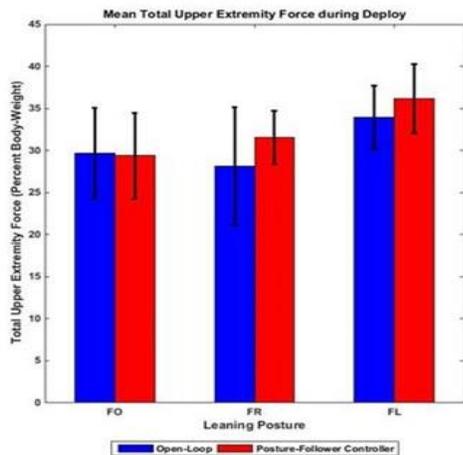

The subject stood erect on force plates (AMTI, Watertown, MA) within a custom walker (80/20, Columbia City, IN) instrumented with load cells to measure hand reaction forces (AMTI). Using visual feedback, he adjusted his resultant CoP to targets located at the extremes of his standing workspace in the forward (FO), forward-right (FR), and forward-left (FL) directions. As the subject adjusted posture, UE force and CoP location were recorded. A total of 12 cycles of movement were collected, in random order, for each leaning posture and control system. To compare standing performance with the PFC to OL control, the mean total resultant UE forces were computed for the deploy phase of each leaning posture. Statistical differences were assessed by applying t-tests at significance level 0.05.

## RESULTS AND DISCUSSION

The PFC did not negatively impact leaning performance over OL standing. No significant differences between the UE loads exerted with OL stimulation and the PFC were observed for any of the leaning postures. The mean total resultant UE forces exerted while the subject adjusted posture with both control systems, represented as a

percentage of the subject's body-weight (BW), are displayed in **Figure 1**.

For postural adjustments in the FO direction, the mean total resultant UE load exerted with OL stimulation was  $29.6 (\pm 5.4)$  % BW and  $29.4 (\pm 5.1)$  % BW with the PFC. When the subject adjusted posture in the FR direction, the mean total resultant UE load exerted was  $28.1 (\pm 7.0)$  % BW with OL stimulation and  $31.6 (\pm 3.1)$  % BW with the PFC. For postural adjustments in the FL direction, the mean total resultant UE loads exerted with OL stimulation was  $34.0 (\pm 3.8)$  % BW and  $36.2 (\pm 4.1)$  % BW with the PFC. These represent mean changes in UE load of 1%, 12% and 2% for FO, FR and FL, respectively.

**Figure 1:** Mean total resultant UE forces exerted as the subject adjusted posture with OL stimulation and PFC for the deploy phase.

While the mean total UE loads were not different across controllers, they were nominal in all cases and typically less than 30% BW on average. Changes in UE exertion with the PFC from already small OL values may be difficult to detect with such a small sample and effect size, particularly since the metric was averaged across the deploy phase of the movement from baseline to target. Comparisons instantaneously on a sample-by-sample basis of OL and PFC conditions, peak values during the movement, or root-mean-squared tracking errors on the trajectories from baseline to target may be more sensitive measures. Furthermore, UE effort may be under-estimated in the OL trials since the plantar flexor muscles were not active and the subject did

not have to actively work against them during forward or diagonal leans. Moreover, the UE effort may be over-estimated in the PFC trials since the plantar flexor muscles were at maximum activation as the subject approached the extremes of his standing workspace. It is possible that the plantar flexor muscles pushed the subject backwards as he approached the targets. Working against the active muscles, he pushed down on the walker.

Future investigations will entail the collection and analysis of repeated measures with additional subjects. In these experiments, the location of the targets and the maximum plantar flexor activation will be reduced. As posture is adjusted, the direction of the individual UE forces exerted will be assessed as well. Also, both deploy and return phases of the movement will be explored, along with the additional measures listed above. Subjective measures of user preference, ease of use and safety will also be acquired.

## CONCLUSIONS

The PFC, an advanced control system designed to allow a neuroprosthesis user to change standing posture was implemented and evaluated with an individual with SCI. Standing performance in terms of UE effort to change posture with the PFC was compared to that with an OL control system. Preliminary results suggest that standing performance with the PFC is similar to OL control. Such advanced control systems may enable neuroprosthesis recipients to adopt task-dependent, user-specified postures at those new set-points to reach and manipulate objects in their standing workspace.

## INTRODUCTION

There exist analytical formulations for the transmission of muscle force to endpoint force in tendon-driven limbs, and how it changes nonlinearly with posture [1]. However, how this information is encoded by the nervous system to control limbs remains unknown. The neuroscience literature proposes neural control based both on deterministic (e.g., internal models, optimal control, synergies, etc) and probabilistic (e.g., Bayesian) models of limb physics and environment. To evaluate the neuromechanical advantages of probabilistic control, we characterized the statistical structure of the transmission of muscle forces for multiple postures of a tendon-driven mechanical finger.

## METHODS

We firmly connected the index fingertip of a Utah/M.I.T hand [2] to a 6-DOF load cell to produce static forces (Fig 1). The load cell was affixed to the endpoint of an AdeptSix300 robot that was moved to change finger posture. Seven index finger tendons were actuated by DC brushless motors [3], routed through pulleys.

The robot moved the limb endpoint to 100 randomly selected endpoint postures on an arc (Fig 2). At each posture, the motors applied 100 force combinations across tendons uniformly at random (spanning 3 to 12N range). The duration of each trial was 0.8s— sufficient for forces to settle. We sampled fingertip and tendon forces at 1kHz.

**Figure 1:** Forces at the tip of the mechanical finger were recorded as motors produced known tendon forces, at different postures. The resulting endpoint force vectors (red) were described in spherical coordinates ( $\rho$ ,  $\theta$ ,  $\phi$ ) in the common frame of reference of the fingertip and sensor.

We calculated the force steady-state of each trial by averaging the last 0.2s. For each posture, we identified the linear static  $3 \times 7$  model ( $A^i$ ) that transforms tendon tensions to endpoint forces using linear regression:

$$\begin{bmatrix} F_x^i(1) & F_y^i(1) & F_z^i(1) \\ \vdots & \ddots & \vdots \\ F_x^i(100) & F_y^i(100) & F_z^i(100) \end{bmatrix} = \begin{bmatrix} F_{m_1}^i(1) & \cdots & F_{m_7}^i(1) \\ \vdots & \ddots & \vdots \\ F_{m_1}^i(100) & \cdots & F_{m_7}^i(100) \end{bmatrix} A^i$$

$$A^i = \begin{bmatrix} a_{m_1,x}^i & a_{m_1,y}^i & a_{m_1,z}^i \\ \vdots & \vdots & \vdots \\ a_{m_7,x}^i & a_{m_7,y}^i & a_{m_7,z}^i \end{bmatrix} = [A_{m_1}^i \cdots A_{m_7}^i]^T$$

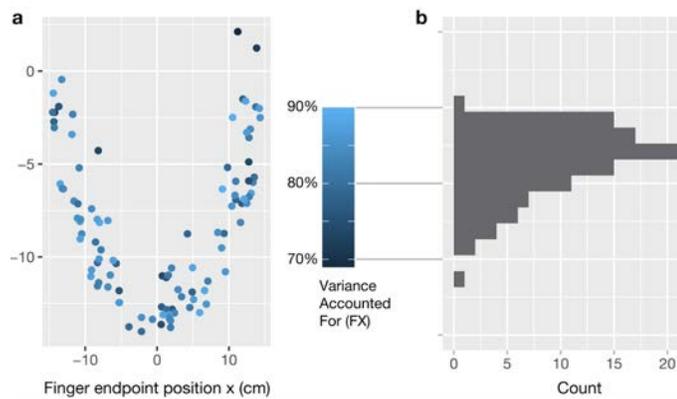

Note this mapping does not consider torques at the endpoint of the finger [1] and serves as a worst-case scenario for model performance.

## RESULTS AND DISCUSSION

For all individual postures, a linear model  $A^i$ , accurately predicted endpoint force as a function of tendon forces, (i.e., high percentage of variance-accounted-for, %VAF, Fig 2). In addition, the negligible residual error did not have a structure

across posture (Fig 2a).

As could be expected given the nonlinear changes in the finger's Jacobian [1], posture had a profound effect on the  $A^i$  matrices that map tension to endpoint force. Interestingly, the effect of posture in fingertip force strength ( $\rho$ , in N) and direction differed widely across muscles. While  $m_2$  had a consistent  $\rho$  across all postures,  $m_3$  had higher variability (Fig 3, left). As for direction,  $m_2$ 's direction in the  $zy$  plane ( $\phi$ ) was consistent across postures— $m_3$  was more variable (Fig 3, right).

**Figure 2:** For each of 100 postures, the color in (a) represents how each  $A^i$  matrix predicts endpoint force in the  $x$  direction (FX), while (b) shows the performance histogram across all postures.

We conclude that linear models (i.e.,  $A^i$  matrices) do not perform uniformly well across postures. Yet

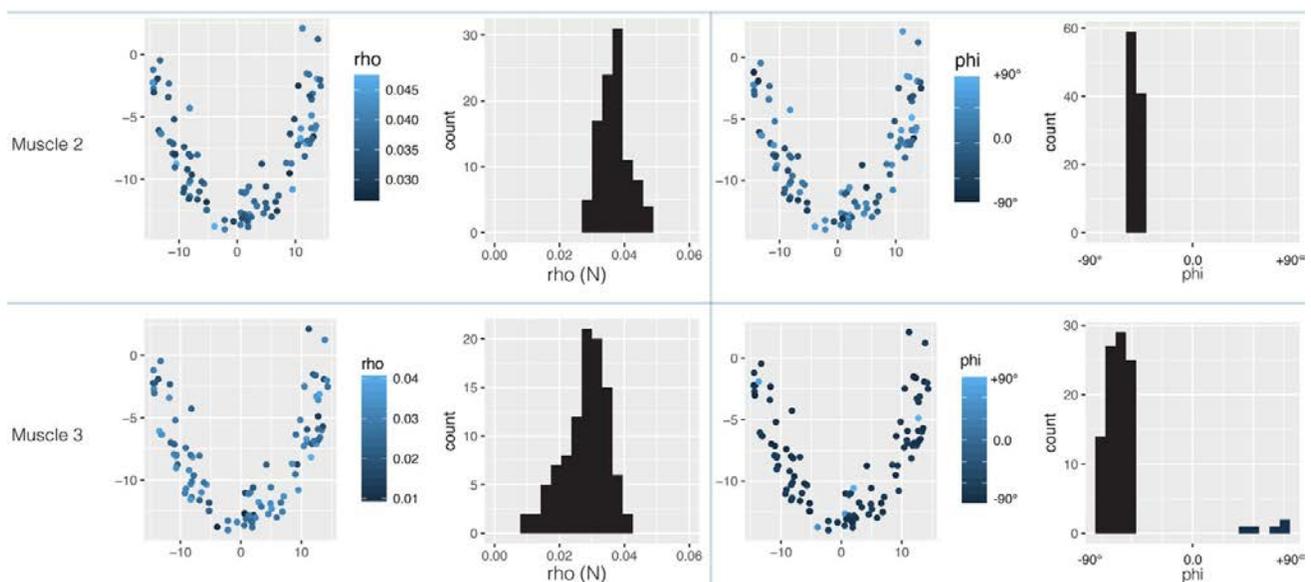

effective neural control of tendon driven limbs should work well across the workspace [4]. Interestingly, our results suggest small changes in posture can lead to large changes in the mechanical actions of muscles—therefore  $A^i$  matrices likely do not generalize well across regions of the workspace. We speculate that the full mechanical output of the limb should be considered (i.e., endpoint torque output), and that exploration of the full workspace is preferable as interpolation will likely not work. Thus, the mechanical structure of the tendinous apparatus can influence motor learning. Moreover, disruption of learning or recall of these mappings can easily lead to motor pathologies.

# Reverse Engineering the Dynamics of Human Pursuit Strategies

<sup>1</sup>Dheepak Arumukhom Revi and <sup>1</sup>Manoj Srinivasan

<sup>1</sup>Mechanical and Aerospace Engineering, The Ohio State University

email: arumukhom-revi.1@osu.edu, srinivasan.88@osu.edu

## INTRODUCTION

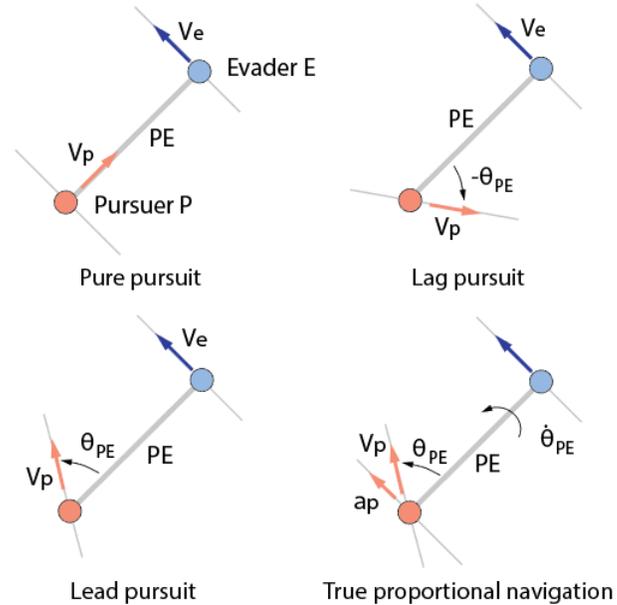

Pursuit and evasion are behavioral traits in many animals and often determines the likelihood of its survival in the wild. While most modern humans do not explicitly have to hunt or evade predators, it maybe that, pursuit and evasion strategies were invaluable during our evolutionary past and may still be inherent in guiding our dynamics. Here, we perform human subject experiments to characterize the control strategies used by a human pursuer to intercept a human evader. Understanding the behavioral dynamics of pursuit or evasion can be useful in a wide range of applications, from sports planning, to missile guidance control.

Military airplanes and missiles have long been using intercepting (pursuit) and maneuvering (evasion) strategies on the battlefield. The three most common types of pursuit maneuvers an airplane pilot can do to catch a target are: pure pursuit<sup>2,3</sup>, where the velocity vector of pursuer ( $\vec{V}_p$ ) is always directly aligned towards evader's velocity vector ( $\vec{V}_e$ ); lead pursuit<sup>2</sup>, where the  $\vec{V}_p$  is always directly ahead of the  $\vec{V}_e$  and lag pursuit<sup>2</sup>, where the  $\vec{V}_p$  is always directly behind the evader's velocity vector  $\vec{V}_e$ . Other common pursuit strategy used in homing missiles is true proportional navigation<sup>1</sup>, where the pursuer acceleration ( $\vec{a}_p$ ) is normal to the vector from pursuer to evader ( $PE$ ) and is made proportional to the rotation rate of the vector  $PE$  ( $\dot{\theta}_{PE}$ ) and the pursuer speed ( $|\vec{V}_p|$ ). All of the described strategies are illustrated in figure 1.

## METHODS

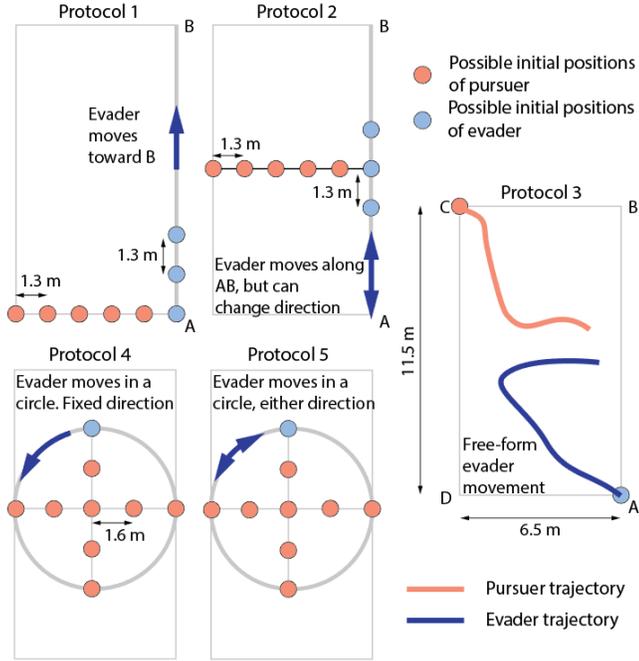

We recruited nine pairs of human subjects (6 male pair and 3 female pair between the ages of 20 -25) and assigned either the role of the pursuer or the evader. Each pair participated in five pursuit-evasion scenarios, differing only in how the evader is allowed to move: moving in a straight line (protocol 1), a circle (protocol 4), or free-form (protocol 3), and

being able to change direction or not (when on a straight line (protocol 2) or circle (protocol 5)), as illustrated in figure 2. In all experiments both pursuer and the evader knew each other constrains.

**Figure 1:** Intercept strategies that can be used by the pursuer during pursuit-evasion scenarios

For each of these protocols, we performed at least 10 trials, with the pursuer starting at different initial positions relative to the evader, presented to subjects in randomized order. In each trial, the pursuer is instructed to catch the evader as soon as possible, and the evader is instructed to avoid the pursuer for as long as possible. In all five protocols, the pursuer was allowed to move however they wished within room available. We used three video cameras to collect visual (video data) of the entire event from three different viewpoints. The raw data was processed using computer vision toolbox in Matlab to yield position data of the pursuer and the evader. We then computed the velocity and acceleration data using finite differencing, and smoothing the obtained derivatives to remove measurement noise. In total, each subject pair performed 102 or fewer trials, with an average number of trials at 78 trials and a standard deviation of 34 trials. Each trial on average was 2.6 sec with standard deviation of 1.2 sec.

**Figure 2:** Five different protocols with possible starting conditions of both pursuer and evader.

## RESULTS AND DISCUSSION

If we imagine that the pursuer is performing either pure, lead or lag pursuit, we can then examine this strategy using the angle between the pursuer velocity vector ( $\vec{V}_p$ ) and PE vector ( $\theta_{PE}$ ).

$$\theta_{PE} = \sin^{-1} \left( \frac{|\vec{PE} \times \vec{V}_p|}{|\vec{PE}| |\vec{V}_p|} \right) \frac{|\vec{V}_p \times \vec{V}_e|}{|\vec{V}_p| |\vec{V}_e|}$$

Using table 1, we see that as we decrease the constraints applied on the evader, i.e. from being bound to a line (P1, P2) or circle (P4, P5) to freeform (P3) the median theta value decreases. This means that if you constrain the evader and therefore make the evader more predictable, the pursuer will choose a lead strategy. Likewise, if the evader is not constrained (less predictable), the pursuer will choose a lag strategy. A formulation of the true proportional navigation strategy was poor at explaining the pursuer dynamics.

To explain the pursuer dynamics (i.e. pursuer speed ( $V_p$ ) and relative heading angle ( $\theta_{PE}$ )) we formulated

**Table 1:** Theta angle and  $R^2$  values of prescribed models

	Protocol 1	Protocol 2	Protocol 3	Protocol 4	Protocol 5
Theta Angle ( $^\circ$ )	$25.3 \pm 25.5$	$8.6 \pm 20.9$	$-3.0 \pm 23.1$	$22.0 \pm 26.7$	$19.0 \pm 28.3$
$R^2$ for pursuer speed model	0.630	0.352	0.345	0.436	0.307
$R^2$ for pursuer heading model	0.631	0.445	0.424	0.572	0.496

a model of the pursuer based on the motion of the evader (i.e. evader speed ( $V_e$ ) and evader relative heading angle ( $\beta_{PE}$ )) and the relative distance between the pursuer-evader ( $PE$ ).

$$V_p = \lambda_1 V_e + \lambda_2 PE + \lambda_3 PE^2 + \lambda_4$$

$$\theta_{PE} = \lambda_5 V_e + \lambda_6 PE + \lambda_7 \beta_{PE} + \lambda_8$$

where  $\lambda_1 \dots \lambda_8$  are constant coefficients.

The model when tested against the experimental data, yield  $R^2$  values as high as 0.631 (Protocol 1) and as low as 0.307 (Protocol 5). Higher order models with more terms and building models using a symbolic regression algorithm<sup>4</sup> yield a slightly better fit (with  $R^2$  at most increased by 0.156), but none of model is simple enough for the improvements in  $R^2$ .

## CONCLUSIONS

In conclusion, we have experimentally characterized the strategies used by humans in pursuing an evading target and compared our experimental data with few pursuit strategies. During pursuit, people use a combination of pure, lead and lag strategy to catch an evading target. The degree of this lead or lag pursuit versus pure pursuit seems to be based on how constrained or predictable the evader's motion is. We found that a simple model that depended linearly on evader speed and quadratic on the pursuer-evader distance explained at worst 31% and at best 63% of the variance in the pursuer speed. We also found that modeling the relative pursuer angle using a simple model that depended linearly on evader speed, pursuer-evader distance and relative evader angle explained at worst 42% and at best 63% of the variance in pursuer angle, depending on evader motion constraints.

# PREDICTION OF MUSCLE ACTIVATIONS FOR REACHING MOVEMENTS USING DEEP NEURAL NETWORKS

Najeeb Khan and Ian Stavness

University of Saskatchewan, Saskatoon, SK, Canada  
email: [ian.stavness@usask.ca](mailto:ian.stavness@usask.ca), web: <http://biglab.ca/>

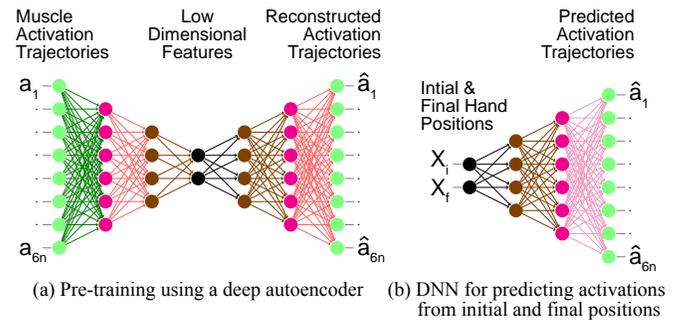

## INTRODUCTION

The motor control problem involves determining the time-varying muscle activation trajectories required to accomplish a given movement. Muscle redundancy makes motor control a challenging task: there are many possible activation trajectories that accomplish the same movement. Despite this redundancy, most movements are accomplished in highly stereotypical ways. For example, point-to-point reaching movements are almost universally performed with very similar smooth trajectories [1].

Optimization methods are commonly used to predict muscle forces for measured movements [2]. However, these approaches require computationally expensive simulations and are sensitive to the chosen optimality criteria and regularization. Linear dimensionality reduction has also been proposed to identify low-dimensional motor modules that can account for stereotyped movements [3]. However, musculoskeletal systems are highly non-linear, making linear methods less reliable.

Deep neural networks (DNNs) are biologically inspired models that can be employed for non-linear dimensionality reduction. Deep autoencoders are DNN models that can automatically learn successively low dimensional features by transforming the input data through different layers of non-linearity. DNNs have been used to predict torque trajectories from initial and final state information in [4]. However, DNNs have yet to be applied to predict time varying muscle activations, in which the redundancy problem exists.

In this work, we investigate deep autoencoders for the prediction of muscle activation trajectories for point-to-point reaching movements. We evaluate our DNN predictions with simulated reaches and two methods to generate the muscle activations:

**Figure 1:** A deep autoencoder is trained to learn low-dimensional features that are used to map initial and final hand positions to muscle activations.

inverse dynamics (ID) and optimal control (OC) criteria. We also investigate optimal network parameters and training criteria to improve the accuracy of the predictions.

## METHODS

*Simulated reaches:* Random initial points for the end-effector of a two-link, six-muscle arm [5] were uniformly sampled in a 50 cm x 20 cm rectangular region in the hand-space. A random direction was chosen for each initial point and a final point for the reaching movement was uniformly selected in that direction within 10 cm. The data set consisted of 4500 pairs of initial/final points for training and 500 pairs for testing.

*Inverse Dynamics:* The initial and final points were connected by a time sampled minimum-jerk trajectory with a duration of 1 second. A sampling rate of 50 samples per second was used for sampling the min-jerk path. For each of the points in the minimum-jerk trajectory a torque control vector was calculated by using inverse kinematics and inverse dynamics of the arm model. 300-dimensional muscle activations for the six muscles were computed by minimizing the quadratic norm of the activations under the target torque constraint.

**Optimal Control:** For each pair of initial/final points, 50-dimensional torque control signals were generated for each joint using the iterative Linear-Quadratic-Gaussian (iLQG) method [5]. Muscle activations were computed using static optimization with a quadratic cost.

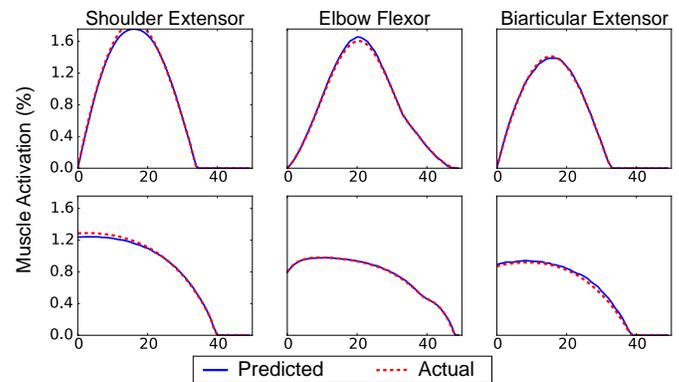

**Network Training:** For each control type, we trained an autoencoder with layer dimensions 300-150-50-4-50-150-300 (Figure 1a). Layer-wise pre-training [6] was used to train the network with the muscle activation trajectories as the inputs and outputs. The decoder part of the autoencoder (Figure 1b) with dimensions 4-50-150-300 was then retrained on the inputs as the initial/final end-effector positions, and outputs as the muscle activations. Both the networks were trained by minimizing the cross-entropy loss between predicted and desired output using the conjugate gradient descent method.

## RESULTS AND DISCUSSION

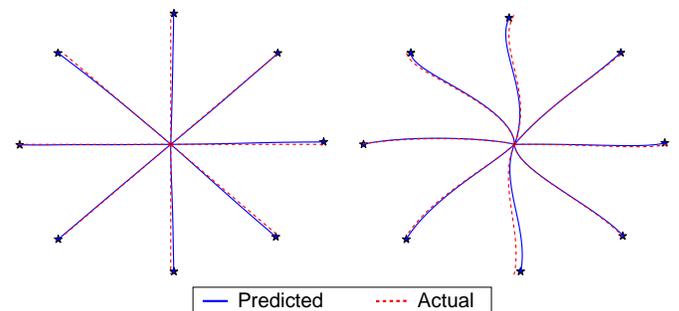

Muscle activations predicted with the DNN matched well with the actual trajectories for both the ID and OC conditions (Figure 2). RMS error in the activation trajectories was 0.0048 and 0.0067 for the ID and OC reaches, respectively.

Simulated hand trajectories, when the arm model is driven with DNN-predicted muscle activations, also matched well with the original hand trajectories (Figure 3). The average error in reaching the target was 0.125 cm and 0.127 cm for the ID and OC reaches, respectively.

Previously, DNNs for predicting joint torques used mean squared error (MSE) as the training criteria and canonical optimization for minimization [4]. We found that using cross entropy loss instead of MSE as the training criteria and using conjugate gradient descent for minimization with mini-batch training outperformed [4]. Even with the problem extended from torques to activations, our predictions resulted in an average endpoint error of 0.127 cm, whereas [4] reported an endpoint error of 0.347 cm. Also, we performed a comprehensive evaluation of our methods and reported our results with 500 samples as compared to only 14 in [4].

**Figure 2:** DNN predicted activations for 3 muscles for a reaching movement generated by inverse-dynamics (top) and optimal control (bottom).

**Figure 3:** Hand trajectories (from center outward) driven by DNN predicted activations for inverse-dynamics (left) and optimal control (right).

## SUMMARY

In this study, we demonstrated that with proper learning criteria and training methods, DNNs can accurately generate simulated muscle-driven reaches with both inverse-dynamics and optimal control based activation trajectories. Our work provides a proof of concept that DNNs can be used for more complex biomechanical models. As future work, we plan to investigate recurrent neural networks to model variable duration reaches.

# Hand-object Kinematics and Gaze Fixation During Bimanual Tasks

Alireza Haji Fathaliyan, Xiaoyu Wang, Sahn Bazargan, and Veronica J. Santos

University of California, Los Angeles, CA, USA

e-mail: [vjsantos@ucla.edu](mailto:vjsantos@ucla.edu) web: <http://BiomechatronicsLab.ucla.edu>

## INTRODUCTION

Many activities of daily living (ADL) involve bimanual tasks. Eye gaze fixations play a large role in gathering visual cues for successful task completion [1]. Prior research on coordination of upper extremities and eye gaze has been reported (e.g. [2]). However, much of this work has focused on unimanual grasp and manipulation. Many daily tasks involve bimanual grasping and bilateral manipulation which is the focus of this study. Few studies have precisely located gaze direction in 3D space or used pupillometry to parameterize the subject's attention shifts during daily tasks (e.g. [3]). The objective of this study is to investigate human hand-eye coordination and vision-based predictors of human intent by quantifying and characterizing spatiotemporal relationships between left- and right-hand palm positions and orientations, hand-object orientation, gaze fixation, and upper limb joint angles in bimanual tasks. The long term goals of this work are to identify kinematic and gaze-based indicators of human intent, and to identify underlying principles of bimanual manipulation.

## METHODS

According to a protocol approved by the UCLA Institutional Review Board, each subject is instructed to perform four bimanual tasks involving everyday objects and actions: lifting, opening, closing, screwing, unscrewing, stirring, scooping, pouring. Objects were selected from the benchmark Yale-CMU-Berkeley (YCB) Object Set: mug, pitcher, spoon, soft scrub bottle, coffee can, sponge, windex spray bottle. Each task is repeated four times; subjects were instructed to narrate their actions during two randomly chosen trials for a parallel study relating action to natural language.

Six T-Series cameras (Vicon, Culver City, CA) are used to track the motion of the objects and subjects' shoulders, upper arms, forearms, and palms (Figure 1). Object and palm kinematics are tracked so that hand-hand and hand-object interactions can be quantified. Subjects are instructed to wear an ETL-500 binocular, head-mounted eye tracker (ISCAN, Inc., Woburn, MA) that tracks subjects' point of regard (POR), pupil dilation, and saccades. 3D gaze vectors are reconstructed from the eye tracker data and combined with YCB object point clouds to produce 3D saliency maps for each object and task.

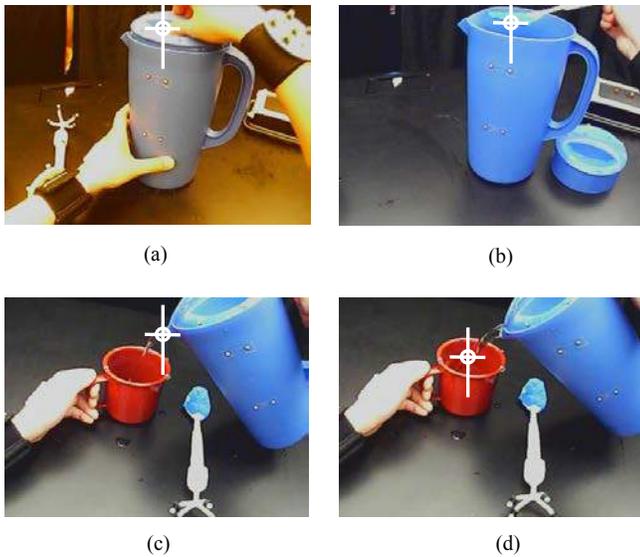

**Figure 1:** Experimental set-up with motion capture cameras, YCB objects, and subject wearing retro-reflective markers and an eye tracker.

## RESULTS AND DISCUSSION

Preliminary results are shown for the task of making a cup of instant coffee. Data collection for the present study is ongoing, and so data from a single representative subject (female, 23 yrs) are discussed here. Figure 2 shows a subject's point of regard overlaid on a screenshot from the head-mounted eye tracker webcam. In one experimental condition, the subject was instructed to remove the lid of a pitcher, transfer some of the liquid contents of the pitcher to a mug using a spoon, and then to pour from the pitcher into the mug. As expected, the subject fixated on different objects in the scene (pitcher in Fig. 2a, spoon in Fig. 2b), depending on the subtask. As we hypothesized based on a 2D gaze fixation

study [4], the subject fixated on different regions of the same object depending on the task. For instance, the subject fixated on the pitcher lid when the subtask was to remove the lid from the pitcher (Fig. 2a), but fixated on the pitcher spout when the subtask was to pour from the pitcher (Fig. 2c). Interestingly, it was noted that the subject repetitively alternated between the spout of the pitcher and the mug (Fig. 2c,d) during the pouring action.

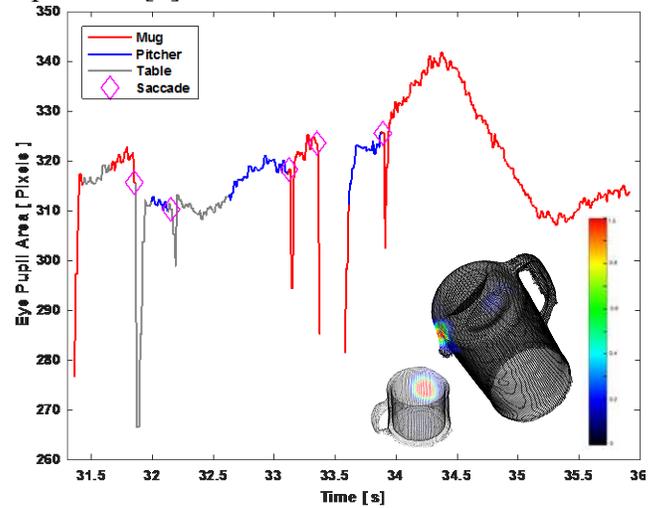

**Figure 2:** The subject's visual point of regard (white cross) is shown on objects during (a) removal of a pitcher lid, (b) transfer of a liquid via spoon, and (c,d) pouring of a liquid from a pitcher to a mug.

Figure 3 shows a subject's pupil area during the subtask of pouring from a pitcher to a mug. The color coded trajectory shows that the subject alternates between fixating on the pitcher and the mug as the liquid is carefully poured from one container to the other. Insets of 3D saliency maps show more specifically where the subject was looking (pitcher spout, inner surface of mug) and for how long (integrated over the pouring period).

Pupil dilation is an indicator of visual detection and attention shift. The saccades shown in Figure 3 occur either as the subject's attention shifts to a new object or to a different location on the same object. Pupil area increases prior to all saccades, which indicates the need for visual cues to proceed to next action such as: location of action-relevant objects

and their geometry features required for motor preparation [5].

**Figure 3:** A subject's pupil area is shown for the subtask of pouring. Different colors of the trajectory indicate whether the object of interest is the pitcher (blue) or mug (red). Magenta diamonds indicate saccades. 3D saliency maps indicate gaze fixation on the pitcher spout and inner surface of the mug.

Future work includes the completion of data collection, kinematic analyses of hand-hand and hand-object interactions, and the creation of population-based 3D saliency maps. 3D gaze fixation information, specifically which features of different objects are of interest, could be used to infer human intent. Inference of human intent could reduce the cognitive burden on teleoperators of complex robotic systems, and improve human-robot collaborations in the home, on the manufacturing line, or in high-risk environments.

# RELATIONSHIP BETWEEN RESIDUAL FORCE ENHANCEMENT AND MUSCLE FATIGUE

<sup>1,2,3</sup> Atsuki Fukutani, <sup>1</sup> Walter Herzog

## INTRODUCTION

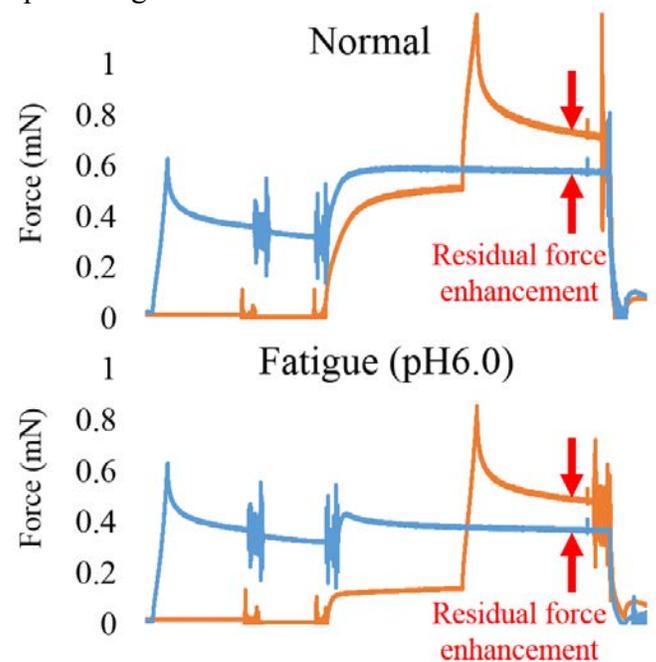

The steady-state, isometric muscle force attained after active stretch is larger than that attained in a purely isometric contraction at the corresponding muscle length. This property of skeletal muscle is referred to as residual force enhancement (RFE). At present, a primary factor thought to contribute to RFE is the modulation of titin elasticity by  $\text{Ca}^{2+}$  release and active stretch [1]. Muscle fatigue is associated with a decreasing force generating capability of muscle [2], possibly caused by a decreasing proportion of attached cross bridges and/or changes in the cross bridge kinetics.

Considering that RFE may be caused by a titin-based passive force, and is independent of the proportion of attached cross bridges, RFE may be preserved in muscle fatigue despite a decrease in force generating potential. We evaluated the magnitude of residual force enhancement in the non-fatigued and fatigued states, and hypothesized that the absolute magnitude of RFE is preserved in fatigue, and thus, the relative amount of RFE (normalized to the isometric reference force) is increased in fatigued compared to non-fatigued muscles.

## METHODS

Skinned fibers of rabbit psoas muscle (N=45) were used for all testing. Three experimental conditions were evaluated. For the first condition (N=15), muscle fatigue was mimicked by a low  $\text{Ca}^{2+}$  concentration (pCa6.0). For the second condition (N=15), muscle fatigue was produced using a low pH (pH6.0) level. For the third condition (N=15), muscle fatigue was induced by adding 20mM butanedione monoxime (BDM) to the activating solution. Typical examples of the experimental trials are shown in Figure 1. In the non-fatigued (Normal, upper panel

Figure 1) and fatigued (Fatigue, lower panel Figure 1) state, RFE trial (blue line) and Control trial (orange line) were conducted. The Normal state was always tested first. In the RFE trial, fibres were actively stretched from an average sarcomere length of 2.4  $\mu\text{m}$  to 3.0  $\mu\text{m}$  in 2 s. The isometric muscle force attained 15 s after the end of active stretching was used for analysis. Then, the control trial was conducted. Fibers were passively stretched from an average sarcomere length of 2.4  $\mu\text{m}$  to 3.0  $\mu\text{m}$  in 2 s. Then, fibers were activated isometrically at this length. This purely isometric force was used for analysis. After that, identical trials were conducted in the Fatigue state. The absolute magnitude of RFE was calculated by subtracting isometric force of the Control trial from that of the RFE trial. The relative RFE was obtained by expressing the absolute RFE as a percentage of the isometric Control force.

**Figure 1:** Example of force responses in the Normal (upper panel) and Fatigue states (lower panel). Blue traces represent Control trials and orange traces represent RFE trials.

## RESULTS AND DISCUSSION

Isometric muscle forces at 2.4  $\mu\text{m}$  in the Fatigue states were smaller by  $76 \pm 14\%$  for pCa6.0,  $54 \pm 7\%$  for pH6.0, and  $62 \pm 12\%$  for BDM20mM compared to those in the Normal states. These results indicate that we successfully reduced muscle forces, thereby mimicking Fatigue.

The absolute value for RFE was similar for Normal and Fatigue states using pH6.0 and BDM20mM. The relative value for RFE for these two conditions was significantly greater than that obtained for the Normal condition. For the pCa6.0 condition, the absolute and relative RFE were greater than the corresponding Normal values (Figure 2). The increase in absolute RFE in pCa6.0 compared to Normal cannot be explained with an increase in the proportion of attached cross-bridges, but might be caused by an increase in passive forces contributed by structural proteins, such as titin.

In the pCa6.0 condition, the decrease in force compared to the Normal conditions is caused by a decrease in the number of attached cross bridges without major effects on the cross bridge kinetics, which is similar to what happens in central fatigue. In contrast, in the low pH and BDM conditions, a

decrease in muscle force is caused primarily by changes to the cross bridge kinetics, which is similar to what is observed in peripheral fatigue. Thus, our findings may be transferable to the physiological conditions of central and peripheral fatigue.

## CONCLUSIONS

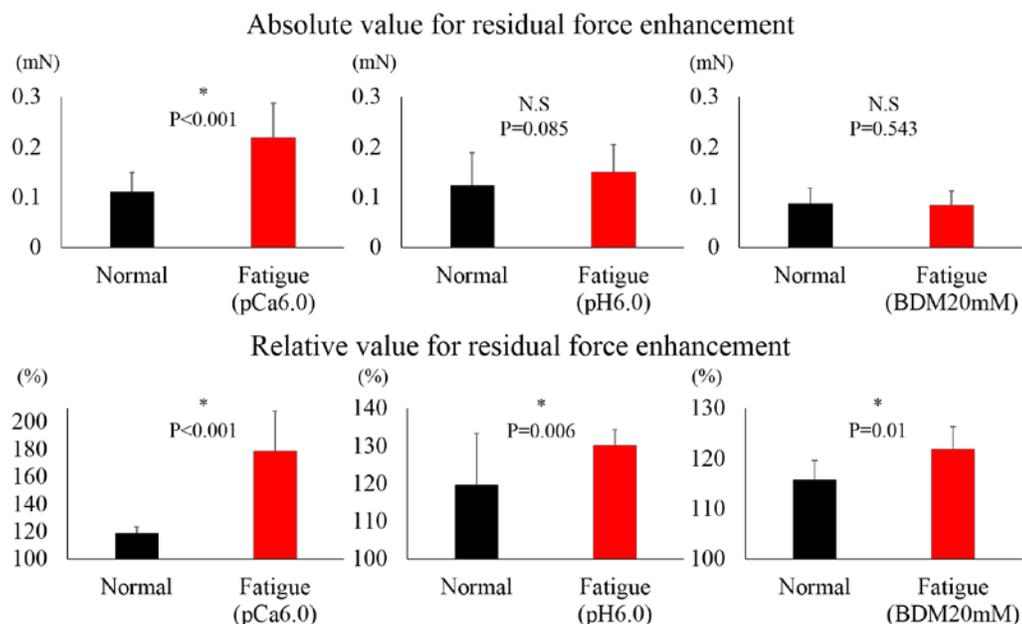

The absolute RFE in all fatigue states was similar to that in the non-fatigued muscle. This finding suggests that RFE may prevent excessive loss of force in fatigued muscles that undergo active stretching.

## INTRODUCTION

Tendon mechanical properties have been of great interest as a measure of tendon structure. In the context of tendon injury, animal studies investigating outcomes following Achilles tendon rupture have found tendon mechanical properties to be responsive to treatment strategy as well as levels of weight-bearing [1]. Quantification of tendon mechanical properties has presented a unique set of challenges, however. While methods involving voluntary contraction have been used to measure Young's modulus *in vivo*, the application of these techniques to an injured population has limitations. Specifically, decreased volitional recruitment of the triceps surae in comparison to the plantar flexors of the deep compartment of the lower leg may result in an overestimation of stress using these methodologies.

Continuous shear wave elastography is a non-invasive method to measure tendon shear modulus and viscosity that does not rely on voluntary contraction [2]. While this technique has been applied to injured tendons [2, 3] the relationship between tendon shear modulus and viscosity compared to *in vivo* methods of measuring Young's modulus has not been described. Therefore, the purpose of this study is to establish the relationship between tendon shear modulus and viscosity measured using cSWE, with Young's modulus.

## METHODS

Participants with healthy Achilles tendons were included in this study. Participants were excluded if they had recent Achilles tendon pain or signs of midportion tendinosis on B-mode ultrasound imaging. Participant's activity level was measured using the Physical Activity Scale [4]. Leg dominance

was determined as the participant's self-reported "kicking" leg. Only right lower extremities were examined.

Shear modulus and viscosity was measured using cSWE as previously described [2]. Strain was measured by measuring the peak displacement of the gastrocnemius myotendinous junction during an isometric contraction using B-mode ultrasound imaging. Stress was simultaneously measured using a KinCom dynamometer. For both cSWE, stress, and strain measurements, the subject was positioned in prone with the foot in four different angles – 20 degrees of plantar flexion, 10 degrees of plantar flexion, neutral (0 degrees of plantar flexion), and 10 degrees of dorsiflexion (-10). The position order was randomized for each participant, and participants were given a 2-minute walking break between positions. Tendon length was measured using extended field of view B-mode ultrasound imaging with the foot in a resting position. Tendon cross-sectional area was measured using B-mode ultrasound imaging with the Achilles tendon in short axis, at a point immediately distal to the soleus myotendinous junction. For all tendon mechanical property and B-mode measurements, the average of 3 trials was used in data analysis. Tendon moment arm was measured using a tape measure from the midpoint of the lateral malleolus to the most superficial aspect of the Achilles tendon.

Young's modulus was calculated as follows:

$$\left( \left( \frac{\tau}{MA} \right) (Lo) \right) / (A\Delta L)$$

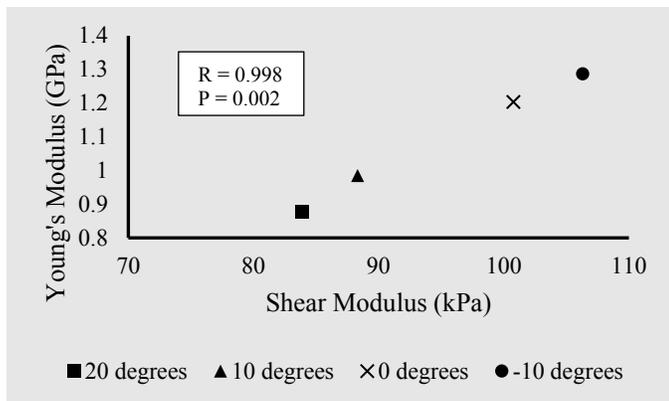

Where  $\tau$  is peak torque,  $MA$  is moment arm,  $Lo$  is tendon length from the calcaneal notch to the gastrocnemius myotendinous junction,  $A$  is cross-

sectional area, and  $\Delta L$  is the peak displacement of the gastrocnemius myotendinous junction.

Descriptive statistics were performed for all variables of interest. Pearson correlation analysis was used to determine the strength of the relationship between properties.

## RESULTS AND DISCUSSION

Five subjects are included in this preliminary analysis. Participants were a mean(SD) age of 20(1) years, weighed 58.4(9.6)kg and were a height of 1.66(0.08)m. Participant's activity level ranged from 4-6 on the 6-point Physical Activity Scale. The right lower extremity was the dominant leg in 4 participants. Mean(SD) Achilles tendon length to the gastrocnemius was 18.4(2.5)cm. Descriptive statistics for shear modulus, viscosity, and Young's modulus are listed in Table 1. A significant correlation was observed between viscosity and Young's modulus ( $R = 0.986$ ,  $p = 0.014$ ) as well as between shear modulus and Young's modulus (Figure 1).

**Figure 1:** Relationship between shear modulus (kPa) and Young's modulus (GPa) at 4 foot angles.

## CONCLUSIONS

The results of this study suggest that mechanical properties quantified using cSWE are strongly related to *in vivo* measurements of Young's modulus in healthy Achilles tendons. The findings of this study support the use of cSWE as an alternative measure that does not require a voluntary contraction of the triceps surae, which may be of interest when examining tendon healing in populations where muscle recruitment may be altered. The results of this study are limited by the small number of subjects.

## INTRODUCTION

Exercise-trained skeletal muscle shows a variety of adaptations when compared to sedentary muscle, including reduced active musculotendinous stiffness coupled with increased passive stiffness, and increased collagen turnover [1-3]. These tissue responses to mechanical stress undoubtedly protect muscle from the high demands of physical activity, though injuries still occur, leading to acute changes in stiffness and strength [4].

Shear wave elastography (SWE) is a quantitative and reliable measure of skeletal muscle stiffness [5,6], with notable applications in pediatric populations, aging, and a variety of pathologies. Despite its significant potential, SWE has yet to be utilized in sports medicine applications.

The purpose of this study was to establish baseline shear modulus values for healthy, exercise-trained hamstring muscles throughout normal range of motion.

## METHODS

27 healthy, exercise-trained individuals (11 males) participated in this study. The mean age was 32.3 years (range: 13-57 years). Inclusion criteria were: 1) healthy individuals over 13 years of age; 2) normal function of both legs; 3) at least 30 minutes of moderate to vigorous exercise at least 3 days per week. Exclusion criteria were history of: 1) hamstring muscle injury; 2) neuromuscular disease or stroke; 3) leg, ankle, or foot surgery; 4) statin medication within the past 6 months. All study procedures were approved by the Mayo Clinic Institutional Review Board (Rochester, MN). Prior to testing, all subjects completed a questionnaire

that included basic demographic information, as well as exercise frequency, intensity, and mode.

We collected SWE images of the biceps femoris long head and semitendinosus while subjects were in side-lying position with the hips flexed to 90° and the knee of the testing leg flexed 80°, 60°, and 30°. We acquired all ultrasound images using the SL10-2 linear array transducer on the Aixplorer (Supersonic Imagine, Aix-en-Provence, France) in SWE mode. Images were collected with the ultrasound transducer oriented parallel with the long axis of the muscle, using liberal coupling gel, and minimal pressure on the skin surface. Surface electromyography confirmed the muscles were relaxed throughout testing. Three SWE images were collected at each location for the three knee angles bilaterally, for a total of 36 SWE images per subject.

SWE images were analyzed in OsiriX (Pixmeo, Geneva, Switzerland) to obtain Young's modulus values for the largest possible high-quality region of interest (ROI) for each image (mean (SD) area: 204.2 mm<sup>2</sup> (3.24)). As muscle is anisotropic, we manually converted the mean Young's modulus ( $E$ ) values for each ROI back to shear modulus ( $G$ ) using Eq (1):

$$G = \frac{E}{2(1+\nu)} \quad (1)$$

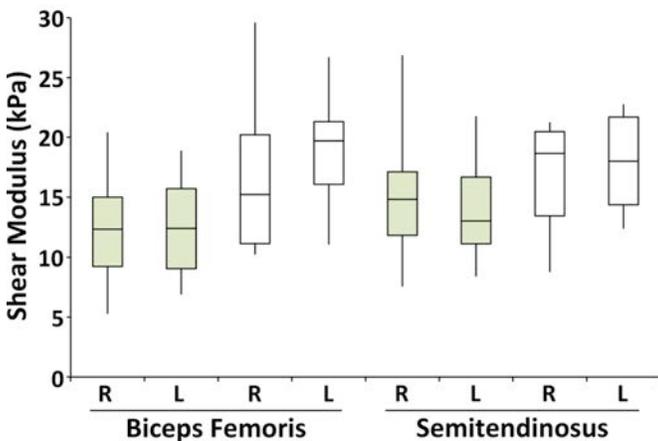

where  $G$  is shear modulus,  $E$  is Young's modulus, and where Poisson's ratio,  $\nu$  is very close to 0.5 if we assume the tissue is incompressible. For statistical analysis, we used the median shear modulus value from the set of three images at each knee angle.

We used a full-factorial repeated measures ANOVA (JMP, SAS Institute, Inc., Cary, USA) using sex and exercise frequency as within-subjects factors; muscle and knee angle were between-subjects factors; shear modulus was the response variable.

## RESULTS AND DISCUSSION

Of the 27 subjects, 9 self-reported exercising at a vigorous intensity 3-4 times per week; 18 reported participating in such activities 5 or more times per week. Mean biceps femoris shear modulus values by decade are provided in Table 1.

Full-factorial repeated measures analysis revealed a significant effect for knee angle; Tukey post-hoc analyses found shear modulus values for each knee angle were significantly different. We also found a

**Figure 1:** Shear modulus values for 30° knee flexion. Green indicates subgroup exercising 5 times or more per week; white indicates subgroup exercising 3-4 times per week. R: right leg; L: left leg.

**Table 1.** Shear modulus values for biceps femoris across age groups. Shear modulus given in kPa, displayed as mean (standard deviation). *n*: number of subjects in each age group; R: right leg; L: left leg.

Ages	<i>n</i> (males)	80° knee flexion		60° knee flexion		30° knee flexion	
		R	L	R	L	R	L
13-19	4 (0)	5.8 (1.8)	5.7 (1.3)	8.3 (1.8)	7.0 (1.4)	12.5 (2.8)	13.3 (3.6)
20-29	9 (4)	5.2 (1.1)	5.7 (1.4)	6.9 (2.0)	7.6 (1.2)	13.4 (3.7)	14.3 (4.4)
30-39	6 (2)	5.3 (1.5)	5.0 (0.9)	8.2 (2.7)	7.7 (1.8)	14.8 (7.7)	16.5 (6.5)
40-49	4 (3)	5.4 (1.4)	5.5 (1.5)	7.7 (1.9)	8.7 (2.1)	15.0 (4.8)	16.3 (2.8)
50-59	4 (2)	5.4 (2.3)	5.0 (1.1)	7.2 (2.5)	6.5 (1.1)	12.1 (5.0)	11.7 (3.0)

significant interaction for exercise frequency and knee angle, with significantly lower shear modulus values at 30° knee flexion for the more frequent exercise group when compared to those exercising 3-4 times per week. Mean shear modulus values by exercise group are shown in Figure 1.

## CONCLUSIONS

As expected, shear modulus varied significantly with knee angle. The most notable study population differences emerged at greater muscle lengths, as with previous investigations of SWE [7].

Study limitations include a relatively small sample size of subjects across a range of ages, with a variety of training regimens.

SWE demonstrates significant potential for evaluating exercise-trained skeletal muscle. Further work should evaluate shear modulus response to a variety of modalities, including stretch, endurance, and strength training, as well as response to injury.

# Shortening-induced force depression is modulated in a time- and speed-dependent manner following a stretch-shortening cycle

<sup>1</sup> Rafael Fortuna, <sup>2</sup> Martin Groeber, <sup>2</sup> Wolfgang Seiberl, <sup>3</sup> Geoffrey A. Power, and <sup>1</sup> Walter Herzog

<sup>3</sup> University of Guelph, Ontario, Canada

## INTRODUCTION

Steady-state isometric force following an active shortening or lengthening contraction is smaller (force depression; FD) or greater (residual force enhancement; RFE) compared to a purely isometric contraction at the corresponding muscle length and same level of activation<sup>1</sup>. Despite muscles undergoing stretch-shortening cycles (SSC) on a regular basis, few studies have investigated the effects SSC on FD and RFE.

It has been shown that stretch preceding shortening does not affect the resulting FD<sup>2</sup>, while recent evidence suggests it might<sup>3</sup>. We hypothesized from the results of these initial studies that stretch might affect force depression in a time-dependent manner, and that the effects of stretch on FD disappear if sufficient time is given between the end of stretching and the end of shortening in SSC.

Therefore, the purpose of the present study was to perform SSC where the time between the end of stretch and the end of shortening was manipulated by (i) adding a pause between the stretch and shortening phases and (ii) by performing the shortening contractions at different speeds.

## METHODS

Subjects: Sixteen healthy subjects (8 male and 8 female; 25±2 years; 170±9 cm; 67±8 kg) participated in protocol 1, and 15 subjects (6 male and 9 female; 26±4 years; 173±7 cm; 69±9 kg) participated in protocol 2.

Experimental setup: Thumb adduction forces and carpometacarpal angular displacements were

measured using a custom-designed dynamometer, with 0° defined as the highest degree of thumb adduction. The Ulnar nerve was electrically stimulated (50 Hz) to evoke 50-60% of the maximum voluntary contraction (MVC) of the adductor pollicis muscle for 7s.

Protocol 1: For FD, the muscle was held isometrically for 1s at 30°, followed by 1s of shortening over a 30° joint excursion at 30°/s. The muscle was then held isometrically at 0° for 5s. Following FD, a purely isometric reference contraction was performed at 0° for 7s.

For the SSCs, the muscle was held isometrically for 1s at 0° and stretched to 30°. Following stretching, the muscle was either immediately shortened back to 0° at 30°/s (SSC\_0s), held isometrically for 0.5s (SSC\_0.5s) then shortened back to 0°, or held isometrically for 1s (SSC\_1s) then shortened back to 0°. Following shortening, muscles were held isometrically at 0° for 4, 3.5, and 3s, respectively for a total stimulation time of 7s for all conditions (protocol 1).

Protocol 2: FD was performed in a similar manner as in protocol 1. For SSCs, the muscle was held isometrically for 1s at 0° and stretched to 30° joint excursion at 30°/s. Following stretching, the muscle was shortened immediately to 0° at either 15°/s (SSC\_15°/s), 20°/s (SSC\_20°/s), 30°/s (SSC\_30°/s), and 60°/s (SSC\_60°/s) and held isometrically at 0° for 3, 3.5, 4, and 4.5s, respectively for a total stimulation time of 7s for all conditions.

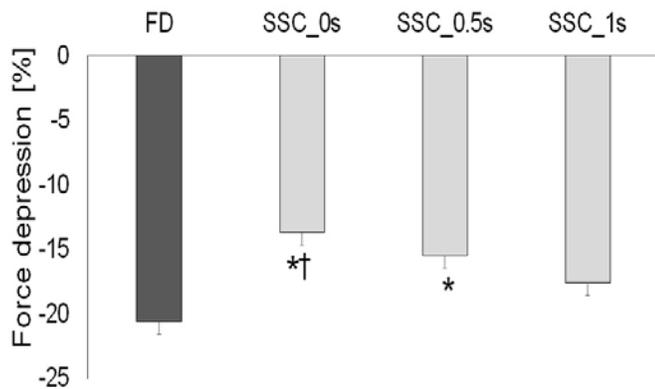

Following SSCs, a 7s isometric reference contraction and a MVC at a thumb adduction angle of 0° was performed.

A one-way ANOVA was used to test for differences between mean steady-state isometric forces following SSCs ( $\alpha=0.05$ ).

## RESULTS AND DISCUSSION

The mean electrically evoked isometric contraction force at a  $0^\circ$  thumb adduction angle was 52% of the MVC force.

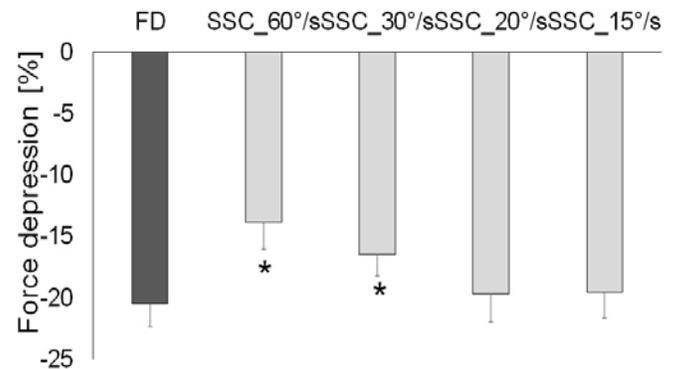

Protocol 1: The steady-state isometric force was significantly depressed ( $20.6\pm6.6\%$ ) following active shortening (FD) compared to the isometric reference contraction at the corresponding thumb angle and same level of activation. For the SSCs, force depression was significantly smaller for SSC\_0s and SSC\_0.5s compared to the pure FD conditions ( $13.7\pm7.4\%$  and  $15.5\pm2.9\%$ , respectively), while force depression for SSC\_1s ( $17.6\pm6.1\%$  force depression) was not statistically different from the pure shortening (FD) contractions (Fig. 1).

**Figure 1:** Mean ( $\pm$ SEM) values of force depression for a pure shortening contraction (FD) and for the contractions involving SSCs with 0, 0.5, and 1s interval between the stretching and the shortening phase. Force depression is normalized relative to the reference isometric contraction at the corresponding angle. (\* compared to FD; † compared to SSC\_1s).

Protocol 2: The steady-state isometric force was significantly depressed by  $20.3\pm1.4\%$  following active shortening (FD) compared to the isometric

reference contractions at the corresponding thumb angle and same level of activation. Force depression in SSC\_60°/s and SSC\_30°/s was significantly reduced compared to the pure FD condition ( $13.2\pm1.3\%$  and  $16.8\pm1.2\%$ , respectively), while FD for SSC\_20°/s and SSC\_15°/s ( $19.6\pm2.1\%$  and  $20.3\pm1.5\%$ ) were similar to the pure FD values (Fig. 2).

**Figure 2:** Mean ( $\pm$ SEM) values of force depression for the pure shortening contraction (FD) and for the SSCs with the shortening speeds of 60, 30, 20, and  $15^\circ$ /s. Shortening in all cases followed stretching without a pause (\* compared to FD).

## CONCLUSIONS

The results of this study support our hypothesis that stretch preceding shortening affects FD in a time-dependent manner. Given sufficient time between the end of stretching and the end of shortening, the effect of stretch on FD is eliminated. This finding provides crucial new information on the potential mechanisms of RFE and FD, as the events occurring during active muscle stretching either inhibit full development of force depression or offset FD in some hitherto unknown manner.

# FINITE ELEMENT ANALYSIS OF INTRAMUSCULAR PRESSURE IN THE HUMAN TIBIALIS ANTERIOR

<sup>1</sup> Benjamin Wheatley, <sup>2</sup> Gregory Odegard, <sup>3</sup> Kenton Kaufman, <sup>1</sup> Tammy Haut Donahue

<sup>1</sup> Colorado State University, Fort Collins, CO

## INTRODUCTION

The strong correlation between muscle force and intramuscular pressure (IMP) provides an opportunity to utilize IMP for measurement of muscle force *in vivo*. However, proper implementation of a pressure microsensor to measure IMP requires knowledge of pressure distributions within the muscle.

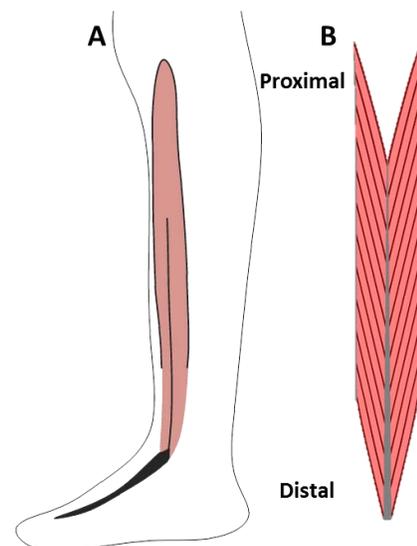

Finite element analysis has been previously used to study IMP under passive stretch conditions in an animal model [1]. However, the force-pressure relationship under contractile conditions in humans is of clinical interest, particularly under sub-maximal contraction levels where gait and locomotion typically occur. Thus, there are three primary goals of this work: 1) investigate potential causes for regional variability of intramuscular pressure with muscle, 2) identify the region of minimal IMP gradient, and 3) model the IMP-force relationship in sub-maximally contracting skeletal muscle.

## METHODS

Eight (n=8) healthy young adults were recruited for simultaneous force-IMP measurements in the human tibialis anterior under isometric activation [2]. Each subject performed isometric contractions to 50% maximum voluntary contraction (MVC) at a rate of 10% per second over fifteen trials.

A previously validated hyper-visco-poroelastic constitutive approach for skeletal muscle [1] was implemented within a finite element model of an idealized human tibialis anterior (Figure 1). To study variability of intramuscular pressure, four different muscle lengths and two different specific tension values were utilized (8.5 and 15.5 N/cm<sup>2</sup>)

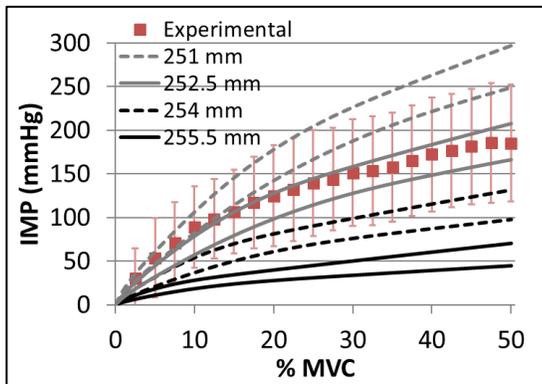

based on previously published literature data [3-5]. Muscle lengths of 255.5, 254, 252.5, and 251 mm were simulated by applying boundary conditions to the un-deformed model length of 260 mm and contraction level was scaled to 50%.

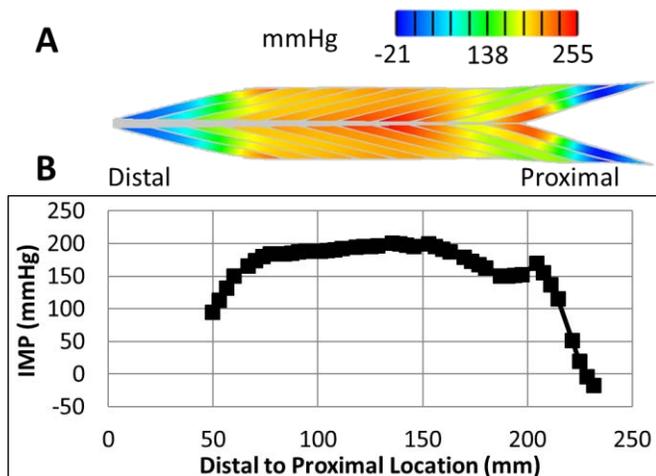

**Figure 1:** A) Drawing of bipennate human tibialis anterior. B) Idealized finite element model.

## RESULTS AND DISCUSSION

Fluid pressure in the finite element model showed a nonlinear increase as a function of contraction level (Figure 2) similar to experimental data. Statistical agreement between model and experimental data ranged from less than 7% normalized root mean square error (NRMSE) to 95% NRMSE for individual pressure-contraction curves. Both muscle length and specific tension affected model fluid pressure (Figure 2). Predicted fluid pressure distribution within the model showed the highest IMP gradients at the distal and proximal regions through a color map (Figure 3A) and graphical analysis (Figure 3B).

**Figure 2:** Experimental data ( $\pm$  standard error bars) and model outputs as a function of muscle length (shown in legend) and specific tension (top and bottom curves for 7.75 and 4.25 N/cm<sup>2</sup>, respectively).

**Figure 3:** A) Color map of model fluid pressure shows high gradients in the distal and proximal regions. B) This is confirmed by plotting pressure values as a function of distal to proximal location.

The data presented in Figures 2 and 3 provide insight into possible contributions to the variability of IMP measurements *in vivo*. While the correlation between muscle force and IMP is strong, variations in relative IMP can make muscle force estimations from multiple patients and muscles more challenging *in vivo*. The model results suggest that fluid pressurization increases as isometric muscle length decreases. While specific tension also yielded changes in pressurization, it appeared to play less of a role than length. Understanding the mechanisms which contribute to IMP allow for

greater confidence in interpreting muscle force through these measurements.

The modeling results also suggest use of pressure microsensors to measure IMP in the muscle midbelly, away from the large pressure gradients observed in the distal and proximal regions (Figure 3). Sensor insertion into regions of high pressure gradients would also contribute to variability of IMP measurements and thus yield inconsistent data.

This work presents the first finite element model of skeletal muscle to study intramuscular pressure at submaximal conditions. The nonlinear pressure-contraction shape observed within the model agreed with the overall shape of experimental data (Figure 2). Specifically, this nonlinear shape showed decreases in change in pressure with increases in contraction. The pressure values at 25% MVC were  $\sim$ 150 mmHg, while the values at 50% MVC were only  $\sim$ 200 mmHg. This further supports the accuracy of this modeling approach in studying intramuscular pressure.

## CONCLUSIONS

This work utilized finite element analysis to study intramuscular pressure in the human tibialis anterior. This was the first study to model IMP in human muscle and at submaximal contraction levels. Modeling results suggested the muscle midbelly is ideal for sensor location due to small pressure gradients. Additionally, muscle length may play a role in variability of IMP *in vivo*. Finally, the model showed good predictability across variable contraction levels from 0-50% MVC.

email: xiaohu@virginia.edu

## INTRODUCTION

Mice are one of the most widely used animal models to study neuromuscular diseases and test new treatments. However, findings from mouse studies often fail to translate to humans due to various factors, including the biomechanical differences between mice and humans.

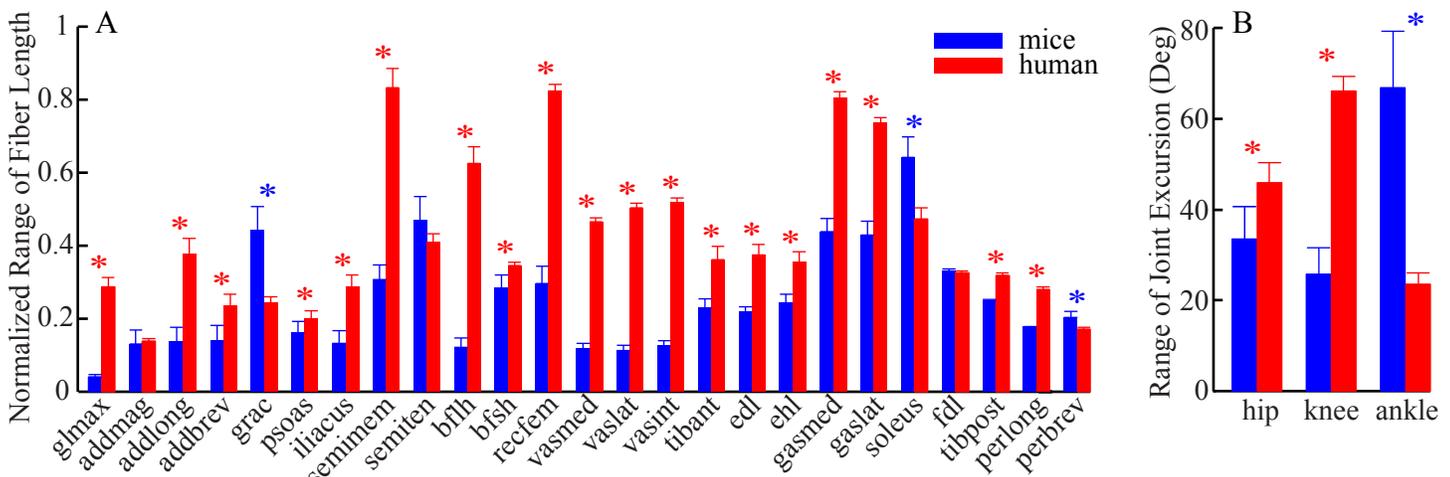

The biomechanical differences may possibly relate to the differed phenotype appearing in mouse models of neuromuscular diseases and whether exercise studies performed in mouse models are relevant to humans' muscle physiology. For example, in the widely used mouse model (*mdx* mice) of Duchenne Muscular Dystrophy (DMD), a genetic, muscle degenerative disorder affecting 1 in 3500 male births, the limb muscles have much milder phenotype than those in humans [1]. Differences in muscle length changes during daily locomotion, such walking and running, between mice and human may contribute to this milder phenotype in mice [2]. However, whether muscle length changes of mice during walking differ from humans remains unknown.

We hypothesized that the feasible ranges of fiber operating lengths of human lower limb muscles in

walking are larger than those of mouse hindlimb muscles. To test this hypothesis, we used newly published musculoskeletal models of the mouse hindlimb [3] and human lower limb [4] to run dynamic simulations, and calculated fiber operating lengths of 25 muscle homologues in these two species.

## METHODS

Dynamic simulations of muscle-tendon dynamics were developed in OpenSim version 3.2 [5] to estimate possible muscle fiber operating lengths in mice and humans during walking. Two newly published musculoskeletal models were used. The first model describes the 3-dimensional (3D) musculoskeletal geometry of a mouse hindlimb [3], and the second model describes the 3D musculoskeletal geometry of the human lower limbs [4]. In both models, each muscle was approximated with one or more line segments from origin to insertion and was represented with a Hill-type muscle model [6]. Joint kinematics measured from 16 mice [7] and 5 human subjects [8] walking on treadmills were prescribed in the simulations. To consider the influences from muscle activation to the possible ranges of fiber operating lengths, two

**Figure 1:** Comparison of the feasible ranges of fiber length (A) and joint excursions (B) during walking between mice and humans. Blue stars indicate mice have larger ranges, while red stars indicate humans have larger ranges ( $p < 0.05$ ).

activation cases were also prescribed: maximum activation in which activation was 1 in all muscles; and minimum activation in which activation was 0.05. Forward dynamic simulations were then run to calculate muscle fiber lengths that satisfied these prescribed constraints.

Fiber length changes during one gait cycle were estimated for maximum and minimum activation cases separately, and were then normalized to each muscle's optimal fiber length. The feasible range of fiber operating length in walking was defined as the difference between the maximum fiber length when activation was 0.05 and the minimum fiber length when activation was 1. Feasible fiber ranges of 25 muscles that have homologues in the two species were compared using a *t*-test with *p* value set at 0.05.

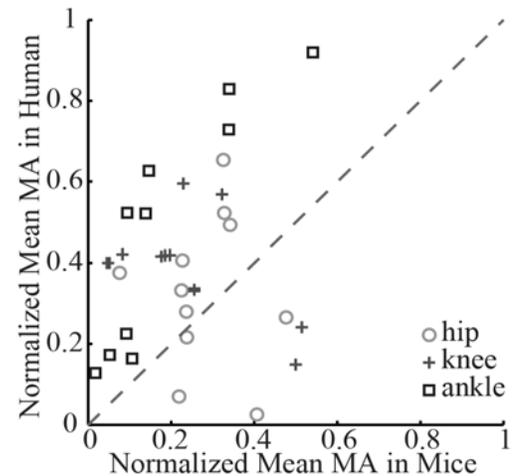

To understand any potential causes of the differences in feasible ranges of fiber operating lengths in walking, ranges of excursions for the hip, knee and ankle joints were computed based on the prescribed kinematics in the simulations. In addition, mean muscle flexion/extension moment arms at the hip, knee and ankle in one gait cycle were calculated and normalized by each muscle's optimal fiber length.

## RESULTS AND DISCUSSION

In general during walking, muscles of the human lower limb have larger feasible ranges of operating lengths than those of mice (Fig. 1A). Out of 25 muscles compared, 19 muscles have significantly larger feasible range of operating lengths in humans than in mice. In contrast, only 3 muscles have significantly larger ranges in mice than in humans. Three muscles have comparable ranges. These results suggest that the majority of mouse hindlimb muscles undergo smaller length changes during walking. This biomechanical difference could potentially contribute to the milder phenotype seen in the *mdx* mice, as muscle lengthening may adversely affect the progress of DMD [2].

Both the ranges of joint excursion and mean moment arms in walking contribute to the larger feasible ranges of fiber operating lengths in most muscles in humans than in mice. Humans have significant larger ranges of joint excursion at the hip and knee (Fig. 1B). In addition, humans have larger normalized moment arms in most muscles acting across the hip

and knee (Fig. 2). These two factors are linked to larger muscle length changes at the hip and knee in humans as compared to mice. Although mice have larger ankle excursions in walking, humans have larger mean moment arms in muscles across the ankle, which counteracts the effect from larger ankle motions in mice.

**Figure 2:** Comparison of mean moment arms (MA) in walking. Each symbol is one muscle. The dashed line is the unity line.

## CONCLUSIONS

Our simulation results demonstrated that biomechanical differences could contribute to the differed disease state in *mdx* mice and humans with DMD. By understanding and accounting for these differences, experiments in mice may be better designed to gain knowledge that could be translated to humans.

# TOO MUCH WORK: REVISITING ULTRASOUND-BASED ESTIMATES OF ACHILLES TENDON ENERGY STORAGE AND RETURN

Jason R. Franz<sup>1</sup> and Karl E. Zelik<sup>2</sup>

<sup>1</sup>University of North Carolina at Chapel Hill and North Carolina State University    <sup>2</sup>Vanderbilt University  
 email: [jrf Franz@email.unc.edu](mailto:jrf Franz@email.unc.edu)    web1: [abl.bme.unc.edu](http://abl.bme.unc.edu)    web2: [my.vanderbilt.edu/batlab/](http://my.vanderbilt.edu/batlab/)

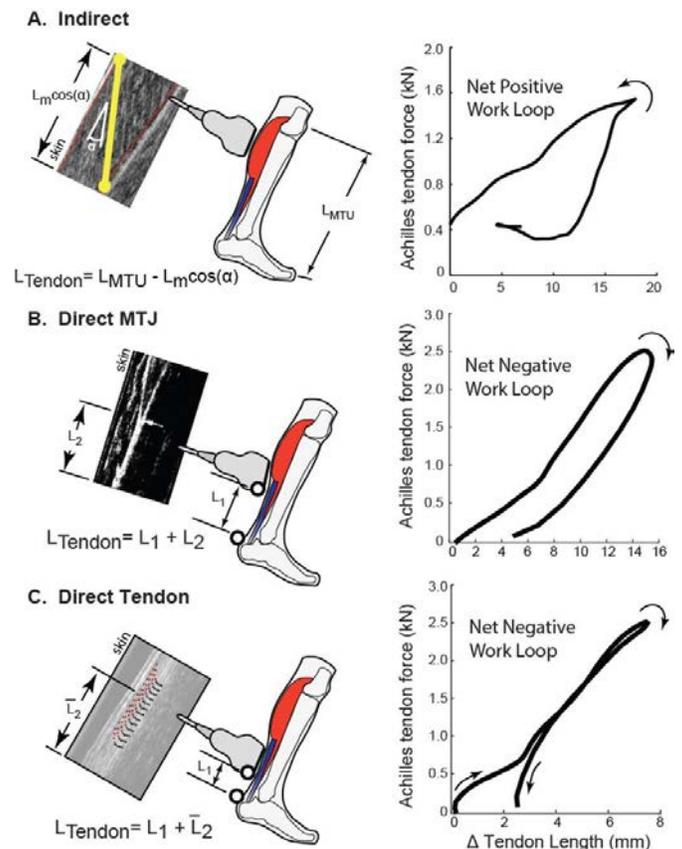

## INTRODUCTION

Ultrasound imaging is increasingly used with motion and force data to quantify tendon dynamics and to understand the functional role of tendons during human and other animal movement. Frequently, tendon dynamics are estimated indirectly from measures of muscle kinematics (by subtracting muscle length from muscle-tendon unit length), but there is mounting evidence that this approach, which we term the *Indirect* method, yields implausible tendon work loops (tendon force vs. elongation) [e.g., 1-2]. Since tendons are passive, viscoelastic structures, they should exhibit negative work loops (i.e., net negative work over a loading-unloading cycle). However, prior studies using Indirect estimates of tendon kinematics report large positive work loops, estimating that tendons return 100-400% more energy than they store [e.g., 1-2]. More direct ultrasound methods have emerged that estimate tendon elongation by tracking either the muscle-tendon junction (termed the *Direct MTJ* method) or localized tendon tissue stretch (termed the *Direct Tendon* method) [3]. However, it is unclear if these Direct estimates yield more plausible tendon work loops. Here, we estimated tendon work loops and hysteresis using these two Direct tendon kinematics estimates during human walking, then compared these results to previously reported values using Indirect kinematics estimates.

## METHODS

We reanalyzed human walking data from our prior work ( $N=8$ , mean  $\pm$  standard deviation, age:  $23.9 \pm 4.6$  years) [3]. Subjects completed two 2-minute walking trials at three walking speeds (0.75, 1.00, and 1.25 m/s) - one trial for each of two probe locations. We collected human motion and force data using standard gait analysis procedures. Simultaneously, we collected raw radiofrequency

(RF) data from longitudinal cross-sections through the right plantarflexor MTU using a 10-MHz, 38-mm linear array transducer (L14-5W/38, Ultrasonix, Richmond, BC) secured using an orthotic. For the Direct MTJ estimate, we recorded (128 frames/s) through a 3 cm depth from a probe centered on the distal lateral gastrocnemius (LG) MTJ, from which we estimated local MTJ displacements. For the Direct Tendon estimate, we recorded (155 frames/s) through a 2 cm depth from a probe on the distal free Achilles tendon. Custom 2D speckle-tracking estimated longitudinal free Achilles tendon tissue

**Figure 1.** Tendon kinematic measurements and group-average tendon work loops during walking. (A) Indirect estimates from digitized published data [1] and Direct estimates via the (B) lateral gastrocnemius MTJ and (C) Achilles free tendon.

displacements [3]. Achilles tendon elongations were then estimated by co-registering local LG MTJ (Direct MTJ) and Achilles free tendon (Direct Tendon) displacements with the calcaneus marker position. Finally, we estimated Achilles tendon force as the net ankle moment divided by subject-specific measures of the Achilles tendon moment arm to create stance phase tendon work loops (tendon force vs. elongation). We integrated tendon work loops to calculate: (i) net stance phase work (J) and (ii) hysteresis (%), defined as one minus the positive work (energy returned during tendon unloading) divided by negative work (energy stored during loading). Tendon hysteresis from Direct MTJ and Direct Tendon methods were compared to Indirect values from literature [e.g., 1-2].

## RESULTS AND DISCUSSION

Based on digitized data from previously published studies [e.g., 1-2], tendon length changes estimated from measured muscle fascicle kinematics consistently produced positive tendon work loops. For example, Achilles tendon hysteresis during walking derived indirectly from soleus and gastrocnemius fascicle kinematics elicited values of approximately -130% and -200%, respectively, indicating considerable but physiologically implausible net positive work performed by the tendon (Fig. 1A) [1].

In contrast to Indirect estimates, we found that both Direct methods yielded, on average, negative tendon work loops and thus positive tendon hysteresis values during the stance phase of walking. Across the range of speeds tested, peak Achilles tendon force during the stance phase averaged 2.2-2.7 kN. This range of peak forces was associated with tendon length changes of 14.3-15.2 mm estimated via LG Direct MTJ and 7.1-7.8 mm estimated via Direct Tendon approaches. Direct MTJ tendon hysteresis (net work) averaged 49.7% (-8.9 J), 37.9% (-8.2 J), and 9.2% (-5.1 J) for walking at 0.75, 1.00, and 1.25 m/s, respectively (Fig. 1B). Direct Tendon estimates averaged 32.9% (-3.4 J), 11.0% (-2.0 J), and 2.1% (-1.2 J), respectively (Fig. 1C). Net tendon work (main effect,  $p=0.04$ ), but not hysteresis (main effect,  $p=0.34$ ), differed significantly between the two

Direct measurement techniques. Finally, both outcome measures decreased significantly and progressively with increasing walking speed (main effect,  $p<0.01$ ). That hysteresis estimates were walking speed-dependent requires further study.

## CONCLUSIONS

As we advance our scientific understanding of movement biomechanics, it is important to continue advancing and validating our experimental methods. It remains unclear which fundamental assumptions or measurement inaccuracies result in the substantial positive tendon work loops obtained from Indirect tendon estimates. Nevertheless, compared to Indirect tendon estimates, Direct estimates may be preferable for understanding tendon dynamics such as energy storage and return, especially during dynamic activities such as walking. The accuracy and completeness of our biomechanical estimates affect our scientific interpretations as well as our applied interventions. Indeed, our results are highly relevant to the degree to which tendon elastic energy storage and return facilitate economical locomotion, and to the bio-inspired design and prescription of assistive devices that seek to restore/augment human calf muscle-tendon function. Musculoskeletal simulations also rely on accurate empirical biomechanical estimates, either as direct inputs or indirectly for validation. Ultimately, we must understand the accuracy, precision, benefits, drawbacks, and assumptions of each measurement approach in order to appropriately interpret the functional role of muscle-tendon dynamics during movement.

## INTRODUCTION

The neck is composed of a complex layering of musculature to move and generate force in three dimensions. Each neck muscle is precisely tuned to have preferred directions where their muscle activity is greatest during isometric or dynamic tasks [1-3]. Tracking the spatial tuning of muscle activations has clinical utility, as the directional specificity of the sternocleidomastoid (SCM) muscles are reduced in patients with chronic neck pain [2], likely producing increased muscle stiffness [4]. Increased *in situ* muscle stiffness is produced at greater muscle activation levels [5], but direct assessments of *in vivo* muscle stiffness are clinically limited to qualitative assessments (e.g. tissue palpation). Recent advances in ultrasound shear wave elastography (SWE) allow for direct measures of muscle elasticity [6]. Our study utilized SWE to determine if the spatial tuning of muscle elasticity and EMG activity are similar within the SCM muscles of healthy participants.

## METHODS

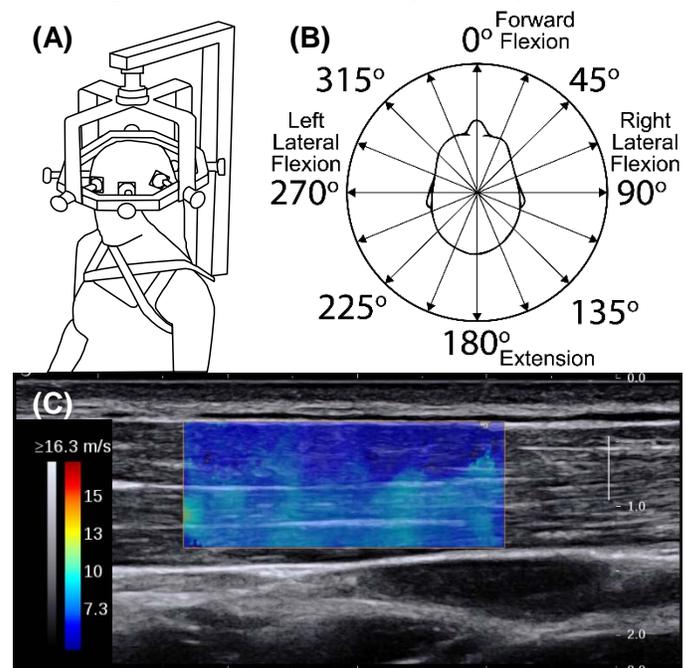

Fifteen healthy adults (8 males; mean (SD) age = 23.6 (2.6) yrs) with no history of neck dysfunction were enrolled. Surface electromyography (EMG) electrodes (Bagnoli, Delsys, Natick, MA) were placed bilaterally on the SCM, upper trapezius (UT), and splenius capitis (SPL) muscles (Fig. 1A). Participants were seated with their head secured within a wall-mounted aluminum halo attached to a biaxial load cell (Fig. 1A) with their torso and pelvis secured to the backrest using straps.

Maximum voluntary contractions (MVCs) were collected in flexion, extension, left flexion, and right flexion. Visual feedback was provided to assist subjects in matching their isometric force production to 16 axially-directed targets scaled to 20% of their maximal MVC (extension in all participants) (Fig. 1B). Participants completed practice trials to familiarize themselves with the force matching task

before completing two blocks of 16 targets in a randomized order.

After collecting EMG data during these trials, the electrodes over the bilateral SCMs were removed to accommodate an ultrasound transducer. SWE ultrasound images were acquired from the muscle bellies of both SCM muscles using a Supersonic Imagine Aixplorer system (Fig. 1C). Images were acquired as subjects performed the same isometric force matching task (two blocks of 16 randomized targets). Muscle elasticity was estimated as the mean shear wave velocity within the SWE color map.

The EMG data was collected at 1 kHz, gained at 1 or 10 kHz, detrended, rectified, and low-pass filtered (7 Hz). EMG values during each contraction were averaged over 500 ms. Tuning curves were generated to compute the directional specificity of muscle

**Figure 1:** (A) Metal halo with embedded force sensor. (B) Experimental procedure involves generating isometric forces in 1 of 16 directions. (C) A representative image of the SCM muscle using ultrasound shear wave elastography. The B-mode image is superimposed with a color map of shear wave velocity, which is directed related to muscle elasticity.

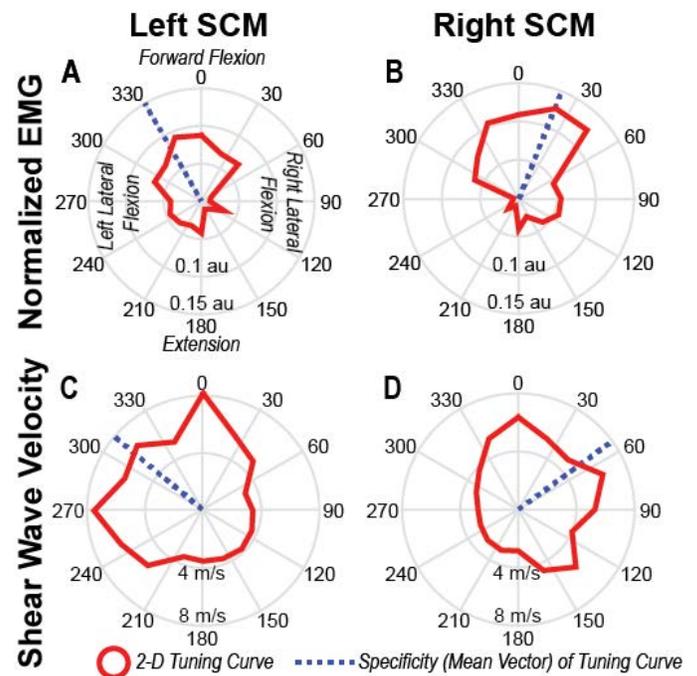

activity of the bilateral SCM, UT, and SPL muscles and muscle elasticity from the shear wave velocity data collected from the bilateral SCMs. Specificity was computed as the mean vector direction of the tuning curve [3], e.g. the vector sum of the normalized EMG or raw SWE data across all force target directions. Differences in the directional specificity of muscle activity and muscle elasticity for the left and right SCMs were assessed using a paired t-test with a significance level of  $P < 0.05$ . A repeated measures ANOVA assessed if the EMG activity specificity for the bilateral UT and SPL muscles differed between the EMG and SWE tasks to insure consistent co-activation patterns.

## RESULTS AND DISCUSSION

Representative EMG and SWE tuning curves for the left and right SCM muscles are shown in Figure 2. Different direction specificities between the left and right SCMs were shown for muscle activity and muscle elasticity. Within each muscle, similar directional specificity patterns between muscle activity and muscle elasticity were observed.

Across subjects, the mean  $\pm$  SD vector direction for the left SCM was  $347^\circ \pm 17^\circ$  for EMG activity and  $332^\circ \pm 24^\circ$  for muscle elasticity ( $p = 0.013$ ). For the right SCM, the mean vector direction was  $12.2^\circ \pm 15^\circ$  for EMG activity and  $22.1^\circ \pm 19^\circ$  for muscle elasticity ( $p = 0.003$ ). The directional specificity of both the left and right SCM were consistent, with both muscles showing preferred activation and elasticity when producing forces in forward and ipsilateral flexion. The mean vector direction for muscle elasticity was significantly more directed towards ipsilateral flexion than the mean vector for muscle activity for both SCMs.

We posited this statistically significant difference in directional specificity could occur due to participants performing the isometric task differently between the EMG and SWE collections. Since the EMG electrodes over the SCM muscles were removed to perform ultrasound SWE, we examined how the specificity of the UT and SPL muscles differed between the EMG and SWE tasks. The directional specificity of the bilateral UT and SPL muscles' EMG activity exhibited no significant task by muscle interactions (left:  $p = 0.809$ ; right:  $p = 0.913$ ) or task main effects (left:  $p = 0.936$ ; right:  $p = 0.707$ ). These

**Figure 2:** Representative tuning curves (red) of (a-b) normalized EMG activity and (c-d) mean shear wave velocity for the left and right SCM muscles for one subject. Dashed blue lines indicate directional specificity for each curve.

findings suggest patients utilized similar muscle co-activation patterns throughout the entire experiment.

The current study provides new insights into healthy neck neuromechanics. The directional specificities of SCM muscle activity were consistent with prior studies [3]. For the first time, we showed that the preferred directions of muscle activity and elasticity are similar for the SCM muscles. This is consistent with greater muscle stiffness at higher activation levels [6]. Future work will investigate if learning adaptations or muscle architecture can explain our observed statistical difference between SCM activity and elasticity. We will also investigate how neck pathologies manifest in regards to underlying changes in muscle elasticity and muscle activity.

## CONCLUSIONS

The SCM muscles exhibit a small but statistically significant difference between the preferred directions of muscle activity and muscle elasticity.

## **HMB preserves strength in contralateral but not in Botox-injected musculature in rabbits**

<sup>1</sup> Rafael Fortuna, <sup>1</sup> Andrew Sawatsky, <sup>2</sup> John Fuller, <sup>1</sup> Walter Herzog

<sup>1</sup> Human Performance Laboratory, University of Calgary, Canada

### **INTRODUCTION**

Botulinum toxin type-A (Botox) induces a dose-dependent muscle paralysis by preventing acetylcholine release at the neuromuscular junctions<sup>1</sup>.

Currently, Botox injections have been applied in clinical settings with the primary aim to relax hyperexcitability of peripheral nerve terminals, such as in patients with cerebral palsy or following a stroke<sup>2</sup>. Additionally, Botox can be used in experimental settings to mimic muscle weakness as seen following injury or in the elderly<sup>3</sup>. Botox-induced muscle weakness models can also be used to test strategies for preventing or reversing loss of strength and muscle mass.

$\beta$ -Hydroxy- $\beta$ -methylbutyrate (HMB) is produced in animals and humans from the amino acid leucine. Studies have shown that HMB supplementation can slow muscle protein breakdown following resistance exercise, and produce gains in lean body mass and strength in a dose-dependent manner. Additionally, HMB is being used as a dietary supplement during rehabilitation following injury, prolonged bed rest, and for hospitalized patients in order to mitigate loss in strength and muscle mass<sup>4</sup>. Despite its ever growing popularity as a diet supplement to prevent muscle wasting, there have been conflicting results regarding the efficacy of HMB to prevent muscle weakness under conditions producing muscle atrophy.

The purpose of the present study was to determine the effects of dietary HMB supplementation on strength and muscle mass following a single Botox injection into the quadriceps femoris muscles of New Zealand white (NZW) rabbits.

### **METHODS**

Twenty-one, one year old female NZW rabbits were divided into: (1) Control (n=7); (2) Botox (n=7); and (3) Botox + HMB (n=7) groups. The Control group received an equal volume of saline injections as the experimental group rabbits, which received a single intramuscular Botox injection (3.5U/kg) unilaterally into the quadriceps femoris musculature.

Two months following the injections, rabbits were evaluated for primary outcome measurements of muscle mass and knee extensor strength in the injected and contralateral non-injected muscles. Muscle mass was assessed by weighing the muscles and maximal isometric knee extensor strength was measured via maximal femoral nerve stimulation at 200 Hz.

The data were analyzed using Proc GLM in SAS (SAS for Windows 9.4, SAS Institute, Inc., Cary, NC) using one-way ANOVA with treatment as the main effect and body weight as a covariate. Data are presented as mean and standard error of the mean (SEM). The level of significance was chosen as  $\alpha=0.05$  a priori.

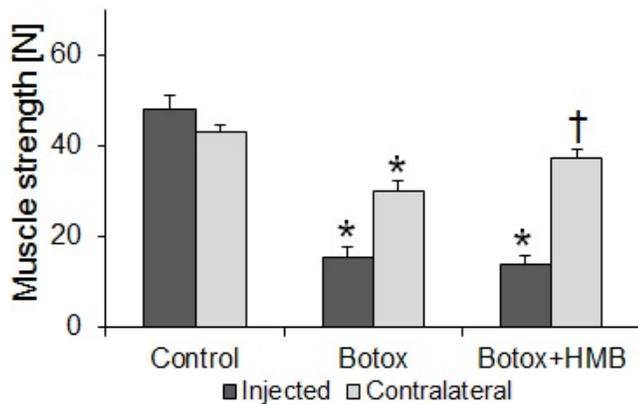

### **RESULTS AND DISCUSSION**

There was no difference in muscle strength between saline and contralateral non-injected limbs of the control rabbits. However, there was a significant reduction in strength of the injected limbs of the Botox group compared to the control group, but no difference in strength between the injected Botox and Botox + HMB group rabbits was observed (Fig. 1).

Muscle strength on the contralateral non-injected limb of Botox group rabbits was decreased compared to control group rabbits. The Botox +

HMB group had significantly higher strength values than the Botox group and did not differ from the values obtained from the control group rabbits (Fig. 1).

Muscle mass between saline and contralateral non-injected limbs of control group rabbits was not different; however, there was a significant loss of muscle mass in muscles of the injected limbs of the Botox and Botox + HMB groups, with no difference in muscle mass between these two groups (Fig. 2).

**Figure 1:** Mean muscle strength ( $\pm$ SEM) for injected (dark bars) and contralateral non-injected (light bars) for control, Botox, and Botox + HMB group rabbits (\* compared to control, † compared to Botox).

While muscle mass of the contralateral musculature as a whole was not different between Botox and Botox + HMB group rabbits, the muscle mass of the contralateral rectus femoris in the Botox + HMB group was significantly greater than in the Botox group rabbits (result not shown).

Muscle strength was reduced by about 60% in Botox and Botox + HMB group rabbits compared to control, while muscle mass was reduced by only about 40%. This result suggests that either the muscle structure was also compromised in the two Botox injected rabbit groups, or that Botox inhibition at the neuromuscular junction during the strength testing affected the strength results. Direct muscle stimulation, rather than nerve stimulation, could possibly provide the conclusive answer to this question as this would bypass any residual Botox effect on the neuromuscular junction.

The contralateral muscle strength of the Botox + HMB rabbits was greater than for the Botox alone group, while muscle masses were similar. This finding may indicate that the HMB supplement might have prevented some structural degeneration typically observed in non-target muscles of Botox injected rabbits<sup>5</sup>, thereby maintaining better strength despite equal mass. Follow up histological assessment of our samples will clarify this issue unequivocally.

**Figure 2:** Mean muscle mass ( $\pm$ SEM) for injected (dark bars) and contralateral non-injected (light bars) for control, Botox, and Botox + HMB group rabbits (\* compared to control).

## CONCLUSIONS

While HMB supplementation did not prevent loss of muscle strength and muscle mass in the Botox-injected musculature, HMB did prevent strength loss in the contralateral non-injected muscle. In conclusion, HMB resulted in maintenance of strength in the contralateral musculature which would be important for overall recovery after an immobilizing injury.

# FROM HOPPING ON LAND TO TREADING IN WATER: UNDERSTANDING LIMITS ON MUSCLE-TENDON PERFORMANCE IN CHANGING ENVIRONMENTS

<sup>1</sup>Jonathan A. Doering and <sup>1</sup>Gregory S. Sawicki

<sup>1</sup>North Carolina State University, Raleigh, NC, USA  
email: jadoerin@ncsu.edu

## INTRODUCTION

Efficient locomotion requires that the neuromuscular system can quickly adapt to internal and external changes [1]. In many terrestrial animals, the external environment in which locomotion occurs may change instantly (*i.e.*, from land to water), resulting in altered locomotion patterns [2]. Determining whether shifts in locomotion behavior are the result of adapted neural commands versus intrinsic mechanics (*e.g.*, shifts in operating point on the FL and FV curves) is difficult to determine *in vivo*.

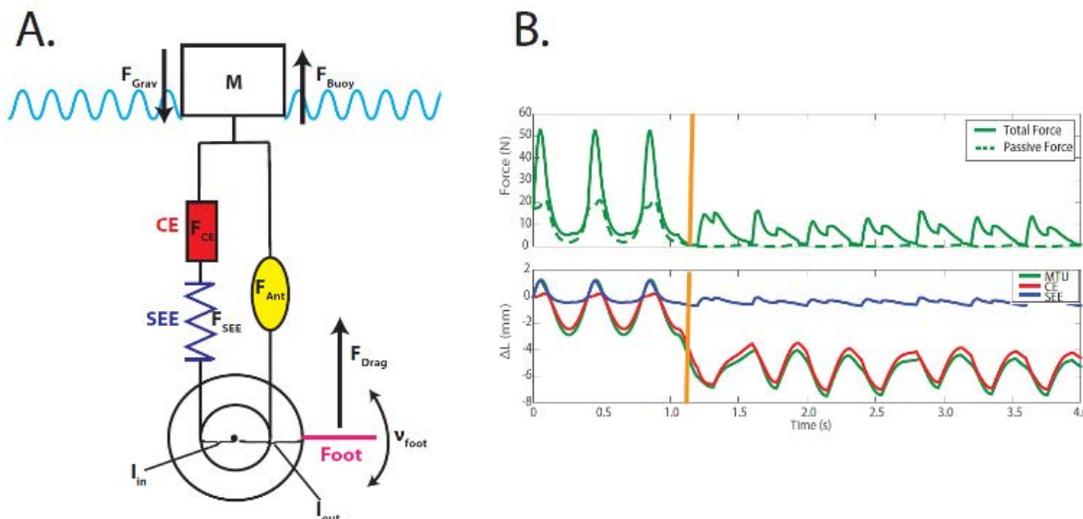

The goal of this study was to develop a computer model to understand the muscle vs. tendon contributions to locomotion performance when changing from terrestrial to a fluid environment.

We hypothesized that with no change in motor control, in the terrestrial environment muscle (CE) would act as a rigid strut, while in fluids the CE would act as a work producing motor. Additionally, increasing or decreasing the driving frequency in a fluid would increase or decrease the net work produced by the CE, respectively.

## METHODS

A mass connected to a muscle-tendon unit (MTU) model containing a contractile element (CE), a

parallel elastic element (PEE), and a series elastic element (SEE) was employed (Fig 1A.). The MTU acted through a mechanical advantage to control the motion of a foot. In terrestrial conditions, the mass experienced constant gravitational forces, simulating MTU dynamics of ankle extensors in hopping. In fluid conditions, the mass also experienced a buoyant force, and drag forces at the foot, simulating a treading body in a fluid. Additionally, in the fluid, an antagonist muscle was used to restore the MTU back to longer lengths after a power stroke. Force was generated in the CE by a Hill-type muscle with classic force-length and -velocity relationships and a stimulation modeled as a square wave pulse with a duty of 10% relative to the cycle period. Both the PEE and SEE had non-linear force-displacement relationships taken from the literature. The buoyant force was modeled by:  $F_{buoy} = \rho A_x ((h/2) - dx)$ , where  $\rho$  was the density of the fluid,  $A_x$  was the surface area of the mass and  $dx$  was the change in position of the mass over time. We set  $A_x$  to result in a neutrally buoyant case with half the mass above water when  $dx=0$ . Drag force experienced by the foot was modeled by:  $F_{drag} = -Kv^2$ , where  $v$  was the velocity of the foot, and  $K$  was the lumped drag coefficient (kg/m). Drag only acted when the MTU was shortening, and diminished to zero when the system

**Figure 1. (A) Hopping/Treading Model, (B) Force and length change of the MTU during a terrestrial to fluid transition.** A body mass/MTU in gravity operating with a fixed mechanical advantage simulates MTU dynamics during cyclic contractions. In terrestrial states, we set drag coefficient to be sufficiently high to allow hopping like behavior. In fluid, drag coefficient is markedly reduced and the mass experiences a buoyant force to assist the restoration of oscillatory behavior (A). In a transition simulation, the MTU operates at longer lengths and higher passive forces in terrestrial vs. fluid state (*i.e.*, before and after the orange line) (B).

reset due to the action of the antagonist muscle. The action of the antagonist muscle was modeled as an acceleration acting to re-lengthen the MTU,  $dV_{MTU}/dt = \alpha * (\Delta L_{MTU})$ , where  $\Delta L_{MTU}$  is the length of the MTU relative to its slack length, and  $\alpha$  is a rate constant. To address the role of environmental changes on MTU dynamics, we drove the system at 2.5 Hz, the passive resonant frequency ( $\omega_0$ ) of the system in terrestrial conditions (*i.e.*, gravity only), in both terrestrial and fluid environments. We then shifted the driving frequency to  $\pm 20\%$  of  $\omega_0$  in fluid to simulate different treading frequencies. To address the hypothesis, we compared the force, length, power dynamics, and work contributions from a steady state contraction in all conditions.

## RESULTS

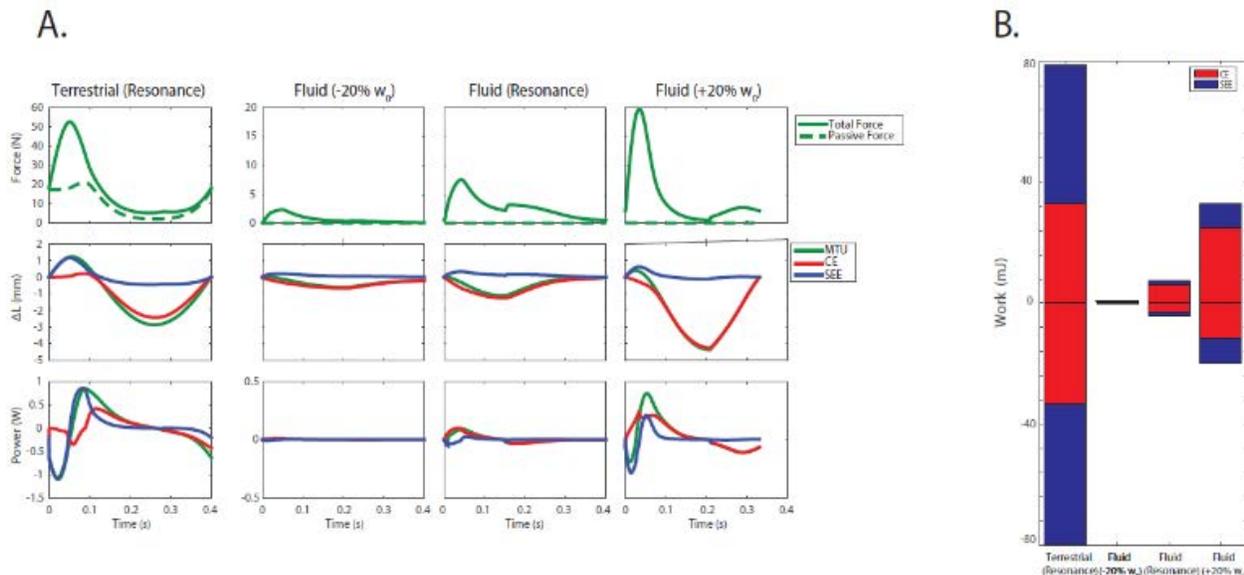

In the terrestrial environment, we observed higher MTU forces with larger passive contribution, longer muscle (CE) operating lengths and higher tendon (SEE) strains than in the fluid (Fig. 1B). In terrestrial simulations, the CE performed isometrically early in the cycle, facilitating large elastic energy cycling to and from the SEE (Fig 2A, B). In fluid simulations, the CE always shortened on stimulation with increasing velocity and force leading to higher power output at higher and higher driving frequencies. higher power outputs (Fig 2A). In fluid, the majority of the MTU work is produced by the CE, rather than the SEE (Fig 2B).

## CONCLUSIONS

These results support our hypothesis that (1) muscle (CE) should generate net positive work (*i.e.*, act as a motor) in fluid, and generate zero net work (*i.e.*, act as a strut) while in terrestrial conditions and (2) the net work produced by the MTU can be directly modulated by increasing neural drive in a fluid. Our results demonstrate that spontaneous changes in MTU mechanical function can be mediated directly through changes in the environment dynamics without any adjustment in motor control. Interestingly, in terms of maximizing peak power output of the MTU, driving the system under optimal conditions on land (*i.e.*, at the resonant frequency) when in a fluid results in suboptimal performance. Finding a MTU morphology that can maximize power output in both terrestrial and fluid environments without shifts in motor control may be exceedingly difficult. Future experiments will explore how changes in environmental dynamics influence MTU mechanical function *in vitro* on the benchtop using biological MTUs attached to a 'smart' feedback controlled force ergometer.

**Figure 2. Force, length, and power responses during environmental simulations (A), and work contributions (B).** In terrestrial environments, the MTU demonstrates high total and passive forces, isometric behavior during contraction, and increased power output compared to fluid conditions. When driving at increasing frequencies in fluid, the MTU generates greater force while undergoing greater length changes and power production (A). On land there is greater elastic cycling of the SEE, while in a fluid, the majority of the MTU work is produced by the CE, rather than the SEE (B). When driving at increasing frequencies in fluid, CE net work also increases.

# CONFOUNDING FACTORS WHEN ANALYZING MOTOR UNIT FIRING ADAPTATIONS DURING MUSCLE FATIGUE

<sup>1</sup> Paola Contessa and <sup>1</sup>Joshua C. Kline

<sup>1</sup>Delsys Inc. and Altec Inc., Natick, USA

email: [pcontessa@delsys.com](mailto:pcontessa@delsys.com), web: <http://www.delsys.com/altec/>

## INTRODUCTION

The control of motor units (MU) during fatiguing contractions has been the subject of debate for decades. Conflicting observations on the firing behavior of MUs during muscle fatigue have reported decreases [1,2] and increases [3] in MU firing rate. The inconsistencies among the observations are often accompanied by differences in the methods used to analyze the MU data. For instance, changes in MU firing rate during repeated isometric contractions are often investigated as a function of MU recruitment threshold. However, this practice may confound the analysis of MU firing adaptations because recruitment threshold itself has been reported to decrease as muscle fatigue develops [1,3]. MU data are also often grouped and averaged across different subjects. Yet, this practice may obscure subject-specific changes in firing rate [2,3]. In this study, we investigated the influence of these analytic approaches on analyzing MU firing adaptations during a fatigue protocol performed with the Vastus Lateralis (VL) muscle.

## METHODS

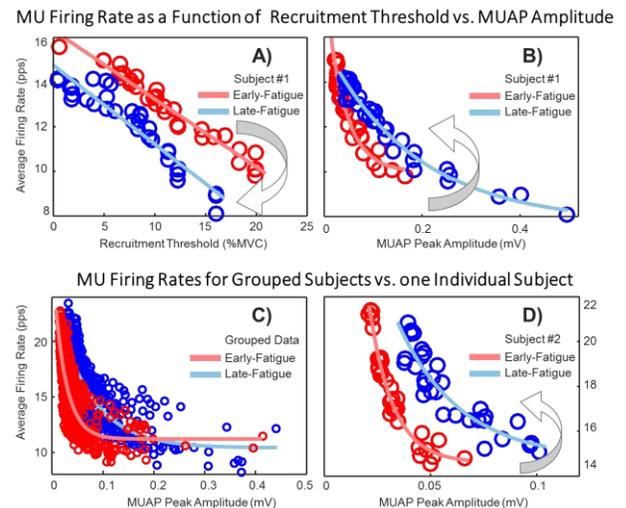

Five healthy subjects (3 males and 2 females, 24-33 yrs.) performed a series of isometric knee-extension contractions sustained at 30% maximal voluntary contraction (MVC) force and repeated until the endurance limit. Torque and surface electromyographic (EMG) signals from the VL muscle during knee extension were recorded during each contraction (dEMG System, Delsys Inc., Natick, MA). Surface EMG signals were decomposed into the constituent MU action potentials (MUAPs) [4]. The firing rate of MUs in subsequent contractions of the fatigue protocol were analyzed:

- 1) As a function of MU recruitment threshold vs. as a function of MUAP amplitude (to highlight the possible confounding effect of decreasing recruitment threshold with fatigue).

- 2) For MU data grouped across subjects vs. for MU data from individual subjects (to highlight the possible confounding effect of neglecting subject-specific firing adaptations).

## RESULTS AND DISCUSSION

When we assessed the changes in MU firing rate as a function of MU recruitment threshold, we observed a decrease in firing rates during subsequent contractions of the fatigue protocol (Figure 1A). But when the same MU data were analyzed as a function of MUAP amplitude, we found a clear indication that MU firing rates progressively increased throughout the series of fatiguing contractions (Figure 1B). When we assessed the changes in MU firing rate for MU data grouped across all subjects, there was no clear trend in MU firing rate during the fatigue protocol (Figure 1C). But when the same MU data were analyzed for each individual subject, a clear trend for firing rates to progressively increase with

**Figure 1:** Fatigue-induced firing adaptations as a function of recruitment threshold (A) vs. MUAP amplitude (B); and for grouped data (C) vs. a representative subject (D).

fatigue was observed consistently in all subjects (Figure 1D).

Figure 1A and 1B show that the practice of analyzing MU firing rates as a function of recruitment threshold reverses the actual pattern in MU firing adaptation with fatigue that occurs when firing rates are analyzed with respect to MUAP amplitude. The shift to lower frequencies can be considered an epiphenomenon as it is likely caused by the progressive decrease in MU recruitment threshold that occurs during muscle fatigue, which has been suggested to compensate for the progressive decrease in force generation capacity [1,2]. Therefore, as MU recruitment threshold decreases, higher-threshold MUs are recruited at progressively lower forces. Because higher-threshold MUs fire at lower firing rates [3], MU firing rates shift to lower frequencies with muscle fatigue. In contrast, the actual increase in MU firing rate during subsequent contractions is maintained when firing rates are analyzed as a function of MUAP amplitude. Even though MUAP amplitude has also been reported to decrease with fatigue [5], the increase in MU firing rate would only be underestimated but not reversed as a result of a fatigue-induced decrease in MUAP amplitude.

Figure 1C and 1D provide evidence that the practice of grouping MU data across subjects obscures subject-specific firing adaptations with fatigue, which are consistent in trend but differ in magnitude among subjects. Subject-specific differences in the magnitude of the firing adaptations are likely due to

individual differences in muscle mechanical and biochemical characteristics.

## CONCLUSIONS

Our study shows that analyzing MU firing rate as a function of recruitment threshold and grouping MU data across subjects may confound our understanding of MU behavior during muscle fatigue. Analysis practices should be carefully considered when investigating fatigue-induced MU firing adaptations or interpreting conflicting results in the literature.

## INTRODUCTION

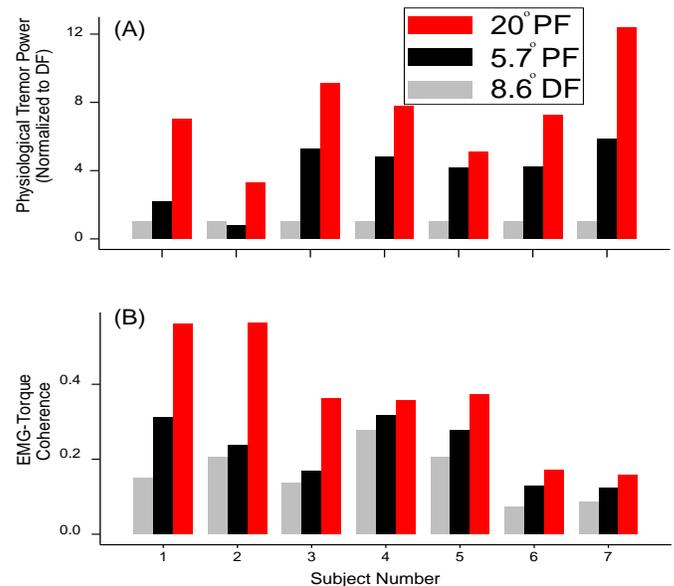

Physiological tremor is the involuntary, rhythmic contraction of muscles in the frequency range of 5-12 Hz. Among other factors, spinal reflex loops have been proposed to lie at the heart of generation, amplification, and persistence of healthy and pathologic tremor [1].

In particular, some reports suggest a strong coupling between physiological tremor and the stretch reflex response—as well as the dependence of stretch reflex amplitude on muscle length [1,2]. Thus, given that stretch reflex amplitude increases with muscle stretch, we hypothesized that muscle stretch would also increase the amplitude of physiological tremor. We tested this hypothesis in the human gastrocnemius muscle by measuring the dependence of physiological tremor on the ankle joint angle.

## METHODS

Seven subjects (2 female) with no history of neuromuscular disease gave informed consent to the experimental procedure approved by the McGill University Institutional Review Board. They lay supine and were instructed to generate tonic, voluntary contractions at 30% of *Maximal Voluntary Contraction* (MVC) of ankle torque aided by real-time visual feedback. Ankle torque and EMG signal from the gastrocnemius muscle were recorded. Three trials lasting 30s each were recorded at three angles (20° plantarflexion, and 5.7° and 8.6° dorsiflexion) in block random order.

Ankle torque was first high-pass filtered at 5 Hz, and its power spectral density was integrated in the physiological tremor range (5-12 Hz) to give the physiological tremor torque power. Also, magnitude-squared coherence between full-wave rectified EMG and torque was calculated to estimate the coupling between muscle activity and torque.

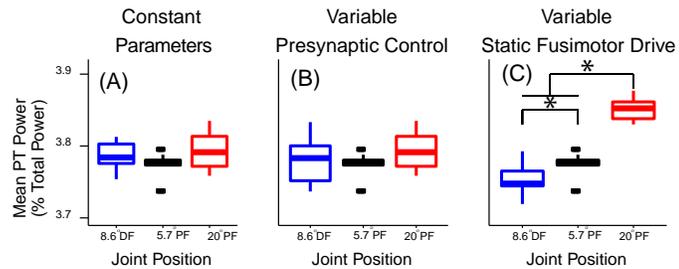

**Figure 1:** Experimental results: (A) physiological tremor and (B) EMG-torque coherence increase from dorsiflexed to plantarflexed angle.

Lastly, a computational model was used to disambiguate neuromechanical contributions to modulation of physiological tremor. This published model has successfully replicated physiological tremor by including muscle-tendon, muscle spindle, Golgi tendon organ and signal dependent noise modules [1]. Given the dynamic and stochastic elements of the model, each isometric gastrocnemius muscle force at 30% MVC was simulated 10 times at each experimental condition. The simulation data were processed using analyses similar to those explained for the experimental data.

## RESULTS AND DISCUSSION

Figure 1A shows that physiological tremor torque power changed consistently as a function of ankle angle; but was always larger in the plantarflexed angle compared to mid and dorsiflexed angles. Thus, physiological tremor was inversely related to muscle

length (i.e., Figure 1A, shorter muscle lengths leads to larger physiological tremor) which contradicts our original hypothesis.

**Figure 2:** Simulations of physiological tremor as a function of joint angle: (A) all the model parameters except muscle-tendon length were kept constant; (B) presynaptic inhibition increased at the dorsiflexed angle; (C)  $\gamma$ -static fusimotor drive increased from the dorsiflexed to plantarflexed angles. Modulation of  $\gamma$ -static fusimotor sufficed to replicate the experimental observations.

Figure 1B shows that EMG-torque coherence, in the physiological tremor frequency range, also consistently increased with plantarflexion. Thus, the coupling between EMG and torque increased with the tremor torque power. Consequently, changes in physiological tremor were likely of neural origin.

We used our model to explore the relationship between physiological tremor and muscle length. First, we held all model parameters constant—except for muscle-tendon length. We found no consistent dependence of tremor on muscle length, indicating that our experimental observations could not be explained solely by changes in joint angle and the induced change in the activity of muscle afferents (Figure 2A).

Then we explored neural factors by varying the gains of the afferent feedback using presynaptic inhibition (i.e. spinal gains, Figure 2B) and fusimotor control (i.e. spindle tuning, Figure 2C) [3]. We implemented the effect of increasing presynaptic inhibition with dorsiflexion angle as has been reported in previous H-reflex studies [4]. This modulation had little impact on physiological tremor as Figure 2B demonstrates. We then tested the effect of fusimotor drive and found that increasing the  $\gamma$ -static fusimotor drive produced an increase in physiological tremor with plantarflexion (i.e., muscle shortening, Figure 2

C). Modulation of  $\gamma$ -dynamic fusimotor drive had no effect.

## CONCLUSIONS

In contrast to the understanding of the relationship between stretch reflex and physiological tremor in the literature, we found that tremor amplitude increased when muscle was shortened. A published computational model of afferented muscle-tendon systems could only replicate these experimental results when  $\gamma$ -static fusimotor drive (but not  $\gamma$ -dynamic) increased as the muscle shortened. This describes a novel mechanism for the control of  $\gamma$  fusimotor drive, which deviates from the widely-accepted  $\alpha$ - $\gamma$  co-activation hypothesis. This work provides a mechanistic approach to interrogate the details of such deviation in future studies. These new findings will also begin to fill important gaps in our knowledge of fusimotor activity that has important clinical implications. By providing a long-needed noninvasive experimental means to probe the fusimotor activity, it is now possible to understand the role of healthy and pathological reflex-driven mechanisms in health and multiple neurological conditions.

# ARE YOU STIFF ENOUGH TO RESPOND TO FOAM ROLLING? A DEPENDENCY ON TISSUE PROPERTIES

Nicolai Kram\*, René Schrader, Thomas L. Milani, Freddy Sichtung

Chemnitz University of Technology, Department of Human Locomotion, Chemnitz, Saxony, Germany

\*email: nicolai.kram@hsw.tu-chemnitz.de, web: <https://www.tu-chemnitz.de/index.html>

## INTRODUCTION

The application of foam rolls in therapeutic settings is increasing continuously, although the mechanisms inside the human body are not yet fully understood. It is thought that a so-called self-myofascial release (SMR) can reduce the tensional state of muscles and fibrous connective tissues which could highlight the importance of foam rolling for medical conditions, e.g. plantar fasciitis [1,2]. However, there are currently no studies on basic research on this topic.

We hypothesize that eight weeks of whole-body SMR can reduce stiffness properties of plantar fascia, Achilles tendon and M. gastrocnemius.

## METHODS

This longitudinal study included 76 healthy subjects (26 men, 50 women, age  $24.7 \pm 4$  yrs, weight  $68.6 \pm 15$  kg, height  $174 \pm 9.5$  cm). They were divided into a control (CG,  $n = 38$ ) and a foam rolling group (FRG,  $n = 38$ ). Participants with a body mass index greater than  $25 \text{ kg/m}^2$  were excluded.

Stiffness [N/m] was measured non-invasively for the following structures using myometry (MyotonPro, Myoton AS, Estonia) in a lying position:

- Plantar fascia (PF), about 15cm posterior from the calcaneus on the medial portion of PF
- Achilles tendon (AT), between the medial and lateral malleoli
- M. gastrocnemius (MG), 20cm above AT

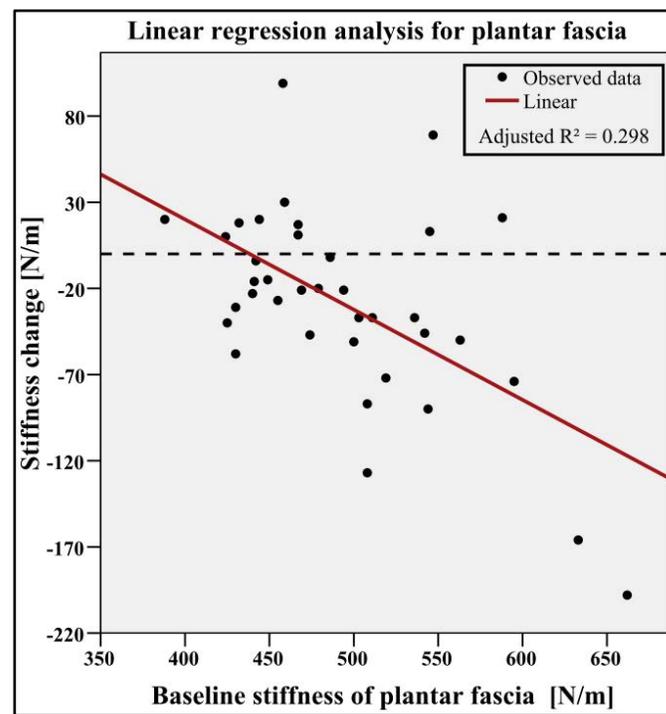

The measurements were realized within one week before and one week after eight weeks of whole-

body SMR with focus on the lower extremities. The 16 sessions (2 sessions à 20 min per week) were instructed by the examiners. The standardization of the foam rolling was ensured by a speed of five seconds per direction for each structure and a pain scale.

Wilcoxon test and regression analysis were used for statistical evaluation.

## RESULTS AND DISCUSSION

After eight weeks, foam rolling causes a significant decrease of 7.4% for PF stiffness ( $p < 0.05$ ). Further, a significant reduction of 4.8% was observed for MG ( $p < 0.05$ ), while no difference was found for AT (-1.4%). The control group remained at constant levels.

**Figure 1:** Linear regression of the stiffness change of PF of the FRG ( $p = 0.0003$ )

The regression analysis of the baseline stiffness and its change after eight weeks results in an adjusted coefficient of determination ( $R^2$ ) of 0.3 for PF (Fig. 1) and 0.26 for MG (both  $p < 0.05$ ). After the subdivision of the data of the FRG in low, middle and high stiffness groups, a clear trend is obvious for PF and MG. PF shows reductions of 2.5% to 4.2% to 9.8% while MG stiffness decreases by 0.8% to 4.4% to 7.5% (Table 1). Again, the CG shows no difference.

**Table 1:** Descriptive statistics of the influence of low, middle and high tissue stiffness levels on the outcome of an SMR intervention.

	<b>Low</b> (n = 12)	<b>Middle</b> (n = 13)	<b>High</b> (n = 13)
<b>PF</b>	-2.5%	-4.2%	-9.8%
<b>MG</b>	-0.8%	-4.4%	-7.5%
<b>AT</b>	1.4%	1.6%	-3.5%

Eight weeks of SMR with foam rollers provide evidence for the first time that stiffness of MG and PF can be reduced. In contrast, the AT shows no change. Thus, there are no consistent results for the connective tissues (PF, AT).

To better understand the tissue response, we further examined whether the effect of a SMR is influenced by the baseline value of tissue stiffness. The adjusted  $R^2$  for both PF and MG shows an obvious influence of foam rolling on tissue stiffness in dependence on the tissue's baseline value (Fig. 1). The formed groups of high, middle and low stiffness also support our assumption (Table 1).

These findings demonstrate for the first time that fibrous connective tissues and muscles may react to a given stimulus in a stiffness-dependent way: The stiffer the tissue, the greater the impact of an SMR intervention, except for the AT. An explanation might be an insufficient stimulus to trigger adaptation processes of the AT as it is the strongest tendon of the human body [3]. The decrease of PF stiffness may be explained by mechanotransduction pathways of fibroblasts [4,5,6], while the reduction of MG stiffness could be due to change in muscle tone. More research is necessary to explain the mechanisms behind our results.

## CONCLUSIONS

Especially the reduction of high tissue stiffness may be important to treat or prevent medical conditions like plantar fasciitis [2].

It is important to understand how the human body reacts to different stimuli like foam rolling to better understand adaptation processes. Therefore, stiffness properties of fibrous connective tissues and muscles are important for tissue reactions and should be in the focus of future studies.

## INTRODUCTION

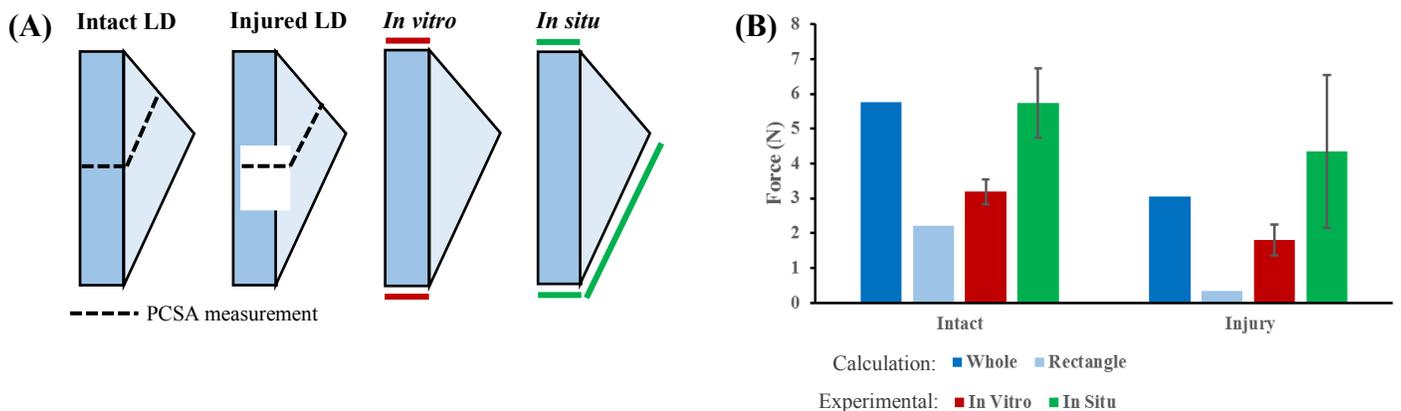

Volumetric muscle loss (VML) injuries can occur in a variety of traumatic injuries and congenital diseases where there is a permanent loss of muscle function. Current treatment options for VML injury are limited to physical therapy and functional free muscle transfer, in which a healthy muscle from the patient is transplanted to the injury site to restore motor function and joint movement. However, these procedures are associated with poor engraftment and donor site morbidity. Alternative therapies are being developed, but the lack of mechanistic insight greatly limits development of therapeutic strategies.

The latissimus dorsi (LD) muscle of rodents is a well-established model for VML injuries, and the current standard for assessing functional recovery after VML injury is to quantify muscle force using an organ bath system after muscle excision [1]. Although this system provides consistent results, only a portion of the muscle is fixed longitudinally. However, a more physiologically relevant characterization of the

muscle force can be achieved using the *in situ* method, where the LD is maintained and anchored in its native environment [2]. We used both testing methods in combination with biomechanical analysis to understand the mechanisms of force transmission in un-injured and injured muscles.

## METHODS

Volumetric muscle loss injuries of size 1.5 x 1.2 cm were assessed in the latissimus dorsi muscle of rats. After 2 months, unrepaired VML injuries were compared to native muscles in 20-week rats. In the *in vitro* method, whole LD muscles were explanted and studied using an organ bath system [1]. The muscles were mounted in an organ bath chamber containing Krebs-Ringer bicarbonate buffer. The distal tendon was attached to a fixed support, and the proximal tendon was attached to the lever arm of a force transducer. Maximum isometric force was determined based on applying direct muscle electrical stimulation at varying frequencies.

**Figure 1:** (A) Schematics of the rat LD represented as rectangle and fan parts and different fixation methods. VML injury, shown as a white rectangle, is in both parts. (B) Calculated LD forces reveal mechanisms of force production measured experimentally.

In the *in situ* method, the LD muscle was minimally dissected and maintained in its native environment with blood supply and nerve innervation. A nerve cuff was placed around the motor nerve and the muscle's distal tendon was attached to the lever arm of a force transducer. The nerve was then stimulated and the peak isometric forces were measured at a range of stimulation frequencies.

To better understand the biomechanical mechanisms of the two different experimental methods, we developed a simplified geometric representation of the muscle to calculate the contractile force, assuming all forces measured were transmitted longitudinally along the length of the muscle fibers (Fig. 1A). To do these calculations, the muscle was simplified as polygonal geometry, consisting of a rectangle portion and triangular portion. Size and thickness were determined based on dissected LD muscles from 20-week rats. In the mid-section of both portions, the physiological cross-sectional area (PCSA) was calculated. Then using a specific tension ( $\sigma_o$ ) of 0.115 N/mm<sup>2</sup>, the total force was determined for each portion (Eqn 1) as well as the entire muscle (Eqn 2).

$$F = PCSA * \sigma_o \quad (1)$$

$$F_{whole} = F_{rect} + (F_{fan} * \cos(28.16^\circ)) \quad (2)$$

## RESULTS AND DISCUSSION

The *in situ* force measurements were approximately twice as large as the *in vitro* forces for intact and injured muscles (Fig. 1B). The *in vitro* setup anchored only the rectangular portion of the muscle and was expected to capture the longitudinal force production. The *in situ* setup anchored both the longitudinal and pennate fibers of the muscle, and given that a much larger portion of the muscle was anchored, it was expected to produce larger forces than the *in vitro* setup. With an injury, nearly the entire rectangular portion of the muscle was removed, yet both testing methods revealed

substantial force production. This observation of the *in vitro* data pointed toward lateral transmission as the underlying mechanism of force production.

The calculated force (assuming all longitudinal force transmission) for the whole LD in the intact muscles was consistent with the *in situ* measurement, suggesting that when all areas of attachment are fixed, longitudinal force transmission dominates force production (Fig. 1B). The calculated force for the injured LD was within one standard deviation of the measurements, though the average was approximately 30% lower than *in situ* measurements. In the intact muscle, the *in vitro* force production (3.19 N) was higher than the rectangular portion (2.21 N), suggesting that the untied fan portion of the muscle likely contributes to the measured force via lateral force transmission. Further, the *in vitro* method (1.8 N) measured a force significantly larger than the rectangular portion (0.33 N), even though only the longitudinal portion was fixed during testing. Therefore, lateral force production from the fan was inferred to be contributing to force production. Moving forward, the observations from this study can be further explored and developed using finite-element modeling.

## CONCLUSIONS

The experimental testing differences between *in vitro* and *in situ* analysis allowed force production to be measured in both longitudinal fibers alone or in combination with pennate fibers. Capitalizing on this distinction, we were able to demonstrate through experimental and biomechanical analysis that lateral force transmission likely affects force production in the cases where not all fibers are fixed end-to-end.

# ELASTIC SHAPE CHANGE AND MECHANICAL BEHAVIOR IN THE APONEUROSSES OF JUMPING AND LANDING TURKEYS

<sup>1</sup> Christopher J. Arellano, <sup>2,3</sup> Nicholas J. Gidmark, <sup>2</sup> Nicolai Konow, and <sup>2</sup> Thomas J. Roberts

<sup>1</sup> University of Houston, Houston, TX, USA

<sup>2</sup> Brown University, RI, USA

<sup>3</sup> Knox College, IL, USA

email: [carellano@uh.edu](mailto:carellano@uh.edu), web: <http://uh.edu/class/hhp/people/cjarellano>

## INTRODUCTION

Aponeuroses are sheet-like elastic structures that undergo complex patterns of biaxial shape change during muscle contractions [1]. In our recent work [2], we suggested that the force resulting from radial expansion (i.e. muscle bulging) of shortening muscle fibers *in situ* drives an increase in aponeurosis width, having the potential to influence its mechanical behavior in the longitudinal direction (along the muscle's line of action).

Elastic mechanisms such as tendons serve the important function of amplifying and attenuating power output and input into muscle, modulating the directional flow of energy that allows animals to perform an array of locomotor activities [3]. Aponeurosis shape change is a prime candidate for such a mechanism because it can modulate its longitudinal stiffness and influence the amount of elastic energy storage and release [2]. We tested two hypotheses: **1)** longitudinal stiffness is reduced when aponeurosis width decreases and because elastic energy (EE) storage is inversely proportional to longitudinal stiffness, **2)** a lower longitudinal stiffness will yield greater elastic energy storage for a given amount of force. Our hypotheses were guided by Hooke's law, which for a linear spring states that force is proportional to stiffness and amount of stretch:

$$F = kx$$

Moreover, the elastic energy stored in the spring is the integral of work performed to stretch the spring:

$$EE = \int_i^f kx dx = \frac{1}{2} kx^2$$

Since we are interested in the amount of EE storage for a given amount of force, we substitute  $x = F/k$  into the previous equation to yield:

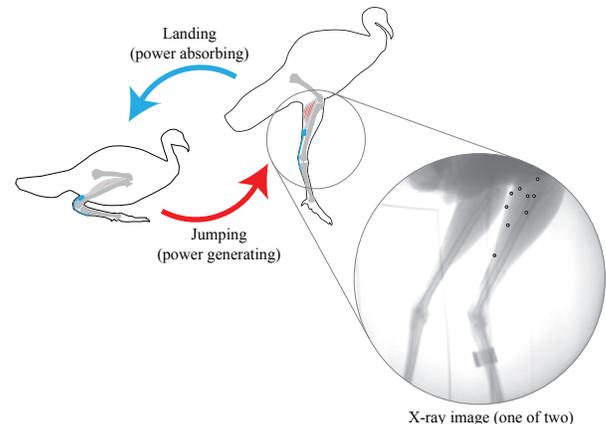

$$EE = \frac{1}{2} k \left( \frac{F}{k} \right)^2 = \frac{1}{2} \frac{F^2}{k}$$

Therefore, if the force required to stretch the spring is constant, the EE stored in the spring will be inversely proportional to its longitudinal stiffness:

$$EE \propto \frac{1}{k}$$

## METHODS

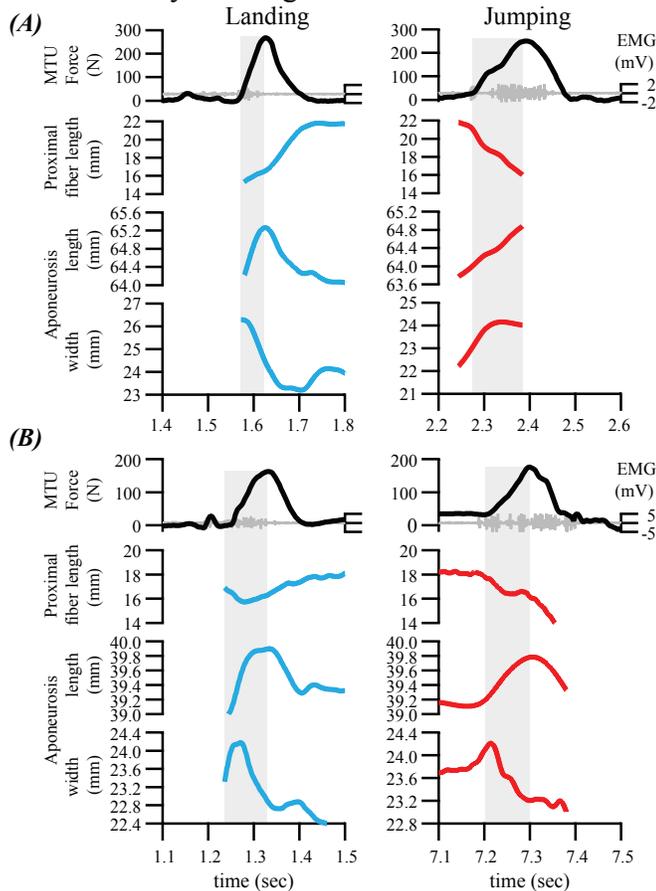

Following established methods [1,3], small (0.8-1.0 mm diameter) radiopaque markers were surgically implanted along muscle fibers and on the aponeurosis of the lateral gastrocnemius (LG) muscle of three wild turkeys, *Meleagris gallopavo* (Fig. 1). Strain gauges were also implanted on the calcified region of the distal tendon [4].

**Figure 1:** In combination with x-ray video, an *in vivo* preparation allowed us to quantify the mechanical behavior of the aponeurosis in landing and jumping turkeys.

*In vivo* measurements of muscle force were combined with high-speed biplanar x-ray video for a series of landing ( $n=16$ ) and jumping ( $n=14$ ) trials. For each trial, radiopaque marker positions were tracked using an established marker-based workflow [3]. We measured the amount of EE storage by plotting MTU force as a function of aponeurosis length and then integrated the area

underneath the curve during the period of force rise from 30N-130N. The linear slope of MTU force versus aponeurosis length during this period was calculated to yield longitudinal stiffness.

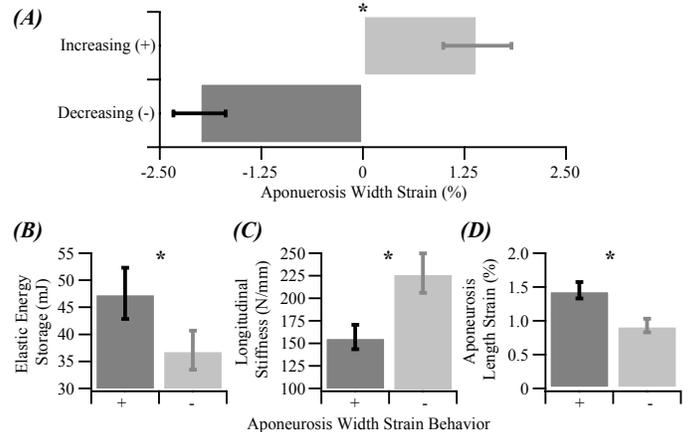

**Figure 2:** Representative trials for two birds (*A and B*). We captured muscle-tendon unit (MTU) force, fiber length, aponeurosis length and width during power absorbing (landing) and power generating (jumping) activities. Shaded regions indicate period of total MTU force rise.

## RESULTS AND DISCUSSION

During MTU force rise, aponeurosis width either increased or decreased. During landing for one bird (Fig. 2A), fiber length increased slightly while aponeurosis length increased and width decreased. During jumping, muscle fibers shortened while aponeurosis length and width increased. Another bird (Fig. 2B) shows the same fiber and aponeurosis behavior during landing. During jumping, however, fibers shortened while aponeurosis length increased and width decreased. To understand the influence of aponeurosis width on the mechanical behavior in the longitudinal direction, we compared trials where aponeurosis width either increased or decreased, irrespective of whether the bird jumped or landed.

*EE Storage and Longitudinal Stiffness:* When aponeurosis width decreased during periods of MTU force rise (Fig. 3A), the elastic energy stored in the aponeurosis was 28% higher ( $p=0.041$ , Fig. 3B) and its longitudinal stiffness was 31% lower ( $p=0.005$ , Fig. 3C) when compared to trials where aponeurosis width increased.

**Figure 3:** Data represent means  $\pm$  S.E.M. for aponeurosis width strain (*A*), elastic energy storage (*B*), longitudinal stiffness (*C*), and aponeurosis length strain (*D*).  $p < 0.05$ .

## CONCLUSIONS

Our findings support our hypotheses that longitudinal stiffness decreases when aponeurosis width decreases and thus, this biological spring has the capacity to store greater amounts of elastic energy. These data reveal that distinct changes in aponeurosis width during periods of MTU force rise *in vivo* have a profound influence on the mechanical behavior of the aponeurosis in the longitudinal direction

## Introduction

The long-term effects of motor impairments on upper limb muscle architecture are unknown post stroke. It is hypothesized that motor impairments may cause decreased use of the paretic upper limb which, over time, may cause muscle atrophy and fatty infiltration. The aim of this research is to quantify long-term changes in muscle volume and intramuscular fat following hemiparetic stroke in the paretic elbow.

## Methods

Eight participants post stroke, five males and three females were recruited to participate in the study. The average age of the participants was 61 years and the average time since stroke was 13 years. The participants were moderate to severely impaired, with an average score of 23 out of 66 on the upper extremity Fugl-Meyer Assessment of Motor Recovery (range: 12/66 to 33/66).

Magnetic resonance images were acquired using a 3D gradient echo pulse sequence of the upper limb (TR=7ms, flip angle=12°, matrix size = 256x216, slice thickness = 3mm). The Dixon method was used to estimate percent fat using an echotime (TE) of 2.39ms, when water and fat are in phase and a TE of 4.77ms, when water and fat are out of phase. Using AnalyzeDirect, manual segmentation of the biceps, triceps and brachialis was done to measure muscle volume and percent intramuscular fat. Percent fat was calculated using a ratio of the intensity of the fat image compared to the intensity of the water image. The volume of intramuscular fat was calculated for each muscle by multiplying the muscle volume by percent fat. The volume of contractile tissue was determined by subtracting the

volume of intramuscular fat from the total muscle volume.

## Results and Discussion

For all three muscles of interest, the volume of contractile element was significantly larger ( $P<0.05$ ) in the non-paretic limb compared to the paretic (Fig. 1). The non-paretic biceps was 33% larger than the paretic, the triceps was 30% larger and the brachialis was 12% larger.

For all three muscles, the percent intramuscular fat was significantly greater ( $P<0.05$ ) in the paretic limb compared to the non-paretic (Fig 2). The percent intramuscular fat for the non-paretic biceps, triceps and brachialis were 7.2%, 7.0% and 8.1%, respectively. The percent intramuscular fat for the paretic biceps, triceps and brachialis were 9.1%, 9.1% and 10.9%, respectively.

The volume of intramuscular fat, however, was similar between the paretic and non-paretic limbs, for all three muscles (Fig. 3). For the biceps and triceps, the volume of intramuscular fat was greater in the non-paretic limb compared to the paretic. The volume of intramuscular fat was 9.97, 24.91 and 9.82 cm<sup>3</sup> for the non-paretic biceps, triceps and brachialis, respectively. The volume of intramuscular fat was 7.79, 22.24 and 11.04 cm<sup>3</sup> for the paretic biceps, triceps and brachialis, respectively.

This study brings new insight to the way in which intramuscular fat is reported. Intramuscular fat is often reported as a percentage of muscle volume [1,2]. However, this study shows that this can be misleading by suggesting an increase in intramuscular fat, reported as a percentage, may be

due to a decrease in muscle volume not an increase in fat volume.

### Conclusions

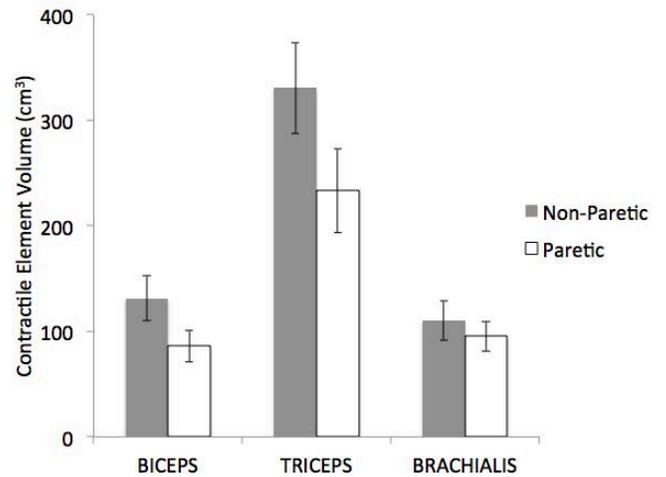

The triceps, biceps and brachioradialis muscle volumes in the paretic limb were reduced compared to the non-paretic limb. This was mostly due to a difference in contractile element volume and not a difference in intramuscular fat.

Detailed information about the pattern of atrophy and changes (if any) in intramuscular fat after stroke will help guide and improve rehabilitation. The methods developed in this study can be used as highly sensitive outcome measures to track the efficacy of rehabilitation techniques aimed at reducing and preventing muscle atrophy. Additionally, the muscle volume measures obtained from this study can be used to improve stroke specific musculoskeletal models, since muscle volume is one parameter relied upon for the accurate prediction of joint torques.

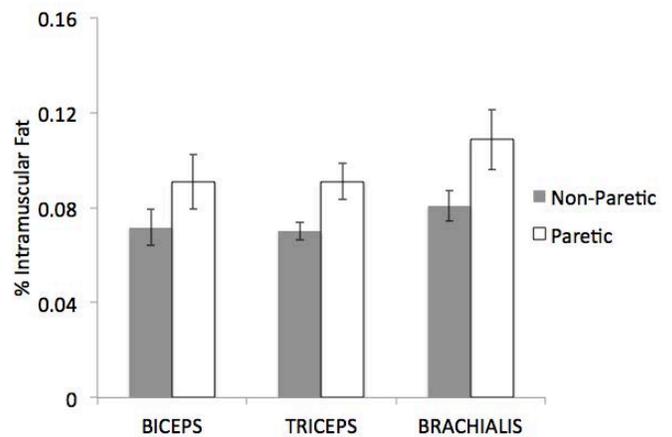

Future work involves the study of changes in volumetric measures at more distal muscles. Since distal joints, like the wrist, often experience greater deficits [3] post stroke, changes in muscle and intramuscular fat volumes may be more pronounced for muscles that cross these joints.

## INTRODUCTION

Aberrant scapular position and movement are believed to contribute to shoulder pain and dysfunction which is a common reason for seeking medical attention [1]. Resting pectoralis minor muscle (PMm) length has been proposed to be a contributing factor to shoulder pain as length of this muscle is thought to influence positioning and movement of the scapula on the thorax [1-3].

Previous research has found that individuals with a short resting PMm length demonstrate scapular kinematics similar to individuals with shoulder impingement syndrome [2]. These researchers theorized that PMm passive tension may be a cause of these aberrant movements; however, PMm elongation (amount the muscle can be stretched) was not measured in their study. The purposes of this research were to determine if: 1) active and passive PMm elongation differed in individuals with short and typical resting PMm lengths, and 2) PMm length change during an overhead reaching task differed between groups.

## METHODS

Twenty-six participants (17 females, age =  $26 \pm 4$  years, height =  $1.69 \pm 0.08$  m, mass =  $66.3 \pm 10.4$  kg), who were asymptomatic for shoulder pathology, volunteered for this study. The study was approved by Drexel University's Institutional Review Board and participants provided written informed consent. PMm length at rest and during active and passive stretch conditions (Figure 1) was measured using a Palpation Meter (Performance Attainment Associates, St. Paul, MN). PMm length was measured as the distance between the coracoid process and the inferior medial aspect of the fourth rib. For active stretch condition, participants were asked to maximally elevate and retract their scapula

(Figure 1B). The passive stretch condition was performed by a physical therapist. The participants arm was placed in approximately  $30^\circ$  of flexion. The therapist placed their hand on the distal humerus and, while stabilizing the participant's spine, pushed their shoulder in a superior/posterior direction until firm tissue resistance was encountered (Figure 1C). Previous research has shown excellent intra- and inter-rater reliability for all measurement conditions [4]. Intra- and inter-rater reliability for resting, active and passive PMm length measures ranged from  $ICC_{3,2} = 0.84-0.92$  and  $ICC_{2,2} = 0.80-0.90$ , respectively. Resting PMm length was normalized to height to calculate the pectoralis minor index (PMI) which was used to assign subjects to groups: short ( $PMI < 8.9$ ) and typical ( $8.9 \leq PMI < 10.5$ ) [2]. PMm muscle elongation (percent change) was determined by  $[(\text{active or passive length} - \text{resting length})/\text{resting length}] * 100$ .

Three-dimensional shoulder girdle kinematics were collected at 100Hz with the Flock of Birds electromagnetic motion capture system (Ascension Technology Corporation, Shelburne, VT) and The Motion Monitor™ software (Innovative Sports Training, Inc., Chicago, IL). Sensor placement was based on the International Society of Biomechanics recommendations for shoulder kinematics [5]. Additional landmarks of the coracoid process and fourth rib were digitized to measure PMm length. Three trials of dominant side scapular plane humeral elevation were used for data analysis. A custom Matlab (MathWorks, Natick, MA) program was used for data processing. PMm length change during overhead reaching was defined as the change in length from rest to  $120^\circ$  of humeral elevation. PMm length change (percent change) was determined by  $[(\text{PMm length at } 120^\circ \text{ of humeral elevation} - \text{PMm length at rest})/\text{PMm length at rest}] * 100$ .

PMm elongation during active and passive lengthening, and PMm length change during overhead reaching, respectively, were compared between groups with separate independent t-tests ( $p < 0.05$ ).

## RESULTS AND DISCUSSION

Active and passive PMm elongation and PMm length change during overhead reaching were similar between groups (Table 1).

**Table 1:** PMm elongation and overhead length changes (mean  $\pm$  standard deviation).

Variable	Short	Typical	P-Value
Active Elongation	14.7 $\pm$ 5.5%	14.0 $\pm$ 7.3%	0.80
Passive Elongation	19.2 $\pm$ 7.6%	19.1 $\pm$ 6.4%	0.95
Overhead Length Change	16.6 $\pm$ 0.4%	16.0 $\pm$ 0.7%	0.80

To the best of our knowledge we are the first to report PMm active and passive elongation values and muscle length change during overhead reaching. Our results indicate that those with short resting PMm length exhibit similar muscle elongation and muscle length changes during overhead motions as those with typical resting PMm length. Borstad and Ludwig found that individuals

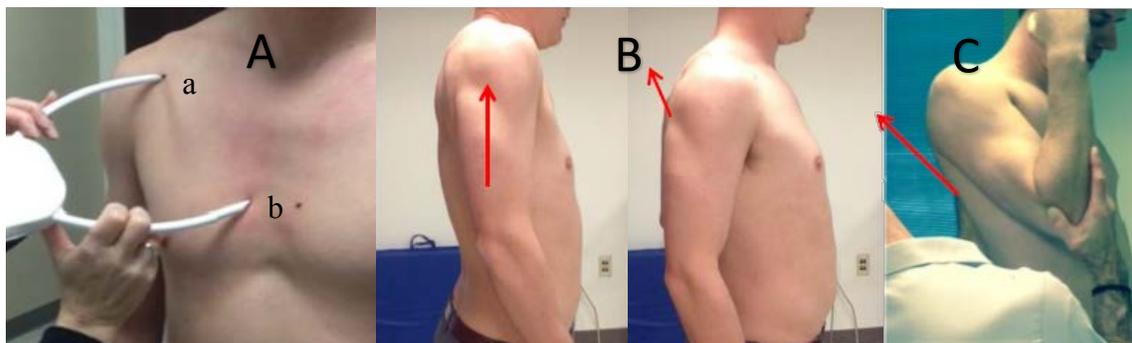

with a short PMm displayed increased scapular internal rotation and reduced posterior tilt compared to individuals with a long PMm [2]. They hypothesized that passive tension of the PMm may have contributed to altered scapulothoracic motion [2]. However, the present findings cast doubt upon the belief that individuals with a short resting PMm length have PMm tightness. Populations differed between the two studies. In our study, individuals with short and typical resting PMm length were compared, whereas Borstad and Ludwig compared short versus long resting PMm length.

## CONCLUSIONS

No differences were found in PMm elongation or length change during overhead motions between individuals with short and typical resting PMm lengths. These findings indicate that resting PMm length is not appropriate for determining whether or not the PMm is tight.

## INTRODUCTION

The plantarflexion moment arm of the Achilles tendon (ATma) influences the mechanical advantage of the triceps surae and is thus a critical determinant of the mechanics of push-off during walking. ATma may be measured *in vivo* from magnetic resonance images as the planar distance from the center of talocrural joint rotation (determined from relative bone motions) to the tendon line of action [1] or by quantifying tendon excursing using ultrasound and relating it to joint rotation [2]. More recently, a hybrid technique has been described in which ATMA is found as the 3D distance from the tendon line of action to the ankle joint center [3,4]. In this technique, the ankle joint center is approximated by the midpoint of the transmalleolar axis, located using retroreflective markers placed over the malleoli. The tendon is located using an ultrasound imaging probe with markers affixed to it in order to locate the tendon within the laboratory.

There is some question, however, as to whether the transmalleolar midpoint or transmalleolar axis are adequate representations of the center or axis of ankle rotation. Roentgen stereophotogrammetric studies of bone motions have revealed the axis of talocrural rotation to differ from the transmalleolar axis and move during dynamic tasks [5]. An approach in which measured motion of the foot with respect to the shank is used to locate the center or axis of rotation may provide better estimates of ATma in the hybrid technique. For example, finite helical axis decomposition of foot-shank rotations may yield improved estimates of the axis of rotation.

The purpose of this study is to quantify ATma using an ultrasound-based geometric method similar to the hybrid approach, with (1) the axis of rotation taken to be the transmalleolar axis (TA); (2) the center of rotation taken to be the transmalleolar midpoint (TM); and (3) a “functional” axis of rotation determined from finite helical axis decomposition

(FA). We hypothesized that ATma estimated using the FA will differ from those obtained using TA and TM, and that ATma computed from TM will be larger than those found from TA.

## METHODS

Eight participants (3 men, 5 women, age:  $27 \pm 6$  years, height:  $1.70 \pm 0.07$  m, mass:  $69 \pm 11$  kg) were recruited for the study. All experimental procedures had the approval of the Institutional Review Board of The Pennsylvania State University. A LogicScan 128 ultrasound probe (HL9.0/60/128Z-2; Telemed) was strapped in place with Coban (3M) elastic wrap over the right Achilles tendon below the musculotendinous junction, with four markers attached to the probe. Additional markers were placed on the right lateral and medial femoral epicondyles and malleoli, and clusters of four markers each were placed on the shank and the heel.

The participants were instructed to rise and lower on their toes in time to a 1 Hz metronome for three seconds, and each of these trials was repeated three times. This was followed by unloaded trials in which the subject stood on the left leg while performing right foot plantar- and dorsiflexion motions at 1 Hz, with the knee fully extended. Marker motions were captured with six Eagle cameras (Motion Analysis Corp.) operating at 100 Hz, whilst the synchronized ultrasound image data were sampled at 15 Hz.

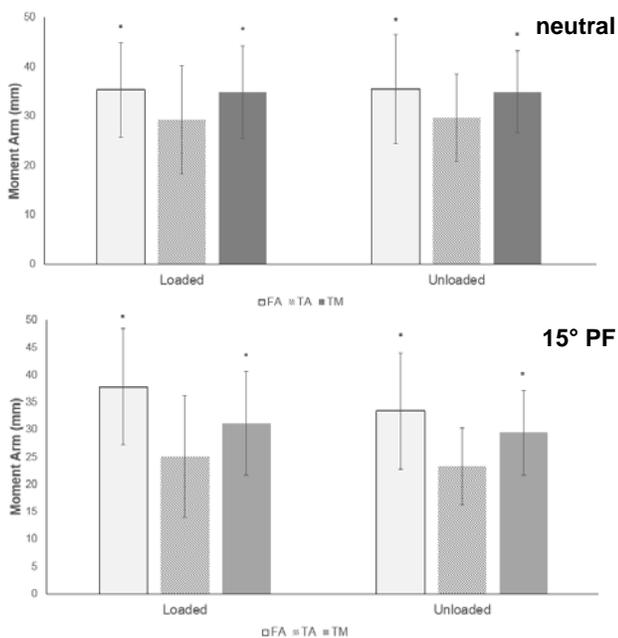

Data processing and image analysis were performed using custom-written routines in MATLAB (MathWorks, Inc.). For the TA and FA methods, ATma was computed as the shortest distance between each axis and the tendon line of action, identified from ultrasound images and transformed to the ground reference frame. For the TM method, ATma was found as the shortest distance between the transmalleolar midpoint and the tendon line of action. Ankle joint angles were computed using Euler/Cardan angles and a modified version of the

ISB joint coordinate system recommendations for the ankle [6].

Each ATma was plotted against plantarflexion-dorsiflexion angle. A second-order polynomial was fit to the ATma versus angle points and these fits were used to estimate moment arms in neutral position (0°) and 15° plantarflexion. Pearson's correlations were computed to quantify relationships between the ATma, and repeated-measures two-way ANOVAs were used to determine differences in ATma at neutral and 15° PF between methods (TA, TM, FA) and loading conditions (loaded, unloaded) in SPSS (v23, IBM, USA) with  $\alpha = 0.05$ .

## RESULTS AND DISCUSSION

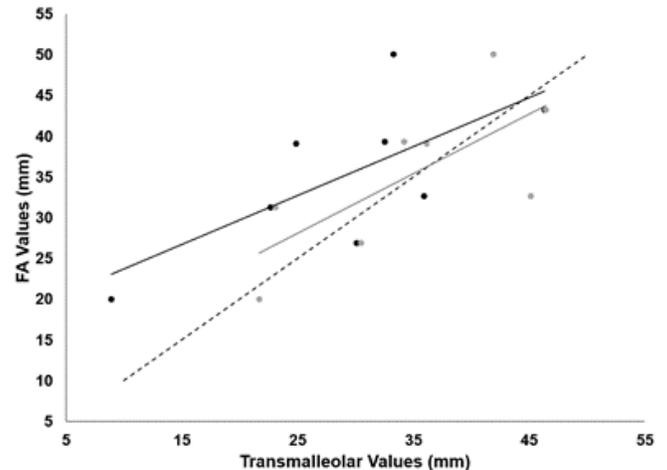

ATma in neutral position and 15° PF computed using FA were larger than corresponding values computed from TA or TM (all  $p < 0.05$ ) (Fig. 1). ATma computed from FA in neutral position were strongly correlated with both TM ( $r = 0.72$ ,  $p < 0.05$ ) and TA ( $r = 0.69$ ,  $p = 0.06$ ), but ATma from FA was more closely approximated by ATma from TM and was underestimated by ATma from TA (Fig. 2).

**Figure 1.** Achilles tendon moment arm for loaded and unloaded trials with the ankle in neutral position (top) and 15° PF (bottom). Asterisks denotes significant differences when compared with TA.

ATma computed from FA or TM in the loaded condition were similar in magnitude to those previously reported for the hybrid technique [3]. ATma from FA in the loaded condition increased

with plantarflexion, following a pattern previously measured using MR imaging [1]. This pattern was not observed, however, with ATma from TA or TM. These results suggest that the combination of ultrasound, motion capture, and a joint axis determined via helical axis decomposition may provide a reasonable approximation of ATma measured using MR imaging.

**Figure 2.** ATma at neutral position from FA plotted versus ATma from TA (black) and versus ATma from TM (gray). The dashed line represents  $y = x$ .

## CONCLUSION

The FA and TM methods give ATma similar to each other and to values previously reported. ATma from FA varies with joint angle in a manner consistent with ATma computed from MR imaging, whilst ATma from TM did not. Using ultrasound and motion capture to estimate ATma is an easier and cost-effective alternative to MRI, but the manner in which the joint center or axis is characterized may affect moment arm estimates in important ways.

These results imply that using ultrasound and a FA approximation of talocrural rotation may be a low-cost and portable method of obtaining three-dimensional ATma, providing insight into locomotor mechanics that may not otherwise be possible.

## INTRODUCTION

Elucidating the design and function of human skeletal muscles is required to understand normal function and pathological conditions, and to suggest surgical interventions to recover function after injury. One of the most important structures that can be used to elucidate muscle design is the sarcomere [1], the functional unit of force generation in muscle whose length is an excellent predictor of active muscle force [2].

Biomechanical models, based on previously published muscle, joint and tendon properties, is one approach used to understand musculoskeletal function. However, the vast majority of these theoretical models are not validated against primary experimental data. It is also fair to critique most human experimental measurements as not being explained theoretically using models to provide a mechanistic understanding of experimental results.

Thus, the purpose of this study was to compare human vasti sarcomere lengths measured intraoperatively during knee flexion in joint replacement patients to biomechanically-determined sarcomere lengths determined using a theoretical model generated from independent muscle and joint measurements on cadaveric specimens.

## METHODS

Sarcomere length was measured from human patients ( $n=7$ ) using a protocol approved by the Committee on the Use of Human Subjects at the University of California, San Diego and the Department of Veterans Affairs, San Diego. Measurements were performed on vastus lateralis (VL) and vastus medialis (VM) muscles of patients

undergoing total knee replacement. After exposing the VL and VM, a muscle clamp was used to obtain a sample when the knee was flexed to  $45^\circ$  ( $0^\circ$  is full extension) and with the knee flexed to  $90^\circ$  taking care to maintain natural muscle planes and lengths. Sarcomere length was measured by diffraction [3].

To provide independent input data for a biomechanical model, cadaveric lower extremities were used for determination of moment arm and muscle architecture ( $n=10$ ). Tendon excursion of patellar tendon and knee joint angle was measured as described in [4] while the knee was passively ranged from  $0-100^\circ$  of flexion. Then, muscle architectural measurements, such as muscle mass, muscle length, fiber length, pennation angle, and sarcomere length, were measured as in [5].

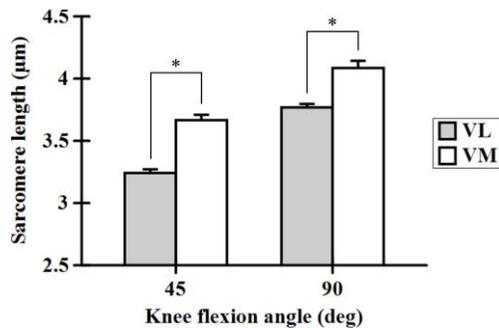

To predict sarcomere length with respect to knee joint angle, a modified Hill-type musculotendon model [6] for each VL and VM was created for each cadaveric specimen. Muscle-tendon length was determined from tendon excursion data and measured muscle length.

To compare intraoperatively-measured and predicted sarcomere VL and VM length, a paired  $t$ -test was performed with a significance level ( $\alpha$ ) of 0.05, using SPSS Statistics (version 21, IBM, Chicago).

## RESULTS AND DISCUSSION

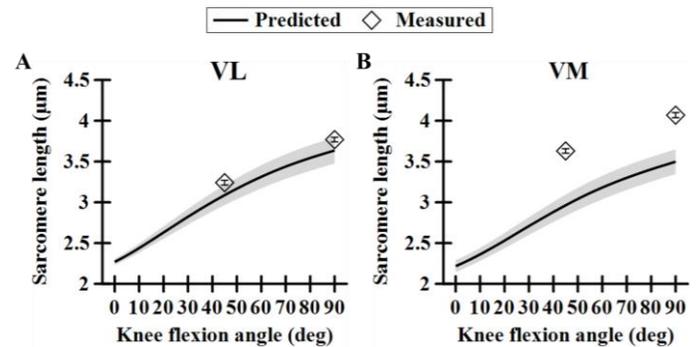

Intraoperatively-measured sarcomere length in the VM was significantly longer, by about  $0.5 \mu\text{m}$ , than VL ( $p<0.01$ ), for both joint angles, and sarcomere length increased by  $\sim 0.5 \mu\text{m}$  when the knee was flexed from  $45^\circ$  to  $90^\circ$  (Figure 1). These data demonstrate that sarcomere length is consistent among humans for a given muscle and that

sarcomere length for VM is consistently longer than that of the VL.

**Figure 1:** Vastus lateralis (VL) and vastus medialis (VM) sarcomere length measured intraoperatively. Asterisk (\*) indicates significant difference between muscles ( $p < 0.01$ ).

Predicted sarcomere length, generated from the model, agreed very well with measured sarcomere length for the VL (Figure 2A), but not as well for the VM (Figure 2B). For the VL, as the knee was flexed from full extension ( $0^\circ$ ) to flexion ( $90^\circ$ ) sarcomere length was predicted to increase from  $\sim 2.3$  to  $\sim 3.6$   $\mu\text{m}$ , which was within a standard error of those measured intraoperatively (Figure 2A). For the VM, predicted sarcomere length ranged from  $\sim 2.2$   $\mu\text{m}$  with the knee fully extended to  $\sim 3.5$   $\mu\text{m}$  with the knee flexed to  $90^\circ$ . However, the measured sarcomere length was  $\sim 3.7$   $\mu\text{m}$  at  $45^\circ$  (compared to a model prediction of  $\sim 3$   $\mu\text{m}$ ) and  $\sim 4.1$   $\mu\text{m}$  at  $90^\circ$ . Thus, intraoperatively-measured values were  $\sim 5$  standard errors away from model predictions. Possible reasons for this disparity are: (1) Intraoperative VM data were obtained from patients undergoing total knee replacement whereas cadaveric data were obtained from subjects without known orthopedic problems. Considering that the range of motion (ROM) of patients is limited, it is possible that the limited ROM resulted in an adaptation of muscle to more extended knee joint angles and/or (2) intraoperative VM data were taken from distal pole of the VM, also known as the vastus medialis obliquus (VMO), since limited surgical exposure made it impossible to obtain samples more proximally. The VMO clearly has different morphology compared to the more proximal VM and thus, VMO properties may not fairly represent whole VM anatomy and function.

**Figure 2:** Comparison between predicted (solid line) and measured (diamond markers) sarcomere lengths of (A) VL and (B) VM. Crosses in diamond markers and shaded regions around lines represent one standard error of the mean.

## CONCLUSIONS

The fact that experimental and theoretical data agree very well for the VL but not for the VM requires a thoughtful consideration of the nature of independent validation experiments, the specific anatomy of these two muscles and the significance of these findings for vastus physiological function. These types of cross-validation experiments must be implemented widely in order to provide support for the application of models to the fields of surgery, sports medicine and kinesiology.

# RELATION BETWEEN FORCE STEADINESS AND EMG AMPLITUDE: EFFECT OF SIGNAL PROCESSING

Jeffrey Peterson and Kevin Keenan

University of Wisconsin-Milwaukee, Milwaukee, WI, USA  
email: peter724@uwm.edu

## INTRODUCTION

Functional limitations, including walking, climbing stairs, and maintaining balance, become increasingly prevalent as adults age. Performance on force steadiness [1] and maximal strength [2] tasks have been related to functional limitations in older adults. However, the underlying neural mechanisms driving the change in performance with aging remain unclear. Changes in electromyogram (EMG) amplitude may be related to performance, and although EMG amplitudes are frequently reported to increase in older vs. young adults [3], few studies examine the relationship between force steadiness and increased EMG amplitude in older adults. This limitation may be due to the inherent variability of single bipolar EMG to estimate muscle activity.

High-density surface EMG can increase the accuracy of muscle force estimation compared to single bipolar EMG, with multichannel bipolar signals reported to more accurately estimate force than monopolar signals [4]. However, whether high-density surface EMG can improve upon the ability of bipolar EMG to predict force steadiness remains unclear. Therefore, the purpose of our study was to examine the differences in EMG amplitude and force steadiness between young and older adults during a 5% maximum voluntary contraction (MVC) dorsiflexion task, to examine the relationship between EMG amplitude and force steadiness, and to examine how processing of the EMG signal influences the strength of this relationship. We also examined differences in dorsiflexion strength and if strength was related to dorsiflexion force steadiness.

## METHODS

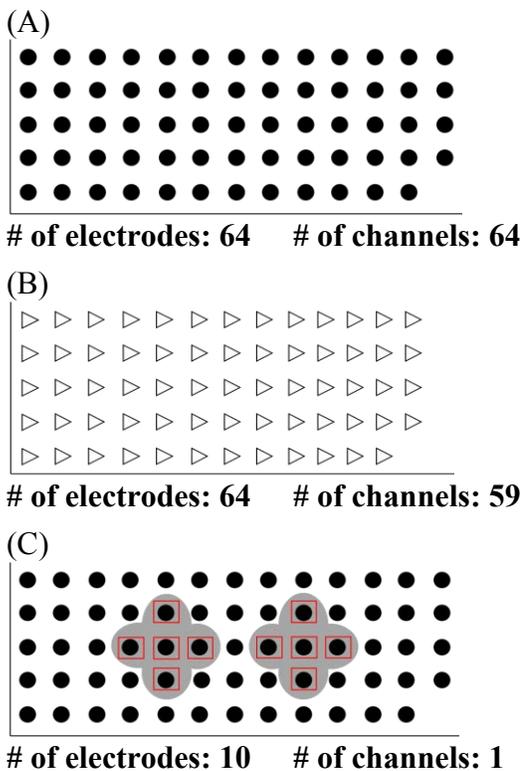

17 young ( $26.5 \pm 4.7$  years, 10 females) and 18 older ( $73.9 \pm 7.6$  years, 8 females) adults performed a

dorsiflexion task with the left knee extended and ankle in a neutral position. Participants performed a series of MVCs followed by two 30 s trials of the steadiness task at 5% MVC. Performance was quantified as the coefficient of variation of force.

High-density surface EMG was collected from tibialis anterior using a 64-channel electrode matrix (OTBioelettronica, Torino, IT) in monopolar mode. EMG recordings were visually inspected and bad quality signals (i.e., low signal to noise ratio, 1.2% of all channels collected) were replaced by inter- or extrapolation. Signals were then rectified and normalized to EMG amplitude during the MVC trials. Three sets of EMG signals were obtained from the collected data: (1) a monopolar matrix of 64 channels (Fig. 1A), (2) a bipolar matrix of 59 channels calculated as the difference between neighboring channels in the longitudinal direction of the matrix (Fig 1B), and (3) a single bipolar pair of simulated electrodes each formed by averaging the signals from 5 neighboring electrodes (Fig. 1C) [4]. EMG amplitudes for the multichannel sets (Fig. 1A & B) were averaged across all channels. Results are reported as mean  $\pm$  standard deviation.

## RESULTS

Student's t-tests indicated increased force fluctuations for the older adults compared with the young adults ( $3.5 \pm 1.6\%$  and  $2.3 \pm 1.0\%$ , respectively,  $p = .013$ ) and increased EMG amplitude for the older adults compared with the young adults for all EMG sets ( $p < .001$ , Table 1). Moreover, there was a positive relationship between the coefficient of variation of force and EMG amplitude during the steadiness task in both age groups for all EMG sets ( $p < .05$ ), except in the monopolar matrix for young adults ( $p = .24$ ; Table 1). Dorsiflexion strength was

**Figure 1:** Configurations for the monopolar matrix (A), bipolar matrix (B), and conventional pair of bipolar electrodes (C). Monopolar channels are represented with closed circles and bipolar channels with triangles. Red squares in lower panel identify channels used to simulate conventional bipolar electrodes. The shape of the recording area of the conventional bipolar electrodes is shown in gray.

greater in the young adults than in the older adults ( $243 \pm 108$  N and  $157 \pm 97$  N, respectively,  $p < .001$ ) but was not related to performance on the steadiness task in the young ( $p = .22$ ) or older adults ( $p = .9$ ).

## DISCUSSION

In contrast to previous studies [3,5], force steadiness and dorsiflexion strength were impaired in older adults compared to in young adults. However, there

was not a relationship between dorsiflexion strength and steadiness in either age group. Performance on the force steadiness task was related to increased activation of tibialis anterior. Moreover, this relationship was influenced by the way in which the EMG was processed. Specifically, no relation with performance was found in the young adults using the monopolar matrix and the relationship was strongest in older adults using the bipolar matrix. This finding is consistent with previous research which has found that that high-density surface EMG improved force estimation compared to conventional bipolar electrodes [4]. These findings also suggest that the collection of a greater number of independent signals improves the ability of EMG to accurately estimate force and performance in a force steadiness task.

Future studies should investigate the mechanisms influencing increased muscle activity (e.g., altered motor unit activity within and across synergist muscles) and whether interventions to reduce the higher levels of muscle activity in older adults can improve performance.

## INTRODUCTION

Ultrasound imaging (USI) has been shown to be a reliable tool to measure the thickness of trunk muscles including: lumbar multifidus and erector spinae (ES) [1], rhomboid major [2], and lower trapezius [3]. USI was also shown to be comparable to magnetic resonance imaging (MRI) for lumbar ES muscle thickness measurements [1].

The thoracic spine is suspected of playing a key role in the load transfer from the shoulder to the low back. Specifically in the upper-thoracic region at the T4 level, the ES act as the upper trunk extensors while providing support for the rib cage, and are deep to the rhomboid major and trapezius muscle groups. Further, the TES have been shown to be active during both trunk and arm movements.

While LES measures are well established, the quantification of the TES architecture has not been validated between USI and MRI. Specifically, it is not known if USI measures can accurately quantify this muscle, compared to MRI, given its relatively deep location as compared to lumbar ES. Therefore, the purpose of this study was to assess the reliability and level of agreement between USI and MRI measurements of TES thickness and fibre angle.

## METHODS

A total of 20 participants (10 male, 10 female) were recruited, all free of neck, back, and shoulder pain. The mean(*SD*) age, height, and weight for the males were: 25(2) y, 1.77(0.07) m, and 80.0(8.5) kg; and for the females: 26(4) y, 1.67(0.08) m, and 65.8(8.9) kg respectively.

The spinous process of T4 was located via palpation from C7, and marked on the skin laterally. The participant was then strapped supine on a transfer board placed on top of a custom-built MR-safe wheeled gurney. The upper right side of the board had a cutout to access the participant's back with the ultrasound transducer. Strapping the participant to the board minimized gross participant movement during transfer to the MR bore.

Sagittal plane USIs were taken using a SonoSite M-Turbo ultrasound system with a linear transducer model HFL38x, 13-6 MHz (SonoSite Canada Inc., Toronto, Canada) to allow for both thickness and fibre angles to be measured. One image was taken per participant. A vitamin E capsule was adhered to the skin at the cutout edge at the level the image was taken to provide a measureable landmark without creating MR interference. Participants were then wheeled to the MR room and scans were taken using a 3T Magnetom Trio system (Siemens Healthcare, Erlangen, Germany).

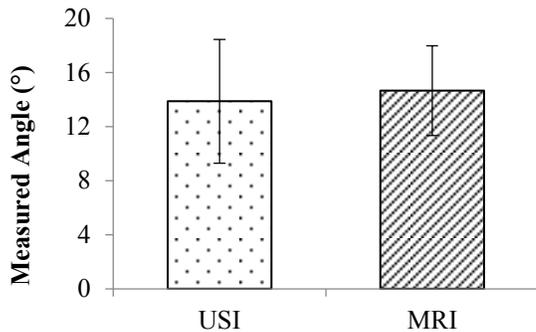

All imaging processing was done offline using eFilm software (Merge Healthcare, Chicago, USA). Orthogonal MRI slices were generated using eFilm's Multi-Planar Reformatting technique to match the orientation of the USI. Thickness and angle measures were repeated three times each: once per day for three consecutive days (Figure 1). The same MRI slice was used for between day analyses, but both USI and MRI were presented in a randomized order each day.

Differences of means for each dependent measure (angle and thickness) were compared using a 2x2 (Imaging Method x Sex) mixed-model ANOVA, with  $\alpha=0.05$ . The overall between day intra-rater reliability was assessed by intraclass correlation coefficient (ICC) for each method and measure

using model (3,1). The ICC ranges for reliability adopted were: poor (<0.40), moderate (0.40-0.59), good (0.60-0.74), or excellent (>0.75), based on previous imaging studies [1]. The standard error of measurement (SEM) was also calculated. The level of agreement between USI and MRI measurements was determined using Bland-Altman plots. All statistical analyses were conducted using SPSS v.24 (IBM Corporation, Armonk, USA)

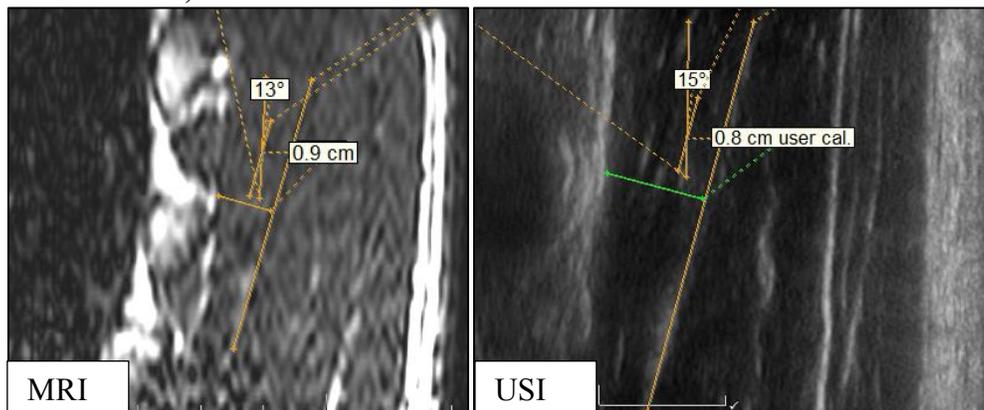

## RESULTS AND DISCUSSION

No differences were found between either the angle mean (Figure 2) or thickness mean measures ( $F(1,18)<3.67, p>0.07$ ). The ICC and SEM results were found to have moderate to excellent reliability (Table 1). The Bland-Altman analyses indicated good agreement, with the mean difference (USI-MRI) for thickness and angle being 0.025 cm and 0.78°, respectively. Also, the upper and lower limits of agreement for both measures were within 10% of the mean difference.

**Figure 2:** Mean(SD) of angle measurements between USI and MRI.

Overall there was good agreement between USI and MRI thickness measurements, but with a lower

**Figure 1:** Representative images of one participant showing the thickness and angles measures.

(moderate) ultrasound ICC value. While the limits of agreement showed larger ranges for the angle measurement, the USI showed higher (excellent) reliability.

**Table 1:** Results of reliability analyses.

	Modality	ICC (3,1)	SEM
Thickness (cm)	USI	0.509	0.20
	MRI	0.772	0.15
Angle (°)	USI	0.765	2.39
	MRI	0.526	2.75

## CONCLUSIONS

USI can be used to reliably measure muscle architecture of TES. Future work will use USI to analyze changes in thickness and angle during upper-extremity and trunk extension movements, and relate findings to muscle activation. The current and future work will determine the role the TES plays during functional tasks.

## INTRODUCTION

A spring-mass model can be used to characterize common movements like running and hopping. During a stride or a hop, the musculoskeletal system is able to store and release elastic energy contributing to center of mass movement [1]. Given the sinusoidal motion of the center of mass in the countermovement jump, the spring-mass model has also been used to explain stiffness in vertical jumping [2]. If a spring-mass system is a valuable model for stretch-shorten cycle type movements, the force-time curve should exhibit symmetry. That is the force development (FD) phase and force attrition (FA) phase should match. This study examined the force development phase and force decline phase for similarity in 3 ballistic upper extremity movements.

## METHODS

Twenty male participants (83.7±7.4kg; height, 1.8±0.07m) were recruited. The ground reaction force (GRF) was measured during plyometric pushups from the modified push-up position under 3 conditions: 1) The nCM was performed from a pre-determined elbow flexed position; 2) the CM, similar to a countermovement jump, involved beginning in the modified push-up position then lowering and pushing vertically; and 3) D, beginning from the modified push-up position participants lifted their hands from the ground and fell into a countermovement.

Once the GRF was obtained, force in equilibrium position was subtracted. The FD phase and FA phase were extracted. These two signals were examined for similarity using dynamic time warping (DTW) [3].

The difference between the two phases was computed by constructing a warping matrix where

$$d(i, j) = \sqrt{(FD_i - FA_j)^2}$$

is the distance between each element of each array. The warping path is the path through the matrix that minimizes the cost of alignment between the two arrays. The path is determined by

$$D(i, j) = d(i, j) + \min \left\{ \begin{array}{l} D(i-1, j-1) \\ D(i-1, j) \\ D(i, j-1) \end{array} \right\}$$

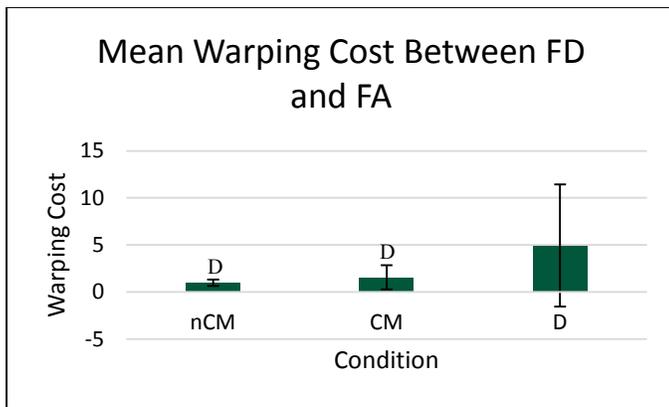

Finally the time-normalized minimum cost of alignment is

$$C = \frac{D(I, J)}{I + J}$$

where  $I$  is the number of rows and  $J$  is the number of columns in the matrix.

## RESULTS AND DISCUSSION

The minimum warping cost values were analyzed using a one-way repeated measures ANOVA. The results of the analysis showed that FD and FA in stretch-shorten cycle conditions are significantly different when compared for similarity using DTW ( $F(2,38) = 6.19, p = 0.0047$ ). The cost of alignment was least for nCM, and CM was less than D (Fig. 1). Post-hoc analyses showed that the cost of alignment was significantly different between nCM and CM ( $p = 0.0066$ ) and between CM and D ( $p = 0.0222$ ).

**Figure 1.** Bar height represents the mean warping cost for each condition. Error bars denote the standard deviations. D denotes a significant difference from D with an alpha level of 0.05.

Results indicate that nCM had the least warping cost followed by CM and D, respectively. Therefore, FD and FA were most similar in nCM followed by CM and D, respectively. Given that force development and force attrition are symmetrical in a spring-mass system, the results of this study imply that nCM and CM are movements that closely mimic the dynamics of a spring-mass system, compared to D. The fact that nCM and CM were not significantly different, is possibly a demonstration of equivalent muscular storage and reutilization of elastic potential energy seen in non-countermovement and countermovement vertical jumps [4]. If movements with and without a stretch-shorten cycle are equivalent in terms of storage and utilization of elastic energy, one can expect a lack of warping to match FD and FA in nCM

and CM compared to D. However, FD is necessarily warped to align with FA. Furthermore the more complex the movement the greater warping necessary to align FD and FA. This suggests that in multi-joint movements of increasing complexity the internal dynamics are not clearly reflected by the external dynamics.

## CONCLUSIONS

In this study force development and force attrition phases were examined for similarity in nCM, CM and D. The greatest similarity was seen in nCM followed by CM and D, respectively. However, perfect similarity expected from a simple spring-mass system was not seen. Therefore multi-joint movements should be studied utilizing models of greater complexity.

# Interactions between Tendon Stiffness and Spindle Afferent Feedback Determine the Magnitude of Involuntary Force Variability

<sup>1</sup>Akira Nagamori, <sup>1</sup>Christopher M Laine, <sup>1</sup>Kian Jalaeddini, and <sup>1</sup>Francisco J Valero-Cuevas

## INTRODUCTION

Tendons influence the transmission of muscle contractions [1]. Moreover, the relative mechanical properties of tendon and muscle determine the changes of muscle and tendon lengths. Therefore, tendon stiffness plays a critical role in the neural control of limb motions and forces [3,4], and is a major factor influencing proprioceptive feedback [2,3].

A basic and popular metric of ‘precision’ in motor control is the ability to produce a constant isometric force. During such tasks, involuntary force variability is an informative and fundamental component of current theories of motor control [5]. We have shown that a closed-loop simulation of peripheral neuromuscular elements can replicate cardinal features of force variability, and can be used to test mechanistic hypotheses about its healthy and pathologic generation/modulation [6]. Thus, we hypothesized that alterations in tendon stiffness would have a distinct influence on the nature of involuntary force variability, and its relationship with proprioceptive feedback.

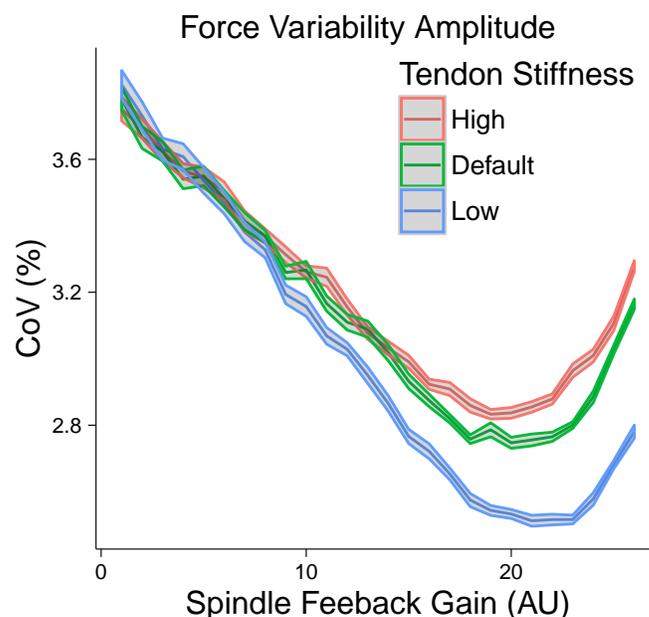

## METHODS

We used a published physiologically-grounded closed-loop simulation of afferented muscle model [6]. The model includes a musculotendon unit, muscle spindle, Golgi tendon organ, and a force-tracking controller, which enables this system to perform force-tracking tasks. In this study, we modeled *gastrocnemius* muscle, and decreased and increased its tendon stiffness by 50% from a default value. We simulated 20 isometric force trials lasting 100s at 20% of maximal voluntary contraction (MVC) for each level of tendon stiffness. We repeated these trials at different levels of spindle

feedback gain. The generated force during the last 90s was analyzed in the time and frequency domains.

## RESULTS AND DISCUSSION

As expected, lower tendon stiffness reduced MVC (208 N, 202 N, and 185 N for high, default, and low tendon stiffness) [1].

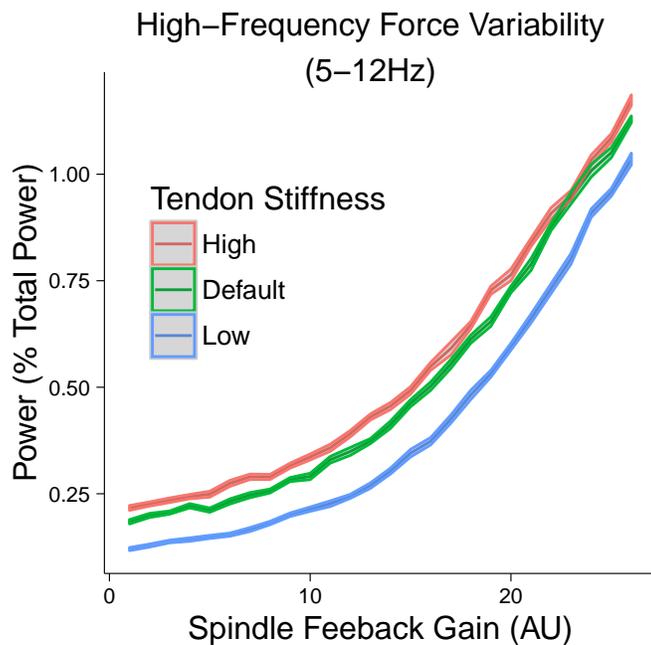

**Figure 1:** Force variability amplitude as per coefficient of variation (CoV) is determined by interactions between tendon stiffness and spindle feedback gain.

Figure 1 shows that the overall amplitude of involuntary force variability depended on spindle feedback gain and tendon stiffness in a non-linear manner. In addition, low tendon stiffness resulted in larger reduction in involuntary force variability amplitude at increased spindle feedback gains. Importantly, tendon stiffness had no effect on force variability at lower spindle feedback gains.

These results demonstrate that tendon stiffness, via changes in spindle feedback gain, affect the regulation of involuntary force variability, and agree with suggestions that compliant tendons improve the control of isometric forces [2-4]. This further suggests that decreased or increased stiffness due to musculoskeletal injuries [7] or aging may require adaptation in neural control and coordination among muscles [8].

We also found frequency-specific effects of interactions between tendon stiffness and spindle feedback gain. Decreases in tendon stiffness led to lower high-frequency (5-12 Hz) force variability across spindle feedback gains (Figure 2).

**Figure 2:** Increases in high-frequency force variability as a function of spindle feedback gain is offset by decreases in tendon stiffness.

This result implies that high-frequency involuntary force variability, often called physiological tremor, might provide insight into peripheral neuromechanical interactions. Importantly, pathological tremor, such as occurs in Parkinson's disease (4-6 Hz), may be exacerbated by the

stiffening of tendons which both accompanies aging and is characteristic of the pathology [9].

## CONCLUSIONS

Our work emphasizes that, as previously suggested [1-4], the mechanical properties of tendons could be an important—yet overlooked—aspect of force control. Moreover, our physiologically-grounded simulations begin to explain this in a mechanistic way that extends our understanding of healthy and pathologic involuntary force variability. These findings suggest that tendon properties may contribute to the mechanisms of disrupted motor control within certain pathologies, and may therefore represent promising targets for treatment/intervention.

# EFFECTS OF CONSTRAINED FORCE APPLICATION ON MUSCLE WORK AND EFFICIENCY

<sup>1</sup> Franziska Onasch, <sup>1</sup> Rafael Fortuna, and <sup>1</sup> Walter Herzog

<sup>1</sup> University of Calgary, Calgary, AB, Canada  
Email: franziska.onasch@ucalgary.ca

## INTRODUCTION

While the outcome of a bike race certainly depends on the strength and endurance of an athlete, as well as the equipment used, there is also an important technical component to cycling:

Looking at the force applied to the pedals, only the component that is directed perpendicular to the crank results in propulsion, and is therefore often referred to as the “effective force”. The final cycling performance depends, at least in part, on the way the rider directs the pedaling forces [1, 2].

One approach to maximize pedaling efficiency is to constrain and instruct cyclists to practice and direct all the applied force perpendicular to the crank only. Cycling coaches and cycling manuals propose this as the optimal cycling technique, as no force applied to the pedals goes to waste. However, it is also known that applying a force in a specific direction may constrain the relative contributions that muscles can make to a movement [3], and thus might negatively affect performance. The purpose of this study was to analyze muscle activity and force output in cycling using a constrained and a non-constrained condition. In the constrained condition, subjects had to apply the pedal force in a direction perpendicular to the crank in the power phase of cycling, while in the unconstrained condition, forces could be applied any way the subject felt most comfortable.

We hypothesized that subjects would be more efficient in the constrained compared to the non-constrained condition, but less effective due to a decrease in force output and muscle activation for the constrained condition.

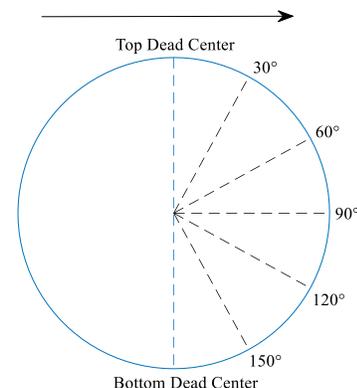

## METHODS

Twenty healthy subjects (28±4 years, 1.77±0.05 m, 74±8 kg; 5 female, 15 male) were recruited for this study. They performed the following two test protocols:

Non-constrained (NC): Five maximum isometric voluntary contractions (MIVC) in randomized order at 5 different crank angles (30, 60, 90, 120, and 150° from top dead center, Fig. 1), for 5s each. The first angle was repeated in a sixth trial to assess fatigue.

Constrained (C): The same crank angles as for the NC condition were tested in the same order. However, subjects were asked to produce MIVC perpendicular to the crank. Continuous feedback about the force direction was provided. An index of efficiency (EI) was calculated as:  $EI = \frac{Force_{effective}}{Force_{resultant}}$ ,

Where  $Force_{effective}$  is the force component perpendicular to the crank, and  $Force_{resultant}$  is the total force applied to the pedal.

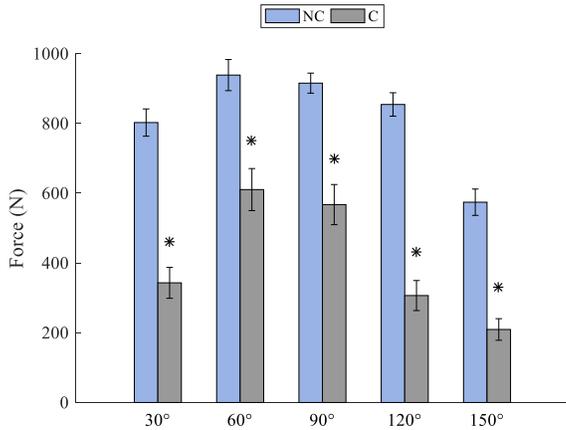

**Figure 1:** Orientation of the tested crank angles with the arrow indicating the direction of pedaling.

Electromyography (EMG) and instrumented pedals (Sensix, Poitiers, France) were used to measure muscle activity of seven lower extremity muscles and the three dimensional pedal forces, respectively.

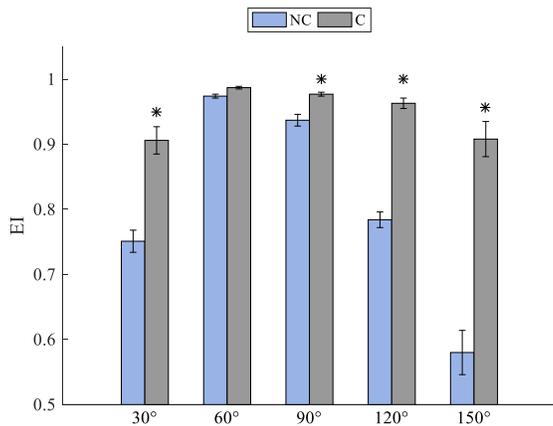

Differences in force and EMG between non-constrained and constrained condition were analyzed with Wilcoxon tests for paired samples and Bonferroni correction for multiple comparisons.

## RESULTS AND DISCUSSION

The effective force in the non-constrained condition (NC) was significantly higher than in the constrained condition (C) for all crank angles (Fig. 2,  $p < .001$ ). The efficiency index (EI) was significantly greater in C than in NC, except for  $60^\circ$  ( $p < .001$ , Fig. 3).

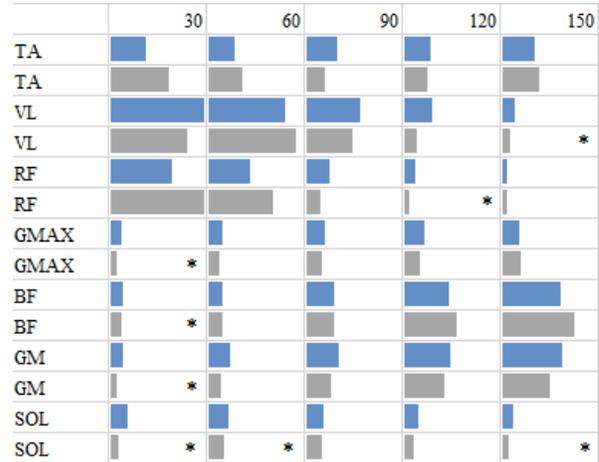

**Figure 2:** Mean ( $\pm$ SEM) of the effective forces for non-constrained (NC) and constrained (C) conditions at all crank angles. (\* significantly different from NC at the corresponding crank angle)

**Figure 3:** Efficiency index ( $\pm$ SEM) for non-constrained and constrained conditions (\* significantly different from NC at the corresponding crank angle).

There was greater muscle activation in NC compared to C. However, these differences were only significant for certain combinations of muscles and angles.

Furthermore, looking at the different crank angles, Figure 4 displays a distinct muscle activation pattern for the different angles. These patterns seem to become more pronounced when switching from the NC to the C condition.

**Figure 4:** Root mean square EMGs of all seven muscles (left column) recorded at the different crank angles (top row) for the NC (blue bars) and the C (grey bars) conditions. (\* significantly different from NC at the corresponding crank angle)

## CONCLUSIONS

We conclude from the results of this study that the coaching wisdom of applying force perpendicular to the crank in the power phase of cycling decreases performance, and thus should not be given. The decrease in force in the C compared to the NC condition is associated with the specific geometry and muscle properties of the lower limb muscles. Therefore, using an optimal technique based on mechanical considerations exclusively is dangerous, and the specific musculoskeletal geometry and muscle properties should always be incorporated when providing athletes with technical advice.

# OPTIMAL FASCICLE LENGTH CHANGES BASED ON SUBMAXIMAL FORCE OR ACTIVATION

<sup>1</sup>Zackary Scalyer and <sup>1</sup>Benjamin W. Infantolino

<sup>1</sup>The Pennsylvania State University - Berks, Reading, PA, USA  
email: bwi100@psu.edu

## INTRODUCTION

de Brito Fontana and Herzog (2016) described the submaximal force-length relationship of the vastus lateralis muscle obtained using force and muscle activation criteria [1]. It was shown that optimal fascicle length shifts towards longer lengths with respect to the maximal force condition when the submaximal measurement criteria is muscle force. However, when muscle activation was the submaximal measurement criteria optimal fascicle length did not shift from the maximal activation condition.

Since the vastus lateralis is one of four muscles to act to extend the knee and one of those muscles acts at the hip it is possible that the knee joint torque is not directly related to the vastus lateralis activation and fascicle lengths. Since it is impossible to separate out individual muscle forces for each of the quadriceps muscles it is possible that different quadriceps muscles produce more knee joint torque throughout knee range of motion.

The first dorsal interosseous muscle (FDI) primarily acts to abduct the second metacarpophalangeal joint and is the only muscle to do so, eliminating the effect of other muscles at that joint. Previous studies have measured the force length curve of the FDI *in vivo* [2]. The purpose of this study was to investigate the phenomena described by de Brito Fontana and Herzog in the FDI.

## METHODS

Two male subjects were used in this study (mean age: 29.5 years, mean height: 175cm, mean mass: 66kg). The right FDI of each subject was tested. A wireless EMG electrode (Trigno mini sensor, Delsys, Natic, MA) was placed over the second metacarpal head of

the FDI. Ultrasound videos were collected using a 10 MHz ultrasound probe (EchoBlaster 128, Telemed, Lithuania). A standoff pad was used in conjunction with the ultrasound probe head to produce a clear image and to avoid letting ultrasound gel touch the EMG electrode.

The subject placed their hand in a custom made apparatus which constrained the thumb and third through fifth fingers, only allowing the second metacarpophalangeal joint to move. The second finger pressed against a force sensor which was fixed a known joint angles (0°, 5°, 10°, 15°, 20°). The subject was instructed to contract from rest to maximal force in a 3 second interval while producing a steady force increase. During this time the force applied to the sensor, the muscle activity of the FDI, and an ultrasound video of the muscle fascicles were recorded during the duration of the trials.

Data were analyzed using custom written Matlab code based on the method described by de Brito Fontana and Herzog [1]. Force and activation data were filtered then normalized to the maximum respective value for each joint angle. Submaximal data points for 20%, 40%, 60%, 80%, and 100% of maximal force and activation for reach joint angle were located. At these points, the corresponding frame from the ultrasound video was manually digitized to determine fascicle length.

Fascicle length and force data were normalized by the respective maximum values for each subject across joint angles and contraction levels. Subject data were averaged together then the average data were fit to a force-length curve using a least squares method with the following equation:

$$F_L(L_F) = 1 - \left( \frac{(L_F - L_{F,OPT})}{w \cdot L_{F,OPT}} \right)^2$$

Where  $L_F$  is the range of fascicle lengths,  $L_{F,OPT}$  is the optimal fascicle length, and  $w$  indicates the width of the force length curve. This produced estimates for the values of maximal muscle force, optimal fascicle length, and the width parameter.

## RESULTS AND DISCUSSION

The results were generally in agreement with that of de Brito Fontana and Herzog (figures 1 and 2). The trend of increasing optimal fascicle length seen during the force condition was present. The trend in the activation condition was not as clear however.

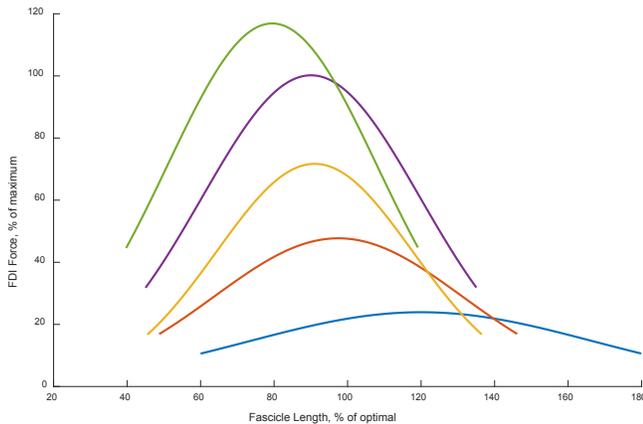

Figure 1. Muscle force length curves based on percent of maximal force.

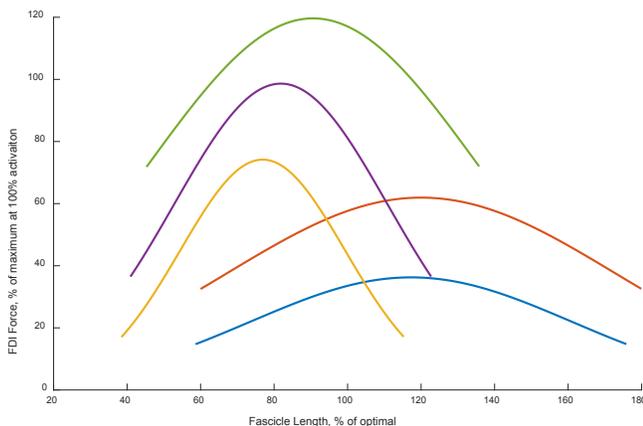

Figure 2. Muscle force length curves based on percent of maximal activation.

Due to low sample size, statistical tests could not be used to better compare the current results with those of the previous study. These findings suggest that even in a muscle with a small range of motion the effect of different measurement criteria has an influence on submaximal optimal fascicle length. Additionally, the current results suggest that difficulty in separating the force contributions of the vastus lateralis through knee range of motion does not have a large effect on the phenomena observed by de Brito Fontana and Herzog.

Limitations with this study include a small sample size and the small range of motion of the FDI. The small range of motion of the FDI made determining the parameters of the force-length difficult since a large range of fascicle lengths could not be directly measured. Using a muscle with a larger range of motion at a joint with fewer muscle acting would help to further clarify the differences in optimal fascicle length based on submaximal measurement criteria.

The results of this study demonstrated that the optimal fascicle length for submaximal conditions will vary depending on the submaximal measurement criteria, either submaximal force or activation.

## INTRODUCTION

Repeated slip training (RST) is a task-specific training methodology that involves practicing the motor skills necessary to avoid a fall following an unexpected slip. Researchers have explored RST as a fall prevention intervention by exposing subjects to slips or slip-like perturbations in a safe, controlled manner. RST has been found to be effective in improving both proactive and reactive responses to subsequent slips [1]. However, current methods for RST require substantial financial resources. More cost-effective methods for implementing RST may improve its potential for adoption.

The purpose of this study was to investigate the efficacy of two cost-effective methods for RST at increasing recovery rate following laboratory-induced slips. Three groups were exposed to either unexpected slip training (UST), expected slip training (EST), or a control condition. Gait characteristics, slip severity, and kinematics of the slipping and trailing feet were compared between the three groups. We hypothesized that UST and EST would exhibit a higher recovery rate, reduced slip severity, and altered trailing limb responses, compared to the control group.

## METHODS

Thirty-six adults (18-31 years, BMI 17.1-34.9 kg/m<sup>2</sup>, 18 female) completed the study. Exclusion criteria included any self-reported musculoskeletal conditions that could affect their balance or gait, participating in  $\geq 30$  minutes of exercise more than four times per week, or participating in  $\geq 30$  minutes of vigorous exercise (e.g. running or jogging) more than two times per week. The study was approved

by the university institutional review board, and written consent was obtained from all subjects.

The study employed a three-group posttest-only design, which involved one training session and one unexpected slip induced while walking on the following day. Six males and six females were randomly assigned to each group: UST, EST, or control. The training session for the control group involved simply walking 20 times along a straight walkway covered in vinyl tile. UST sessions involved 20 unexpected slips while walking across the walkway. Slips were induced by placing a 1 x 1 m polyethylene sheet onto the walkway, which provided a low-friction interface. EST sessions involved repeated slip-like perturbations while walking over a known slippery surface. Subjects were instructed to step onto nylon fabric placed over a polycarbonate sheet (which provided a low-friction interface), simulate a slip, and then recover their balance by stepping with the trailing limb (80 repetitions). The session on the following day was the same for all subjects, during which they were exposed to one unexpected slip while walking by stepping onto a contaminated surface [2]. Subjects wore a safety harness to prevent falls to the floor during all sessions.

Segmental kinematics were sampled at 100 Hz using an 8-camera motion capture system (Qualisys North America, Inc., Buffalo Grove, IL). Ground reaction force during walking and forces applied to the harness rope were sampled at 1000 Hz using a force platform (Bertec Corporation, Columbus, OH) and a uniaxial load cell (Cooper Instruments and Systems, Warrenton, VA), respectively. Slip outcome was determined based on forces applied to the harness rope [3]. During slip trials, gait characteristics (gait speed and step length), slip severity (slip distance and peak slip speed), and

spatial characteristics of the slipping heel and trailing toe at trailing foot lift-off (LO) and touch-down (TD) were measured. Spatial characteristics included slipping heel trailing toe positions, both relative to the sacrum (expressed as percent body height, %bh). During walking trials prior to the slip, step length, heel contact angle (between the foot and floor at heel contact), and required coefficient of friction (RCOF) were measured. A Fisher's exact test was used to compare recovery rates between groups, and analyses of variance (ANOVA) to compare continuous variables between groups. Tukey's HSD test was used for pairwise comparisons between groups where relevant. Statistical analyses were performed using JMP Pro 12 (SAS Institute Inc., Cary, NC) and a significance level of  $\alpha=0.05$ .

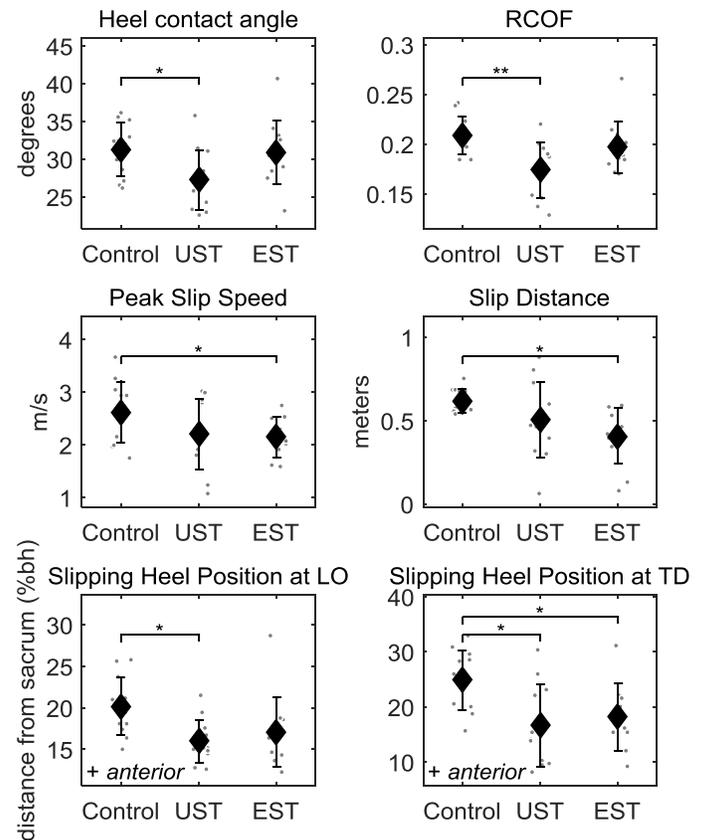

## RESULTS AND DISCUSSION

Recovery rates differed between the three groups, in that seven UST subjects, eight EST subjects, and two control group subjects recovered their balance ( $p=0.039$ ). Gait speed ( $1.28\pm0.06$  m/s) and step length ( $0.71\pm0.04$  m) did not differ between groups.

Subjects in the UST group exhibited more cautious gait prior to the slip, and the slipping heel was less anterior to the sacrum at LO and TD (Fig. 1). Compared to the control group, heel contact angle was 4.1 degrees less ( $p=0.030$ ), RCOF was 0.035 lower ( $p=0.003$ ), AP slipping heel position at LO was 4.0%bh less anterior to the sacrum ( $p=0.024$ ), and AP slipping heel position at TD was 8.3%bh less anterior to the sacrum ( $p=0.011$ ).

Subjects in the EST group experienced less severe slips compared to the control group, and their slipping heel was less anterior to the sacrum at TD. Peak slip speed was 0.71 m/s slower ( $p=0.023$ ), slip distance was 21.3 cm shorter ( $p=0.011$ ), and AP slipping heel position at TD was 6.8%bh less anterior to the sacrum ( $p=0.0496$ ), compared to the control group.

There were no significant differences in gait characteristics, slip severity, or slipping and trailing foot kinematics between the UST and EST groups.

**Figure 1:** Variables that differed between groups (mean and standard deviation, \* $p<0.05$ , \*\* $p<0.01$ )

Compared to the control condition, both interventions resulted in a higher recovery rate in response to laboratory-induced slips. Both interventions also resulted in slipping heel positions less anterior to the sacrum during a slip, which is associated with increased stability. Relative to controls, the UST group exhibited proactive changes in gait, evidenced by reduced heel contact angle and RCOF, while the EST group experienced less severe slips. Since no proactive changes in gait were detected for the EST group, this latter outcome is likely due to an improved reactive response to slipping. Based on these results, both UST and EST appear to have potential use as cost-effective methods for reducing the number of falls due to slipping.

## INTRODUCTION

Falls are one of the leading causes of accidental or injury-related death in the aging population and people with neurological disorders. Dynamic gait stability has been identified as a key factor of slip-related falls [1]. Treadmill-based perturbation training has recently emerged as a new modality to reduce falls. It was shown that perturbation training could be effective in improving dynamic stability responding to a slip induced in gait [2].

Most previous studies examining the effects of perturbation training were conducted during walking on a treadmill, which requires that participants walk independently for a long walking distance. Given that limited mobility is common in frail older adults and individuals affected by neurological dysfunctions, some participants may not be willing or able to comply with this training paradigm. Therefore, a simple perturbation-based training program would be of particular interest to those who lack sufficient mobility.

Perturbation training performed during standing could be one of the simple modalities. However, it remains unknown if a static perturbation training program on a treadmill could improve dynamic stability when adults are exposed to an unexpected slip perturbation over ground. The primary purpose of this study was to examine if and to what extent a standing-perturbation training program on a treadmill could improve dynamic stability in response to an unexpected slip perturbation during overground gait among young adults.

## METHODS

Twenty healthy young participants were recruited for the study after providing written informed consent

approved by the Institutional Review Board. Participants were randomly divided into a control ( $n = 10$ , age:  $22.6 \pm 3.09$  years; body height:  $1.68 \pm 0.09$  m; body mass:  $73.36 \pm 15.98$  kg, 3 females) and a training group ( $n = 10$ , age:  $22.33 \pm 1.65$  years; body height:  $1.70 \pm 0.13$  m; body mass:  $73.87 \pm 20.19$  kg, 3 females).

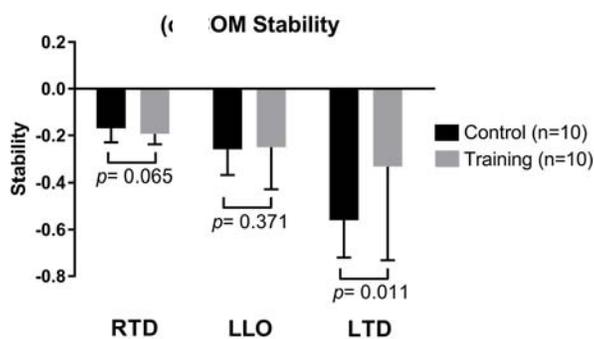

The training group underwent a treadmill-based static perturbation training protocol which consisted of 5 normal walking trials and then 8 slips induced when subjects were standing on the treadmill. The slip was created by moving the treadmill belt rapidly forward for a distance of 24 cm within 200 ms. The control group was exposed to a placebo training protocol on the same treadmill but consisting of 13 normal walking trials. After either training protocol, both groups were exposed to an identical, unannounced slip when they walked over a 14-m walkway. Such an overground slip was induced by a customized sliding device embedded in the middle of the walkway. This device included a movable platform which could travel along a 1.5-m linear track smoothly. When subjects' right foot was in contact with the platform, it slides forward with the foot, creating a real-life slip perturbation. Participants were protected by a safety harness during all trials.

The responses to the unexpected overground slip were recorded from 27 reflective markers attached to the body (26) and the platform (1) using an 8-camera motion capture system (Vicon, UK) at 120 Hz. Marker paths were low-pass filtered at marker-specific cut-off frequencies (ranging from 4.5 to 9 Hz) using fourth-order, zero-lag Butterworth filters [3]. Locations of joint centers, heels, and toes were computed from the filtered marker positions. The body center of mass (COM) kinematics were calculated using the joint center data based on a 13-

segment model [4]. The two components of the COM motion state, i.e. its position and velocity, were calculated relative to the rear of the BOS (i.e., the leading heel) and normalized by the foot length and  $\sqrt{g \times bh}$ , respectively, where  $g$  is the gravitational acceleration and  $bh$  the body height. Dynamic stability was calculated as the shortest distance from the COM motion state to the limit of stability [5] at three consecutive events: the slipping (or right) foot touchdown (RTD), the recovery (or left) foot liftoff (LLO) and its touchdown (LTD). These three events were determined from the foot kinematics. Independent  $t$ -tests were applied to compare dynamic stability between groups at all three events. All statistical analyses were performed using SPSS 21.0 (IBM, NY), and a significance level of 0.05 was implemented throughout.

## RESULTS

At RTD and LLO during the overground slip, dynamic stability was comparable between groups (Fig. 1,  $-0.17 \pm 0.06$  vs.  $-0.19 \pm 0.04$ ,  $p > 0.05$  for RTD;  $-0.26 \pm 0.11$  vs.  $-0.25 \pm 0.17$ ,  $p > 0.05$  for LLO). Nevertheless, the training group was less unstable against backward balance loss than the control group at LTD after the slip onset ( $-0.33 \pm 0.39$  vs.  $-0.57 \pm 0.16$ ,  $p < 0.05$ ).

**Figure 1:** Comparison of dynamic stability between the training and control groups during the overground slip at the right touchdown (RTD), left liftoff (LLO), and left touchdown (LTD).

## DISCUSSION

The overall objective of this study was to examine the efficacy of a static treadmill-based perturbation training program on improving dynamic stability in

response to an unexpected overground slip in young adults. The results indicated that participants in the training group exhibited better dynamic stability control than those in the control group at the recovery foot touchdown when exposed to a large-scale, unannounced overground slip. The observed improvement in dynamic stability implies that static treadmill perturbations may serve as an effective means to strengthen one's resistance to slips and falls. Our results demonstrated that a reduced perturbation training intensity (i.e., the perturbation is induced during static standing instead of during dynamic walking) could still incur motor adaptations that can be transferred to improve falls recovery upon the exposure to an overground slip. More studies based on a large sample size and other populations are desired to comprehensively understand the effectiveness, generalizability, and safety of this training modality in reducing falls. The comparison of the training effects between standing-perturbation and gait-perturbation training programs deserves further investigations as well.

## CONCLUSIONS

In summary, the static treadmill-slip training could improve the reactive COM dynamic stability control in response to a real-life like slip perturbation. The finding from this study introduces a new paradigm, which could potentially present numerous benefits to populations with limited mobility to reduce their likelihood of falls.

# AGE AND FALLS HISTORY EFFECTS ON ANTAGONIST LEG MUSCLE COACTIVATION DURING WALKING WITH OPTICAL FLOW PERTURBATIONS

Jessica D. Thompson and Jason R. Franz

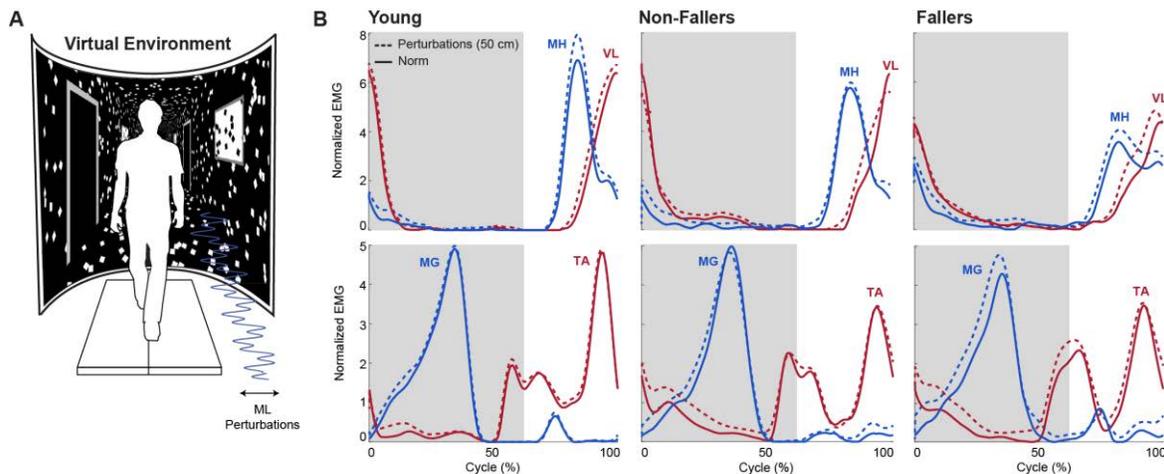

University of North Carolina at Chapel Hill and North Carolina State University, Chapel Hill, NC, USA  
Email: jdtthomp4@email.unc.edu, web: <http://abl.bme.unc.edu/>

## INTRODUCTION

Sensory perturbations are increasingly used to study balance control mechanisms in walking due to their ability to elicit corrective motor responses from step to step [1,2]. Advanced age increases the reliance on visual feedback for motor planning and execution [3]. Thus, optical flow perturbations in particular may represent a promising diagnostic tool for age-associated falls risk [2]. Antagonist leg muscle coactivation, a well-documented phenomenon in motor control thought to increase leg stiffness to improve joint stability, increases with age [4] and may further increase during walking to mitigate the effects of perturbations. Therefore, the purpose of this study was to investigate age and falls history effects on antagonist leg muscle coactivation during walking with and without optical flow perturbations of different amplitudes. We hypothesized that: (1) compared to young adults, aging and falls history would increase antagonist muscle coactivation during walking, and (2) these differences would increase in the presence of optical flow perturbations.

## METHODS

11 healthy young adults (mean±sd, age: 24.8±4.8 years), 11 healthy older adults (age: 75.3±5.4 years) and 11 older adults with a history of falls (age: 78±7.6 years) walked on an instrumented dual belt treadmill (Bertec Cor., Columbus, OH). Older adults were considered to have a fall history if they had experienced one or more unanticipated falls within the last year. Young adults walked on the treadmill at 1.25 m/s while both groups of older adults walked at their preferred walking speed (Nonfallers: 1.19±0.20 m/s, Fallers: 1.03±0.22 m/s). While walking, subjects watched a speed-matched, virtual hallway rear projected onto a semi-circular screen surrounding the treadmill with and without continuous mediolateral oscillations of optical flow. In randomized order, subjects walked for two minutes normally and with optical flow perturbations at amplitudes of 20, 35, and 50 cm. We collected electromyographic (EMG) recordings from wireless electrodes (Delsys, Inc.) placed over five right leg muscles: medial gastrocnemius (MG), soleus (SOL),

**Figure 1.** (A) Virtual Environment. (B) Normalized EMG linear envelopes for normal and perturbed walking. MH/VL coactivation on the top panel and MG/TA coactivation on the bottom. Shaded area indicates stance.

tibialis anterior (TA), vastus lateralis (VL) and medial hamstring (MH). We bandpass (20-450 Hz) filtered and rectified the data before normalizing the amplitudes to the mean values during normal walking. We then used 10 Hz linear envelopes to calculate antagonist muscle coactivation indices as the normalized shared area of overlap of activations between three muscle pairs: MG/TA, SOL/TA, and VL/MH. A two-way repeated measures ANOVA tested for main effects of perturbation amplitude and muscle coactivation for each subject group during stance and during leg swing. Exploratory independent t-tests compared fallers and non-fallers during walking with and without perturbations.

## RESULTS AND DISCUSSION

Age, independent of falls history, significantly increased stance phase lower leg antagonist muscle coactivation compared to young adults, by an average of 138% for MG/TA and 125% for SOL/TA ( $p < 0.05$ ) (Fig. 2BC). Compared to walking normally, optical flow perturbations had no significant effect on leg muscle coactivation in

young adults. In contrast, in both older adult groups, perturbations significantly increased TA/SOL antagonist coactivation, by on average up to 56% during stance and 170% during swing compared to normal, unperturbed walking (Fig. 2C). Perturbations also revealed age-related differences in swing phase TA/SOL antagonist coactivation that were not otherwise apparent during normal walking (Fig. 2C). Although modest compared to non-fallers, only in older fallers did perturbations significantly increase TA/MG antagonist coactivation, by up to 54% during stance and up to 106% during swing (Fig. 2B). Finally, we found no significant difference between older fallers and non-fallers for any measure of antagonist coactivation during unperturbed walking. However, perturbations revealed up to 109% more stance phase VL/MH coactivation in older fallers compared to non-fallers (Fig. 2A).

## CONCLUSIONS

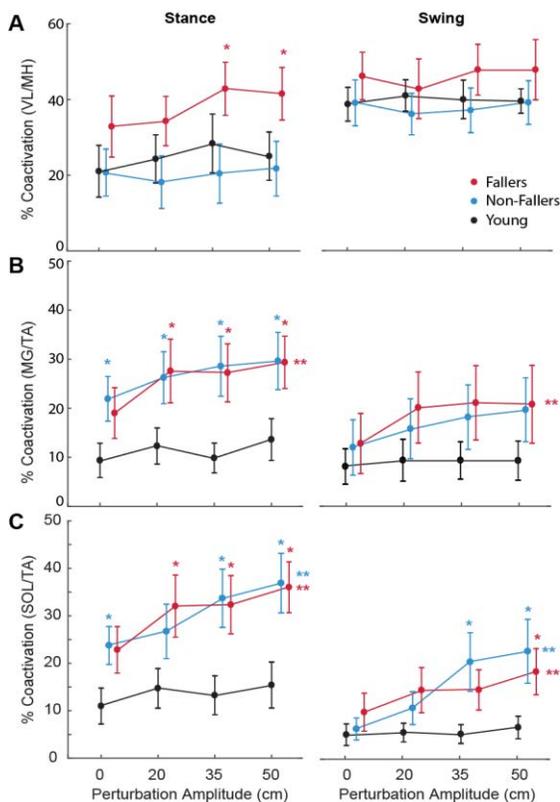

In partial support of our hypotheses, lower leg antagonist leg muscle coactivation during walking increased with age, independent of falls history. Also, as hypothesized, these effects were larger in the presence of optical flow perturbations. One interpretation of this finding is that older adults rely more on increased leg joint stiffness than young adults to accommodate balance challenges during walking. Moreover, elevated antagonist upper leg muscle coactivation at larger perturbation amplitudes, unique to older adults with a history of falls, may allude to an increased susceptibility to optical flow perturbations that requires further study.

# QUANTIFYING THE CONTRIBUTION OF COUNTER-ROTATION MOVEMENTS DURING FALL RECOVERY: A VALIDATION STUDY

<sup>1</sup> Elizabeth A. Rapp, <sup>1</sup> R. Tyler Richardson, <sup>1</sup> Benjamin C. Conner, <sup>1</sup> Drew A. Petersen, <sup>1</sup> Jamie Pigman, <sup>1</sup> Jeremy R. Crenshaw

<sup>1</sup> University of Delaware, Newark, DE, USA  
email: crenshaw@udel.edu

## INTRODUCTION

Standing balance is maintained by 1) moving the center of pressure under the base of support, 2) applying an external force, and 3) counter-rotating segments about the whole-body COM [1]. Rapid shoulder flexion or extension can serve as a counter-rotation strategy to recover from a fall [2,3]. Although joint angles and velocities can characterize this strategy, the contribution of such movements to fall recovery depends upon the motion timing and influence of other mechanisms. Hof [1] and Halvorsen [4] have proposed a method to specifically quantify the contribution of counter-rotations to balance maintenance. Still, these contributions have not been evaluated during fall recovery after an external perturbation, nor have specific upper extremity contributions been identified.

The purpose of this study was to evaluate the construct validity of measures that quantify the counter-rotation contribution to recovery from a posterior fall. We evaluated a measure that included whole-body counter-rotation [1,4] as well as a modified measure that focused on upper extremity rotations. As a form of treatment validation, we hypothesized that counter-rotation contributions would be reduced during fall-recovery responses in which arm motion was constrained. As a form of convergent validation, we hypothesized that arm contributions would be positively correlated with peak shoulder flexion velocities.

## METHODS

Five healthy adults (age:  $21.8 \pm 1.3$ ; BMI:  $22.3 \pm 4.3$ ) stood on a microprocessor-controlled treadmill (Active Step<sup>®</sup>, Simbex, Lebanon, NH) and proceeded through a single-stepping threshold protocol [5]. Increasingly larger disturbances were delivered as subjects attempted to recover with a

feet-in-place response. This protocol was performed under two conditions: 1) unconstrained (no limitations to arm motion) and 2) arms constrained (both hands holding a rope behind the back). The trials representing the largest disturbance magnitude in which a step was prevented in both conditions were analyzed for each subject.

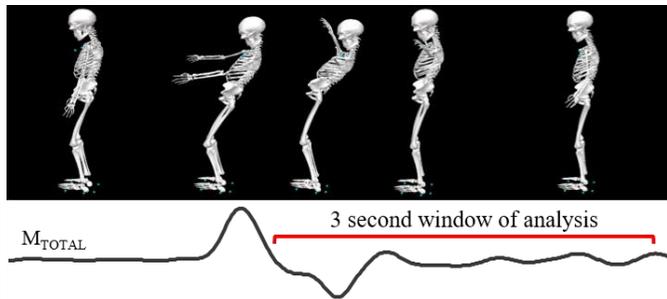

Trials were recorded with motion capture technology (Motion Analysis<sup>®</sup>, Santa Rosa, CA: 120 Hz). Thirty-five markers facilitated the definition of thirteen body segments (Visual3D, C-Motion<sup>®</sup>, Germantown, MD). Marker trajectories were low-pass filtered at 6 Hz before calculating segment positions, orientations, and accelerations, as well as whole-body angular momentum.

Balance mechanisms were calculated with custom LabVIEW software (National Instruments<sup>®</sup>, Austin, TX) utilizing the following equation [3]:

$$\frac{(r_{COP} - r_{COM}) \times F_G}{M_1} - \frac{d}{dt} \frac{H}{M_2} = \frac{(r_{COM} - r_{COM'}) \times m a_{COM} + I_{BODY} \alpha_{COM}}{M_{TOTAL}}$$

where  $r_{COP}$  is the center of pressure,  $r_{COM}$  is the COM position,  $r_{COM'}$  is the vertical projection of the COM onto the treadmill,  $F_G$  is the force due to gravity,  $\frac{d}{dt}H$  is the rate of change of whole-body angular momentum about its COM,  $m$  is body mass,  $a_{COM}$  is the linear acceleration of the COM,  $I_{BODY}$  is the whole-body moment of inertia and  $\alpha_{COM}$  is the angular acceleration of the COM about the ankle joint center. The contribution of counter-rotation ( $M_2$ ) was calculated as the slope of the total least squares regression [6] of  $M_2$  onto  $M_{TOTAL}$ . Arm-specific counter-rotation contribution was calculated as the slope of the total least squares regression of  $M_{ARMS}$  on  $M_{TOTAL}$ , where  $M_{ARMS}$  equals the rate of change of arm angular momentum about the whole-

body COM. Data were analyzed from the three-second period after the initiation of recovery, defined as a change in direction of  $M_{TOTAL}$  (Fig. 1). To evaluate the construct validity of the contribution measures, constrained and unconstrained conditions were compared using percent changes and effect sizes. To evaluate the convergent validity, Pearson correlations were calculated between peak shoulder flexion velocity and contribution measures in the unconstrained condition.

**Figure 1:** Subject model and graph depiction of a trial with the recovery segment highlighted to indicate window of regression analysis.

## RESULTS AND DISCUSSION

*Treatment validity:* The effects of arm constraint on counter-rotation contributions were small. Four out of five subjects demonstrated less counter-rotation (Fig. 2A) and all subjects demonstrated less arm-specific counter-rotation (Fig. 2B) in the arms constrained condition. Arm-specific contributions were low in the unconstrained condition (<11%), suggesting that the arms may not play a major role in recovering from these types of disturbances. Given

this limitation, we were unable to support the treatment validity of our contribution measures.

*Convergent validity:* The correlation between peak shoulder flexion velocity (range = 22 - 326 deg/s) and whole-body counter-rotation contribution was small and negative ( $r = -0.26$ ). In contrast, the correlation between peak flexion velocity and arm-specific counter-rotation was strong ( $r = 0.78$ ). This result supports the convergent validity of our arm-specific contribution measure.

## CONCLUSIONS

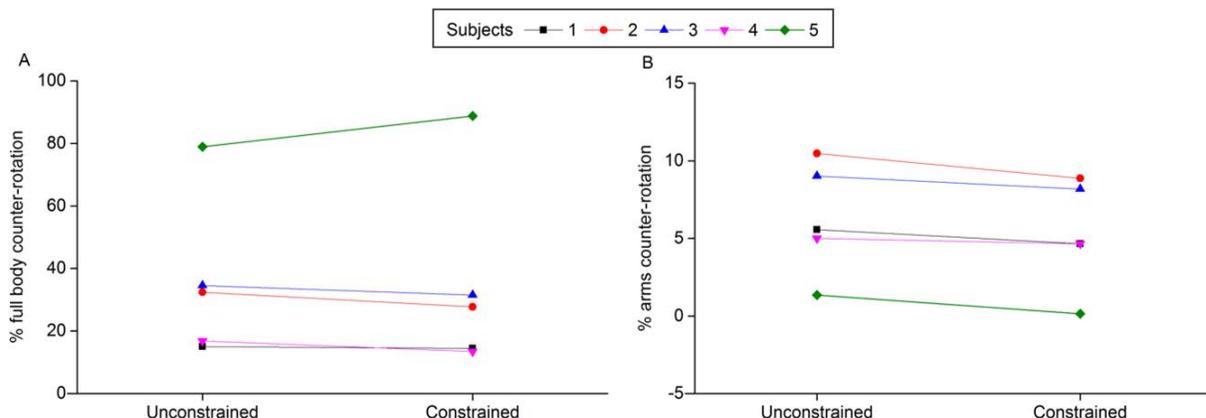

- Constraining the arms did not notably reduce the contribution of counter-rotations to fall recovery in this study.
- An arm-specific contribution measure more adequately reflected the use of the arms during fall recovery than a whole-body measure.

# POSTERIOR FALL-RECOVERY TRAINING OF INDIVIDUALS WITH CHRONIC STROKE: PRELIMINARY RESULTS

<sup>1</sup> Jamie Pigman, <sup>1</sup> Drew Petersen, <sup>1</sup> Benjamin C. Conner, <sup>1</sup> Darcy S. Reisman, and <sup>1</sup> Jeremy R. Crenshaw

<sup>1</sup> University of Delaware, Newark, DE, USA  
email: crenshaw@udel.edu

## INTRODUCTION

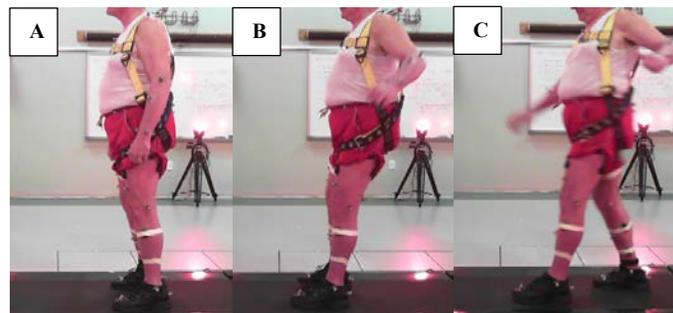

Individuals living with chronic stroke have a risk of falling that is twice that of age- and gender-matched controls [1]. A third of all post-stroke falls are a result of a trip or a slip [2]. Therefore, interventions that focus specifically on the stepping response necessary to recover from a slip may reduce fall incidence and fall-related injury for this population.

Perturbation-based balance training has significantly reduced falls in other populations including older adults and individuals with Parkinson's disease [3]. Fall-recovery training focused on slip-recovery has reduced fall rates in a laboratory setting by 50% for unimpaired adults [4]. The extent to which the posterior fall-recovery response is modifiable in individuals with chronic stroke is not known. The purpose of this study was to quantify the within-training adaptations to posterior fall recovery over the course of six sessions. We focused on initial step placement relative to the whole-body center of mass (CoM) due the variable's documented importance to slip-recovery [5] and impairment for individuals with chronic stroke [6,7]. We hypothesized that, from the first to last training session, the initial recovery step would be placed more posteriorly and medially relative to the CoM. As another indicator of performance, we also evaluated the percentage of successful trials within the first and last training session. We hypothesized that the proportion of successful trials would increase from the first to last session.

## METHODS

We recruited six participants (age:  $58 \pm 16.6$  yrs, BMI:  $29.2 \pm 5.2$  kg/m<sup>2</sup>, Fugl-Meyer LE  $24.1 \pm 2.4$ ) for this IRB-approved study. Participants performed

six fall-recovery training sessions. Each session consisted of simulated slips delivered as the participants stood on a computer-controlled treadmill (ActiveStep<sup>®</sup>, Simbex, Lebanon, NH; Figure 1). Participants were instructed to "try to recover in a single step". Two progressively challenging, 7-minute series of disturbances were delivered within each session. In the first series, participants were instructed to initially step with their non-paretic limb. In the second series, the participants were instructed to initially step with the paretic limb. Initial belt accelerations ranged from 0.5-6.5 m/s<sup>2</sup> over a 200 ms period, with belt displacements ranging from 1-13 cm. For each trial, subsequent initial accelerations were incremented or reduced by 0.5 m/s<sup>2</sup>, depending on successful fall recovery. Failure was defined as stepping with the wrong limb, taking more than one step to recover, or recording more than 20% of body weight support from an instrumented harness system (Dillon, Fairmont, MN) [8]. The trajectories of a whole-body, reflective marker set were recorded using motion capture technology (Motion Analysis Corp., Santa Rosa CA; 120 Hz).

**Figure 1:** A simulated slip (initial belt acceleration 6.5 m/s<sup>2</sup>) (A) pre-disturbance onset, (B) disturbance onset, (C) successful stepping response with the non-paretic limb.

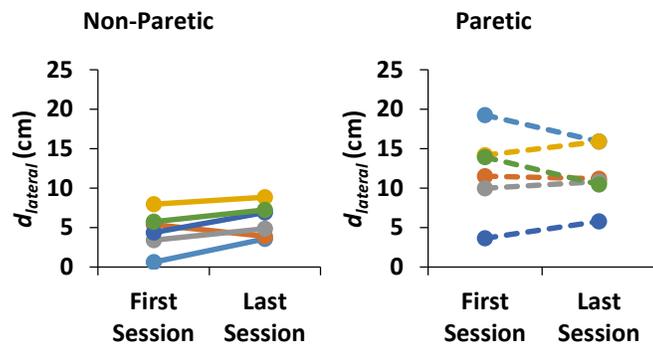

Dependent variables were evaluated for the first and last training session. Recovery kinematics were evaluated at the highest disturbance magnitude common across sessions and stepping limb.

Separate repeated measures 2 x 2 factorial ANOVA's were conducted to evaluate the effects of stepping limb and training day on the lateral and posterior distances between the stepping foot and the whole-body CoM, as well as the percentage of successful trials within each session.

## RESULTS AND DISCUSSION

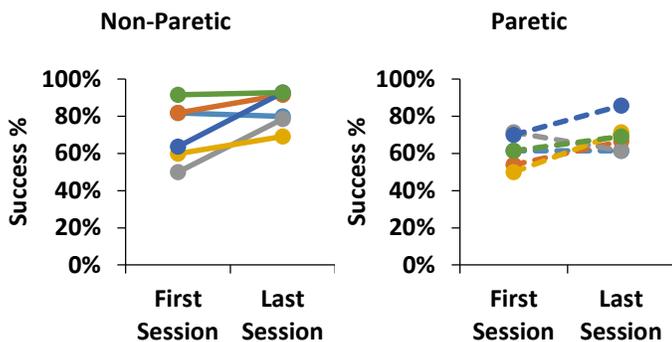

### Step Kinematics

The paretic limb step was placed significantly wider than the non-paretic limb (Figure 2). However, the effect of the training day on this lateral distance was weak.

**Figure 2:** The lateral distance ( $d_{lateral}$ ) between the whole-body CoM and the non-paretic or paretic stepping foot. Steps with the paretic limb were significantly wider than steps with the non-paretic limb ( $p = 0.03$ ). There were no apparent changes in this distance from the first to the last session (*Cohen's d* < 0.20;  $p = 0.44$ ).

There were no significant effects or interactions of the training day or stepping limb in the posterior step distance ( $p > 0.32$ ). Against our expectations, we observed a moderate (*Cohen's d* > 0.37) shortening of this distance from the first ( $232.8 \pm 27.0$  cm) to last ( $204.4 \pm 8.0$  cm) sessions.

**Figure 3:** The percentage of trials in which balance was recovered successfully in a single step. There were significant increases in success from the first to last training session ( $p = 0.03$ ).

### Fall-Recovery Success

Despite a lack of strong evidence supporting a training benefit in step placement, other evidence suggests that fall-recovery improved. On the last day of training, a higher percentage of trials were performed successfully (Figure 3).

## CONCLUSIONS

- Individuals with chronic stroke demonstrated a wider paretic limb step compared to that with the non-paretic limb. A wider step decreases the likelihood of successful slip recovery in individuals that have not had a stroke [5].
- With six training sessions, the effects on step placement were, at most moderate. We plan to extend the number of sessions and within-session time to ensure that training exposure was not a limiting factor.
- On the last training session, there was an increase in the percentage of successfully performed trials. Improvements were most notably achieved by reducing the number of steps needed to recover.
- In order to avoid a “ceiling effect” of training, we aim to enroll participants who have lower functional capabilities. Work is in progress to evaluate the benefits of this training on clinical balance, balance confidence, and walking activity.

# CONSTRAINING THE ARMS REDUCES POSTERIOR, BUT NOT ANTERIOR, SINGLE-STEPPING THRESHOLDS OF FALL RECOVERY

<sup>1</sup> Drew A. Petersen, <sup>1</sup> Jamie Pigman, <sup>1</sup> Benjamin C. Conner, <sup>1</sup> Jeremy R. Crenshaw

<sup>1</sup> The University of Delaware, Newark, DE, USA  
email: crenshaw@udel.edu

## INTRODUCTION

Rapid arm movements have been reported to play a substantial role during successful fall recovery [1, 2]. When arm motion is constrained, the success of a feet-in-place fall-recovery response is reduced and the duration of recovery is prolonged [1].

Anterior and posterior single stepping thresholds, defined as the minimum disturbance magnitudes that consistently elicit a compensatory step, quantify a person's ability to recover from a fall. These measures are reliable [3], decline with age [4], and evaluate the feet-in-place response that is prospectively related to falls in older adults [5]. It is not known, however, if arm motion influences performance on this assessment of fall-recovery.

The purpose of this study was to determine if arm motion benefitted single-stepping thresholds. Our hypothesis was that thresholds would be reduced by constraining arm motion. In the case that our hypothesis was supported, we evaluated the resulting dynamic stability [6] of the feet-in-place response as a means to explain observed differences.

## METHODS

We recruited six healthy participants, (age:  $21.83 \pm 1.33$  years; BMI:  $22.49 \pm 3.87$  kg/m<sup>2</sup>) for this IRB approved study.

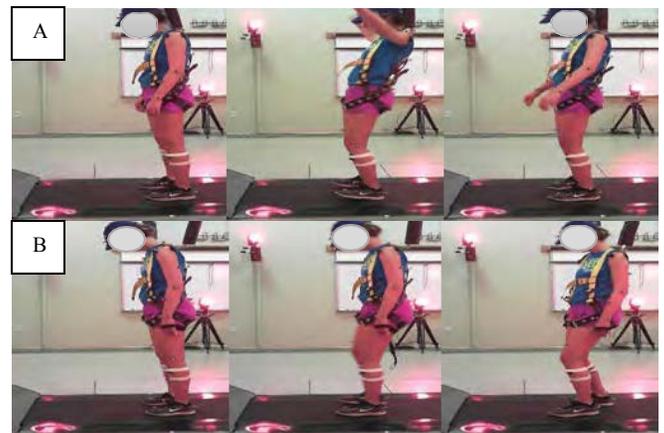

**Single-Stepping Thresholds:** Participants stood on a computer-controlled treadmill (ActiveStep<sup>®</sup>, Simbex, Lebanon, NH) and were instructed to "try to prevent a step" in response to rapid 400 ms belt movements. Initial belt accelerations began at 0.5 m/s<sup>2</sup>, resulting in a 1 cm displacement. For subsequent trials, the initial accelerations were increased or decreased by 0.5 m/s<sup>2</sup> depending on the response, success or failure, respectively. The

progression continued until anterior and posterior thresholds were identified, as evident by four failed attempts at a given disturbance magnitude. Thresholds were expressed as the ankle torque (N·m) necessary to maintain an upright posture [3]:

$$\tau = |m \cdot \ddot{x} \cdot l|$$

where  $m$  is the participant's mass,  $\ddot{x}$  is the initial acceleration of the treadmill belt, and  $l$  is the estimated length of the inverted pendulum representing the participant ( $l = 0.586 \cdot \text{height}$ ) [7].

Stepping thresholds were evaluated under two conditions: unconstrained (Figure 1A) and with arms constrained by holding a rope with both hands behind the participant (Figure 1B).

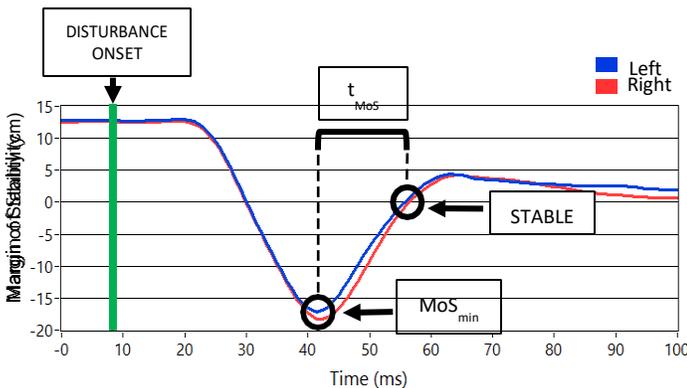

**Figure 1:** Posterior disturbances at a magnitude of ( $\ddot{x} = 3$  m/s<sup>2</sup>). (A) A successful posterior recovery with the arms unconstrained. (B) A failed posterior recovery with the arms constrained.

**Dynamic Stability Measures:** For all trials, the trajectories of 35 markers placed on the extremities, pelvis, trunk, and head were recorded with motion capture technology (Motion Analysis, Santa Rosa, CA; 120 Hz). Dynamic stability, represented as the margin of stability (MoS) [6], was calculated for disturbances as follows:

$$MoS = d + \frac{v}{\sqrt{\frac{g}{l}}}$$

Where  $d$  is the anteroposterior distance between the whole body center of mass and the toe or heel marker, and  $v$  is the velocity of the center of mass relative to that marker. The term  $g$  represents gravity ( $9.81 \text{ m/s}^2$ ), and  $l$  again represents the inverted pendulum length. The minimum MoS (i.e. most negative value,  $MoS_{\min}$ ) as well as the time from this minimum MoS value to a positive stability state ( $t_{MoS}$ ) was determined for each trial (Figure 2) using custom software (National Instruments, Austin, TX).

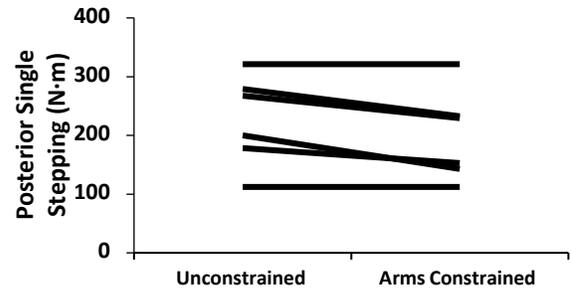

**Figure 2.** Depiction of posterior margin of stability in the arms constrained condition. The difference in time between the  $MoS_{\min}$  and where the MoS becomes stable again ( $MoS > 0$ ) represents  $t_{MoS}$ .

For both anterior and posterior stepping thresholds, constrained and unconstrained conditions were compared using repeated-measures t-tests and effect sizes. In the case that thresholds were different between conditions, dynamic stability measures were compared for the largest disturbance magnitude achieved without stepping across conditions.

## RESULTS AND DISCUSSION

**Single Stepping Thresholds:** Posterior thresholds were lower when the arms were constrained (Figure 3). No differences in anterior stepping thresholds were apparent between constrained ( $290.429 \pm 93.586 \text{ N}\cdot\text{m}$ ) and unconstrained ( $281.194 \pm 91.071 \text{ N}\cdot\text{m}$ ) conditions ( $p = 0.599$ , Cohen's  $d = 0.266$ ).

**Dynamic Stability Measures:** In the posterior direction, no significant differences were found in the minimum margin of stability ( $p=0.284$ , Cohen's  $d=0.171$ ) between the unconstrained ( $-13.919 \pm$

**Figure 3.** Posterior thresholds between the unconstrained ( $226.391 \pm 76.783 \text{ N}\cdot\text{m}$ ) and arms constrained ( $198.499 \pm 77.161 \text{ N}\cdot\text{m}$ ) conditions. Constraining the arms resulted in lower thresholds ( $p = 0.019$ , Cohen's  $d = 1.164$ ).

$8.771 \text{ cm}$ ) and arms constrained ( $-14.131 \pm 9.204 \text{ cm}$ ) conditions. There were no significant differences in duration of recovery ( $p= 0.638$ , Cohen's  $d= 0.231$ ) between unconstrained ( $93 \pm 45 \text{ ms}$ ) and arms constrained ( $87 \pm 51 \text{ ms}$ ) conditions.

## CONCLUSIONS

Constraining the arms reduced performance in fall recovery in the posterior direction, but not in the anterior direction. At a given posterior disturbance magnitude, there were no apparent differences in the level of instability experienced between the two conditions. For this reason, we cannot conclude that the arms altered the ability to prevent or recover from dynamic instability. Thus, between-condition differences may be a result of non-mechanical influences, such as a lower self-efficacy, which may have led to a more conservative stepping strategy.

## INTRODUCTION

Annually, injuries caused by slips, trips, and falls contribute to the loss of over \$16 billion [1]. Slips and resulting falls contribute to a significant share of these injuries [2]. Understanding how gait patterns influence the risk of a severe slip may lead to new methods of targeting and developing slip prevention strategies.

Previous research suggests that the control of gait may influence an individual's risk of experiencing a slip. For example, kinematic gait metrics like shoe-floor angle, step length and cadence are known to be associated with slip severity [3]. The kinematics of gait are effected predominantly by muscle activation patterns in the lower extremities. It has been suggested that the central nervous system may control the gait and slipping using a lower dimensional organization of muscle synergies [5]. Therefore, a logical next step in understanding how gait patterns influence slipping risk is to quantify differences in gait synergies between individuals whose gait leads to high severity slips versus those who did not.

The objective of this study is to compare the walking muscle synergies of the mild and severe slippers to find the possible inter-group discrepancies.

## METHODS

A total number of twenty healthy subjects (11 male/9 female, age (mean  $\pm$  SD): 23.6  $\pm$  2.52), free of walking disorders, were asked to walk at their self-selected speed in a pathway with an embedded force plate. The starting location of each subject was altered in a way to secure a foot strike on the force plate. Subjects were fitted with appropriate size PVC-soled shoes and donned an overhead safety harness and gave written consent prior to participation in this IRB-approved study at University of Pittsburgh. The data analysis was done at Texas A&M University upon approval of the IRB of both institutions.

Throughout the experiment, EMG signals were recorded at 1080 Hz from medial hamstring (*MH*), tibialis anterior (*TA*), vastus lateralis (*VL*), and medial gastrocnemius (*MG*) on both limbs (right/trailing/non-slipping leg (*NS*) and left/leading/slipping leg (*S*)). The slipping leg refers to the leg that experienced a slip in the following trial since EMG data was only collected from baseline walking conditions. A motion capture system

(Vicon 612, Oxford, UK) was utilized to capture heel kinematics at 120 Hz.

Subjects first performed a normal walking trial in which the data was recorded for synergy extraction. After the normal walking trials, without informing the subjects of a change in walkway condition, a slippery solution (75% glycerol, 25% water) was applied to the surface and a "slip trial" was recorded. The peak heel velocity (PHV) of each subject was used as representative of slip severity: Persons with a PHV higher than 1.44 m/s were considered severe slippers [4].

EMG signals were processed (demeaned, rectified, filtered) for the walking trial according to the procedures in [5]. The gait duration was then normalized to 100 points (0 being right heel strike) and a matrix factorization technique was used to extract four walking synergies and their coefficients from the normalized gait cycle for each subject [5]. Muscle synergies of each severity group were then sorted and ordered according to their similarity using correlation coefficients (*r*) [5]. An independent *t*-test ( $\alpha=0.05$ ) was used (SPSS v21, IBM, Chicago, IL) to detect the significant differences in gain coefficient and muscle activation levels between mild and severe slippers' synergies.

## RESULTS AND DISCUSSION

PHV measurement classified twelve subjects as mild slippers. No significant differences were found in sex, height, mass, and age across severity levels. Statistical analysis revealed significant differences in both walking synergies and their activation coefficients (Fig.1). Significant differences in gains of three muscles were found. *MH\_S* and *VL\_NS* activation were significantly higher for mild slippers while *TA\_S* activation was significantly higher in severe slippers (Fig. 1, W1 and W3). The inter-group comparison also found differences in activation of the first and the third walking synergies (Fig. 1, C1 and C3). The first synergy coefficient 'C1', was statistically different between mild and severe slippers from 10<sup>th</sup> until 18<sup>th</sup> percent (Fig.1) of the gait cycle (Table 1). Also, the activation coefficient of the third muscle synergy, 'C3', was found to be different for the two groups from 37<sup>th</sup> percent to 46<sup>th</sup> percent (Fig. 1) of the gait cycle (Table 1).

**Table 1** Significant differences according to the *t*-test

Variable		p-value	Variable		p-value
W1	VL_NS	0.003	C1	18 <sup>th</sup>	0.043
W3	MH_S	0.010	C3	37 <sup>th</sup>	0.019
	TA_S	0.009		38 <sup>th</sup>	0.008
C1	10 <sup>th</sup>	0.037		39 <sup>th</sup>	0.007
	11 <sup>th</sup>	0.015		40 <sup>th</sup>	0.029
	12 <sup>th</sup>	0.011		41 <sup>st</sup>	0.023
	13 <sup>th</sup>	0.008		42 <sup>nd</sup>	0.019
	14 <sup>th</sup>	0.008		43 <sup>rd</sup>	0.012
	15 <sup>th</sup>	0.012		44 <sup>th</sup>	0.010
	16 <sup>th</sup>	0.025		45 <sup>th</sup>	0.023
	17 <sup>th</sup>	0.026		46 <sup>th</sup>	0.033

According to the results, it can be argued that a higher activation of the *MH* muscle right before the heel strike is associated with less severe slips. This point can be seen in both higher contribution of *MH\_S* in the third synergy (W3), and in its higher activation coefficient (C3), right before the *S* limb's heel strike (which happens at 50%). Hamstring muscle is known to be involved in deceleration of the swing leg in terminal swing phase [6], hence, contributing to less slip severity.

Moreover, the results suggest that a higher activation of the *VL* muscle right after the heel strike is associated with less severity in slips. This conclusion was made upon observation of a higher contribution of *VL\_NS* in W1 along with a higher activation in C1, right after the *NS* limb's heel strike (which happens at 0%, Fig. 1). Considering the role of *VL* in load acceptance, this conclusion stays consistent with existing studies claiming that a late activation of the *VL* may reduce the forward velocity of the center of mass relative to the base of support, resulting in less stability [7].

The results also revealed an association between higher activation of the *TA* muscle before the heel strike and high slip severity. *TA\_S* muscle has both a higher contribution in the third muscle synergy (W3) and a higher activation coefficient (C3) before the *S* limb's heel strike (at 50%). High activation of *TA* may increase

the foot-floor-angle (FFA) which is known to be associated with severe slips [3]. To verify that, using our markers data we calculate the FFA for both mild and severe slippers and found that FFA at heel strike was significantly lower for mild slippers from 25<sup>th</sup> to 49<sup>th</sup> percent of the gait ( $p < 0.05$ ). It is also known that a zero FFA (i.e. flat-foot walking) is a strategy used by individuals to increase dynamic stability of the gait [8] that substantiates our findings.

## CONCLUSION

Our study investigated the walking differences between mild and severe slippers using a muscle synergy approach. We found that mild slippers and severe slippers have different muscle contributions and activation pattern in their normal walking muscle synergies. The findings of this study may have identified underlying gait control patterns that influence slip risk. Future studies would assess the efficacy of these methods in identification severe slippers and developing strategies that modify their gait control.

## INTRODUCTION

Despite demonstrated need to reduce the incidence of falls among older Americans [1], clinicians lack quantifiable measures of falls risk that can be used to identify and track those at risk *before* they suffer a first fall. In 1994, Maki et al. reported a biomechanical measure of balance control that identified individuals at risk for falls before they fell: the variability of a person's sway in the medial-lateral direction during comfortable, quiet standing with eyes closed (RMSx\_EC) with those showing more than 2.3mm of RMSx\_EC being at greater risk of falling within the year [2]. RMSx\_EC is a simple measure, collected on equipment that has become relatively affordable of late, that shows promise to identify those at risk of falls before they happen and assess progress over the course of interventions intended to be preventative. Barriers remain, however, to clinical implementation of this quantified measure for the purpose of longitudinal tracking and assessment of patients.

One such challenge is a dearth of information about the *expected variability* (EV) over time, or the variability that normally occurs in balance control within-subject from day to day. Clinicians see patients intermittently and record outcome measures even less frequently. To interpret their measures, and conclude that balance control has/has not improved post treatment on any given day, change due to intervention must exceed expected, day-to-day variability. Past studies have revealed group changes in RMSx\_EC over time [3], however translating this knowledge to clinical care necessitates a consideration of EV. The EV concept is related to both minimum detectable change (MDC) and minimum clinically important

difference (MCID), but is distinct from both. The purpose of this study was to characterize EV over multiple days in RMSx\_EC for a group of healthy middle-aged adults. This information furthers our ultimate goal of identifying a quantified measure of balance control that can be used in clinical settings to identify and longitudinally track falls risk for individual patients.

## METHODS

This research was reviewed and approved by The Ohio State University Institutional Review Board. Thirteen middle-aged adults without neurologic or orthopedic impairment consented to participate (55 +/-9 years; 76 +/- 18 kg; 11 females/2 males). Balance data were recorded (1000 Hz) during quiet standing with eyes closed. Recordings were taken on 6 different days, for 5 minutes each day, in 1 minute intervals as follows: participants stood on a balance board (Bertec Corp), feet comfortable width apart and hands clasped in front of the body, as if they were in a "line up" [2]. At the end of each 1 minute interval, participants were instructed to open their eyes, "get their bearings" by sighting a point approximately 8 ft in front of them at eye level, and close their eyes when ready. Once the participant closed their eyes on their own timing, we commenced the next 1 minute data collection interval. At the beginning of testing on the first day, each participant's foot position was traced on paper that was affixed to the force platform with paper tape, labeled with their study code, and used to ensure that the participant's feet did not move from their original position on the platform between trials [2] or over the course of the study.

Data were filtered (4<sup>th</sup> order, 20 Hz low pass, Butterworth) and RMSx\_EC was calculated as the root-mean-squared of center of pressure (COP) excursion within the frontal plane of motion (i.e., postural sway in the medial-lateral direction) over the course of each 1 minute collection period [2].

For this analysis the first minute of quiet standing data per day was not included, consistent with Maki et al [2]. Variance components analysis was performed on minutes 2-5 to determine the relative variances coming from (A) between subjects, (B) within-subject minute-to-minute variations, (C) within-subject day-to-day variations, and (D) residual variations. To get an estimate of within-subject standard deviation over multiple days in RMSx\_EC, the square root of the sum of variances B-D was calculated. The 95% confidence interval of the within-subject between-day difference (EV) was then calculated as (SD \* 1.96).

## RESULTS AND DISCUSSION

The output for the variance component analysis identified that between-subject variability was greater than within-subject day-to-day variations, which exceeded, within-subject minute-to-minute variations (Table 1).

**Table 1.** Variance component analysis of RMSx\_EC.

Variance Component	Variance (mm <sup>2</sup> )
A. Between Subjects	0.597
B. Minute-to-Minute	0.027
C. Day-to-Day	0.111
D. Residual	0.409

Within-subject standard deviation over multiple days in RMSx was calculated to be 0.74mm and EV to be 1.45mm. **Thus, changes in balance control (as measured by RMSx\_EC) above 1.45mm are expected to represent more change than could be explained by typical day-to-day variability among a middle-aged, healthy participant.** This represents a starting point for determining whether an observed change within-subject is real or simply reflects expected minute-to-minute and day-to-day variability in the measure.

## CONCLUSIONS

Medial-lateral balance control, as measured by a force platform, continues to be a promising measure for identifying those at risk of falling *before* they suffer their first fall and assessing their progress as clinicians intervene to improve their balance control. Quiet standing with eyes closed for up to 5 minutes is a feasible and reasonable quantified test for patients to undergo within standard clinical care. While MCID for this measure remains to be determined, identifying the EV is an important first step toward implementing this measure clinically to impact and improve patient's lives.

## INTRODUCTION

Balance disorders and falls are highly prevalent among patients with Multiple Sclerosis (MS) and other neuromuscular pathologies with an estimated \$31 billion spent on fall-related injuries in 2015 [1]. Despite its socio-economic burden, current clinical assessment of balance and fall risk relies heavily on functional tests such as the Berg balance test that show limited accuracy and association with fall risk [2]. In contrast, Center of Pressure (COP)-based assessment of balance via force plates is accurate but isn't always feasible in clinical settings. So while COP-based balance parameters are related to increased fall risk, there are no known demarcation thresholds that are indicative of clinically-relevant balance deterioration and fall risk.

The purpose of this study was to examine the ability of a Wii Balance Board (WBB) to predict fall status and determine optimal parameter thresholds that identify increased fall risk in patients with MS.

## METHODS

A subset of 19 patients with reported fall histories were included from a total of 35 patients with MS, recruited from University of Iowa. Patients with other major medical or neurological conditions such as diabetes, stroke, Parkinson's, spinal deformities etc. were excluded. Patients were asked to report any occurrences of fall(s) in the last year. Three fall status levels were defined as: 1. Non-fallers (0 falls), 2. Non-recurrent fallers (1-2 falls), 3. Recurrent fallers ( $\geq 3$  falls).

Subjects were asked to stand independently on the WBB to record COP measurements for 30 seconds.

Path length (total vector distance covered by the COP signal) was calculated.

Receiver operating characteristic (ROC) analysis was performed using two fall status criteria:  $\geq 1$  falls (all fallers vs. non-fallers) and  $\geq 3$  (recurrent fallers vs. all others). Overall test accuracy of the WBB was evaluated using area under the ROC curve (AUC). For each cut-off value used to generate the ROC curve, sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and the Youden Index ( $J = \text{sensitivity} + \text{specificity} - 1$  [3]) were calculated.

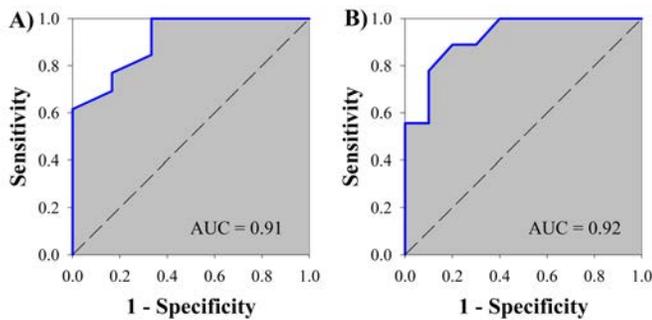

One-way Analysis of Variance (ANOVA) was conducted to assess for differences in path length between fall status groups, 1. non-fallers, 2. non-recurrent fallers, 3. recurrent fallers.

## RESULTS AND DISCUSSION

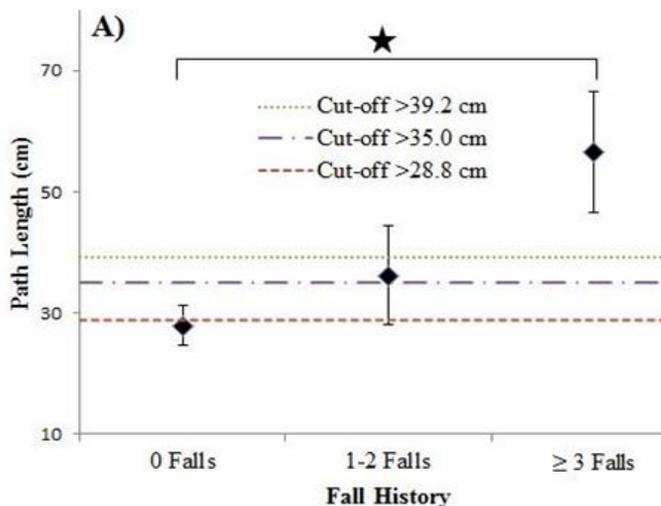

The patients consisted of 17 females and 2 males; mean age:  $43.7 \pm 10.9$  years; BMI:  $26.5 \pm 4.9$  kg/m<sup>2</sup>; 6 with no falls, 4 with 1-2 falls and 9 with  $\geq 3$  falls.

The WBB assessed path length was highly accurate in identifying fallers ( $\geq 1$  falls) from non-fallers and discerning recurrent fallers from all others (91% and 92% accuracy, respectively) (Fig 1). Choice of the optimal cut-off is a trade-off between sensitivity and specificity (Table 1). For example, at cut-off path length of 28.8 cm, the WBB test correctly identified all fallers (sensitivity = 1), but misclassified 33% of non-fallers as fallers (specificity = 0.67). Conversely, increasing the cut-off path length to 39.2 cm improved the specificity (100%) but 31% of fallers were misclassified as non-fallers (false negatives). The cut-off of 35 cm provided a reasonable tradeoff,

resulting in nearly equal, high sensitivity (85%) and specificity (83%).

**Figure 1:** ROC curves for path length (cm) considering A)  $\geq 1$  fall(s) in the last year (fallers compared to non-fallers) B)  $\geq 3$  falls in the last year (recurrent fallers from others).

**Figure 2:** Mean (SE) path length in patients with MS who reported no falls, 1-2 falls, or  $\geq 3$  falls in the past year. \*Denotes significant differences ( $p \leq 0.05$ ).

Standing balance deteriorates with a positive history of falls (Fig 2). Path length for patients who reported recurrent falls ( $\geq 3$  falls) was approximately twice as high as those who reported no falls. The cut-off path lengths indicate that if a subject has fallen once or twice, there is a 85% probability that he/she has a path length greater than 35.0 cm, but if a subject reported 3 or more falls, there is a 100% probability that their path length will be higher than 35 cm. Additionally, 89% of the recurrent fallers have path length higher than 39.2 cm and 90% of non-recurrent fallers have a path length lower than 39.2cm.

## CONCLUSIONS

This study demonstrates that quantitative balance assessment using a WBB in patients with MS is highly accurate in discerning increased fall risk based on fall history. Cut-off path length of 35 cm shows excellent sensitivity and specificity in identifying patients with MS who have sustained a fall in the last year. However, future prospective studies investigating its accuracy in predicting fall risk are needed. The WBB test could provide a clinically feasible, practical assessment of fall risk and may be indicative for rehabilitation interventions.

# Effects of Lower Extremity Muscle Fatigue on Dual-Task Obstacle-Crossing

Szu-Hua (Teresa) Chen, Jocelyn Taylor, and Li-Shan Chou

Department of Human Physiology, University of Oregon, OR, USA  
email: [chou@uoregon.edu](mailto:chou@uoregon.edu); web: <http://choulab.uoregon.edu>

## INTRODUCTION

Lower limb muscle fatigue has been shown to cause motor adjustments during walking and obstacle crossing [1]. Walking and simultaneously performing an attention demanding task could take place with the presence of fatigue, especially at the end of a working day. Tripping over an obstacle during walking is one of the most frequently mentioned causes of falls [2]. Although previous studies have demonstrated how a concurrent cognitive task and muscle fatigue affects walking performance [3], the effect of muscle fatigue on dual-task obstacle-crossing remains unclear. The purpose of this study was to examine changes in gait balance control and concurrent working memory task performance in healthy young adults when lower extremity muscles are fatigued.

## METHODS

Ten healthy adults (4 females, 21.5±2.6 yrs) performed the following three tasks before and after a muscle fatigue protocol with a random order: 1) walking and crossing over an obstacle with height set at 10% of body height (OC), 2) sitting and performing a 3-back test, in which participants listened a series of digits over a loud speaker and were instructed to verbally respond “yes” whenever a digit is heard that is the same as presented three positions back in the series (Nback), 3) Obstacle-crossing and performing a 3-back test simultaneously (OC+Nback).

A 30-minutes sit-to-stand task at a pace of 0.5 Hz was performed to induce the muscle fatigue as indicated by the participant’s response of inability to continue or when the movement frequency falling below 0.5 Hz after the examiner’s encouragement. The maximal voluntary isometric strength of knee extensors was assessed using a dynamometer immediately before and after the fatigue protocol and at the completion of the entire study protocol.

Whole body motion data were collected from a set of 29 retro-reflective markers placed on bony landmarks with a 10-camera motion system. The whole-body center of mass (CoM) was calculated as the weighted sum of 13 body segments. Measurements during crossing stride, defined as the gait cycle during stepping over the obstacle between heel strikes of the trailing foot immediately before and after crossing the obstacle were analyzed. Gait speeds were calculated as the average forward CoM velocity during a gait cycle. Gait balance control was examined using the total medial-lateral center of mass displacement (M-LCoM) and peak forward velocity of center of mass (vCoM). Dependent variables for crossing characteristics included the toe-obstacle clearance and foot placements. Toe-obstacle clearance (TC) was calculated as the vertical distance between the obstacle and toe marker at the time of crossing. Foot placements (FP) of trailing foot and leading foot were measured as the horizontal distance between the obstacle and toe marker and heel marker, respectively.

Two-way ANOVA with repeated measures and with the gait velocity as a covariate was used to examine effects of fatigue (pre- and post-fatigue) and gait condition (single- and dual-tasks). Alpha level was set at .05.

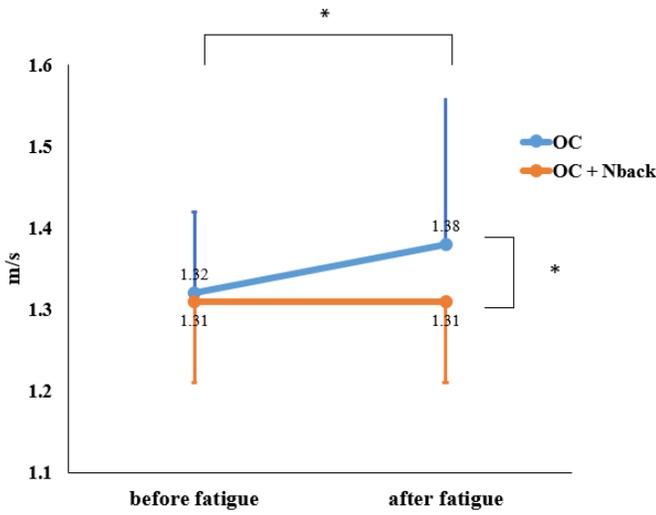

## RESULTS AND DISCUSSION

An average of 20.7% knee extensor strength reduction was observed immediately after the completion of fatigue protocol, and it was recovered to approximately 16.2% by the completion of study protocol. The average time-to-fatigue during the sit-to-stand task was 24.3 minutes.

Gait speeds showed a significant main effect of gait condition. Participants crossed over the obstacle

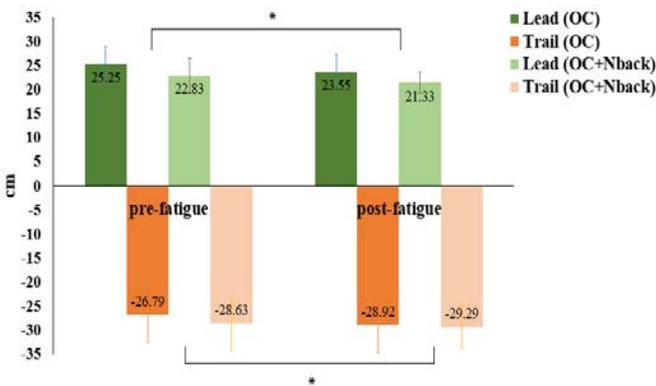

significantly slower when responding concurrent 3-back task than they did under single task condition.

Accuracy of working memory task and M-L CoM were not affected by muscle fatigue or gait condition. Peak forward CoM velocity showed a significant interaction effect. After fatigue, vCoM was significantly slower in the dual-task condition than in the single-task condition. Interestingly, a significantly faster vCoM after fatigue was observed in the single-task condition (**Figure 1**).

**Figure 1:** Peak forward CoM velocity across gait conditions before and after muscle fatigue. \*  $p < .05$ .

Toe-clearances were not affected by the fatigue or gait condition. However, muscle fatigue significantly decreased foot placement of leading foot after crossing an obstacle and increased foot placement of trailing foot before crossing. (**Figure 2**).

**Figure 2:** Foot placements of leading (top) and trailing (bottom) feet across different conditions before and after muscle fatigue. \*significant main effect.

## CONCLUSIONS

Findings from this study indicated that the acute muscle fatigue induced in this study did not affect the frontal plane balance control or accuracy of concurrent working memory test during obstacle crossing. Instead, sagittal plane CoM momentum control and foot placements were affected by muscle fatigue. This may be due to the selected sit-to-stand fatigue protocol that is more effectively in fatiguing the knee extensors.

# EFFECTS OF A VERBAL FLUENCY TASK ON STABILITY WHILE WALKING AND OBSTACLE CROSSING IN AGING

Sarah A. Brinkerhoff, Tiphonie E. Raffegeau, Grace Kellaher, Matthew J. Terza, Jaimie A. Roper, Lori J. Altmann, and Chris J. Hass  
University of Florida, Gainesville, FL, USA  
email: sbrinkerhoff@ufl.edu

## INTRODUCTION

Older adults (OA) exhibit impaired performance during tasks that simultaneously challenge cognitive and motor resources [1]. Dual-task studies frequently challenge executive function using a concurrent verbal fluency task [2] while participants perform mobility tasks such as walking and stepping over obstacles [3].

One goal during walking is to maintain some minimum margin of stability (minMOS) [4]. Thus, evaluating alterations in minMOS may provide insight into control of stability as motor demands rise. Although gait kinematics have been reported in dual-task walking and obstacle crossing (OC), dynamic stability changes in these constraints remain unclear. Therefore, the purpose of this study was to observe changes in dynamic stability (minMOS) with increasing motor complexity and cognitive load in older adults. Further, we aimed to better understand the relationship between cognitive performance and changes in stability.

## METHODS

Thirty-six community-dwelling older adults (12 females,  $72 \pm 1$  yr) participated as part of a larger intervention study and provided informed consent. Validated clinical cognitive assessments were administered during the first visit. In the second visit, participants performed four walking conditions in the order: self-selected walk (SS Walk), walking while generating words from an assigned word category (Fluency Walk), walking and stepping over a 10-cm obstacle (SS OC), and walking and stepping over an obstacle while generating words (Fluency OC).

Whole-body three-dimensional kinematics (10 camera Vicon Motion System, 120 Hz) were collected while participants performed each task. In addition to foot placement, the anterior minMOS was determined as described previously [5]. Anterior

minMOS was analyzed because crossing an obstacle generally perturbs the A/P direction more so than the M/L [5]. This measure quantifies the extent the extrapolated center of mass (xCOM) approaches the anterior boundary of the base of support (BOS). When anterior MOS is negative, the xCOM is past the BOS and therefore represents an unstable position. In walk trials, right and left legs were matched to the participant's lead and trail limbs in OC to directly compare each phase of an over ground step to the step over the obstacle. Results are presented in order of events: trail limb single support, lead limb double support, lead limb single support, and trail limb double support.

Repeated measures MANOVA evaluated the effect of condition on foot placement in OC. A  $2 \times 2$  (Motor task  $\times$  Condition) repeated measures MANOVA analyzed differences in anterior minMOS. Post-hocs with Bonferroni adjustments were used to determine the direction of significant differences in anterior minMOS. In addition to evaluating minMOS, obstacle crossing costs (OCC) were calculated for self-selected  $\left(\frac{SS\ Walk - SS\ OC}{SS\ Walk}\right)$  and fluency  $\left(\frac{Fluency\ Walk - Fluency\ OC}{Fluency\ Walk}\right)$  conditions. The OCC represent the adjustments to stability in each condition as an obstacle is introduced. A repeated measures MANOVA determined differences between SS and Fluency OCC. Two-tailed partial bivariate correlations (controlling for Age, Education, & Gender) evaluated the relationship between SS and Fluency OCC and cognitive measures. Significance was set at  $p=.05$ .

## RESULTS AND DISCUSSION

Compared to SS OC, Fluency OC displayed a higher vertical toe clearance (lead limb  $p<0.001$ , trail limb  $p=0.006$ ) and closer distance after crossing the obstacle (lead limb  $p<0.001$ , trail limb  $p<0.001$ ). Approach steps were not significantly affected by the cognitive task.

The 2x2 MANOVA revealed a significant effect of condition ( $F(24, 12)=3.271, p=.007$ ) and motor task ( $F(24, 12)=25.033, p<0.001$ ). A significant interaction of condition and motor task ( $F(24, 12)=4.736, p=.001$ ) supported that stability performance was affected by task and condition manipulations and these differences were interdependent. Participants displayed lower anterior minMOS scores (less stability) in SS Walk than in Fluency Walk and lower anterior minMOS scores in SS OC than in Fluency OC. As expected, both SS OC and Fluency OC had significantly lower anterior minMOS than their respective walk trials in trail limb single support (SS  $p=0.04$ , fluency  $p<0.001$ ) and lead limb single support (SS  $p<0.001$ , fluency  $p<0.001$ ). Anterior minMOS was lower in trail limb double support in SS OC than in SS Walk ( $p=0.046$ ) and anterior minMOS trended towards significantly lower in Fluency OC than in Fluency Walk ( $p=0.08$ ). In all phases but lead limb double support, participants exhibited lower anterior minMOS scores (less stability) when crossing an obstacle compared to walking over ground with or without a dual-task. Only in lead limb double support did anterior minMOS increase from SS Walk to SS OC ( $p<0.001$ ) and Fluency Walk to Fluency OC ( $p<0.001$ ), indicating a more stable step over the obstacle. Increased stability in lead limb double support in OC may be due to the fact that forward momentum is arrested while the obstacle is in between the lower limbs, restraining the COM to closer to the anterior BOS. Importantly, the added verbal fluency condition limited the anterior minMOS excursion in both walk and OC.

The MANOVA comparing OCC in SS and Fluency show that OCC for SS were smaller than Fluency only in trail limb single support ( $p=0.005$ ). This may be due to a lower (more unstable) anterior minMOS in SS Walk than in Fluency Walk. SS Walk allowed for more excursion in anterior minMOS than Fluency

Walk resulting in a smaller difference between SS Walk and SS OC. Because Fluency resulted in more stable walking, larger changes in anterior minMOS occurred when an obstacle was in the path. Double support showed no significant differences in trail and lead limbs between SS and Fluency. Rather, an additional cognitive load exaggerated changes to anterior minMOS in single support when adjusting steps to cross an obstacle.

The partial bivariate correlations showed that OCC in SS was not related to executive functions. However, the OCC during Fluency was related to several measures of executive function. Clinical cognitive tests related to OCC in Fluency measure global executive function (Montreal Cognitive Assessment,  $r=.39, p=.027$ ), inhibition (Stroop Color Word,  $r=0.455, p=0.009$ ), working memory (Forward digit span,  $r=0.385, p=0.03$ ), and set-switching (Trails B,  $r=-0.624, p<0.001$ ). Overall, greater changes in OCC with a dual-task are related to better executive function. Thus, the aptitude of these aspects of cognition is related to the ability to modulate dynamic stability in order to perform a more complex motor task while generating words.

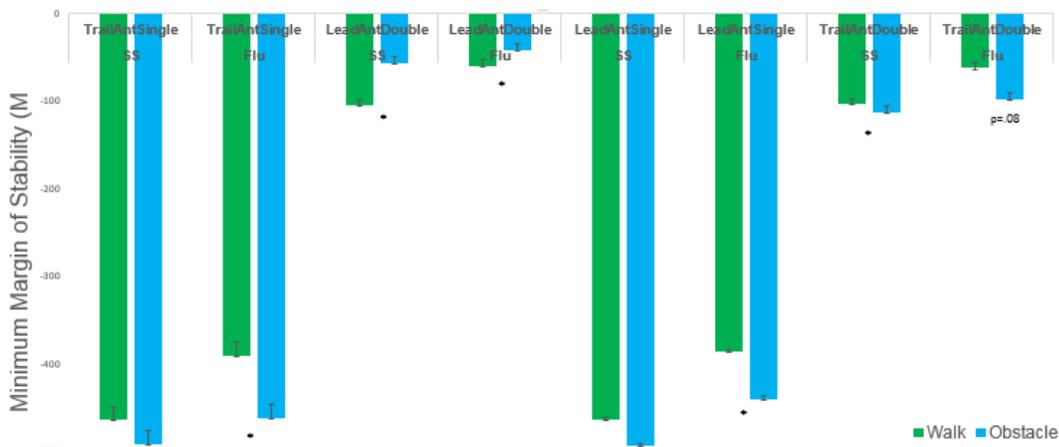

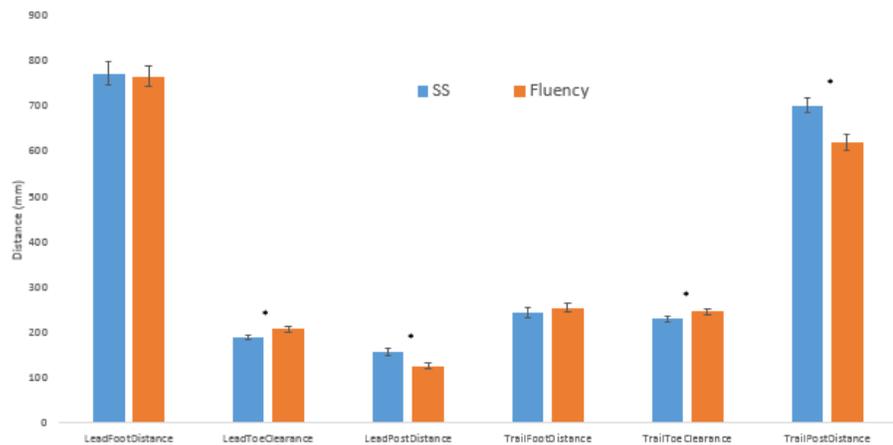

## CONCLUSIONS

Dynamic stability changes due to increasing motor complexity and a cognitive load provide insight into mobility impairments in OA. We determined that anterior minMOS is more tightly controlled during walking when a cognitive task is added. This may be because walking is less dynamically challenging than OC. Therefore, stability changes are limited in OC with a cognitive load in community-dwelling older adults.

## INTRODUCTION

Turns comprises 8-50% of all steps taken during a typical day [1] and occur at a rate of 65-70 turns per hour [2, 3]. Turning gait of individuals with lower-limb loss has been studied during tasks of steady state curved-path walking and transient turns. Comparison in these studies were between individuals with lower-limb loss and controls, prosthetic componentry (torsion adapters), and limb-loss etiology. A limitation among the existing turn literature is the lack of within-subject comparisons between turns towards the sound side and turns towards the prosthetic side. Turns toward the prosthetic limb are likely more challenging for individuals with unilateral lower-limb loss because specific gait characteristics are required. The stride length of the inner leg decreases and the stride length of the outer leg increases as compared to straight-path walking. Simultaneously, the body's center of mass shifts to the inner leg and stance time of the inner leg increases. The ability to successfully shift the body's center of mass over the prosthetic limb may be more difficult given decreased balance confidence and gait asymmetries.

The purpose of this study was to investigate within-subject comparisons of turn performance when turning towards the sound limb and when turning towards the prosthetic limb. We hypothesized that individuals with a history of falls would have decreased turn performance when turning towards the prosthetic limb compared to the sound limb.

## METHODS

Participants: Individuals with unilateral transtibial (TT) and transfemoral (TF) lower-limb amputation using a prosthetic were recruited to participate in this IRB approved study.

Instrumentation: Fall history was assess by asking "How many times have you fallen to the ground in the past year?" Participants were categorized as nonfaller (0 falls in the past year) and faller ( $\geq 1$  fall in the past year). Four wireless inertial sensors (Opal, APDM, Inc., Portland, OR) were secured to the sternum, lumbar spine, and feet using elastic straps. Each sensor recorded at 128 Hz.

Experimental Procedures: Participants walked as quickly and smoothly as possible around a pair of cones (spaced 1.525 m apart) in a figure-of-8. Two laps were performed without pausing, which resulted in two turns towards the sound limb and two turns towards the prosthetic limb.

Data Reduction: Angular velocity in the transverse plane at the lumbar spine (L5) was measured with the gyroscope of the inertial sensor. Data from each turn were segmented from the time series using  $0^\circ/\text{s}$  as a cut point. Turn performance of each turn was quantified using measures of central tendency, variability, and frequency content. Central tendency measures included mean and peak angular velocity, variability included variance and standard deviation of angular velocity, and frequency included 1<sup>st</sup> and 2<sup>nd</sup> dominant frequencies of the angular velocity signal. Turn performance was calculated for each turn and the mean of turns in each direction were used in the analysis.

Statistical Analysis: Related-samples Wilcoxon Signed Rank tests were performed to obtain within-subject comparisons (turns towards the sound limb and turns toward the prosthetic limb) for each participant group: TT nonfallers, TT fallers, TF nonfallers, and TF fallers. Alpha was set to 0.05 *a priori*.

## RESULTS AND DISCUSSION

Sixty-nine individuals with unilateral lower-limb amputation completed the study procedures (Table 1).

**Table 1:** Demographic data

	Transtibial		Transfemoral	
n	36		33	
Gender (M / F)	19	/ 17	21	/ 12
Fallers / Nonfallers	15	/ 21	22	/ 11
Age (years)	47.0	± 14.3	42.8	± 12.9
Height (cm)	174.9	± 10.3	174.2	± 11.2
Mass (kg)	92.7	± 21.0	82.7	± 16.4

**TT nonfallers:** Turn performance was not significantly different when turning towards the sound and prosthetic limb (Table 2). **TT Fallers:** Mean angular velocity was significantly increased when turn towards the sound limb ( $p = .027$ ). Variability was significantly greater when turning towards the sound limb ( $p \leq .015$ ). Turning towards the sound limb was significantly slower ( $p = .020$ ). **TF Nonfallers:** Mean and peak angular velocity were significantly greater when turning toward the sound limb ( $p \leq .033$ ). Variability was significantly greater when turning towards the sound limb ( $p \leq .010$ ). Turning towards the sound limb was significantly slower ( $p = .008$ ). **TF Fallers:** Peak angular velocity was significantly greater when turning towards the sound limb ( $p = .007$ ). Variability was significantly greater when during towards the sound limb ( $p \leq$

.002). The 1<sup>st</sup> dominant frequency was significantly higher when turning towards the sound limb ( $p = .004$ ). No difference in turning times ( $p = .144$ ).

Increased variability when turning towards the sound limb was found for all groups except for TT nonfallers. A possible explanation is that a mechanical (or electromechanical) device was the inner limb when turning towards the prosthetic limb as compared to a biological limb with active control and degrees of freedom when turning towards the sound limb. Increased stability of the prosthetic limb to promote better balance and gait may, in fact, reduce needed variability during curved path walking.

## CONCLUSIONS

Turn performance was quantified using central tendency, variability, and frequency content of the angular velocity signal measured at the lumbar spine. TT nonfallers had no significant differences in turn performance. Signals in addition to angular velocity of the lumbar spine should be explored to further explain these findings.
